Bisphosphonates induce osteoclast apoptosis to decrease bone turnover and reduce bone loss due to estrogen-deficiency. Two commonly used bisphosphonates (alendronate [ALN] and risedronate [RIS]) have different skeletal pharmacokinetics. It has been suggested that ALN has a longer terminal half-life (10 years in humans) than RIS (20 days in humans). Given the potentially longer skeletal half-life of ALN, normal rates of bone remodeling may be expected to take longer to re-establish following its withdrawal than with equivalent doses of risedronate. The objective of this study was to determine the time required to re-establish normal bone turnover following the discontinuation of ALN and RIS. Female Sprague-Dawley rats (n=210) were ovariectomized (ovx) and starting 6 wks post ovx were treated 3x/wk for 8 wks with either vehicle, ALN (2.4μg/kg), low-dose RIS (1.2 μg/kg), or high-dose RIS (2.4 μg/kg) via subcutaneous injection. Doses were based on clinical dose levels (on an oral mg/kg basis) and on doses known to inhibit bone loss in ovx rats. Animals (10/group) were sacrificed at 0, 4, 8, 12 and 16 wks after treatment withdrawal. Histomorphometry was performed on tibial metaphysis, and pQCT and DXA scanning on distal femur. At the end of treatment (0 wk withdrawal), bone turnover within the proximal tibial metaphysis was significantly suppressed in all drug treated animals. This was evidenced by significant reductions in bone formation rate (BFR/BS; P<0.05) and mineralizing surface (MS/BS; P<0.05), and lack of double label. BFR/BS and MS/BS began to increase gradually in all drug-treated animals within as little as 4 wks after withdrawal, but remained significantly lower than vehicle-treated animals (P<0.05). Sixteen weeks after treatment withdrawal, BFR/BS and MS/BS in drug-treated animals returned to levels found in vehicle-treated animals. There were no significant differences between ALN and RIS in the rate at which bone turnover returned to baseline levels following treatment withdrawal. The histological data from the tibia were supported by the gradual but significant decline in bone mineral content of the distal femur during withdrawal in drug-treated animals (P<0.05), as assessed by pQCT and DXA, and a similar return to levels found in vehicle-treated controls by 16 wks after treatment withdrawal. We conclude that despite different clinical biological half-lives of ALN and RIS, the rate of return to untreated bone turnover rates after treatment discontinuation was similar in ovx rats.

Zinc Supplements Accelerate the Increase of IGF-I in Response to Protein Supplements and Decrease Bone Resorption. A. Rodondi*, P. Ammann, R. Rizzoli. Department of rehabilitation and geriatrics, Division of bone diseases, Geneva, Switzerland.

Protein undernutrition is frequently encountered in elderly. It is associated with decreased bone formation and increased bone resorption, together with lower IGF-I levels. Previous clinical and preclinical studies have demonstrated the favorable effect of aminoacids supplements on bone turnover and mineral density. On the other hand, dietary zinc supplement positively influences IGF-I production in zinc-depleted patients. To evaluate the possible additive effects of zinc and aminoacids supplements on serum IGF-I and bone turnover, we randomized 61 frail elderly with a mini nutritional assessment score between 17 and 24 (corresponding to a failure to thrive) into a daily oral protein supplement containing 15g whey protein, 5g essential aminoacids and 550mg calcium with or without 30 mg/day of zinc for 4 weeks on a double-blind trial. Fasting serum IGF-I (µg/l), IGF-BP3 (µg/l), Osteocalcin (µg/l) and CrossLapsTM (ng/ml) were measured at baseline, and after 1, 2 and 4 weeks of protein/zinc supplementation. Functional performance was assessed by an activity of daily living (ADL) score. At baseline, mean age was 83.6±1.3 (x±SEM) and 86.4±1.3 (NS), serum IGF-I 82.6±9.0 and 73.3±8.3 (NS), and albumin 31.0±0.8 and 30.4±0.8 (NS) in the zinc supplemented group and the controls, respectively. During essential aminoacids/whey protein supplements, serum IGF-I increased and reached a maximal of +40% by 2 weeks. Zinc accelerated this increase with changes of +48.3±14.3* vs +22.4± 4.7 % (*,p<0.05) by 1 week, in the zinc supplemented group and the controls, respectively. IGF-I/IGF-BP3 ratio, taken as a reflection of IGF-I bioactivity, increased by +37.3±10.7* vs 13.1±3.4% after one week. Zinc significantly decreased serum CrossLapsTM (-10.3±4.9* vs +3.9±4.7%) already by 1 week. Osteocalcin increased in both groups (+16.4±7.0 and +21.5±9.0%) irrespective of zinc supplements. ADL score significantly increased more in response to zinc in the subgroup of patients with baseline albumin lower than the mean (+25.7±8.1* vs +11.9±6.5%). In conclusion, zinc supplement accelerated IGF-I response to essential amino acids/whey protein supplement and decreased bone resorption together with an increase in bone formation, in elderly. These results suggest that zinc supplements should thus be considered during protein repletion of undernourished elderly.

Morning and Evening Dosing of Oral Salmon Calcitonin (SM021): The Influence of Food Intake on the Bioavailability and Efficacy of the Evening Dose. L. B. Tankó, I. Byrjalsen, B. J. Riis*, A. Moelgaard*, C. Christiansen. CCBR A/S, Ballerup, Denmark.

The aim of the study was to investigate the influence of food intake on the bioavailability and efficacy of salmon calcitonin (CT) in healthy postmenopausal women. The study was a single-blind, randomized, partly placebo controlled study. Participants were 36 postmenopausal women 62-74 years old, who were randomly assigned to one of 18 different treatment schedule involving 3 consecutive visits with at least 48 hours in between. This protocol resulted in 12 measurements of each response elicited by the following dosing regimes: 1) 0.8 mg CT at 10 pm followed by meal at 10:10 pm, 2) meal at 9 pm followed by 0.8 mg CT at 10 pm, 3) meal at 8 pm followed by 0.8 mg CT at 10 pm, 4) meal at 6 pm followed by 0.8 mg CT at 10 pm, 5) 0.8 mg CT at 10 pm but no meal 6) meal at 8 pm + placebo. Study parameters were the changes in plasma CT and bone turnover markers (serum and urinary C-terminal telopeptide of collagen type I, CTX I, and serum levels of osteocalcin, OC). For comparison of morning and evening benefits under fasting conditions, CTX I responses during fasting conditions elicited by 0.8 mg CT given at 8:00 am were also investigated. Postprandial intake of 0.8 mg CT at 10 pm was associated with decreased peak plasma concentrations of CT compared with peak concentrations associated with the same oral dose taken 10 min before meal or in the fasting state (Fig. 1). Furthermore, CT intake at 10 pm elicited smaller (Fig. 2) and shorter-lasting relative decreases in CTX I when administered after food intake. However, the AUC characterizing the 4-hour response elicited by 0.8 mg CT taken in the fasting state was comparable with that elicited by CT taken 10 min before food intake (group C vs. G, Fig. 2). Furthermore, the AUC of 4-hour CTX I responses elicited by preprandial dosing of 0.8 mg CT in the morning hours was comparable with that obtained by the same dose taken in the evening hours (253±16 vs. 237±36 % x hours). Salmon CT did not exert significant effects on osteocalcin, independent of the relative time of drug intake. In conclusion, postprandial dosing may limit the bioavailability of oral sCT. However, the rapid absorption to the plasma suggests that maximal benefits in terms of inhibiting the nocturnal rise in bone resorption can be achieved if dosing occurs before evening meal.

Influence of Two Different Calcium and Vitamin D Dose on Parathyroid Hormone Secretion among Women over the Age of 65. M. T. Tuppurainen[1], M. H. Komulainen*[2], R. Honkanen[1], H. J. Kröger[1], E. M. Alhava*[3]. [1]Bone and Cartilage Research Unit, Kuopio University, Kuopio, Finland, [2]Obstetrics and Gynecology, Kuopio University Hospital, Kuopio, Finland, [3]Department of Surgery, Kuopio University, Kuopio, Finland.

Calcium and vitamin D supplementation have been shown to reduce secondary hyperparathyroidism and play a protective role in age-related osteoporosis. In order to define the optimal regimen of calcium and vitamin D supplementation to produce the maximal inhibition of parathyroid -hormone (PTH) secretion, we compared the administration of a calcium-vitamin D supplement as a single morning dose with the administration of two divided doses at 8 -hour intervals among 30 healthy women over the age of 65 from OSTPRE- Fracture Prevention Study. This was an open, crossover study, where the sequence of administration of the two regimens was randomised. The two regimens were: treatment A, two calcium (500mg) + vitamin D3 (400IU) tablets (Calcichew- D3 Forte®, Leiras Nycomed) once a day in the morning during breakfast, treatment B; one calcium+ vitamin D tablet twice a day at 8 hours interval, first during breakfast and second during lunch. Venous blood samples were drawn for analysis prior to the study drug intake and every hour 11 hours after the first dose. RMANOVA was used for statistical analysis. During the first time interval (0-480 minutes) the PTH levels decreased rapidly until 120 minutes and then started gradually to increase until 480 minutes. However, the PTH levels did not rise back to their baseline level. When outlying observations were removed there were no statistically significant differences between the treatment groups in the PTH levels. During the second time interval (480-660 minutes) there was a statistically significant difference in the PTH levels between the treatment groups with the group B having lower PTH levels after the second administration. Both treatment groups seemed to have similar lowering effects on PTH levels during the first administration, but after the second administration the B- group lowered the PTH levels while in the A group the PTH levels continued to increase. Both treatment groups seemed to have similar effects on S-calcium levels during the first administration, but after the second administration the B- group had higher S-calcium levels than the A- group. In conclusion, by administering calcium and vitamin D in two separate doses, the secretion of PTH is decreased more effectively than by single daily dosing. Twice a day dosing may provide more effective protection against secondary hyperparathyroidism, bone resorption and may offer more fracture prevention than single dosing among elderly women.

Inulin and Fructo-Oligosaccharides Differ in their Ability to Enhance both the Bone Mineral Density and the Mucosal Levels of 9-kDa Calcium Binding Proteins in Rats. D. H. Manicourt*, A. Nzeusseu Toukap*, J. P. Devogelaer. Rheumatology Unit, St-Luc University Hospital, Brussels, Belgium.

The increase in BMD observed in growing rats fed with chicory fructans can be related, at least partly, to an increase in calcium absorption in the colon. It is generally believed that products of the colonic fermentation of fructans improve calcium absorption by increasing the solubility of calcium salts by lowering the luminal pH and by inducing hypertrophy of cecal walls, but direct effects such as an increase in the levels of calcium binding proteins (CaBPs) in the mucosal cells of the large bowel cannot be excluded. Therefore, for a 3-month time period, 3 groups of 13 six-week-old male rats each received either the standard AO4 diet (CTL group), the standard diet containing 5% inulin (INU group) or the standard containing 5% chicory oligofructose (OLF group). At sacrifice, rats of the 2 fructan groups both had a similar median cecal wall weight (1.5 g) that was significantly higher than that of the CTL group (0.9 g; $p < 0.001$). Mucosal proteins were subjected to Western blots and semi-quantification of blots probed with anti- 9-kDa-Calbindin antibodies showed that the levels of this CaBP was increased by a factor of 2 in the OLF group and by a factor of 3 in the INU group. Surprisingly, a monoclonal anti-28-kDa-Calbindin antibody detected a signal at the expected molecular weight in all specimens; further, when compared to the CTL group, the signal intensity was increased by a factor of 3 in the OLF group and by a factor of 5 in the INU group. Tibia and the third lumbar vertebra (L-3) stripped off adherent tissues were analyzed by using pQCT (Research SA+, Stratec, Germany). In both L3 and proximal tibia, the BMD of cancellous bone was significantly increased by INU (0.27 versus 0.23 and 0.33 versus 0.22 g/cm3, respectively; $p<0.001$) and to a lower extent by OLF (0.26 and 0.28 g/cm3; $p<0.05$). Further, inulin but not OLF, enhanced the BMD of cortical bone in both L-3 (0.98 versus 0.93 g/cm3; $p < 0.01$) and tibia (0.88 versus 0.83 g/cm3; $p<0.01$). In conclusion, although inulin and OLF both have a positive effect of the BMD of the axial and peripheral skeleton of growing rats, the stronger effect of inulin cannot be related to an increase in the exchange surface area of the gut, as assessed by the cecal wall weight, but is likely to be related, at least partly, to a strongest increase in the mucosal levels of the 9 kDa and 28 kDa calcium binding proteins which both contribute to intestinal calcium absorption.

Effect on Bone Turnover and BMD of Low Dose Oral Silicon as an Adjunct to Calcium/Vitamin D3 in a Randomized, Placebo-Controlled Trial. T. D. Spector[1], M. R. Calomme[2], S. Anderson*[1], R. Swaminathan*[1], R. Jugdaohsingh*[1], D. A. Vanden Berghe*[2], J. J. Powell*[3]. [1]St Thomas' Hospital, London, United Kingdom, [2]Faculty of Pharmaceutical Sciences, University of Antwerp, Antwerp, Belgium, [3]MRC Human Nutrition Research, Cambridge, United Kingdom.

Mounting evidence supports a physiological role for silicon (Si) as orthosilicic acid (OSA; $Si(OH)_4$) in bone formation. Mechanisms are unclear but collagen synthesis and improved mineralization have been demonstrated in cellular and animal models. Human data are lacking so here we have investigated the effect of low dose oral silicon on markers of bone turnover and BMD in a randomized, placebo-controlled trial. Over 12 months, 114 women (mean age: 61 y) out of 184 randomized (T score spine < -1) completed the study and received, daily, 1000 mg Ca and 800 IU cholecalciferol (Vit D3) ± Si as choline-stabilized orthosilicic acid (ch-OSA). Three different Si doses were used (Table) which, in this population, would typically increase dietary Si intakes by 12.5, 25 and 50%. In all groups, there was wide variation in the changes to bone markers at 6 and 12 months compared to baseline (Table) so covariate analysis was used to adjust for baseline values. Overall, there was a trend for Si to confer some additional benefit to Ca & VitD3, especially for markers of bone formation (Table), but only PINP was significant by ANCOVA: LSD post-hoc analysis indicated significance at 12 months for the 6 and 12 mg Si dose ($p < 0.05$ *vs* placebo) where there was also a trend for a corresponding increase in the bone resorption marker, collagen type I C-terminal telopeptide (data not shown).

Change in Markers of Bone Formation vs Baseline (%, mean ± SD)

Calcium/Vit D3 plus:		Placebo	3 mg Si	6 mg Si	12 mg Si
Serum Marker	Change at	n = 30	n = 26	n = 28	n = 30
PINP	6 mo	-12.9 ± 17.5	-8.92 ± 26.2	-11.3 ± 21.8	-9.03 ± 21.7
	12 mo	-19.9 ± 24.7	-15.9 ± 26.6	-0.88 ± 27.6*	-7.42 ± 20.7*
BAP	6 mo	-11.6 ± 16.6	-2.40 ± 20	-5.44 ± 12.8	-3.31 ± 15.5
	12 mo	-12.0 ± 20	-5.28 ± 15.5	-7.27 ± 16.6	-5.69 ± 17.3
Osteocalcin	6 mo	-4.62 ± 31.4	-3.36 ± 33.6	-7.24 ± 18.6	-3.65 ± 20.4
	12 mo	-15.0 ± 23.6	-6.08 ± 54.5	-12.4 ± 18.2	-7.79 ± 26.4

BAP = bone specific alkaline phosphatase. PINP = procollagen type I N-terminal propeptide. *p< 0.05 *vs* placebo (ANCOVA).

BMD in the spine did not change significantly. Subgroup analysis (femur T score < -1) however was significant for the 6 mg dose at the femoral neck (t-test). This study suggests that combined therapy of ch-OSA plus Ca/vit D3 is a safe, well tolerated treatment that has a potentially beneficial effect on bone turnover, especially bone collagen, and possibly the femoral BMD compared to Ca/vit D3 alone.

We acknowledge support of the National Osteoporosis Society and Bio Minerals n.v.

Effects of Calcium Supplementation on Body Composition and Fat Distribution in Korean Obese Postmenopausal Women. D. Kim*, Y. Rhee, C. Ahn*, B. Cha*, K. Kim*, H. Lee*, S. Lim. Internal Medicine, College of Medicine, Yonsei Univ., Seoul, Republic of Korea.

Backgrounds and aims According to National Health and Nutrition survey reported in 2002, daily dietary calcium consumption was unexpectedly low and tended to decrease gradually with increasing intake of protein especially in postmenopausal women. In this context, we hypothesized that low calcium intake at baseline would increase susceptibility to effects of calcium supplementation in view of a threshold effect. Thus, the aim of this study was to investigate the efficacy of elementary calcium on serum lipids, body composition and fat distribution, and insulin sensitivity and to identify the factors affecting weight change during calcium supplementation in Korean obese postmenopausal women. **Subjects and methods** Forty-four obese postmenopausal women (age=60±8.8years, BMI=29±4.6kg/m^2) received a daily dose of 300mg calcium in addition to basal dietary calcium (400±200 mg per day) for 48 weeks. Lipid profiles, whole-body dual X-ray absorptiometry, fat Computed Tomography, and HOMA-IR scores were assessed at baseline and after 48 weeks. According to calcium intake at baseline, subjects were divided into low CA group (moderate-to-severe calcium deficiency, calcium intake <400 mg per day) and high CA group (mild calcium deficiency, calcium intake > 400mg per day). Calcium intake was assessed by calculating average amount of dietary calcium on the basis of 72-h diet diary. **Results** After 48 weeks, body weight decreased by 3.0±0.3kg (P<0.05). Total body fat (by 2.0±0.2%, P<0.05 and by 2.1±0.2kg, P<0.01), and areas of abdominal visceral fat and mid-thigh low-density muscle decreased (P<0.01). Serum triglyceride and 25-(OH) vitamin D levels decreased (P<0.05 in each case). Serum insulin and HOMA-IR scores showed a tendency to decrease (P=0.06 and p=0.05, respectively). Low CA group was more obese than high CA group at the time of entry. Low CA group achieved more weight and fat loss and improvement of insulin sensitivity after 48-week calcium supplementation than high CA group. **Conclusions** We confirmed that calcium supplementation induces body weight and fat loss with favorable changes of fat distribution (reduced abdominal visceral fat and low-density muscle), directing toward improvement of insulin sensitivity. We found adiposity and calcium intake at baseline may partially determine the magnitude of the response to calcium supplementation. In the presence of moderate calcium deficiency, Korean obese postmenopausal women may benefit from calcium supplementation for favorable changes of serum lipids and body composition.

The Effect of Phytoestrogens on Intestinal Calcium Absorption. L. E. Ryan[1], D. L. Habash*[2], K. A. Foland*[3], H. N. Nagaraja*[2], R. D. Jackson[1]. [1]Division of Endocrinology, Diabetes and Metabolism, The Ohio State University, Columbus, OH, USA, [2]General Clinical Research Center, The Ohio State University, Columbus, OH, USA, [3]Department of Geological Sciences, The Ohio State University, Columbus, OH, USA.

One of the mechanisms by which estrogen improves bone strength is its positive effect on intestinal calcium absorption efficiency. Phytoestrogens have emerged as a possible alternative to hormone therapy for protection against osteoporosis. Using a dual-isotope method in a pre-/post- design, we have evaluated the effect of high-dose dietary phytoestrogens (90mg/day of genistein + daidzein) on intestinal calcium absorption in postmenopausal women. Eleven participants were included in the study; their average age was 57 years (range 53 - 60) and time since menopause ranged from 1-9 years. For three months, during the Ohio winter season, the women ingested the soy or placebo protein (average 36gm protein/d), incorporated into muffins. One participant terminated the study after eight weeks secondary to nausea and constipation; the other ten women tolerated the protein well. All data will be presented in an intention-to-treat analysis. All subjects met the adherence criteria based upon urinary phytoestrogen levels and frequent muffin counts. From baseline to the end of the dietary intervention at 12 weeks the urinary daidzein increased from 0.06 μmol/L to 8.27 μmol/L, genistein 0.20 to 3.17 μmol/L, and equol 0.56 to 10.08 μmol/L, while those in the placebo group did not differ. Total dietary protein intake increased 12.9% from an average of 82.4gm/d to 92.9gm/d, and daily calcium intake increased by 49.7% from an average of 980mg/d to 1467mg/d. Fiber and vitamin D intake did not change with dietary intervention and was within the adequate intake (AI) range for each. The peak of intestinal calcium absorption at baseline and at three months was consistently reached, in each participant, between 3-4 hours after ingestion of the oral Ca42. A small but statistically insignificant increase in intestinal calcium absorption was noted in the group taking soy protein. In summary, although phytoestrogen levels significantly increased with dietary intervention, we found no correlation between ingestion of high dose phytoestrogens and peak intestinal calcium absorption.

Effects of Raloxifene on Lumbar BMD and Bone Markers in Postmenopausal Osteoporotic Korean Women. I. Joo*, T. Bae*, H. Oh*. Family Medicine, Sungkyunkwan University, Seoul, Republic of Korea.

To determine the effects of Raloxifene on BMD and markers of bone turnover , we evaluated 68 postmenopausal osteoporotic Korean women who visited the Osteoporosis clinic in Samsung Cheil Hospital & Women's Health Care Center stratified in three groups ; raloxifene+alendronate(N=20), raloxifene(N=18), HRT(etradiol 2.0mg)(N=20). BMD at lumbar spine and markers of bone turnover(osteocalcin, alkaline phosphatase) were measured in the beginning and after 1-year treatment. BMD did not increase significantly in raloxifene alone group. However raloxifene with alendronate in combination and HRT groups showed the significant increase of BMD compared with raloxifene alone. All of three groups showed significant decrease of bone turnover markers such as osteocalcin and alkaline phosphatase. Serum levels of osteocalcin was significantly decreased in raloxifene with alendronate in combination and HRT groups compared with raloxifene alone. Raloxifene with alendronate in combination showed significant decrease of alkaline phosphatase level. In postmenopausal osteoporotic Korean women, treatment with raloxifene alone did not show significant increase in lumbar BMD. However, it decreased bone turnover markers not so much as raloxifene with alendronate in combination or HRT. Raloxifene might have an preventive effects on losing BMD in postmenopausal osteoporotic Korean women.

Variables	Baseline characteristics of the Subjects Raloxifene with Alendronate(n=27)	Raloxifene Only(n=18)	HRT(n=23)	Total(n=68)
Age	61.4±6.9*	57.5±8.3	56.1±7.2	58.6±7.1
Height	156.5±5.9	154.6±3.1	154.4±4.7	155.3±4.9
Weight	60.6±7.8	57.5±5.9	53.5±4.7	57.4±7.0
BMI	24.7±2.3	24.1±2.2	22.4±1.7	23.8±2.3
Spinal BMD	0.726±0.039	0.746±0.041	0.740±0.038	0.736±0.040
Osteocalcin	6.7±2.6	7.8±2.6	6.9±2.1	7.0±2.4
Total alkaline phosphatase	81.3±33.4	80.7±13.4	85.3±23.2	82.5±25.7

3 Year-Follow-Up of Bone Mineral Density after a Randomised Trial of 12-Month Treatment with a GnRH Agonist (leuprorelin 3.75 mg) Associated with 2 Options of Steroidal "Add-Back" Regimens in Patients with Endometriosis. C. Roux[1], C. Lucas*[2], K. Briot*[1], S. Kolta[1], J. Fechtenbaum[1], H. Fernandez*[3]. [1]Rheumatology, Cochin University Hospital, Paris, France, [2]Medical, Laboratoires Takeda, Puteaux, France, [3]Gynaecology, Antoine Béclère University Hospital, Clamart, France.

We previously compared, in a 12-month double-blind trial involving 78 patients with symptomatic endometriosis, the efficacy and safety of 2 add-back regimens associated with leuprorelin acetate 3.75 mg: promegestone 0.5 mg (P) plus either placebo (PL) or estradiol 2 mg (E) per day (Hum Reprod. 2004 19: 1465-71). The BMD decrease was significantly more pronounced in the PL-group: -6.1 ± 3.7% (n=30) versus -1.9 ± 3.1% (n=29) in E-group ($p<0.0001$). Here, we report the post-treatment effects on a 3-year follow-up (FU). Methods: patients with a significant decrease of BMD at the end of the 12-month therapeutic period (> 2.8% from baseline at the L2-L4 vertebral site, related to the precision method) had an annual BMD (central analysis of scans; quality control 3 times/ week on a spine phantom) until recovery or during 3 years. No patient received anti-osteoporotic drug during follow-up. Results: among the 59 patients assessed at the end of the trial, 36 (26 PL-group, 10 E-group) had a significant BMD decrease from baseline: 9 were lost for BMD FU while 2 (all PL-group) were excluded because their agonist treatment was prolonged off-protocol. Finally, 25 patients (19 PL- group, 6 E-group) had at least one BMD measurement during the 3-year follow-up: 8/21 (38%) patients recovered by 1 year, 16/24 (67%) by 2 years and 18/25 (72%) by 3 years (14/19 PL group, 4/6 E-group) with a mean delay until recovery of 19.3 ± 8 months (median 18.7). Bone loss during treatment was a determinant of the delay until recovery ($p<0.05$). Changes of BMD at the end of the treatment phase, after 1, 2 and 3 year FU (cumulated data) were:

	Post-treatment N = 25	12 month FU N = 21	24 month FU N = 24	36 month FU N= 25
Changes from baseline Mean % ± SD	-6.61 ± 2.9	-3.16 ± 2.6	-2.20 ± 2.2	-2.04 ± 2.2
Changes from baseline Median %	-6.01	-3.48	-1.81	-1.81
Changes from post-treatment Median %	_	+3.39	+4.33	+4.65

In conclusion, majority of patients receiving a one-year treatment regimen combining leuprorelin 3.75 mg plus P-E recovered spontaneously their baseline BMD within 3 years (out of 29, 2 didn't and 4 were lost for FU) while 5 out of 30 didn't recover in the P-PL add-back group (5 lost for FU, 2 not interpretable). In case a significant bone loss occurs during treatment, recovery is reached within 2 year in 2/3 women.

Pharmacological Actions of a Selective Estrogen Receptor β (ERβ) Agonist in Overiectomized Rats. G. Krishnan[1], Q. Q. Zeng*[1], R. L. Cain*[1], J. Oskins*[1], K. Chen*[1], B. Norman*[2], T. I. Richardson*[2], D. A. Dodge*[2], C. Montrose-Rafizadeh*[3], B. C. Yaden*[1], S. Cockerham*[3], C. Frolik[1], M. Sato[1], H. U. Bryant[1], Y. L. Ma[1]. [1]Endocrine Research, Eli Lilly and Company, Indianapolis, IN, USA, [2]Discovery Chemistry, Eli Lilly and Company, Indianapolis, IN, USA, [3]Lead Optimization Biology, Eli Lilly and Company, Indianapolis, IN, USA.

The key role of estrogen in the regulation of skeletal growth and maintenance of bone mass has been demonstrated in human and animal models. Studies demonstrated that mice lacking ER β show increased cortical bone in adolescent females and protection against age-related trabecular bone loss in aged females (*Windahl et al, JCI, 1999, JBMR 2001*). Therefore, it was important to evaluate the effects of an ER agonist in an estrogen deficient skeleton. The aim for this study was to examine the pharmacological effects of LSN500307, a tissue-selective ER β agonist in ovariectomized (Ovx) rats. LSN500307 had high affinity binding to the *hERβ*(Ki-0.19 nM) -and *hERα*(Ki-2.7 nM) receptors, and induced alkaline phosphatase activity in Ishikawa cells EC_{50}=78 nM. In addition, it was found to reduce prostate weight in 12-week-old male CD-1 mice in a dose-dependent manner (ED_{50} = 0.05 mg/Kg/day). We orally dosed 6 months old ovariectomized (Ovx) rats with 0.1, 0.3, 1 and 3mg/kg/d LSN500307 starting at 1 week post surgery for 5 weeks. LSN500307 prevented ovx-induced increases in body weight and serum cholesterol in a dose dependent manner, with similar efficacy to ethynyl- estradiol (EE, 0.1mg/kg/d) at a 1mg/kg dose. LSN 500307 also dose dependently maintained the uterine wet weight in Ovx rats. The uterine wet weight at 3mg/kg dose was 2.5 fold higher than Ovx but it was 50% less than Sham controls. Quantitative computed tomographic analyses of femur showed that LSN500307 did not affect bone mineral content at any dose in distal femur metaphysis and mid femur but had significantly higher bone mineral density at 1and 3 mg/ kg/d doses in distal femur metaphysis when compared to Ovx control. Similar results were seen in cortical bone site of mid femur. Our data suggest that a novel ER β agonist LSN500307 has positive effects on body weight and neutral/positive effects on bone in Ovx rats.

Extraskeletal Effects of Lasofoxifene on Postmenopausal Women. M. Davidson[1], A. Moffett*[2], F. Welty*[3], J. Simon*[4], M. Bolognese[5], N. deMelo[6], K. Wolter[7], J. Proulx[7], D. Radecki[7]. [1]Rush University Medical Center, Chicago, IL, USA, [2]OB-GYN Associates of Mid-Florida, Leesburg, FL, USA, [3]Beth Israel Deaconess Medical Ctr, Boston, MA, USA, [4]Women's Health Research Ctr, Laurel, MD, USA, [5]The Bethesda Health Research Ctr, Bethesda, MD, USA, [6]Instituto de Saude e Bem-Estar da Mulher, Sao Paulo, Brazil, [7]Pfizer Global R&D, New London, CT, USA.

Lasofoxifene, a next-generation selective estrogen receptor modulator that prevents bone loss, interacts with the estrogen receptor differently in various tissues. It was important to determine the effects of lasofoxifene on extraskeletal targets i.e. breast, vagina, brain, and cardiovascular system. In 2 identical, phase 3, double-blind trials, 1907 postmenopausal women were randomized to lasofoxifene 0.025 mg/d, 0.25 mg/d, or 0.5 mg/d or placebo (PBO) daily, plus calcium and vitamin D. Changes in signs and self-assessed symptoms of vaginal atrophy (VA), cognitive function, and lipids were periodically analyzed over 24 months (mos). Neither breast density nor breast pain increased in the lasofoxifene groups. Vaginal pH and the maturation index were improved at 12 and 24 mos in all 3 lasofoxifene groups. At 24 mos, lasofoxifene subjects had significantly lower percentages of parabasal cells and significantly higher percentages of immediate cells and superficial cells versus PBO (p 0.004). There was a significant improvement in vaginal pH at 12 and 24 mos for all doses of lasofoxifene versus PBO ($p<0.001$). Cognitive function and mood, examined in a subset of subjects (n=267), showed no significant differences in the lasofoxifene groups versus PBO except a lower CESD-10 depression score at 12 mos in the 0.025 mg group (p=0.017) and a lower Digits Forward score at 24 m (p=0.026), neither clinically meaningful. At 12 mos, all lasofoxifene doses significantly decreased median LDL-C, total cholesterol (TC), TC/ HDL-C ratio, apolipoprotein B100 (apo B-100), apo B-100/apolipoprotein A1 (apo A1) ratio, hs-C-Reactive Protein and lipoprotein (a) versus PBO. There was a beneficial effect on apo A1, a small decrease in HDL-C in one lasofoxifene group, and a 0.5 to 7.3% increase in median triglyceride levels. At 24 mos, fibrinogen levels significantly decreased from baseline for all lasofoxifene groups versus PBO. Adverse events often reported during lasofoxifene treatment included hot flushes, leg cramps and increased vaginal moisture. Lasofoxifene had no effect on breast density. VA parameters (pH and maturation index) were improved with lasofoxifene treatment. Cognitive function and mood were not affected. Lasofoxifene had a favorable effect on lipid and lipoprotein levels and established biomarkers of CV risk.

Hormone Interventions Lead to Favorable Changes in Hip Geometric Structure ---Results from the Hormone Trials in the Women's Health Initiative (WHI). Z. Chen[1], C. E. Lewis[2], J. Cauley[3], A. LaCroix*[4], T. Beck[5], D. Nelson[6], S. Green*[1], D. Sherrill*[1], T. Lohman*[1], R. Jackson*[7], M. LeBoff*[8], G. Wu*[1], N. Wright*[1], S. Nicholas*[1], L. Arendell*[1], E. Outwater*[1], Z. Wang*[9], S. Heymsfield*[9], T. Bassford*[1]. [1]University of Arizona, Tucson, AZ, USA, [2]University of Alabama at Birmingham, Birmingham, AL, USA, [3]University of Pittsburgh, Pittsburgh, PA, USA, [4]Fred Hutchinson Cancer Research Center, Seattle, WA, USA, [5]Johns Hopkins University, Baltimore, MD, USA, [6]Wayne State University, Detroit, MI, USA, [7]Ohio State University, Columbus, OH, USA, [8]Harvard Medical School, Boston, MA, USA, [9]Columbia University, New York, NY, USA.

Loss of bone mechanical strength underlies osteoporotic fragility fractures and an effective therapy should demonstrably improve either the structural geometry or bone tissue strength. We hypothesized that hormone interventions among postmenopausal women significantly improve the structural geometry of the proximal femur. Study participants were a subgroup of women (one WHI clinical center) from the WHI randomized controlled hormone intervention trials: either conjugated equine estrogen only (CEE) or estrogen plus progestin (E+P), who were 50 to 79 years old at baseline and were followed up to 6 years. Bone densitometry, including scans at the hip, were conducted by dual-energy x-ray absorptiometry (DXA) at baseline, year1, year 3 and year 6. Hip structural analyses (HSA) on the DXA hip scans were conducted using the BECK HSA program. Mixed effect models with the intent-to-treat analysis approach were used. There were no differences in hip geometric measurements at baseline between the intervention and the placebo group in the CEE trial ($N_{placebo}$ = 97, N_{CEE} = 87) or in the E+P trial ($N_{placebo}$ = 114, N_{E+P} = 124). Statistically significant treatment benefits ($p<0.05$) of hormone interventions on hip strength were observed as early as one year after the starting of the intervention: Section Modulus (a measure of maximum bending stress) was preserved (figure 1), Buckling Ratio (a index of cortical instability under compression) was reduced by hormone interventions. In conclusion, hormone interventions led to favorable changes in femur cross-sectional geometry, which may help to explain the reduced fracture risk observed in hormone interventions.

Bazedoxifene Prevents Ovariectomy-Induced Bone Loss in the Cynomolgus Monkey. S. Y. Smith[1], D. Minck*[2], J. Jolette*[1], L. Chouinard[1], C. H. Turner[3], B. Komm[4]. [1]Charles River Laboratories Preclinical Services•CTBR, Senneville, PQ, Canada, [2]Wyeth Research, Chazy, NY, USA, [3]Indiana University, Indianapolis, IN, USA, [4]Wyeth Research, Collegeville, PA, USA.

Bazedoxifene (BZA) is a selective estrogen receptor modulator (SERM) currently in phase III development for the prevention and treatment of osteoporosis. The purposes of this study were to determine the efficacy of BZA after 18 months of treatment on bone mass, strength and architecture, and to evaluate effects on plasma lipids and reproductive tract histology, in surgically-induced postmenopausal monkeys. Ovariectomized (OVX) animals (18/group) were administered control article or BZA by daily oral gavage at 0.2, 0.5, 1, 5, or 25 mg/kg/day. A sham-operated control group was administered control article. Blood and/or urine were evaluated for markers of bone turnover (bone specific alkaline phosphatase, osteocalcin, serum C-telopeptide and urinary N-telopeptide), and serum lipids. BMD was determined *in vivo* by DXA for the lumbar spine and proximal femur, and by pQCT at the proximal tibia. Soft tissues were examined histologically, and histomorphometric analysis and biomechanical testing were performed on bones. Administration of BZA for 18 months to OVX animals had no meaningful effect on serum calcium, cholesterol, HDLC or triglycerides and showed no uterotrophic effect at any dose level. BZA partially prevented the OVX-induced rise in biochemical markers of bone turnover at all dose levels. The highest dose levels of BZA generally maintained BMD at pre-OVX levels at all sites evaluated, but most notably at the lumbar spine. BZA treatment partially prevented the OVX-induced accelerated bone remodeling in cortical bone with variable effects on indices of cancellous bone turnover. There were no deleterious effects of BZA on bone mineralization or structural parameters. BZA treatment up to 25 mg/kg/day for 18 months had no adverse effect on biomechanical strength parameters at the femur, femoral neck or lumbar spine. Bone strength parameters were significantly correlated with bone mass at the femur diaphysis, femoral neck and lumbar vertebrae. In conclusion, BZA treatment of OVX monkeys at dose levels up to 25 mg/kg/day for 18 months resulted in the partial preservation of bone mass as determined by bone densitometry. This was achieved by significant reductions in OVX-induced increases in bone turnover, evaluated by biochemical markers and histomorphometric indices in cancellous and cortical bone. BZA was well tolerated and was not associated with any adverse effects on plasma lipids or reproductive tract histology. Importantly, treatment with BZA did not adversely affect any measures of bone strength at the skeletal sites evaluated.

SA432

Response of BMD and Back Pain to 12 Months of Teriparatide (rhPTH 1-34) in Patients with and without Prior Antiresorptive Treatment: One-Year Interim Results from the EUROFORS Study. H. Minne[1], M. Audran*[2], E. Simoes*[3], B. Obermayer-Pietsch[4], G. Sigurdsson*[5], T. Nicholson*[6], F. Marin[6], T. N. Nickelsen[6]. [1]Klinik Fuerstenhof, Bad Pyrmont, Germany, [2]Centre Hosp. Universitaire, Angers, France, [3]Inst. Portugues de Reumatologia, Lisbon, Portugal, [4]Med. Univ.-Klinik, Graz, Austria, [5]Landspitalinn Univ. Hospital, Reykjavik, Iceland, [6]Eli Lilly & Company, Windlesham, United Kingdom.

EUROFORS is an ongoing prospective, randomized trial, designed to investigate various sequential treatments of teriparatide over 2 years in postmenopausal women with established osteoporosis. In year 1, all patients received open-label teriparatide 20 µg/d and supplements of 500 mg/d calcium and 400-800 IU/d vitamin D. For the 1-year analysis, we pre-defined 3 subgroups: (1) Osteoporosis treatment-naïve patients, patients with (2) adequate or (3) inadequate clinical outcome to prior antiresorptive (AR) therapy, with the latter defined as: (a) sustaining ≥1 new clinical fragility fracture(s) despite prescription of AR therapy during the 12 months prior to fracture; (b) T-score ≤ -3,0 SD or (c) BMD decrease ≥3.5% at lumbar spine (LS), total hip (TH) or femoral neck (FN) ≥2 years after initiating AR therapy. In 87.7% of pre-treated patients (groups 2 and 3 combined), a bisphosphonate (BP) was used preceding the study for a mean of 33.5 months. There were 159 early study discontinuations during year 1 (18.4%), 50 for adverse events and 31 for patients' decisions associated with the medication or injection device. The best adherence was seen in Group 3. In the total cohort, BMD showed a statistically significant increase from baseline at the LS and FN, and a reversal of the transient 0.5% loss after 6 months at the TH. The Table lists the results by subgroup [% change, mean(SD); *<.05, **<.01, ***<.001]. Twenty patients (2.6%) showed a LS BMD loss of >3.5%, while 531 (68.3%) had an increase by >3.5%. Back pain, self-assessed by the patients on a 100 mm visual analog scale, decreased by a mean of 11.5 mm (p<0.001) in the total cohort. The proportion of patients with a clinically relevant pain improvement (defined as a decrease of ≥15 mm) was largest in those with severe pain at baseline (defined as a score >60 mm). We conclude that 12 months of treatment with teriparatide is well tolerated and associated with a BMD increase at the lumbar spine and femoral neck and a decrease in back pain.

Increased Focal Uptake of Tc-99m Labelled MDP on Bone Scan Suggestive of Hyperostosis Frontalis Interna in a Patient Being Treated with Teriparatide. G. C. Lim*, W. S. Wafa*, A. M. Moses. Department of Medicine- Endocrinology, Diabetes and Metabolism, SUNY Upstate Medical University, Syracuse, NY, USA.

An 86-year-old woman with history of nontraumatic fractures including the right hip, wrists, and a thoracic vertebra was referred to our bone clinic because she continued to develop nontraumatic fractures even while taking alendronate for 5 years. Baseline lab tests showed a normal serum calcium, phosphorus, PTH, 25-hydroxy vitamin D and 24-hour urinary calcium. Serum alkaline phosphatase (SAP) was 116 U/L (36-126). T-score of the left total hip was -3.4 and Z-score was -1.1. Her lumbar spine bone density was factitiously elevated. She was then started on teriparatide. After being on teriparatide for 4 or 5 months, she developed increasingly severe dull headaches over the vertex and right frontoparietal areas of the skull. Follow-up SAP was 155 U/L. A bone specific alkaline phosphatase (BSAP) was 38 ng/ml (12-23). A bone scan showed a diffusely increased uptake in the skull which was not present 20 months before teriparatide was intitiated. Routine radiographs and CT were more suggestive of hyperostosis frontalis interna than Paget's disease. Bone biopsy could not be obtained. On the basis of the lab and radiologic findings, teriparatide was discontinued. The patient noted immediate improvement in the frequency and severity of her headaches. Six weeks after discontinuing teriparatide, SAP was 134 U/L and BSAP was 37 ng/ml. Bone turnover markers are expected to increase during teriparatide treatment and this increase may correlate with improvement in bone density. However, there are no clear guidelines to alert the physician when to consider the development of other bone diseases such as Paget's disease, hyperostosis frontalis interna or even osteosarcoma. In summary, we present a case that raises a concern about when an elevation of turnover marker during tereparatide therapy should warrant radiologic evaluation. Follow-up bone turnover markers and bone scan on our patient will be made available at the meeting.

Bone Mass, Cortical Bone Histomorphometry and Trabecular Bone 3D-Microarchitecture in Ovariectomized Rats Treated with Intermittent PTH Administration. S. Gomez*[1], C. de la Piedra*[2], M. Montero*[2], S. Luna*[1], D. Sarasa*[1], V. Crespo*[3], J. García*[3], M. Diaz-Curiel*[4]. [1]Anatomic Pathology, Cadiz University, Cadiz, Spain, [2]Fisiopatologia Osea, Fundacion Jimenez Diaz, Madrid, Spain, [3]Histology, Granada University, Granada, Spain, [4]Medicina Interna, Fundacion Jimenez Diaz, Madrid, Spain.

Bone formation response in long bones produced by intermittent PTH-treatment ($4x10^{-6}$ g/Kg/day) was studied in ovariectomized rats under two perspectives: PTH was administered immediately after ovariectomy or in ovariectomized rats after a 6 months period of bone loss. 122 female rats 9 months old, 86 ovariectomized (OVX) and 38 Sham, were used. Rats were separated in two groups for experiments A and B. In experiment A, rats 11.5 months old were sacrificed and named Sham 1 (n=10); OVX 1 (n=10), and OVX+PTH 1 (n=10, PTH treatment for 2.5m). In experiment B, 2 subgroups 15 months old were sacrificed: Sham 2 (n=12), OVX 2(n=12), and 3 more 17.5 months old: Sham 3(n=16), OVX 3 (n=10), and OVX+PTH 3 (n=12, PTH treatment for the last 2.5m). Bone mineral density (BMD) was determined in the whole femur by DEXA using a Hologic QDR-100 TM (S/N 277). Bone morphometry (cortical bone area, bone marrow area, cortical bone thickness) was performed in 20µm thick ground sections of tibia diaphysis stained with von Kossa. Bone trabecular 3D-microarchitecture was studied using

stereoscopic optical microscopy and scanning electron microscopy (FEI Quanta 200) in anorganic 0.5mm thick tibia sections and apparent trabecular bone area was calculated. Data are summarized in the next table.

	FEMUR BMD g/cm2	TIBIA CORTICAL BONE AREA mm2	TIBIA BONE MARROW AREA mm2	TIBIA CORTICAL BONE THICKNESS µm	TIBIA APPARENT TRABECULAR AREA mm2
SHAM 1 11.5m	0.293±0.016	3.98±0.33	1.19±0.23	229±15	18.24±3.30
OVX 1 11.5m (2.5m)	0.284±0.012	3.99±0.16	1.38±0.21	219±11	14.44±3.33
OVX+PTH 1 11.5m (2.5m+2.5m)	0.324±0.016	4.70±0.32	1.53±0.30	244±19	20.06±3.28
SHAM 2 15m	n.d	3.98±0.33	1.41±0.26	210±12	15.09±2.85
OVX 2 15m (6m)	n.d	3.54±0.33	1.58±0.32	197±13	6.51±1.91
SHAM 3 17.5m	0.320±0.014	4.03±0.45	1.43±0.25	220±18	18.06±3.90
OVX 3 17.5m (8.5m)	0.255±0.002	3.93±0.31	1.59±0.33	215±13	7.51±2.04
OVX+PTH 3 17.5m (8.5m+2.5m)	0.279±0.005	4.13±0.34	1.31±0.28	236±14	7.92±2.07

Though an overall anabolic action of PTH was verified in long bones in both experiments, there are some differences. Cortical and trabecular bone formation was apparent in the first experiment. On the other hand, in the second experiment, when bone loss was established after a 6 month period of ovariectomy, only cortical bone responded considerably. In conclusion, PTH treatment results were conditioned by previous bone mass, bone microarchitecture, and presumably bone turnover status.

Factors Associated with Patient Compliance to Teriparatide: Study Addendum to the DANCE Observational Study. M. D. Rousculp[1], M. Brod*[2], P. Chen*[3], R. B. Wagman[3]. [1]Health Outcomes, Eli Lilly and Company, Duluth, GA, USA, [2]The Brod Group, San Francisco, CA, USA, [3]US Medical, Eli Lilly and Company, Indianapolis, IN, USA.

The World Health Organization identifies compliance to therapy as a primary determinant in treatment success. The National Osteoporosis Foundation's guide for physicians further emphasizes that osteoporosis requires lifelong management and that physicians should encourage patients to be compliant to therapy. Although previous studies have examined compliance with osteoporosis therapies, there is interest in understanding potential factors barriers for an injectable osteoporosis therapy. In a retrospective study of community-based pharmacy claims records, persistency with therapy was relatively higher for patients initiating teriparatide than with patients initiating an oral, anti-resorptive therapy (64.6% vs. 59.9% at 60 days). To further identify potential factors associated with non-compliance with teriparatide, a qualitative study was conducted, including both community-based physicians who prescribed teriparatide and their patients. The results from this study indicated that compliance to therapy involves a dynamic relationship among physicians, patients, drug characteristics and health systems. The factors associated with compliance, and its relative importance, were different for short-term and long-term compliance as well as for adherence and persistence to treatment. Based on this qualitative study, a series of patient-administered surveys were created to be a part of the third phase of the Direct Assessment of Non-vertebral fractures in Community Experience (DANCE) study. The surveys are to be completed at baseline, at the first follow-up visit, and at the first annual follow-up visit. The baseline survey is intended to understand the subject's perception of their severity of disease, expectation of therapy, and concern over treatment modality. The second survey queries the patient's perception of availability of training and support for use of the FORTEO pen, therapy adherence, and persistence shortly after the therapy initiation visit. The third survey asks patients about perception of treatment modality, therapy training and support, therapy affordability, and therapy adherence and persistence one year after initiation of therapy. The data gathered via the surveys should provide better insight on the dynamic nature of compliance and as such could assist clinicians and researchers in identify potential interventions for improving both adherence and persistence to an injectable osteoporosis therapy.

A Novel LRP5 Mutation in the Osteoporosis Pseudoglioma Syndrome. R. Levasseur[1], Y. Allanore*[2], M. Abi Fadel*[3], M. Varret*[3], C. Cormier[2], A. Kahan*[2], C. Boileau*[3]. [1]Rheumatology, Angers teaching hospital, Angers, France, [2]Rheumatology A Department, Cochin Hospital Paris 5 University, Paris, France, [3]Inserm U 383, Necker Hospital Paris 5 University,, Paris, France.

Osteoporosis pseudoglioma syndrome (OPPG) is a rare autosomal recessive disorder caused by inactivating mutations in LRP5 (Low density lipoprotein receptor-related protein 5) localized in 11q13.4. This pediatric syndrome includes early-onset blindness with severe osteoporosis and sometimes other clinical features (1). To date, only 12 mutations have been described in OPPG. Here we report a case of OPPG in a 19 year-old boy with a new LRP5 mutation. This patient is from a consanguineous family of Tunisian origin, has already had 8 fractures in childhood (tibias) and surgery for inter-auricular communication. Clinical examination showed a short stature (1.32m for 42 kg), hypotonia, lower limbs deformities and blindness with microphtalmia. The DXA (Hologic QDR1000, Waltham, MA) results are a lumbar BMD of 0.409 g/cm² and a lumbar Z-score of - 4.3. Calcemia, calciuria, phosphatemia, phosphaturia, intact PTH, 25OHVitD are normal. Mutation analysis of the LRP5 gene revealed a homozygous 5-base pair insertion (1048_1049insGGACA) in exon 5. This would cause a frame shift at amino acid 334 (R334fsX51) and lead to the appearance of a stop codon 51 amino acid downstream. Also the protein would lack 1231 amino acids and the co-receptor would not be functionnal. The treatment of this severe osteoporosis includes regular perfusion of pamidronate with no new fracture. This new case of OPPG emphasizes the major role of LRP5 in bone accrual and eye development (2).

Variable Structure of Osteogenesis Imperfecta Bone. F. Shapiro, E. Flynn*. Department of Orthopedic Surgery, Children's Hospital Boston, Boston, MA, USA.

This study assessed the histologic structure of osteogenesis imperfecta (OI) bone obtained from human long bone diaphyses. Bone samples were obtained from 30 patients, 4 at post-mortem study from Type II OI and 26 from patients undergoing osteotomy with Types I, III, and IV OI. Tissue underwent paraffin or plastic embedding, staining with hematoxylin and eosin or toluidine blue, and examination by light microscopy (LM) and polarizing LM. Assessments included: osteocyte cellularity in relation to matrix structure (woven or lamellar), the proportions and appearances of woven and lamellar bone where both were present simultaneously, and the structure of lamellar tissue deposition. The LM structure of normal diaphyseal bone from embryo onwards includes all woven bone (grade I), combinations of woven and lamellar bone (grade II), and all lamellar bone (grade III) progressing towards compact Haversian (osteonal) conformation. OI bone showed a non-mature pattern but developed along the normal pathway of woven and lamellar although the lamellar pattern differed from the normal in all but the mildest instances. The more tissue there was deposited, the more mature the tissue deposition pattern. The grading system applied to the OI bone follows. Grade I: woven bone only. This was seen in Type II OI (4 cases) as discontinuous spicules of woven bone. Grade II: both woven and lamellar bone, in 3 groupings. In Types II and IV OI (25 cases) the full spectrum of Grade II was seen: Grade IIa (woven bone greater in amount than lamellar bone)--only traces of lamellae on the woven scaffold, insufficient to promote osteonal synthesis; Grade IIb (woven and lamellar bone equal in amount)--allowing for beginning osteonal formation; and Grade IIc (lamellar bone greater in amount than woven bone)--leading to increased osteonal formation and compaction. Grade III: lamellar bone only, in 2 groupings; grade IIIa (partially compacted, forming osteonal systems) and grade IIIb (fully compacted lamellar osteonal bone). In Type I OI (1 case) normal appearing lamellar osteonal bone was present with slightly diminished compaction. All Grade II specimens had a mosaic structure: woven bone accumulations on which were deposited lamellar tissue and the lamellar tissue itself characterized by blocks of shortened, discontinuous, and multiplanar accumulations. Bone tissue compaction increased from Grade I to Grade IIIb. This study revealed the considerable variability in the structure of OI bone but also the tendency to develop a progression towards the normal. This categorization can be applied to all variants of OI bone, allowing for a qualitative and quantitative assessment of several structural variables, each of which is important in determining OI bone strength.

Treatment of Osteogenesis Imperfecta Type I with Weekly Alendronate. R. C. Gensure, T. Ponnapakkam*. Pediatrics, Ochsner Clinic Foundation, New Orleans, LA, USA.

Treatment of severe forms of osteogenesis imperfecta (OI) (type III/IV) has been revolutionized by the report that cyclical administration of intravenous pamidronate results in significant increases in bone density and reduction in fracture rates (Glorieux F, et. al., NEJM, 1998). While children with OI type 1 have a much milder disease, the increased fracture rate and pain from microfractures results in significant morbidity and limitation on physical activity. Cyclical administration of IV pamidronate, and more recently daily administration of alendronate (Dimeglio LA, et. al., J Pediatr Endocrinol Metab. 2005),

have been shown to be efficacious in the treatment of OI type 1. To avoid complications of IV therapy and improve compliance over daily dosing, we treated four patients (ages 5-6) with OI type 1 with weekly oral alendronate (1 mg/kg/wk) and assessed the effects on bone mineral density after 6 months therapy. Each patient showed reduction in markers of bone turnover and improvement in bone mineral density z-score over the treatment period (Z-score increased by 1.08 +/- 0.35, $p<0.05$). None of the patients had any fractures during treatment. There were no incidents of esophagitis, and growth rates remained normal (growth velocity 7.6 +/- 1.0 cm/yr). While not formally assessed, all patients described a marked reduction in pain and increased physical activity while on treatment. Interestingly, one of the patients who had ankle films to evaluate for possible fracture showed transverse lines on the fibula similar to those described after cyclical pamidronate administration. For patients with milder forms of osteogenesis imperfecta, treatment with a simplified regimen of weekly oral alendronate provided an acceptable alternative to intravenous therapy.

Bone Mineral Density in Patients with Myelomeningocele. G. Luisetto*[1], V. Camozzi*[1], G. de Eccher*[2], E. Bertossi*[2], B. Disarò*[2], A. Marucco*[2], P. Drigo*[2]. [1]Dept. of Surgical and Gastroenterological Science, University of Padua, Padua, Italy, [2]Dept. of Pediatrics, University of Padua, Padua, Italy.

Myelomeningocele (MMC) is a relatively frequent disease with a prevalence of 1/1000 newborns. The lower limbs motor deficiency of the patients with MMC prevents the normal bone growth and increases the risk of fracture. Although the fractures represent a main clinical problem, there is a little information about bone status in these patients. Purposes of this study are: 1) to establish the diagnostic significance of two different methods employed to evaluate bone status: Dual-energy X ray absorptiometry (DXA) and Quantitative Ultrasound technique (QUS); 2) to correlate BMD at spine and femur with the level of injury and the degree of motor deficiency. Sixty one patients, 27 females and 34 male, (mean age ± SD: 15 ± 6.2 years) have been studied. The level of injury was above L3 in 19 subjects, between L4-S1 in 25, and below S1 in 17. Regarding motor deficiency, patients were divided into three groups: completely unable to walk (NW, N=15, age = 18.7 ± 6.2 years), partially walking (PW; N= 17, age 15.0± 6.1), and able to walk (W; N=29, age = 16 ± 6.8). Anthropometric variables, daily calcium intake, common laboratory parameters of bone and mineral metabolism, as well as DXA and QUS parameters have been assessed in each patient. BMD was measured using a Hologic QDR 4500 C densitometer (Waltham, Mass, USA) and values were expressed as BMD Z-Score at lumbar spine and proximal epiphysis of the left femur. QUS parameters have been measured at the proximal phalanges of the finger 2 to 5 of both hands with a DBM Sonic Profile device (Igea, Carpi, Italy). Results are expressed as amplitude-dependent speed of sound (AD-SOS). All DXA values were lower than reference normal values at both spine and femur. W patients showed spine Z-score higher than that of PW, and the latter showed spine Z-score higher than NW. (W: -1.04 ± 1.89; PW. -1.26 ± 1.26; NW: -2.17 ± 1.86. ANOVA: $p<0.01$). At femoral level, PW patients showed BMD lower than that found in the other two groups of patients (Femoral neck BMD Z-score, PW: -2.65 ± 1.13; NW: -1.66 ± 1.49; W: -1.31 ± 1.40; ANOVA: $p<0.01$). Patients with injury below S1 showed BMD values significantly higher than those found in the other two groups ($p<0.05$). QUS parameters, as well as laboratory variables did not differ among the groups. In conclusion, our findings show that the ability of walking doesn't have a significant influence on BMD in patients suffering from myelomeningocele. BMD is lower in the denervated sites, suggesting a pivot role of nervous system in the skeletal trophism, independent of motility. The lower BMD explains, at least in part, the high number of fractures at the lower limbs in these patients.

Safety and Efficacy of the Use of Zoledronic Acid (AZ) in Children with Osteogenesis Imperfecta - Preliminary Data. E. Ribeiro*, G. Saraiva*, S. Maeda*, A. Castaldoni*, M. Lazaretti-Castro. Endocrinology, Universidade Federal de São Paulo, Sao Paulo, Brazil.

Osteogenesis imperfecta (OI) is a genetic disorder of increased bone fragility and low bone mass. Severity varies widely, ranging from intrauterine fractures and perinatal lethality to very mild forms without fractures. The diagnostic clinical of OI is based mainly on signs and symptoms: blue sclera, dentinogenesis imperfecta, hyper laxity of ligaments and skin, hearing impairment. The most widely used classification of OI is by Sillence and col with four clinical types. Recently three additional groups were described: Type I, II, III, IV, V, VII and VII. Clinical treatment with pamidronate has show to be safe and efficient to reduce fracture and improve the life quality in OI patients. The ZA is the most powerful available bisphosphonate and has a faster time of IV infusion than pamidronate. This possibility makes a great difference mainly for children, reducing the time of hospitalization and the costs of treatment. Its efficacy and safety in children with OI, however, has not yet been tested.AIM: To verity the safety and efficacy of ZA during one year treatment in children with OI type III and IV. METHODS: Nine children were selected to participate of a research protocol to receive ZA (Zometa™ from Novartis), in a dose of 0.4±0.08mg/kg/year in a 30 minutes IV infusion every three to four months. Five patients have finished one year of treatment and the remaining, still under treatment; have received at least two infusions. Before each infusion, blood was collected for total and ionized calcium, alkaline phosphatase, phosphate, CTX and osteocalcin in serum, intact PTH, renal and hepatic function and hemogram. Bone Mineral density (BMD) at lumbar spine and total body were measured at the baseline and at the end of the study. RESULTS: Out of 9 patients (7 boys, 2 girls), 5 had type IV and 4 type III. The average age was the 5.1±2.8 years (from 1.6 to 9.4). The adverse events were: fever (n=9), nausea (n=5), and vomiting (n=2) during the 24 hours following the first infusion. Except for one patient with anemia at baseline, all had normal laboratory until the end of the study. From baseline to the end of treatment, spine BMD increased significantly (0.310±0.073 to 0.462±0.019mg/cm2, respectively, $p<0.016$) and total body BMD almost reached significance (0.672±0.126 to 0.758±0.064mg/cm2, $p<0.059$). CONCLUSION: ZA infusion was safe and efficient in increasing BMD in our group of children with OI. Due to its fast procedure, it is more convenient for children. However, a ZA effect on fracture risk, in despite to be likely, still has to be proved.

Bone Loss in Mice after Spinal Cord Injury; an Histomorphometrical, Biomechanical and Densitometrical Study. S. Picard[1], J. P. Brown[1], J. Frenette*[2], S. Jean*[1], P. A. Guertin*[3]. [1]Rheumatology and Immunology Research Department, CHUL Research Center, Laval University, Sainte-Foy, PQ, Canada, [2]Department of Rehabilitation, Laval University, Sainte-Foy, PQ, Canada, [3]Neuroscience Research Center, CHUL Research Center, Laval University, Sainte-Foy, PQ, Canada.

Mechanical loading in daily life helps maintain bone strength. Conversely, immobilization activates osteoclast recruitment and depresses osteoblast activity, resulting in an unbalance in bone metabolism and significant bone losses. Although bone density loss after spinal cord injury is well-documented in humans, there is a lack of data with quantitative histology measurements after spinal cord injury in animal models. This study reports the development of a model of spinal cord injury in mice for which histomorphometric, biomechanic and bone mineral density (BMD) measurements were performed at fixed delays post-spinalization. At 10, 15, and 30 days post-spinal cord transection (low-thoracic level), left femoral bones were processed, paraffin embedded, and stained with Masson's trichrome procedures. Histomorphomeric analyses were performed with a NOVA Prime, Bioquant's image analysis system for primary bone morphometric parameters. The right femoral was preserved within humid condition at -20°C prior densitometrical and biomechanical testing. There was a marked decrease in bone volume (-25 %, p 0,0217), trabecular thickness (-12 %, p 0,0397) but no significative change for trabecular number (16 % p 0,0933) and trabecular separation (+ 25 %, p 0,0775). Results using three-point bending testing indicated a 23,7% p:0,035 decrease in elastic force with a rapid decrease, although non-significant, of total strength one month post-transection. BMD measurements using dual energy x-ray absorption (DEXA) revealed a significant 15% decrease of bone mineral contents. The complementary assessment methods shall help describe the overall changes in bone morphometry, strength, and mineral content occurring after spinal cord injury in paraplegic mice. Results obtained with this model may contribute to the development of new pharmacological approaches to prevent or reverse severe bone problems associated with complete immobilization.

Predictors of Bone Mineral Density in Patients on Antiepileptic Drugs. L. Dib*[1], M. A. Mikati*[2], B. Yamout*[1], R. Sawaya*[1], G. El-Hajj Fuleihan[1]. [1]Internal Medicine, American University of Beirut, Beirut, Lebanon, [2]Pediatrics, American University of Beirut, Beirut, Lebanon.

Use of antiepileptic drugs (AEDs) is associated with metabolic bone disease. Bone density in epileptic patients can be affected by seizure duration, 25(OH) vitamin D levels[25(OH)D], type of seizure and possibly type or mode of therapy. Characteristics of ambulatory subjects on AED therapy for at least 6 months and their relationship to bone mineral density (BMD) and content (BMC) were studied. The adult group included 106 subjects; 57 women/49 men, age 29.7±10.5 years, duration of AED therapy 11.9±10.2 years, mean 25(OH)D 14.9±9 ng/ml. The pediatric group included 88 subjects, 45 boys/43 girls, age 13.0± 2 years, duration of AED therapy 4.7± 4 years, mean 25(OH)D 18.5±8 ng/ml. In adults, but not in children, 25(OH)D levels and bone density at the spine and hip were significantly lower than that of age, gender matched controls using both the Western database, as well as the local database [1] ($p<0.04$). Around 50% of overall subjects had low 25(OH)D levels, but vitamin D levels did not correlate with BMD in either age group. In adults only, duration of AED therapy negatively correlated with BMD at the trochanter ($r=-0.23$, $p<0.05$). Total duration of phenytoin use (current and previous) negatively correlated with total hip, femoral neck and trochanter BMD, R= 0.3-0.39, $p<0.05$. Similarly, in adult women the negative correlations varied between 0.5-0.7 at lumbar spine, total hip, femoral neck, and trochanter BMD, $p< 0.05$. Such correlations were not detected with the use of phenobarbital, carbamazepine, or with the non-enzyme-inducing AEDs. Similar bivariate analyses in children did not reveal any significant correlations. Linear regression analyses adjusting for age, weight and duration of therapy revealed a significant negative effect of enzyme-inducing AEDs on BMD in the adult group at the LS ($p=0.04$), FN ($p=0.036$) and an almost significant negative effect at the trochanter ($p=0.07$). In the pediatric group, there

was a significant negative effect of polypharmacy on subtotal BMD (p=0.04), and a similar negative effect on subtotal BMC in girls (p=0.024). In conclusion, ambulatory adults but not children on chronic AEDs had low BMD compared to age, gender and ethnic-matched controls. Vitamin D levels, in the range noted, were not correlated to BMD/BMC at any site. In adults, cumulative phenytoin use (past and current) and the use enzyme-inducing drugs were significant negative predictors of BMD. Polypharmacy adversely affected BMD in children.

The Importance of Fibroblast Growth Ractor-23 in Regulating the Phosphate Homeostasis in the Hyperphosphatemic Situation as in Untreated Graves' Disease. Y. Rhee[1], S. Park*[1], S. Kang*[1], S. Park*[1], D. Kim*[1], S. Lee*[1], Y. Kim[2], S. Lim[1]. [1]Internal Medicine, College of Medicine, Yonsei Univ., Seoul, Republic of Korea, [2]Internal Medicine, National Health Insurance Corporation Ilsan Hospital, Kyungki, Republic of Korea.

Fibroblast growth factor-23(FGF-23) is one of the phosphatonins that regulate phosphate homeostasis, have been discovered through studies of phosphate-wasting disorders such as X-linked hypophosphatemia, autosomal dominant hypophosphatemic rickets and oncogenic osteomalacia. The key role of the calcium and phosphate homeostasis was always assigned to parathyroid hormone and vitamin D axis. However, to identify the role of FGF-23 in the mineral metabolism, we selected the patient with hyperthyroidism which usually accompany with the elevated calcium and phosphate. The study group comprised 44 patients with or without Graves' disease. There were 23 patients with biochemically and radiologically proven Graves' disease (GD) blood sample taken before starting the anti-thyroid drug. The control group was composed of 21 people who were proven to be euthyroid without any diseases affecting mineral metabolism. Plasma FGF-23, calcium, phosphate, parathyroid hormone (PTH), 25-hydroxyvitamin D (25(OH)D) and bone turnover markers were compared between these groups. Plasma FGF-23 assay was to detect the intact form. (Immuopics, USA) As expected, the calcium and phosphate in the GD were significantly higher with elevated free T4. ($P < 0.05$) The bone turnover markers - osteocalcin and serum C-telopeptide were significantly elevated respectively in the GD group(13.3 +/- 4.9 ng/mL vs. 43.7 +/- 7.9 ng/mL and 0.38+/-0.44 vs. 1.13+/-0.67, $P<0.05$)) In the GD group, the serum FGF-23 level was significantly higher ($P < 0.05$) than in the control group (62.3 +/- 89.0 ng/L vs. 41.4 +/- 3.6 ng/L). However, there was no significantly lowered PTH in the GD group with surprisingly lower 25(OH)D level(12.5 ng/mL in GD) which would have affected the PTH level. Serum FGF-23 levels were positively correlated with serum phosphate levels ($r=0.457$, $P < 0.05$) and with free T4 levels ($r=0.393$, $P < 0.05$). The significant positive correlation between serum levels of phosphate and FGF-23 and the compensatory increase in GD group indicate that FGF-23 is an important regulator of serum phosphate homeostasis.

Epidermal Nevus Syndrome with Focal Bone Defects and Hypophosphatemic Rickets: FGF23, *GNAS1*, and Skeletal Histology Evaluation. D. Wenkert[1], S. L. Teitelbaum[2], W. H. McAlister*[3], F. H. Gannon[4], S. Mumm[5], M. P. Whyte[1]. [1]Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children, St. Louis, MO, USA, [2]Department of Pathology, Washington University School of Medicine, St. Louis, MO, USA, [3]Department of Pediatric Radiology, Mallinckrodt Institute of Radiology, St. Louis Children's Hospital, St. Louis, MO, USA, [4]Armed Forces Institute of Pathology, Washington, DC, USA, [5]Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA.

Epidermal nevus syndrome (ENS) is a rare, sporadic condition sometimes associated with focal bone defects and renal phosphate (Pi) wasting causing hypophosphatemic rickets (HR) and weakness. The etiology of ENS is unknown. One such patient (# 2, submitted) leads us to report 2 additional cases listed below in descending order of the degree of skin and bone involvement. In each, HR and weakness responded to treatment with $1,25(OH)_2D3$ and Pi supplementation as extensive removal of nevi was also performed. In DNA isolated from nevi of the first 2 patients and peripheral WBCs of all 3, no *GNAS1* mutation was found. *Patient 1,* first evaluated at age 3, had predominately right-sided skin but bilateral focal bone lesions. Weakness was profound if she stopped medical therapy. She died at age 26 from pneumonia complicating severe skeletal disease. Histology of femoral bone at age 12 years showed a patchy area of fibrous dysplasia (FD) seen radiographically despite normal gross appearance. However, FD was not detected 14 years later at limited autopsy. Serum FGF23 at age 21 yrs was > 2,470 (63 +/- 33 (SD)). *Patient 2,* a 20-year-old, was referred at age 15 years with x-rays changes reminiscent of FD ipsilateral to his nevi. Bone from his affected and unaffected iliac crests revealed osteomalacia and decreased numbers of trabeculae, but no FD. His FGF23 level was elevated at 215. *Patient 3*, an 11-year-old, was referred at age 3 with schizencephaly, temporal lobe atrophy, seizures, and x-ray changes suggestive of FD limited to his skull. Bone biopsies were not obtained. His FGF23 level was normal at 90. Histologic evaluation of the extensive focal bone defects in our most severely affected patient showed at least one patchy area of FD. Serum FGF23 levels seemed to reflect the extent of skin involvement and extent of focal bone defects. The third patient despite having the lowest FGF23 and the least skin and bone involvement had neurological findings of ENS. Many features of ENS are suggestive of McCune Albright syndrome (skin involvement, FD, HR, sometimes precocious puberty) yet our evaluation of *GNAS1* was unremarkable. Studies of *GNAS1* in dysplastic bone were not performed.

Cinacalcet Is Associated with Decreased Serum FGF-23 and Improved Phosphorous Homeostasis in Patients with Tumor-Induced Osteomalacia. J. L. Geller*[1], C. Cutler*[2], M. H. Kelly*[2], J. S. Adams[1], M. T. Collins[2]. [1]Burns and Allen Research Institute, Division of Endocrinology, Cedars-Sinai Medical Center, David Geffen School of Medicine at UCLA, Los Angeles, CA, USA, [2]Craniofacial and Skeletal Diseases Branch, NIDCR, NIH, DHHS, Bethesda, MD, USA.

FGF-23 is a circulating peptide hormone, which plays a key role in mineral homeostasis by inhibiting renal phosphorus reabsorption and the formation of 1,25-dihydroxyvitamin D (1,25-D). Tumor-induced osteomalacia (TIO) is an acquired syndrome of hypophosphatemic osteomalacia often caused by tumoral production of FGF-23. Patients exhibit hypophosphatemia, hyperphosphaturia, low or inappropriately normal 1,25-D levels and osteomalacia. Tumors are notoriously difficult to localize and medical therapy, consisting of large doses of oral phosphorous and 1,25-D, is often required. We have previously shown (Gupta et al. JCEM 89:4489, 2004) that high circulating levels of FGF-23 in patients with hypoparathyrodism were unable to bring about significant phosphaturia, suggesting that parathyroid hormone (PTH) is downstream of FGF-23 in the phosphaturic response. Therefore, we proposed that induction of (relative) hypoparathyroidism with the calcium sensing receptor agonist, cinacalcet, might improve phosphorous balance in TIO. Two patients with bone pain, pathological fractures, hypophosphatemia, phosphaturia, low serum 1,25-D and elevated serum FGF-23 were evaluated (Table 1). In both cases, despite extensive diagnostic studies, the source of FGF-23 remained elusive. Both were treated with a regimen of high dose oral calcitriol and phosphorus, which was poorly tolerated due to diarrhea. Treatment with cinacalcet at 30 mg daily was initiated. Serial measurements of serum FGF-23, (Kainos, Tokyo, Japan), calcium, phosphorus, iPTH and urine tubular reabsorption of phosphorus (TRP) were obtained.

Table 1. Response to cinacalcet in two patients with TIO

Patient & time post cinacalcet	FGF-23 pg/ml	Serum Ca mg/dl	Phos mg/dl	iPTH pg/ml	Urine TRP %	Daily Rx K-Phos neutral mg/day
1 0 hour	3625	9.7	2.2	29	66	1500
1 24 hours	2836	8.6	3.2	12	73	1500
1 4 weeks	2290	8.1	3.0	11	64	750
2 0 hour	190	9.1	1.9	24.1	48	2000
2 4 hours	178	8.9	2.5	11.2	82	2000
2 24 hours	73	8.7	2.1	25.5	64	2000
2 4 weeks	--	8.9	2.2	21.0	68	0

Initiation of cinacalcet resulted in 37% and 62% decrease in serum FGF-23 levels by 24 hours in both subjects, which was accompanied by an increase in TRP and serum phosphorus, and an eventual (4 weeks) decrease or elimination of oral phosphate supplementation. Via its ability to diminish PTH-directed phospahaturia, or by decreasing serum FGF-23, cinacalcet may prove to be an effective adjuvant in the medical management of FGF-23-mediated TIO.

Disclosures: ***J.L. Geller****, None.*

Secreted Frizzled Related Protein-4 Reduces Sodium-Phosphate Co-transporter Abundance and Activity in Proximal Tubule Cells. T. Berndt*[1], T. Craig*[1], B. Bielesz*[2], P. Tebben[1], D. Bacic*[2], C. Wagner*[2], S. O'Brien*[3], S. Schiavi[3], J. Biber*[2], H. Murer*[2], R. Kumar[1]. [1]Nephrology Research, Department of Medicine, Biochemistry and Molecular Biology, Mayo College of Medicine, Rochester, MN, USA, [2]Institute of Physiology, University of Zurich, Zurich, Switzerland, [3]Receptor Ligand Therapeutics, Genzyme Corporation, Framingham, MA, USA.

The phosphatonin, secreted frizzled related protein (sFRP-4), a protein over-expressed in tumors associated with renal phosphate wasting, induces phosphaturia and inhibits 25-hydroxyvitamin D 1α-hydroxylase activity that is normally induced in response to a hypophosphatemic stimulus. To determine the mechanism by which sFRP-4 acutely alters renal phosphate (Pi) transport, we examined the effect of intravenous infusion of sFRP-4 (n=10), vehicle (n=7), or PTH (n=7) on renal brush border membrane (BBMV) Na^+-dependent Pi uptake and the abundance and localization of the major Na^+-Pi IIa co-transporter in the proximal tubule and in opossum kidney cells. As reported earlier, short-term infusion of sFRP-4 (0.3 µg/kg/Hr) significantly increased the fractional excretion of Pi (FE Pi) from 10±2 to 25±5% ($P<0.05$) and decreased β-catenin concentrations in the kidney. PTH infusion (8µg/kg/Hr) increased the FE Pi from 11±2 to 33±5% ($P<0.05$). The increase in FE Pi with sFRP-4 infusion was associated with a 21.9±3.4 % decrease in BBMV Na^+-dependent Pi uptake ($P<0.001$) compared with a 39.5±2.1 % inhibition of Na^+-dependent Pi transport in renal BBMV induced by PTH ($P<0.001$). The decrease in BBMV Na^+-Pi uptake induced by sFRP-4 was associated with a 30.7±4.8 % decrease in Na^+-Pi IIa

co-transporter protein abundance (P<0.01)as assessed by Western blotting methods compared to a 45.4±8.8 % decrease induced by PTH (P<0.001). In opossum kidney cells, sFRP-4 significantly reduced surface expression of a heterologous Na^+-Pi IIa co-transporter. We conclude that sFRP-4 increases renal Pi excretion by reducing Na^+-Pi IIa transporter abundance in the brush border of proximal tubule through enhanced internalization of the protein.

Fibroblast Growth Factor-23 Is Regulated by 1,25-Dihydroxyvitamin D. M. T. Collins[1], J. R. Lindsay*[2], A. Jain*[3], M. H. Kelly*[4], C. M. Cutler*[1], L. S. Weinstein[5], L. Jie*[5], N. S. Fedarko[6], K. K. Winer*[7]. [1]CSDB/NIDCR, National Institutes of Health, Bethesda, MD, USA, [2]PREB/NICHD, National Institutes of Health, Bethesda, MD, USA, [3]GCRC, Johns Hopkins, Baltimore, MD, USA, [4]Nursing and Patient Care Services, National Institutes of Health, Bethesda, MD, USA, [5]MDB/NIDDK, National Institutes of Health, Bethesda, MD, USA, [6]Division of Geriatric Medicine, Department of Medicine, Johns Hopkins University, Baltimore, MD, USA, [7]NICHD, National Institutes of Health, Bethesda, MD, USA.

FGF-23 is a recently described hormone that has been demonstrated to be involved in the regulation of phosphate and vitamin D metabolism. The physiologic role of FGF-23 in mineral metabolism and how serum FGF-23 levels are regulated have yet to be elucidated. Three patients with mineral metabolism defects that allowed for the investigation of the regulation of FGF-23 were studied. Patient 1 had post-surgical hypoparathyroidism and Munchausen's syndrome and consumed a pharmacologic dose of calcitriol. Patient 2 had post-surgical hypoparathyroidism and fibrous dysplasia of bone. She was treated with increasing doses of calcitriol followed by synthetic PTH 1-34. Patient 3 had pseudohypoparathyroidism type 1B and tertiary hyperparathyroidism. She underwent parathyroidectomy, which was followed by the development of hungry bone syndrome and hypocalcemia requiring treatment with calcitriol. Serum FGF-23 (Immutopics, San Clemente, CA) and serum and urine levels of mineral metabolites were measured in all 3 patients. Patient 1 had an acute and marked increase in serum FGF-23 (70 to 670 RU/ml, normal range 18-108) within 24 hours in response to high-dose calcitriol administration. Patient 2 demonstrated stepwise increases in serum FGF-23 from 117 to 824 RU/ml in response to increasing serum levels of 1,25-dihydroxyvitamin D (1,25-D). Finally, prior to parathyroidectomy, while hypercalcemic, euphosphatemic, with low levels of 1,25-D (10 pg/ml, normal 22-67), and very high serum PTH (863.7 pg/ml, normal 6.0-40.0), patient 3 had high serum FGF-23 levels (217 RU/ml). Following surgery, while hypocalcemic, euphosphatemic and with high serum levels of serum 1,25-D (140 pg/ml), FGF-23 levels were higher than preoperative levels (305 RU/ml). In the absence of PTH or a PTH effect, marked elevations of FGF-23 were not associated with a marked lowering of serum phosphorus or increases in phosphorus excretion. Serum FGF-23 is regulated by serum 1,25-D, but its phosphaturic effect may be diminished in the absence of PTH.

The Kidneys of X-Linked Hypophosphatemic (*Hyp*) Mice Have Altered mRNA Expression of Many Membrane Transporters Besides Phosphate. M. H. Meyer, R. A. Meyer. Department of Orthopaedic Surgery, Carolinas Medical Center, Charlotte, NC, USA.

X-linked hypophosphatemia is characterized by decreased renal reabsorption of phosphate, low plasma phosphate, and rachitic and osteomalacic bone disease. No other defects in the kidney are known to exist. To explore the impact of this mutation further, kidneys from five-week-old mice, normal and *Hyp* (hemizygous male and heterozygous female), were collected, and RNA was extracted and hybridized to Affymetrix Mouse 430A and 430B microarrays with probe sets for over 40,000 genes. The RNA for each array was pooled from three mice. A total of 24 arrays, six for each genotype and gender, were done. The data were transferred to an Excel spreadsheet, formulas for factorial analysis of variance were added, and the formulas were copied to all genes. GenMAPP (www.genmapp.org) was used to identify transport-related genes with a significant main effect of genotype (normal vs. *Hyp*). RNA levels for all phosphate transporters were significantly decreased ($P < 0.001$) in the *Hyp* mice. In addition, mRNA for the sulfate transporter, slc13a1, increased 2 fold ($P < 0.001$) in *Hyp*. mRNA for the chloride transporter, slc12a3, increased over 50% ($P < 0.001$). mRNA for organic anion transporters (OAT) also changed with a 16% decrease in OAT1 (slc22a6, $P < 0.001$), a 50% increase in OAT2 (slc22a7, $P < 0.01$), a 50% decrease in OATP1 (slco1a1, $P < 0.001$, only expressed in males), and a 33% decrease in females for slc13a3 ($P < 0.01$). The organic cation transporter, slc22-like 2 (slc22al2), also had a 33% decrease ($P < 0.001$) in the *Hyp* mice. mRNA for the sodium/potassium transporting ATPase, alpha 2 polypeptide, atp1a2, has four probe sets on the arrays, and all increased 2 to 8 fold ($P < 0.001$), while the thiazide-sensitive NaCl transporter, slc12a3, increased 50% ($P < 0.001$) in the *Hyp* mice. Changes in mRNA for glucose transporters were mixed with the low affinity sodium-dependent glucose transporter, slc5a2, decreasing 33% in *Hyp* mice ($P < 0.001$), along with smaller decreases in the facilitated glucose transporter, slc2a2 ($P < 0.001$). mRNA for the high affinity sodium/glucose transporter, slc5a1 increased 50% ($P < 0.001$), along with a smaller increase in the insulin-responsive facilitated glucose transporter slc2a4 ($P < 0.01$). In summary, the *Hyp* mutation causes changes in the mRNA expression of transporters in the kidney other than for phosphate. This suggests a broader metabolic effect of the *Hyp* mutation. (Supported in part by the NIH, DK064049.)

Sensitivity of FGF23 Measurements in Tumor Induced Osteomalacia. E. A. Imel*[1], M. Peacock[1], P. Pitukcheewanont*[2], H. J. Heller*[3], L. M. Ward[4], D. Shulman*[5], M. Kassem*[6], P. Rackoff*[7], M. Zimering*[8], A. Dalkin*[9], E. Drobney*[10], G. Colussi*[11], J. Shaker*[12], E. H. Hoogendorn*[13], M. J. Econs[1]. [1]Indiana U, Indianapolis, IN, USA, [2]USC, Los Angeles, CA, USA, [3]U T SW Med Ctr, Dallas, TX, USA, [4]U of Ottawa, Ottawa, ON, Canada, [5]USF, St. Petersburg, FL, USA, [6]U Hosp of Odense, Odense, Denmark, [7]Beth Israel Hosp, NY, NY, USA, [8]Dept of VA, New Jersey Hlth Care System, Lyons, NJ, USA, [9]UVA Hlth System, Charlottesville, VA, USA, [10]Medical College of Wisconsin, Milwaukee, WI, USA, [11]Circolo &Fondazione Macchi Hosp, Varese, Italy, [12]St Luke's Med Ctr, Milwaukee, WI, USA, [13]U Hosp at Radboud,, Nijmegen, Netherlands Antilles.

Tumor induced osteomalacia (TIO) is a paraneoplastic syndrome consisting of hypophosphatemia, hyperphosphaturia, inappropriately normal or low calcitriol concentrations and osteomalacia. Fibroblast growth factor 23 (FGF23) is mutated in autosomal dominant hypophosphatemic rickets, and elevated in patients with X-linked hypophosphatemic rickets and TIO. We measured plasma FGF23 levels by three ELISA assays in 22 patients with clinical presentation of TIO. Samples were assessed for plasma FGF23 levels and compared for sensitivity to the diagnosis of TIO and to serum phosphate levels. Diagnosis of TIO was based on clinical history of new onset hypophosphatemia and renal phosphate wasting, with bone pain and weakness. The sensitivity for TIO for the C-terminal (C-term) assay was 73%, for the Immunotopics Intact assay 45%, and for the Kainos assay 86%. FGF23 was undetectable in 22% of cases by Immunotopics Intact assay. In 13 cases we obtained tissue confirmation of TIO, and another had a nonresectable brain tumor. In the patients with confirmed tumors the sensitivity increased to 93% for the C-term assay, 100% by Kainos assay, and 57% for the Immunotopics Intact assay. There was an inverse correlation between FGF23 levels and phosphorous levels with R^2 values for C-term, Immunotopics Intact and Kainos assays of 0.23, 0.24 and 0.30 respectively. Nine patients had repeat FGF23 levels tested after tumor removal. FGF23 levels assessed by C-term assay and Kainos assay declined after surgery in 7 of 9 patients (p=0.04). One patient had a tumor that was not fully resectable. The other had renal insufficiency and lower Kainos assay values after surgery, but continued to have elevated results on the C-term assay. Patients with TIO overexpress FGF23. Two assays had good sensitivity for TIO. Normal concentrations of FGF23 in some TIO patients may indicate that sensitivity is not optimal for any currently available assay, that other phosphaturic factors are responsible for the syndrome in some patients, or like many other endocrine tumors, the tumors are partially responsive to the metabolic state of the patient.

MEPE Is Overexpressed in Osteocytes of the DMP1 (Dentin Matrix Protein 1) Null Mouse, Contributing to the Hypophosphatemia and Osteomalacia. S. E. Harris[1], J. Gluhak-Heinrich[2], M. A. Harris[1], W. Yang[1], P. S. N. Rowe[3], Y. Xie*[4], H. Rios*[4], S. Zhang*[4], M. D. McKee*[5], L. F. Bonewald[4], J. Q. Feng[4]. [1]Dept. of Periodontics and Cellular and Structural Biol, University of Texas Health Science Center at San Antonio Health Science Center, San Antonio, TX, USA, [2]Dept. of Orthodontics, University of Texas Health Science Center at San Antonio Health Science Center, San Antonio, TX, USA, [3]Dept. of Periodontics, University of Texas Health Science Center at San Antonio Health Science Center, San Antonio, TX, USA, [4]Dept. of Oral Biology, U. of Missouri at Kansas City, Kansas City, MO, USA, [5]McGill University, Montreal, PQ, Canada.

DMP1 and Spp1 are localized in the canalicular and lacunar walls, as is MEPE protein. Previously we showed that DMP1 null mice display hypophosphatemia(30%), and excess woven bone with large amount of osteoid, similar to the Hyp mice and X-linked hypophosphatemic rickets in humans. Phex gene mutations are the major cause of Hyp phenotype, resulting in overexpression of MEPE, a gene predominately expressed in mature osteocytes. MEPE gene is also extremely sensitive to mechanical stimulation in osteocytes. Loads at low as 2.4N at 60 cycle at 2Hz(30sec) can stimulate osteocyte specific MEPE expression 3-10 fold at 24hr after loading. We now studied MEPE expression, with the hypothesis that osteocytes in the DMP1 null are overstimulated at basal load levels compared to wild-type mice. Bones of the DMP1 null mice are less stiff and may receive more strain for a given load. We mapped MEPE expression at the midshaft, both distally

and proximally at 1mm intervals, in the ulnae of control and DMP1 null mice. By quantitative in situ hybridization we found that MEPE expression is elevated 3-8 fold near the mid-shaft and distally in the DMP1 knock-out mice compared to control. This supports the hypothesis the osteocytes are overstimulated in the DMP1 null mice compared to control. With a 3D model we clearly visualized changes of these MEPE expression patterns. The overexpression of MEPE will most likely lead to production of excess ASARM peptide that will contribute to the hypophosphatemia and osteomalacia of the DMP1 null mouse.

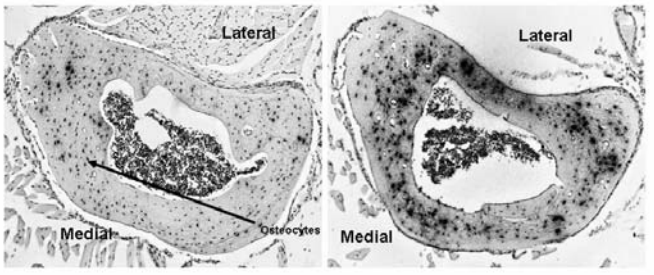

Figure 1. MEPE mRNA expression in osteocytes of the ulna in DMP1 knock-out mice is increased 3-8 fold with selective increased expression on the Lateral and Medial sides and just distal to the mid-shaft.

Safety and Efficacy of a Single 4 mg Infusion of Zoledronic Acid in the Treatment of Paget's Disease of Bone. G. Guardia*[1], A. Al-Shoha*[2], V. Reddy*[1], Y. Bernardo*[1], D. Rao[1]. [1]Bone & Mineral Metabolism, Henry Ford Hospital, Detroit, MI, USA, [2]Internal Medicine, Henry Ford Hospital, Detroit, MI, USA.

Paget's disease of bone is the third most common metabolic bone disease after osteoporosis and renal osteodystrophy. Over the past 20 years, several treatment modalities have been used including oral and IV bisphosphonates. Zoledronic acid is a potent third generation biphosphonate, which inhibits bone resorption after a single 4 mg intravenous infusion. We report our experience with 26 patients with Paget's disease of bone treated with Zoledronic acid between the years 2003 and 2004. Mean age was 75.9 ± 9.6 years; 42% were men, 58% were white, and 61% had polyostotic disease. Zoledronic acid was the initial treatment in 3 of the 26 patients. Mean ± SD pre-treatment values for the relevant measurements were as follows: serum Alkaline Phosphatase (AP) 174 ± 111 IU/L, bone specific AP (BSAP) 86 ± 79 IU/L, urine N-telopeptide (NTx) 142 ± 134 nM/mM, serum calcium (Ca) 9.6 ± 0.4 mg/dl and serum creatinine (Cr) 1.0 ± 0.3 mg/dl. One month after a single 4 mg infusion of Zoledronic acid, the mean AP fell to 102 ± 43 IU/L (a 41.3 % decline), BSAP fell to 46 ± 20 IU/L (46.9 % decline) and NTx fell to 30 ± 32 nM/mM (78.5 % decline; p<0.001). At 6 months, mean AP fell to 87 ± 37 IU/L (a 50 % decline; p= 0.003), mean BSAP fell to 26 ± 10 IU/L (70% decline; p=0.006) and mean uNTx fell to 36 ± 30 nM/mM (74.5 % decline; p<0.001). At 1 year, the mean NTx was still low at 38 ± 25 nM/mM (73.5 % decline; p<0.001), not significantly different from the one and six month values. No significant change from baseline was noted in either serum Ca or Cr at 6 months. Response defined as 50% decrease or normalization in AP at 6 months was achieved in 53% of patients. NTx normalized in 86% and 90% of the patients at 6 months and 1 year after treatment respectively. In conclusion, Zoledronic acid is a safe and effective treatment for patients with both mono and polyostotic Paget's disease of bone.

Economic Evaluation of Long Term Management Strategies for Paget's Disease of Bone. M. Al*[1], M. Groot*[1], C. Galani*[2], A. Engbersen*[2]. [1]Institute for Medical Technology Assessment, Erasmus MC, Rotterdam, The Netherlands, [2]Novartis Pharma AG, Basel, Switzerland.

In two pivotal registration trials, zoledronic acid (5 mg one time infusion) has been shown to be superior to risedronate (30 mg/day orally for 2 months) in terms of response rates, time to response and duration of response in the treatment of Paget's disease of bone (PDB). The aim of this study was to estimate the cost-effectiveness of zoledronic acid (ZOL) relative to risedronate (RIS), applied to the Dutch situation from a societal perspective. A decision tree was developed to estimate costs and effects of ZOL versus RIS over a period of 2 years. The tree consists of 4 half-year cycles and 4 possible health states, i.e. response, non-response, relapse and no relapse. Response was defined as SAP normalisation (SAP=serum alkaline phosphatase) and relapse as an increase in SAP of at least 50% from the measurement at 6 months and to at least 1.25 times the upper normal limit. Effectiveness was defined as time in response. All probabilities and the time-to-response were derived from the trial data. Based on information from local experts (physicians), resource use was defined for all 4 health states. It was assumed that both non-response and a relapse would trigger re-treatment. All direct medical costs and travel costs were included, while costs due to production losses were assumed to be negligible. All costs and effects were discounted by 4%, in accordance with Dutch pharmacoeconomic guidelines. To address uncertainty around the outcomes, a probabilistic sensitivity analysis was performed, in which all parameters were varied simultaneously in 2,500 consecutive simulations. Probabilities were varied within 95% CI limits and costs were varied ±20%. Using this model, it was estimated that over 24 months, 19.6 months are spent with normalized SAP levels in the ZOL group, versus 13.2 in the RIS group, leading to an incremental effectiveness of 6.4 months in response. The average numbers of treatments per year are estimated at 0.58 in the ZOL group and 0.94 in the RIS group. The costs in the ZOL group were lower (EUR 891) than in the RIS group (EUR 1217), leading to savings of € 326, mainly due to the smaller average number of treatments per year. Our probabilistic sensitivity analysis showed that ZOL is the dominant strategy with both increased time in response and a reduction in costs in 100% of the simulations. In conclusion, treatment of PDB with ZOL is more effective than treatment with RIS with a reduction in costs of treatment. Therefore, ZOL offers a dominant alternative to RIS for the treatment of PDB in the Netherlands.

Costs of Treating Paget's Disease in a Privately Insured Population. B. Briesacher*[1], D. Orwig*[2], M. Seton[3], M. Omar*[4], K. Kristijan*[4]. [1]Division of Geriatric Medicine, University of Massachusetts Medical School, Worcester, MA, USA, [2]Department of Epidemiology and Preventive Medicine, University of Maryland School of Medicine, Baltimore, MD, USA, [3]New England Registry for Paget's Disease of Bone, Massachusetts General Hospital, Boston, MA, USA, [4]Novartis Pharmaceuticals Corporation, East Hanover, NJ, USA.

This retrospective observational study was designed to assess treatment costs for patients with Paget's disease of bone (PDB) compared to those of matched controls (MC) as a surrogate marker for the burden of disease. Epidemiological research and clinical reviews detailing the complications of Paget's disease since its initial description by Sir James Paget in 1876, served as the basis for the radiographs, laboratory tests and selected conditions examined in this study. Using 2001-2002 MarketScan Research databases, we linked medical claims, prescription records, and encounter data on 2.8 million active or retired employees to create a longitudinal panel with 24 months of observation. Patients with PDB were identified by ICD-9 code 731.0. The MC was identified through an exact match procedure using gender, age and risk adjustment score based on the DCG/HCC classification system. This analysis extracted all diagnostic and expenditure records for the sample and calculated the prevalence of 22 conditions potentially linked to PDB and their related costs. The prevalence of co-morbidities and health care costs were compared in PDB and MC, and differences tested using chi-square and t-tests. We identified 244 persons with PDB and 244 matched comparators (MC). The average age was 72.7 years; 50.8% were female. Significant differences in co-morbidities detected between PDB patients and MC (p<0.05) were as follows: pathological fractures (4.9% vs. 0.4%), heart murmurs (3.3% vs. 0.4%), fractures of femur other than neck (2.9% vs. 0.4), spinal stenosis (2.5% vs. 0.4%), hypercalcemia (1.6% vs. 0.4%), and bone neoplasms (7.8% vs. 2.5%), respectively. Biannual per patient outpatient costs were significantly higher in PDB patients (PDB $9301 vs. MC $6339, p < 0 .05). There is a significant difference in morbidity in persons with PDB compared to MC as expressed in the complications measured and the excess costs detected in this analysis. This is the first study to examine the burden of PDB in this way. Future research should assess the impact of drug therapy to slow the progression of PDB, and the consequent morbidity and economic impact on patients' lives.

Elevated Serum High Molecular Weight Kininogen in Patients with Paget's Disease of Bone. E. Tsuruga*[1], S. Rao[2], S. V. Reddy[1]. [1]Children's Research Institute, Medical University of South Carolina, Charleston, SC, USA, [2]Bone and Mineral Metabolism, Henry Ford Hospital, Detroit, MI, USA.

Paget's disease of bone (PD) is a chronic focal skeletal disorder characterized by excessive bone resorption followed by abundant new bone formation, with eventual replacement of normal bone marrow by vascular and fibrous tissue. Enhanced levels of IL-6, M-CSF and endothelin-1 have been associated with PD, implicated in its pathogenesis and indicator of disease activity. RANK ligand (RANKL), a critical osteoclastogenic factor that is expressed on marrow stromal/osteoblast cells is upregulated in areas involved with PD. We have recently demonstrated that heat shock factor-2 (HSF-2) is a downstream target of fibroblast growth factor-2 (FGF-2) to induce RANKL expression in stromal/ preosteoblast cells. These data suggest that heat shock proteins/heat shock factors may play an important role in bone remodeling. To further identify serum factors that are over-expressed in patients with PD, we performed 2D gel electrophoresis and mass spectrometric analysis of serum from patients. We identified increased serum levels of high molecular weight glycosylated kininogen (KNG) in a patient with PD compared to normal serum. Western blot analysis of serum samples (6 µg total protein) from three PD patients further identified two to five-fold increase in levels of KNG heavy chain (63 kDa) compared to five normal subjects. However, there was no significant change in the serum levels KNG light chain (58 kDa) expression in these patients. We then examined the effects of KNG on human bone marrow derived stromal cells (SAKA-T cells). Treatment of SAKA-T cells with recombinant KNG (25 ng/ml) for 24 hr period resulted in a five-fold increase in the levels of phospho-HSP-27 and a three-fold increase in ERK1/2 phosphorylation in these cells. However, SAKA-T cells stimulated with KNG in the

presence of ERK activation inhibitor peptide-1 (25 μM) which binds to ERK2 and prevents interaction with MEK did not significantly affect the levels of phospho-HSP-27. These data suggest that KNG may play an important role in modulating stromal/preosteoblastic cell proliferation/differentiation. These results may implicate a potential pathophysiologic role for KNG in the progression of pagetic lesions in patients with PD.

Hypocalcemia as a Presenting Feature of Celiac Disease in a Patient with DiGeorge Syndrome. I. M. Gelfand*[1], L. A. DiMeglio[2]. [1]Departments of Medicine and Pediatrics, Endocrinology and Pediatric Endocrinology, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Pediatric Endocrinology, Indiana University School of Medicine, Indianapolis, IN, USA.

DiGeorge syndrome is a genetic disorder, resulting from deletions on chromosome 22q11.2. DiGeorge is often associated with hypocalcemia in the neonatal period that resolves by the end of the first year of life, however, hypocalcemia may present in older patients under conditions of physiological stress or illness. Celiac Disease (CD) is an autoimmune malabsorption disorder that results in villous atrophy of the small intestinal mucosa after exposure to gluten-containing foods. Even though the incidence of autoimmune conditions such as juvenile rheumatoid arthritis, Graves' disease, and hemolytic anemia is increased in DiGeorge syndrome, only one case of CD has been reported to date, with no reported cases of CD presenting with hypocalcemia in DiGeorge patients. Here we describe a first case of a child with DiGeorge syndrome who presented with hypocalcemia due to CD. A 5 1/2 -year-old white female with DiGeorge syndrome presented to her pediatrician with short stature and weekly emesis. Her past medical history was complicated by a congenital heart disease requiring surgical correction, multiple infections requiring hospitalizations, asthma, and iron deficiency anemia. She had not had episodes of neonatal hypocalcemia. Her height was 100.2 cm (< 3rd percentile for age), and weight 15 kg (< 3rd percentile). Her abdomen was distended. Chvostek and Trousseau signs were absent. Her calcium was 6.5 mg/dL (8.5-10.5), phosphorus 4.5 mg/dL (3.4-5.5), and intact PTH 54 pg/mL (10-65). 25-hydroxy-vitamin D level was 19 ng/mL (20-57). She had a microcytic hypochromic anemia with hemoglobin of 9.0 g/dL (11.5-14.5). She was diagnosed with partial hypoparathyroidism due to DiGeorge syndrome and started on calcitriol and calcium supplementations. Celiac antibodies were evaluated, and tissue transglutaminase (tTG) antibody was positive. Endoscopic evaluation with small bowel biopsies was consistent with diagnosis of CD. A gluten free diet was initiated upon making diagnosis of CD with a marked improvement in the energy level, resolution of abdominal distension, and improved growth velocity and weight gain. Within four months she was weaned off calcitriol. By six months of gluten-free diet her calcium supplementation was decreased to 30 mg/kg of elemental calcium. In conclusion, we present a case where malabsorption caused by CD unmasked partial hypoparathyroidism in a patient with DiGeorge syndrome. Therefore, new hypocalcemia in previously stable patients with DiGeorge syndrome should prompt an evaluation for Celiac Disease.

Insulin-like Growth Factor -1 (IGF-1), It's Binding Proteins, and Bone Turnover in Adolescent Girls with Type 1 Diabetes. M. A. Murray[1], D. McClain*[2], L. J. Moyer-Mileur[1]. [1]Pediatrics, University of Utah, Salt Lake City, UT, USA, [2]Internal Medicine, University of Utah, Salt Lake City, UT, USA.

Background: Children and adolescents with Type 1 diabetes (Type 1 DM) are at risk for decreased bone mass. We have reported significantly lower bone mass and mineral acquisition at axial and peripheral sites measured by densitometry in adolescents with Type 1 DM when compared to a non-diabetic reference population. (*J Peds* 2004;145:662-9.) Growth hormone (GH) and its mediators (IGF-1 and -2) and binding proteins (BP1 &-5), promote skeletal growth and mineral acquisition. Pubertal diabetics have an altered GH-IGF axis. **Hypothesis:** S*uppression of the insulin-like growth factor type 1 (IGF-1) response to GH or alterations in IGF-1 BPs (↑BP-1, BP-4; ↓BP-5) decreases osteoblast recruitment and bone matrix mineralization and increases collagen degradation*. **Purpose**: To compare bone metabolism in adolescents with Type 1 diabetes mellitus and matched controls. **Design**: Girls age 12-15 y (n=5) with Type 1 DM and healthy age, maturation-matched controls (n=5) were recruited and admitted overnight to the GCRC. Following consumption of a standardized meal, blood and urine samples were collected hourly (2300 to 0800). GH, IGF-1, IGFBPs (-1,-3,-4,-5), bone-specific alkaline phosphatase (BAP), and urine pyridinium to deoxypyridinium crosslinks ratio (Pyr/Dpyd) were measured and area under the curve (AUC) determined for GH, IGF-1, and BP-1. Statistical analysis included t-test, regression and ANCOVA. **Results**: Age, Tanner stage, body weight and height, and physical activity levels were similar between groups. Type 1 DM girls had significantly greater GH and BP-1AUC, BP-5,and Pyr/Dpyd values ($p \leq 0.04$) while IGF-1AUC was higher in controls (p=0.003) (Table 1). BP-3, -4, and BAP values were not significant. **Conclusions:** Our results suggest: 1) diminished IGF-1 bioavailability secondary to hepatic resistance to GH or sequestering by BP-1 and 2) collagen degradation greater than bone mineralization in adolescents girls with Type 1 DM. These preliminary findings may support our hypothesis that alterations in the GH/IGF axis decreases osteoblast recruitment and matrix mineralization limiting pubertal bone mineral acquisition. Additional studies are needed to further characterize mechanisms of bone growth and mineralization in adolescents with Type 1 DM.

Table 1. IGF-1, IGF-BPs and Bone Turnover (Mean (+/-sd); *p<0.04)

	Type 1 DM	Control
GH AUC	59.4 (33.9)*	32.9 (16.5)
IGF-1 AUC	2822 (947)	3709 (517)*
BP-1 AUC	314 (130)*	184 (111)
BP-4 ng/mL	552 (350)	581 (363)

Bone Density in Children with Early Classical Congenital Adrenal Hyperplasia. A. Fleischman*, J. Ringelheim*, H. A. Feldman*, C. M. Gordon. Children's Hospital Boston, Harvard Medical School, Boston, MA, USA.

Classic congenital adrenal hyperplasia (CAH), a deficiency of 21-hydroxylase, causes increased secretion of cortisol and aldosterone precursors that are diverted to androgens. Full suppression is usually not possible, and individuals are exposed to chronic glucocorticoids, and a mildly hyperandrogenic milieu. Therefore, children with CAH are at risk for glucocorticoid induced osteopenia. The goal of this study was to evaluate bone mineral density (BMD) in children with CAH to test the hypothesis that a hyperandrogenic state and altered body composition may provide skeletal protection. Thirteen subjects, ages 8 to 20 years from the endocrinology program of a tertiary care pediatric referral center, were evaluated with adrenal steroids, urine and serum bone markers, and a dual-energy absorptiometry (DXA) measurement for body composition, bone mineral content (BMC), and areal BMD of the hip, spine and total body using a Hologic 4500 scanner. The subjects received an average glucocorticoid dose of 14.4 mg/m2/day hydrocortisone equivalent (range 7.1-29.4). The protocol was approved by the local IRB.

DXA results

	Minimum	Maximum	Mean	Std. Deviation
Age	8.1	20.3	12.3	4.5
Z score:				
Total Body	-1.2	1.9	.6	.9
Hip	-1.4	2.2	.8	1.1
Spine	-1.5	2.5	.7	1.1

11/13 (85%, 95% CI 55-98%) participants had a BMD at or above the mean for age. The 2 participants with age-adjusted BMD <-1 standard deviation (SD) were the oldest and on the highest glucocorticoid doses (>20 mg/m2/day). Eight participants (62%) had Z-scores > +1 SD, with 2 (15%) > +2 SD. The total body BMD Z-scores were negatively correlated with the glucocorticoid dose in mg/m2/day (Spearman r= -0.63, p=0.02) or mg/kg/day (r=-0.66, p=0.01). Body mass index percentile, DXA- derived fat mass, weight in kilograms, and serum adrenal steroid concentrations showed no correlation with age-adjusted areal BMD. In summary, these children with CAH and life-long glucocorticoid supplementation had normal or above normal BMD, except for those with the highest dose and duration of therapy. In this model, glucocorticoids had the expected negative effect on BMD. However, the normal mean BMD supports the presence of a protective factor which is apparently not fat mass accumulation or measurable adrenal steroids. Contributory factors may include other alterations in body composition, androgen effect or disease specific modulators.

Bone Cross-Sectional Geometry in Adolescents with Anorexia Nervosa: A Hip Structural Analysis Study. A. D. DiVasta*[1], T. J. Beck[2], H. A. Feldman*[3], M. S. LeBoff*[4], C. M. Gordon[5]. [1]Adolescent Medicine, Children's Hospital, Boston, MA, USA, [2]Radiology, Johns Hopkins University, Baltimore, MD, USA, [3]Clinical Research Program, Children's Hospital, Boston, MA, USA, [4]Endocrine/Hypertension, Brigham & Women's Hospital, Boston, MA, USA, [5]Adolescent Medicine/Endocrinology, Children's Hospital, Boston, MA, USA.

Low bone mass and fractures are well-established complications of anorexia nervosa (AN). However, changes in bone geometry and strength may occur independently of changes in bone mineral density (BMD), and may be a better predictor of fracture risk. The purpose of this study was to determine the relationships among areal BMD, anthropometric measurements, and parameters of hip cross-sectional geometry in adolescents with AN. Baseline BMD measurements of the hip and spine were obtained in 88 young women with AN by dual x-ray absorptiometry (DXA) (Hologic 4500 Elite). We used the Hip Structural Analysis (HSA) Program to determine BMD, cross-sectional area (CSA), cross-sectional moment of inertia (CSMI), and section modulus (Z) at the femoral neck and femoral shaft regions. Height and weight were determined by standard procedures, and lean body and fat

mass measured by DXA. The protocol was approved by the local committee on clinical investigation. T-tests were used to compare study mean values to age- and gender-based normative data [Penn State Young Women's Health study]. Femoral neck BMD (mean ± SD, 0.86 ± 0.15 g/cm^2) was significantly lower than age-based normal values (p<.001); femoral shaft BMD (1.4 ± 0.15 g/cm^2) was not. The hip BMD Z-score (-0.63 ± 0.89, range -2.7 to 1.5) and lumbar spine BMD Z-score (-1.09 ± 0.88, range -3.1 to 0.8) were also significantly below normal. Both height and weight were positively correlated with parameters of bone strength, as assessed by femoral neck CSA and Z (Pearson r = 0.41-0.56, p<.001). Total hip BMD was correlated with femoral neck Z (r=0.45, p<.001) and CSA (r=0.81, p<.001). While lean body mass was correlated with femoral neck HSA variables (p<.001), body fat was not. In summary, in this sample of adolescent girls with AN, spinal bone density was more significantly compromised than that of the hip, indicating a larger deficit within trabecular bone. Anthropometric measures were correlated with variables of hip structural geometry. The hip structural variables were strongly correlated with standard areal BMD measurements by DXA. Lean tissue was predictive of bone strength, suggesting a beneficial effect of muscle on bone. The positive correlation between BMD and variables of hip structural geometry suggests that bone strength is also compromised in these patients.

Bone Mineral Density (BMD) in 5-8 Year Olds Who Were Treated with Corticosteroids (CS) for Chronic Lung Disease (CLD) of Prematurity. J. A. Eelloo*[1], S. A. Roberts*[2], A. J. B. Emmerson*[1], K. A. Ward[2], J. E. Adams[2], M. Z. Mughal[1]. [1]Central Manchester & Manchester Childrens University Hospitals NHS Trust, Manchester, United Kingdom, [2]The University of Manchester, Manchester, United Kingdom.

The adverse short-term effects of CS on growth and bone mineralisation in preterm infants are well known. However, it is not known whether these effects persist throughout childhood. We hypothesised that BMD would be reduced in pre-pubertal children who had received CS for the treatment of CLD. A group of 51, 5-8 year old children (32 male) born at < 34 weeks gestation took part in the study. BMD of the lumbar spine (LS) was measured using dual energy x-ray absorptiometry and the data expressed as LS bone mineral apparent density (LS BMAD; g/cm^3). Volumetric total (vtotBMD; mg/mm^3) and trabecular (vtrabBMD; mg/mm^3) BMD of the distal radius was measured using peripheral quantitative computed tomography. Height and weight were measured at the time of bone densitometry and transformed into Z scores using the U.K reference data. All bone data was transformed into Z scores using the Manchester normative reference data (n=420). Z scores for each of the variables were compared to zero using an independent samples t-test. Children treated with CS had a mean (SD) gestation of 26.73 (2.86) weeks, the control group 29.94 (2.17) weeks. The mean (SD) birth weight (g) in the children treated with CS was 1061.93 (529.43) and in the control group 1356.97 (451.59).

	Mean (SD) Z score		t-test (P =)	
	Steroids (n=15)	Controls (n=36)	Steroids	Controls
Height	-0.43 (1.24)	-0.09 (1.48)	0.20	0.73
Weight	-0.74 (0.96)	0.22 (1.58)	0.01	0.40
vtotBMD	0.32 (0.94)	0.60 (1.03)	0.21	0.001
vtrabBMD	0.13 (1.31)	0.24 (1.06)	0.71	0.18
LS BMAD	-1.42 (1.05)	-0.74 (0.90)	<0.0001	<0.0001

Children who received CS during the neonatal period were lighter compared with UK reference data. The distal radial vtotBMD was higher in the controls compared with the reference data. In both the groups the LS BMAD was lower compared with the reference data but the deficit was greater in the CS group. This greater deficit in the LS BMAD might be due to the effect of CS or being born on average 2-3 weeks earlier and approximately 300 grams lighter than the controls.

Altered Bone Turnover in Children with Crohn Disease. M. Harpavat[1], Q. Dang*[2], D. Keljo*[1], S. Greenspan[2]. [1]Pediatrics, University of Pittsburgh, Pittsburgh, PA, USA, [2]Medicine, University of Pittsburgh, Pittsburgh, PA, USA.

Bone turnover increases during childhood growth and development and can be altered in children with Crohn Disease (CD). This change has been attributed to corticosteroid use. This longitudinal study was designed to evaluate associations between markers of bone turnover and bone mass in childhood CD. 22 otherwise healthy, steroid naïve children newly diagnosed with CD were studied. After baseline data were obtained, all children were started on corticosteroids (equivalent to 2mg/kg prednisone) which were stopped by 4 months. Biochemical markers of bone formation (serum P1NP) and resorption (urine NTx) were measured at baseline, one, 3, and 6 months from initiation of therapy. Age and gender adjusted Z scores were calculated. Bone mineral content (BMC) and bone mineral density (BMD) of the total body (TB) and lumbar spine (LS) were obtained by DXA (Lunar Prodigy) at baseline, 6, and 12 months. 13 of the 22 children were male. Mean age was 12.3 years (range 5.5-16.7 years). CD patients had significantly reduced mean P1NP Z scores at baseline (-2.05 ± 1.1; p<0.001). By 6 months mean P1NP Z scores had significantly increased above normal range (0.97 ± 1.9; p=0.03, figure). Mean NTx Z scores at baseline were slightly reduced (-0.41 ± 0.77; p=0.02) and remained stable through 3 months but returned to normal by 6 months. The percent increase in P1NP from baseline to 6 months positively correlated with the percent increase in LS BMC from baseline to 6 months (r=0.59, p<0.01) and 12 months (r=0.48, p=0.02). The percent increase in P1NP from baseline to 6 months positively correlated with the percent increase in LS BMD from baseline to 6 months (r=0.50, p=0.02) and 12 months (r=0.64, p<0.01). No significant correlations were found between changes in NTx and changes in TB or LS BMC or BMD. In summary, steroid naïve children newly diagnosed with CD have decreased bone formation. Despite corticosteroid use, bone formation increased over time and changes in mean P1NP Z scores correlated positively with changes in BMC and BMD of the LS. Bone resorption changed minimally. We conclude the improvement in bone mass in children treated for CD may be explained by the increase in bone formation, with minimal change in bone resorption.

Implication of G Beta-Gamma Proteins and c-SRC Tyrosine Kinase in PTH-Induced Signal Transduction in Rat Intestinal Cells. C. Gentili*, R. Boland*, A. Russo de Boland*. Biologia, Bioquimica & Farmacia, Universidad Nacional del Sur, Bahia Blanca, Argentina.

PTH interacts in target tissues with a G protein-coupled receptor (GPCR) localized in the plasma membrane. Although activation of GPCR can elicit rapid stimulation of cellular protein tyrosine phosphorylation, the mechanism by which G proteins activate protein-tyrosine kinases is not completely understood. In the present work we demonstrated that PTH rapidly increases the activity of non-receptor tyrosine kinase c-Src in rat intestinal cells (enterocytes). The response is biphasic, the early phase is fast and transient, peaking at 30 sec (+120 %), while the second phase progressively increases up to 5 min (+220%). The hormone activates c-Src in intestinal cells through fast changes in the tyrosine phosphorylation of the enzyme. The first event in the activation of c-Src is the dephosphorylation of Tyr 527 (that happens at few seconds of PTH treatment), followed by a second event of activation with phosphorylation at Tyr 416 (+2 fold , 5 min). Removal of external Ca^{2+} (EGTA 0.5 mM) and chelation of intracellular Ca^{2+} with BAPTA (5μM) suppressed Tyr 416 phosphorylation and Tyr 527 dephosphorylation, indicating that Ca^{2+} is an upstream activator of c-Src in enterocytes stimulated with PTH. The G-protein subunits, Gαs and Gβ, are associated with c-Src in basal conditions and this association increases two-three fold in cells treated with PTH. Sequestration of Gβ subunits abolished hormone-dependent c-Src Tyr 416 phosphorylation and ERK1/ERK2 activation. The results of this work show that PTH activates c-Src in intestinal cells through conformational changes via G proteins and calcium-dependent modulation of tyrosine phosphorylation of the enzyme and that PTH receptor activation leads via Gβγ-c-Src to the phosphorylation of the MAP kinases ERK1 and ERK2.

Distinct Conformations of the Parathyroid Hormone Receptor Mediate G Protein and β-Arrestin Dependent Activation of ERK1/2. D. Gesty-Palmer[1], E. Reiter*[2], R. F. Spurney[3], L. M. Luttrell*[4], R. J. Lefkowitz*[5]. [1]Endocrinolgy and Metabolism, Duke University Medical Center and The Geriatrics Research, Education and Clinical Center, Durham Veterans Affairs Medical Center, Durham, NC, USA, [2]Medicine, Duke University Medical Center, Durham, NC, USA, [3]Nephrology, Duke University Medical Center, Durham, NC, USA, [4]Medicine and Biochemistry, Medical University of South Carolina, Charleston, SC, USA, [5]Medicine and Biochemistry, The Howard Hughes Medical Institute Duke University Medical Center, Durham, NC, USA.

Parathyroid hormone (PTH) regulates calcium homeostasis *via* the type I PTH/PTH-related protein receptor (PTH1R). The purpose of the present study was to identify the contributions of distinct signaling mechanisms to PTH-stimulated activation of the mitogen-activated protein kinases (MAPK) ERK1/2. In HEK293 cells transiently transfected with hPTH1R, PTH stimulated a dose-dependent increase in ERK activity. The time course of ERK1/2 activation was biphasic with an early peak followed by a significant period of sustained ERK1/2 activation. Pretreatment of HEK293 cells with the PKA inhibitor H89 and the PKC inhibitor GF109203X (GFX), individually or in combination blocked the early component of PTH-stimulated ERK activity. These inhibitors of second messenger dependent kinases had little effect on the later phase of PTH-stimulated ERK1/2 phosphorylation. This later phase of ERK1/2 activation, however, was blocked by depletion of cellular β-arrestin 2 or β-arrestin 1 by small interfering RNA. Further, we found that stimulation of hPTH1R with a PTH analogue, (D-Trp^{12}, Tyr^{34})-PTH(7-34), previously characterized as an inverse agonist for cAMP generation fails to activate classical heterotrimeric G protein signaling but does lead to receptor recruitment of β-arrestin 1 and 2 and activation of ERK1/2. This G protein-independent activation of ERK1/2 is abolished by depletion of cellular β-arrestin 2 or β-arrestin 1. It is concluded that PTH stimulates ERK1/2 through several distinct signal transduction pathways: an early G protein dependent pathway meditated by PKA and PKC and a late pathway independent of G proteins mediated through β-arrestin. Moreover these findings imply the existence of distinct active conformations for hPTH1R responsible for the two pathways, which can be stimulated by unique ligands. Such ligands may have distinct and valuable therapeutic properties.

Effects of Genetic Background on Phenotype of Cyclooxygenase-2 Knockout Mice. M. Xu, S. Choudhary, Q. Gao*, O. S. Voznesensky*, D. J. Adams, L. G. Raisz, C. C. Pilbeam. Dept. of Medicine, University of Connecticut Health Center, Farmington, CT, USA.

The phenotype of a gene knockout (KO) may depend on the genetic background in which it is expressed. Previous comparison of cyclooxygenase-2 (COX-2) KO and wild type (WT) mice was reported in a C57Bl/6x129 background. A mixed background was necessary since few KO mice could be generated in an increasingly pure C57Bl/6 background. In the C57Bl/6x129 background, COX-2 KO mice died 4-5 times faster than WT mice after weaning, secondary to renal failure. Some surviving KO mice with renal failure had marked secondary hyperparathyroidism with low serum calcium, high serum phosphorus and PTH levels greater than 1000 ng/dl. In C57Bl/6x129 COX-2 KO mice with intact renal function, there was still a trend toward elevated PTH levels but serum calcium levels were normal or increased, serum phosphorus levels were normal, and 1,25-dihydroxyvitamin D_3 levels were elevated 2-fold, suggesting primary hyperparathyroidism. We have begun to characterize calcium metabolism and bone phenotype in COX-2 WT, heterozygous (HET), and KO mice in an outbred CD-1 background. Experimental mice are the offspring of COX-2 HET mice that have been backcrossed into the CD-1 background more than 9 generations. In the CD-1 background, there is no increased mortality in COX-2 KO mice after weaning. In CD-1 male mice analyzed at 5 mo of age, weights were 10% lower in KO mice (n=11) than in WT (n=12) or HET (n=14) mice. Serum creatinine and serum calcium did not differ among WT, HET and KO mice. However, PTH levels were variably elevated ($p<0.05$) in the 5-mo old male KO mice. The mean (± SD) PTH level in the KO mice was 114 ± 130 ng/dl, compared to 30 ± 23 ng/dl and 28 ± 15 ng/dl in WT and HET mice, respectively. In the KO mice, 6/11 had PTH levels above 60 ng/dl. In 3.5 mo old CD-1 female mice, WT (n=11) and KO (n=8) mice had similar weights, serum creatinine and serum calcium. The mean PTH level in the KO females was only 1.5-fold greater ($p<0.05$) than that in WT females. In 9 mo old CD-1 mice (n=4-7 per group), KO mice had similar serum creatinine and calcium levels as WT and HET mice. In males, but not females, the mean PTH level was 2.5-fold greater ($p<0.05$) than that of WT or HET mice. These preliminary studies indicate that COX-2 KO mice in a CD-1 background do not have the increased mortality secondary to renal failure seen in KO mice in C57Bl/6x129 background. However, significant numbers of CD-1 COX-2 KO mice, especially male KO mice, have increased PTH levels with normal serum calcium levels. We speculate that the absence of COX-2 associated prostaglandins in KO mice may down regulate the sensitivity of calcium sensing pathways.

Predicting Bone Biomarker Response to PTH(1-34) Dosing in Rats with a Mathematical Model for the Remodeling Cycle. L. Potter[1], G. Stroup[2], D. Rickard[2], J. Vasko-Moser*[2], S. M. Hwang*[2], B. Votta[2], Z. Wu*[2], F. Tobin*[3]. [1]Scientific Computing & Mathematical Modeling, GlaxoSmithKline, Research Triangle Park, NC, USA, [2]GlaxoSmithKline, Collegeville, PA, USA, [3]GlaxoSmithKline, King of Prussia, PA, USA.

A mathematical model has been developed for the bone remodeling cycle in rats that predicts the bone biomarker response to dosing with PTH(1-34). The model describes the kinetics of osteoblast and osteoclast maturation and activity, while incorporating only the key biological features necessary to capture the effects of PTH dosing on bone remodeling and biomarkers. Model components include the proliferation, differentiation and apoptosis of osteoblasts and osteoclasts, the kinetics of bone formation and resorption, osteoblast-osteoclast interactions via the RANK/RANKL/OPG pathway, PTH receptor kinetics, and the effects of PTH signaling on bone formation and resorption. Bone formation and resorption biomarker levels are predicted through a correlation with model-simulated active osteoblasts and osteoclasts, respectively. Model parameters associated with PTH receptor kinetics were calibrated using *in vitro* PTH(1-34) radioligand binding data in membrane fractions from HEK-293 cells transfected with type 1 PTH/PTHrP receptor. Other parameters were calibrated in comparison with *in vivo* plasma osteocalcin and urinary deoxypyridinoline data from intact female rats dosed with PTH(1-34). The model captures the observed behavior that small doses given daily result in greater bone formation than larger doses given weekly. Moreover, the model is able to predict the range of variability in biomarker response to PTH(1-34) dosing expected across a population. Using Monte Carlo simulations with both day-to-day and population variability in PTH(1-34) pharmacokinetics, the model predicts greater variability in the resorption biomarker response than the formation response. This mathematical model is a powerful tool that can help design optimal PTH dosing regimens across a population of patients.

Identification of a Novel Activating Mutation in the Calcium Sensing Receptor Gene Supports the Physiological Relevance of the Venus Flytrap Module. C. Silve[1], C. Petrel*[2], C. Leroy*[1], E. Mallet*[3], H. Bruel*[4], D. Rognan*[5], M. Ruat*[2]. [1]Faculté de Médecine Xavier Bichat, INSERM U426, Paris, France, [2]Institut de Neurobiologie, CNRS UPR9040, Gif sur Yvette, France, [3]Hôpital Charles Nicolle, Rouen, France, [4]Groupe Hospitalier Le Havre, Le Havre, France, [5]UMR7081, Illkirch, France.

Class III G-protein coupled receptors (GPCRs), which include metabotropic glutamate receptors (mGluRs) and the Ca^{2+} sensing receptor (CaSR), are characterized by a long extracellular aminoterminal domain called a Venus flytrap module (VFTM) containing the ligand binding pocket, as demonstrated for mGluRs. Pathophysiological relevance of the VFTM remains to be ascertained, in part because no mutation associated with genetic disease has been identified in the mGluR binding site. Identification of a novel CaSR activating mutation, E297D, associated with autosomal dominant hypocalcemia (ADH), provides clinical evidence for the pathophysiological relevance of GPCR class III VFTM. E297 is structurally homologous to a D conserved in all VFTM mGluRs, and is essential for agonist binding and proper mGluR activation. Interestingly, replacement of the same glutamate by lysine (E297K) results in a loss of function of CaSR, a mutation previously observed in familial hypocalciuric hypercalcemia (FHH). Functional characterisation of the mutant receptors expressed in HEK-293 cells indicated that the E297D mutant was left-shifted in Ca^{2+} sensitivity compared to the wild-type receptor (EC_{50} = 2.53 ± 0.18 mM vs 3.75 ± 0.22 mM, mean ± SEM, n=4, $p<0.001$), whereas the E297K mutation was accompanied by a loss in Ca^{2+} sensitivity. A model of the CaSR VFTM was constructed based on mGluR1 crystal structure and on alignment between mGluRs and CaSR amino-acid sequences, which allowed us to predict potential residues involved in the calcium binding site. These residues, which include E297, are localized within the cleft of the two lobes thought to form the VFTM. The enhanced Ca^{2+} sensitivity of E297D mutant can be explained by a lower desolvation energy ($\Delta\Delta G_{desolv}$ = -4.53 kcal.mol^{-1}), which would favour stabilization of closed VFTMs by Ca^{2+} and subsequent CaSR activation. In the E297K mutant, the lysine 297 side chain ammonium exactly occupies the Ca^{2+} binding area and would keep the VFTMs closed, thus preventing Ca^{2+} binding. The clinical observation that the E297D and E297K mutations are respectively responsible for ADH and FHH and our *in vitro* data characterising their biochemical effects, are in agreement with the model, thereby supporting the physiological relevance of the VFTMs in the activation of receptors stimulated by the binding of small ligands in their extracellular domain.

The Calcium-sensing Receptor (CASR) Dimerizes in the Endoplasmic Reticulum: Biochemical and Biophysical Characterization of CASR Mutants Retained Intracellularly. S. Pidasheva*, M. Grant*, L. Canaff, U. Kumar*, G. N. Hendy. Medicine, McGill University, Montreal, PQ, Canada.

The calcium-sensing receptor (CASR) belongs to group C of the G protein-coupled receptor superfamily. The CASR exists at the plasma membrane as a homodimer. Although other members of group C have been shown to be constitutive homodimers it has not been precisely documented at which point in the biosynthetic pathway the CASR dimerizes. To address this issue we have made a biochemical and biophysical analysis of wild-type and mutant CASRs (harboring R66H, R66C or N538X inactivating mutations identified in familial hypocalciuric hypercalcemia/neonatal severe hyperparathyroid patients) that were transiently expressed in human embryonic kidney (HEK) 293 cells. By a trans-reporting assay (measuring MAP kinase activity) and an aequorin assay (measuring intracellular calcium release), all mutants were shown to be markedly deficient in cell signaling in response to increases in the extracellular CASR ligands, calcium and gadolinium, relative to wild-type. By immunoblot analysis of cell extracts, all mutants, although as well-expressed as wild-type, lacked mature glycosylation, indicating impaired trafficking from the endoplasmic reticulum (ER). In addition, whereas dimerized forms of wild-type, R66H and R66C mutants were present, none was observed with the truncated N583X mutant. By immunofluorescent confocal microscopy of nonpermeabilized cells, while strong staining at the plasma membrane was observed for the wild-type, little or no staining was seen for the mutants. In permeabilized cells strong perinuclear staining was observed for both wild-type and mutants. By fluorescent confocal microscopy using two different fluorophors, one for the CASR and the other for markers of the ER or Golgi apparatus, the mutant CASRs were localized within the ER but not the Golgi apparatus. By the use of the photobleaching fluorescence resonance energy transfer (pbFRET) method, it was demonstrated that the wild-type, R66H and R66C mutants were dimerized in the ER whereas the N583X mutant was not. Hence, CASR dimerization in the ER occurs as an early event and is likely to be necessary (but is not sufficient) for exit of the receptor from the ER and trafficking to the cell surface.

Intracellular Localization of Mutant PTH/PTHrP Receptors in Cultured Osteoblasts. J. Shimomura*[1], N. Amizuka[2], T. Kojima*[2], T. Maeda*[2], D. Goltzman[3], A. Karaplis[4], S. Shimooka*[1]. [1]Pediatric Dentistry, School of Dentistry at Niigata, The Nippon Dental University, Niigata, Japan, [2]Division of Oral Anatomy, Niigata University, Niigata, Japan, [3]Calcium Research laboratory, Royal Victoria Hospital, McGill University, Montreal, PQ, Canada, [4]Lady Davis Institute for Medical Research, Jewish General Hospital, McGill University, Montreal, PQ, Canada.

Mutations of the PTH/PTHrP receptor (PTH-R) have been discovered in Blomstrand's lethal chondrodysplasia (PTH-R^{P132L}) and Jansen type metaphyseal chondrodysplasia (PTH-R^{H223R}). Congenital deformities in these chondrodysplasia syndromes appear to be attributable to altered signal transduction linked to the receptor with diminished signal transduction in the Blomstrand lesion and constitutive signal transduction in the Jansen mutation. In the present study, we examined the possibility that mutations of these receptors result in abnormal intracellular localization and transport of the PTH-R proteins. MC3T3-E1 cells were transfected with pAlter-Max expression vectors containing cDNAs encoding rat wild-type PTH-R, and mutated PTH-Rs identical to those causing Blomstrand type and Jansen type chondrodysplasias. The cellular localization of these receptor-proteins was examined by immunofluorecence and immunoelectron microscopy. MC3T3-E1 cells transfected with the wild-type PTH-R cDNA displayed receptor immunoreactivity mainly on the cell surface, and partially in the region of Golgi apparatus. In contrast, the PTH-R protein carrying the Blomstrand type mutation was barely detectable on the cell surface. Instead, some mutant PTH-R was concentrated in the endoplasmic reticulum (ER), and some was present in the peripheral cytoplasm adjacent to the ER in the transfected cells. The Jansen type mutant PTH-R protein was localized mainly on the cell surface, but a minor amount was dispersed in the cytoplasm around the ER. The abnormal accumulation of the Jansen type mutant receptor in the ER and peripheral cytoplasm was therefore rare compared to that of the Blomstrand type mutation. Taken together, the findings show that wild-type PTH-R protein can be quickly transported to the Golgi apparatus and the cell surface after translation in the ER. Most of the Jansen receptor also appears to be incorporated in the cell membrane. In contrast, the Blomstrand type mutant PTH-R accumulates in the ER after translation, or leaks from the ER to the cytoplasmic region. Thus, skeletal deformities of Blomstrand's chondrodysplasia may result, at least in part, from receptor accumulation in the ER by cellular mechanisms of "quality control".

TIP39/Parathyroid Hormone Receptor 2 Signaling Inhibits Chondrocyte Proliferation and Differentiation by Negatively Regulating *Sox9* Gene Expression. D. Panda[1], H. Juppner[2], D. Goltzman[1], A. C. Karaplis[1]. [1]Medicine, McGill University, Montreal, PQ, Canada, [2]Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA.

TIP39 is the extended member of the parathyroid hormone super family that exerts its function by interacting with its specific receptor, parathyroid hormone receptor 2 (PTHR2). PTHR2 is highly expressed in thyroid cartilage, which persists as hyaline cartilage, while its expression in growth plate cartilage chondrocytes is restricted to certain cell populations. To investigate the role of G-protein mediated TIP39/PTHR2 signaling in chondrocyte biology, we first generated stably transfected CFK2 chondrocytic cells overexpressing PTHR2. Clones expressing PTHR2 were selected which demonstrated both G418 resistance and expression of the PTHR2 transcript by northern blotting. TIP39 (10^{-7}M) treatment of CFK2 cells stably transfected with PTHR2 inhibited their proliferation in culture. In addition, TIP39 treatment of PTHR2-expressing CFK2 cells restricted cells at the G0/G1 phase of the cell cycle. The inhibition of proliferation and cell cycle restriction were tightly associated with decreases in the expression of cyclin dependent kinases, CDK2 and CDK4, while p21, an inhibitor of CDKs, was upregulated. Moreover, TIP39 down-regulated expression of the differentiation markers (alkaline phosphatase activity, proteoglycan, type II, and type X collagen) in CFK2 cells. Transcription of *Sox9*, the master regulator of cartilage development, was dramatically reduced in TIP39 treated cells. *Sox9* gene promoter activity as measured by luciferase reporter analysis was also severely impaired following TIP39 treatment. In summary our results show that TIP39/PTHR2 signaling regulates the proliferation and differentiation of chondrocytes by down-regulating the expression of the master transcriptional regulator Sox9, and therefore illustrate the functional significance of the parathyroid hormone family member TIP39 in chondrocyte biology.

Development of a Novel Cell-Scanning System (Cell Track) for Expression Cloning of The Carboxyl-Terminal Parathyroid Hormone Receptor (CPTHR). A. Selim[1], B. McKenna*[2], S. El-Difrawy*[2], H. Juppner[1], P. Divieti[1], D. Ehrlich*[2], R. Bringhurst[1]. [1]Endocrine Unit, MGH, Boston, MA, USA, [2]White Head Institute, MIT, Boston, MA, USA.

Parathyroid hormone (PTH), an 84-amino-acid polypeptide, is a major systemic regulator of calcium homeostasis and bone remodeling and elicits its classical functions by activating PTH/PTHrP receptors (PTHRs) on target cells. Carboxyl (C) fragments of PTH, secreted by the parathyroids in a calcium-dependent manner or generated by PTH proteolysis in the liver, circulate in blood at concentrations much higher than intact PTH(1-84) but cannot activate PTHRs. Receptors specific for C-PTH fragments (CPTHRs), distinct from PTHRs, are expressed by bone cells, especially osteocytes, in which they may regulate intercellular communication and cell survival. Cloning of the CPTH receptor is essential for characterization of its function(s) and mechanism of action(s). We are using an expression cloning approach to clone the CPTH receptor. Expression cloning requires a highly sensitive, specific and rapid technique for detecting receptor expression in single cells transfected with pools of the cDNA library of interest. We have tested the sensitivity of a novel cell scanning system, "Cell Track", adapted from an instrument originally designed for analysis of multiplexed short tandem repeat DNA. The system supports a glass microdevice with 16 parallel channels, each of 20 cm effective length, and double-T cross injectors. A high-speed rotatory conofocal line scanner with four-color detector enables detection of single-cell fluorescence(s) and was specially designed to accommodate the high elution rates on the microdevice. To examine the sensitivity of the Cell Track system, we tested samples in which 0.1% of cells (osteocytes) expressed CPTHRs and were pre-bound to biotinylated human [Bio85, Tyr34]PTH (23-84) and then reacted with fluorescent streptavidin (Texas Red). The remaining cells in these samples (99.9%) were COS-7 cells that are known not to express CPTHRs. The Cell Track System reliably detected the cells expressing CPTHR in these samples (0.1%), displaying data as images of single positive cells with corresponding fluorescent signal intensity. No signal was detected in control samples consisting of COS-7 cells alone. The Cell Track System, which is adaptable for analysis of 384 samples simultaneously, provides rapid, reliable and highly sensitive detection and promises to facilitate CPTHR expression cloning and other applications requiring analysis of low-frequency subpopulations of cells identifiable by fluorescent markers.

The Receptor for Carboxyl-Terminal Parathyroid Hormone Regulates Osteocyte Cytoskeleton through Calcium Influx Dependent Mechanisms. A. A. Selim, G. Suliman*, H. Juppner, J. Potts, R. Bringhurst, P. Divieti. Endocrine unit, MGH, Boston, MA, USA.

Parathyroid hormone (PTH), an 84-amino-acid polypeptide, is a major systemic regulator of calcium homeostasis and bone remodeling and elicits its classical functions by activating PTH/PTHrP receptors (PTHRs) on target cells. Carboxyl (C) fragments of PTH, secreted by the parathyroids in a calcium-dependent manner or generated by PTH proteolysis in the liver, circulate in blood at concentrations much higher than intact PTH(1-84) but cannot activate PTHRs. Receptors specific for C-PTH fragments (CPTHRs), distinct from PTHRs, are expressed by bone cells, especially osteocytes, in which they may regulate intercellular communication and cell survival. Activation of CPTHRs previously was reported to modify intracellular calcium within chondrocytes. Our laboratory previously examined calcium signaling in several cell lines that express CPTHRs including osteocytes, ROS 17/2.8 osteosarcoma cells and RAW 264.7 myelomonocytic cells. Signaling studies demonstrated that CPTH induces voltage-sensitive calcium channel (VSCC) dependent calcium influx in the previously mentioned cells. Since calcium is a major regulator of the cytoskeleton, we examined the effect of CPTHR-dependent calcium influx on cytoskeletal structure in the PTHR1-null osteocyte cell line (OC-59). OC-59 cells were treated with 100 nM CPTH (53-84) for 2 or 10 minutes and then examined by immuno-fluorescent staining of cytoskeletal components (actin and vinculin). OC-59 cells treated with 100 nM PTH(53-84) for 10 minutes demonstrated marked actin and vinculin condensations compared to cells treated with vehicles or cells treated with PTH(53-84) for only 2 minutes. The specificity of the cytoskeletal changes in response to CPTH treatment was examined by treating cells with the mutant CPTH analog, [Ala^{55-57}]PTH(53-84), which does not bind to CPTHRs nor induce a calcium signal in OC-59 cells. [Ala^{55-57}]PTH(53-84) failed to induce any cytoskeletal changes in OC-59 cells treated for 10 minutes. Similar results were observed using PTH 1-34, which does not bind to or activate CPTHRs. The role of calcium influx in cytoskeletal changes induced by CPTH treatment was examined by blocking calcium influx using gadolinium chloride (GdCl). PTH(53-84) failed to induce cytoskeletal changes in OC-59 cells pretreated with GdCl (1 and 10 μM). In our previous calcium studies, GdCl completely inhibited the calcium signal in response to CPTH treatment. Collectively these data suggested that calcium signals induced by CPTHRs may play an important role in regulation of osteocyte cytoskeletal assembly and structure.

1,25(OH)2D3 Regulates Vascular Invasion in Long Bone Development during Embryonal Period. K. Hasegawa*[1], Y. Seino[2], S. Kato*[3], H. Tanaka[1]. [1]Department of Pediatrics, Okayama university graduate school of medicine & Dentistry, Okayama city, Japan, [2]Department of Pediatrics, Osaka Kosei Nenkin Hospital, Okayama city, Japan, [3]Tokyo University, Tokyo, Japan.

Vitamin D has been thought as an important factor in bone formation. We have shown that Vitamin D receptor Knock Out mice (VDRKO) clearly showed increased membranous bone formation in bone transplantation experiment, in bone organ culture system, and in fetal skeletal development. These results led us to the idea that 1,25(OH)2D3 (D3) directly suppresses bone formation. But the underling mechanism has not been fully understood. To clarify the roles of D3 in endochondral ossification, we analyzed the bone development focusing on the vascular invasion in long bone development during embryonal period. At first, we made skeletal preparation of Wild type mice (WT) and VDRKO during embryonal period. Then we determined when the diaphyseal ossification starts in long bones such as femur of WT and VDRKO. At p.c.d 14.5, we could identify diaphyseal ossification in VDRKO in contrast to Wt in which no bone collar was yet formed. Histology using von Kossa staining confirmed the same consequence. Because endochondral ossification starts with vascular invasion into the cartilage, we investigated the expression pattern of angiogenic factor such as vascular endothelial factor (VEGF), its receptors and PCAM-1 (CD31) as a vascular endothelial marker, by immunohistochemistry and we quantified expression of VEGF and VEGF receptor 2(FLK) by real time PCR. . As a result, FLK and PECAM-1 appeared earlier in VDRKO than WT. Thus we consider that D3 suppress vascular invasion into long bone via expression of FLK and PECAM-1 during embryonal period. From these results, we concluded that D3 suppresses endchondral bone formation by inhibiting the vascular invasion during long bone development.

Two New SNPs in the Human Vitamin D Receptor Promoter Switch Transcription Factor Binding, Change Promoter Activity and Are Associated with Growth in Female Adolescents. A. d'Alésio*[1], M. Garabedian[1], J. Sabatier*[2], G. Guaydier-Souquières*[2], C. Marcelli*[2], A. Lemaçon*[1], O. Walrant-Debray*[1], F. Jehan*[1]. [1]Inserm U561, Paris, France, [2]Service de Rhumatologie, Centre Hospitalier Universitaire, Caen, France.

We have hypothesized that clinical or biological features may also be associated with variations in the expression of vitamin D receptor (VDR) due to the presence of single-nucleotide polymorphisms (SNPs) in promoter regions. In the present work, we have identified two SNPs located -1521 bp (G/C) and -1012 bp (A/G) upstream of the transcriptional start site of the main human VDR gene promoter (hVDRp) so-called 1a-promoter. Genetic analysis evidenced two major haplotypes -1521G/-1012A and -1521C/-1012G and three main genotypes: homozygous for -1521G/-1012A (21.1%), homozygous for -1521C/-1012G (17.3%), and heterozygous -1521CG/-1012GA (57.3%). Electrophoretic mobility shift assays (EMSA) and competition experiments showed that one-base change at either polymorphism site was sufficient to switch the nature of the transcription factor bound, using either nuclear extracts from renal HEK293, intestinal Caco-2 or fibroblastic COS-7 cells. Transfection experiments performed in HEK293 or COS-7 cell lines revealed that the hVDR promoter activity was nearly 2 fold higher with the -1521G/-1012A haplotype, as compared to the -1521C/-1012G haplotype. Association between VDRp genotype and several features (clinical, radiological, and biological) were studied in a cohort of 185 healthy adolescent girls (14.7±2.8 years; range: 11-22 years), enrolled for a 4-year survey. Results show no association between VDRp genotype and parameters of calcium metabolism (serum calcium, urinary calcium excretion, serum PTH, serum 1.25-(OH)2 D) or bone mineralisation (bone mineral density, bone age, serum osteocalcin, or serum alkaline phosphatase activity). However, in comparison with girls with a GG/AA genotype, girls with a CC/GG genotype had: (i) lower circulating levels of 25-dihydroxyvitamin D (p=0.006); (ii) lower serum IGF-1 levels (p=0.03) and (iii) smaller height (p<0.008) from 11 years of age up to adult height. The significant association between hVDRp genotype and height could be overridden by sufficient calcium intake during puberty (> 865 mg/day). In conclusion, genotype variations at the two hVDRp SNPs are likely to change transcription factor docking and VDR expression, and may influence linear growth before and during puberty, especially in girls with low calcium intakes.

The Vitamin D Receptor Antagonist, (23S)-25-dehydro-1α-hydroxyvitamin D_3-26,23-lactone, Blocks RANK Ligand Induced Osteoclast Formation. S. Ishizuka[1], N. Kurihara[2], G. D. Roodman[3]. [1]Bone and Calcium Metabolism, Teijin Institute for Bio-Medical Research, Tokyo, Japan, [2]Medicine/Hem-Onc, University of Pittsburgh, Pittsburgh, PA, USA, [3]Medicine/Hem-Onc, University of Pittsburgh and VA Pittsburgh Healthcare System, Pittsburgh, PA, USA.

We recently demonstrated that (23S)-25-dehydro-1α-hydroxyvitamin D_3-26,23-lactone (TEI-9647), a vitamin D_3 receptor (VDR) antagonist, inhibited both normal and Paget's disease (PD) osteoclast (OCL) formation in response to 1α,25-$(OH)_2D_3$, and decreased the hypersensitivity of PD OCL precursors to 1α,25-$(OH)_2D_3$. Compounds such as TEI-9647 and its naturally occurring structural analogue, 23(S)25(R)-1α,25-$(OH)_2D_3$ -26,23-lactone (1α,25-$(OH)_2D_3$ -lactone), which is not a vitamin D antagonist, have unique binding properties that may allow them to interact with other proteins in addition to VDR. Therefore we determined if TEI-9647 blocked OCL formation induced by RANKL as well, since many of the effects of 1α,25-$(OH)_2D_3$ on OCL formation are mediated via induction of RANKL expression. Both TEI-9647 and 1α,25-$(OH)_2D_3$-26,23-lactone, dose-dependently (10^{-10}M to 10^{-6}M) blocked OCL formation induced not only by 10^{-10}M of 1α,25-$(OH)_2D_3$ but also by 50ng/ml of RANKL in pagetic and normal bone marrow cultures. This inhibition was not due to toxicity of these compounds since 10^{-6} M concentrations of these compounds did not inhibit CFU-GM colony formation. Importantly, another VDR antagonist that is not a lactone, the 25-carboxylic ester analogue of 1α, 25-$(OH)_2D_3$ (ZK-159222), dose-dependently blocked osteoclast formation induced by 1α, 25-$(OH)_2D_3$, but did not block RANKL induced OCL formation. These data suggest TEI-9647 and its natural analogue have VDR independent effects on OCL formation. To confirm that VDR was not mediating their effects on OCL formation, we tested the capacity of these compounds to inhibit OCL formation by VDR-/- marrow cells. Both TEI-9647 and 1α, 25-$(OH)_2D_3$-26, 23-lactone blocked osteoclast formation induced by RANKL in bone marrow cultures of VDR -/- mouse. In contrast, ZK159222 did not inhibit OCL formation induced by RANKL. These data suggest that TEI-9647 has two mechanisms of action to inhibit osteoclast formation: One is a VDR-mediated antagonistic action and the other is a VDR independent 1α, 25-$(OH)_2D_3$-26, 23-lactone-like action. Thus TEI-9647 is a novel OCL inhibitor that blocks both VDR and RANKL-mediated OCL formation. These data suggest TEI-9647 may be useful for treating diseases associated with increased OCL activity such as osteoporosis, bone metastasis and PD.

Identification of Vitamin D Response Element Binding Proteins and Transcription Factors by Oligonucleotide Trapping. W. Lutz*, R. Kumar. Nephrology Research, Department of Medicine, Biochemistry and Molecular Biology, Mayo Clinic College of Medicine, Rochester, MN, USA.

DNA affinity chromatography is widely used for purification of transcription factors and other DNA binding proteins. A recently developed approach for transcription factor purification involves an oligonucleotide trapping method in which a decameric oligonucleotide coupled to a resin is used to capture a complex of transcription factors bound to a specific DNA element. We investigated the suitability of this oligonucleotide trapping method for identifying transcription factors recruited to an osteopontin vitamin D response element (OP-VDRE). A DNA template consisting of two OP-VDREs flanked by $(GT)_5$ overhangs was incubated with nuclear extract protein prepared from rat osteosarcoma cells (ROS 17/2.8) which had been treated with 10^{-7} M 1,25$(OH)D_3$ for 6 hours. The DNA template and bound proteins were captured by applying mixture to a Sepharose resin to which the complementary oligonucleotide $(CA)_5$ was covalently coupled. After washing the

resin template-bound proteins were eluted with 1M NaCl. Eluted proteins were identified by Western blotting and liquid chromatography mass spectrometry/mass spectrometry. For Western blotting, an aliquot of the eluant was applied to a 4-15% SDS-PAGE gel and separated proteins transferred to PVDF membranes. The following antibodies were used: anti-VDR (rabbit polyclonal), anti-RXR (rabbit polyclonal, sc-774, Santa Cruz Biotechnology, Santa Cruz, CA), anti-RNA polymerase II (rabbit polyclonal, sc-899, Santa Cruz Biotech.), anti-CREB-binding protein (rabbit polyclonal, sc-369, Santa Cruz Biotech.), anti-p300 (rabbit polyclonal, sc-584, Santa Cruz Biotech.), anti-SRC-1 (goat polyclonal, sc-6098, Santa Cruz Biotech.), anti-GRIP-1 (rabbit polyclonal, sc-8996, Santa Cruz Biotech.), anti-TRAP150 (goat ploycloncal, sc-5378, Santa Cruz Biotech.), and TFIIA-γ (goat ploycloncal, sc-5316, Santa Cruz Biotech.). The remainder of the eluant was analyzed by mass spectrometry following concentration on PVDF membrane, trypsin digestion and liquid chromatography. Western blotting identified the following proteins bound to the OP-VDRE: VDR, RXR, and GRIP-1. The following DNA-associated proteins were identified by mass spectrometry: nucleolin, cellular nucleic acid binding protein, nonhistone chromosomal protein HMG-17, histone H1.2, nucleophosmin, FUSE binding protein 2, and general transcription factor II-I. These results indicate that the oligonucleotide trapping method is a powerful method for identifying VDRE-binding proteins.

1,25(OH)2D3 Induces Rapid Response in Growth Plate Chondrocytes and Osteoblasts through Its Membrane-Associated Binding Protein, ERp60. L. Wang, R. A. Chaudhri*, K. L. Wong*, Z. Schwartz, B. D. Boyan. Georgia Institute of Technology, Atlanta, GA, USA.

Steroid hormones act via traditional nuclear receptor mechanisms, as well as rapid non-genomic pathways by activating membrane associated protein kinases. 1,25-dihydroxyvitamin D3 [1,25] activates the PKCα signaling pathway in prehypertrophic and upper hypertrophic zone (growth zone) growth plate chondrocytes via activation of phospholipase A_2 (PLA_2), cyclooxygenase-1 (Cox) and PLC. Factors that upregulate responsiveness to 1,25 in growth plate chondrocytes increase expression of PLA_2 activating protein (PLAA), suggesting that it links ERp60 to PLA_2. Antibodies to the N-terminal amino acid sequence of ERp60 (Ab100), a 1,25 binding protein present in chondrocyte and osteoblast plasma membranes, block the signaling cascade. Growth zone chondrocytes from $VDR^{-/-}$ mice also respond to 1,25 with a rapid increase in PKC via the same PLC-dependent mechanism. To better understand the role of ERp60, we examined its tissue distribution in the tibial growth plate of $VDR^{-/-}$ mice using immunohistochemistry and compared this to PLAA; we determined its subcellular localization and relationship to the caveolar scaffolding protein caveolin-1 and to the nVDR by confocal microscopy of rat growth zone cells; we assessed the relative contributions of the N and C terminals to the overall mechanism; and we examined response to 1,25 in osteoblast-like ROS 17/2.8 cells (stable) after silencing ERp60 expression with siRNA. Immunohistochemistry using Ab100 showed that ERp60 and PLAA were limited to the prehypertrophic and upper hypertrophic cell zones of the growth plate and to the metaphyseal osteoblasts, both of which are responsive to 1,25. Immunostain was absent from the resting zone, which lacks a rapid PKC response. ERp60 and caveolin-1 were present in the plasma membrane whereas the nVDR was primarily in the nuclei of growth zone cells. Ab100 and Ab101 (generated to the C-terminus of ERp60) both blocked PLC and PKC activation and downstream biological responses, suggesting that both termini are involved in the mechanism. Compared to scrambled siRNA treated cells, Erp60 siRNA significantly decreased the effect of 1,25 on PKC activity in ROS 17/2.8 cells. Additional studies showed that activation of PKC in ROS 17/2.8 cells was via PLC and Cox. In conclusion, 1,25 binding protein ERp60 and PLAA are present in 1,25-responsive chondrocytes and osteoblasts in vivo and in vitro, ERp60 and Cav-1 are present in the plasma membrane, and rapid PKC signaling requires functional activation of ERp60 signaling via PLC and COX.

VDR Gene Polymorphism and Falls in the Elderly. H. A. Bischoff-Ferrari[1], M. Conzelman*[2], H. B. Staehelin*[3], R. Theiler*[4], P. Geusens[5], W. Dick*[6]. [1]Medicine, Brigham and Women's Hospital, Boston, MA, USA, [2]Geriatrics, Felix Platter Spital, Basel, Switzerland, [3]Geriatrics, University Basel, Basel, Switzerland, [4]Rheumatology, Triemli Hospital, Zurich, Switzerland, [5]Rheumatology, Limburg University Center, Diepenbeek, Belgium, [6]Orthopedics, Basel University, Basel, Switzerland.

Background: The Vitamin D receptor (VDR) is present in muscle tissue. Thus its allelic variation may have an independent effect on falls. **Aim:** To study the role of the Bsm1 VDR polymorphism and baseline vitamin D status as predictors of falls. **Methods:** This is a 12-week prospective study including 117 frail elderly women in long-stay geriatric care (mean age 85 years; range 63-99). The rate of falls was the primary outcome of this analysis. We used Poisson regression to evaluate whether the VDR polymorphism is a determinant of the risk of falling controlling for age, sex, body mass index, intact PTH, baseline 25-hydroxyvitamin D, number of comorbid conditions, Folstein Mini Mental Status, vitamin D treatment and length of follow-up. **Results:** 66 falls occurred in 117 persons. Mean baseline 25-hydroxyvitamin D levels were 16.3 ng/ml (SD ± 10.3). Bsm1 VDR alleles were distributed as follows: Bb = 56%, bb = 32% and BB = 12% of sample. Controlling for all other covariates**,** the bb VDR genotype carried a 2-fold increased risk of falls compared to the heterozygote genotype (RR = 2.0; 95% CI [1.12,3.58])**.** The BB genotype did not carry an increased risk. Independent of the VDR and controlling for all other covariates, a 1 ng/ml higher baseline 25-hydroxyvitamin D serum level accounted for a 5% reduction of falls (95% CI [1% - 8%]). **Conclusion:** Elderly women carrying the bb VDR genotype had a 2-fold increased rate of falls. However, independent of the VDR genotype, a higher baseline 25-hydroxyvitamin D level reduced falls by 5% per 1 ng/ml.

VDR Heterodimer Binding to the Human PTHSP1/NF-Y_{DIST} DNA Element and Supression ofSP1/NF-Y Transactivation. A. P. Alimov[1], O. K. Park-Sarge*[2], K. D. Sarge*[3], H. H. Malluche[1], N. J. Koszewski*[1]. [1]Division Nephrology, Bone & Mineral Metabolism, University of Kentucky, Lexington, KY, USA, [2]Dept. Physiology, University of Kentucky, Lexington, KY, USA, [3]Dept. Molecular & Cellular Biochemistry, University of Kentucky, Lexington, KY, USA.

We previously identified a NF-Y binding site (NF-Y_{DIST}) unique to the human PTH (hPTH) promoter adjoining a Sp1 DNA element that is highly conserved in a variety of mammalian PTH promoters. We also showed that a second NF-Y element (NF-Y_{PROX}) is located ca. 30 bp downstream from the Sp1/NF-Y_{DIST} site in the hPTH promoter. NF-Y_{PROX} overlaps with the repressor DNA binding site for the vitamin D receptor (VDR) heterodimer complex and the two factors compete for DNA-binding in vitro. In the present study, addition of recombinant VDR heterodimer to nuclear extracts possessing NF-Y binding activity revealed that the VDR heterodimer also formed a distinct complex on the hPTH Sp1/NF-Y_{DIST} element and could compete with NF-Y for binding to this DNA element. The binding activity was specific for the heterodimer and interference footprint analysis indicated the sites of DNA contacted by the complex comprised an everted repeat. Cold competition analysis indicated VDR heterodimer binding to the hPTH Sp1/NF-Y_{DIST} site was weaker compared to the downstream VDRE/NF-Y_{PROX} element, and interactions with a contiguous DNA sequence containing both binding sites did not reveal evidence of cooperativity. Sp1 and NF-Y can synergistically enhance transcription from the hPTH promoter; however, co-expression of the VDR heterodimer complex resulted in strong $1,25(OH)_2D_3$-dependent suppression (>80%) of Sp1/NF-Y synergistic transactivation. This suppressive capability was lost when transient expression of the wild-type VDR in the heterodimer complex was replaced by VDR mutants L417S or E420Q. Thus, synergistic transactivation of the hPTH promoter by Sp1/NF-Y complexes can be suppressed by $1,25(OH)_2D_3$ and requires hormone interactions with an intact VDR AF-2 domain. The data suggest that VDR heterodimer binding to the hPTH Sp1/NF-Y_{DIST} element may be contributing to the overall suppression of enhanced promoter activity.

Elucidation of the Molecular Mechanism of Antagonism of $1\alpha,25(OH)_2$-vitamin D_3 (1,25D)/ Nuclear Vitamin D Receptor (VDR) Transactivation by its 25-dehydro-26,23-lactone Analogs. M. T. Mizwicki*[1], C. M. Bula*[1], J. E. Bishop[1], S. Ishizuka[2], A. W. Norman[1]. [1]Biochem, UC, Riverside, CA, USA, [2]Teijin Inst. for Bio-Medical Res., Tokyo, Japan.

One class of 1,25D-VDR genomic antagonists has a (23S)-25-dehydro-26,23-lactone (MK) side-chain. Here we will use computer modeling (CM), site-directed mutagenesis (SDM) and protease sensitivity (PSA) to show that the mechanism underlying MK antagonism is novel to the nuclear receptor (NR) field because destabilization of the activation helix (H12) results from a reduction, rather than an increase in the molecular volume of the synthetic NR ligand (1,25D: ~421; MK: ~402 $Å^3$). Furthermore, analysis of the VDRwt-1,25D and MK models prompted the design of VDR mutants that made MK a more potent 1,25D/VDR antagonist or VDR agonist. Novel to the 1,25D-VDR complex, 1,25D's terminal side-chain CH_3 groups (C26/C27) are held in place by the 25-OH H-bonds to H305 and H397 so they make direct van der Waals (vdW) contacts with the VDR hydrophobic crown residues L227 (H3, Helix-3), L404 (H11), L414 (H12), and V418 (H12). The importance of proper intra- and intermolecular vdW contacts in this area was confirmed by 1,25D's genomic EC_{50}'s in VDRwt & V418L (~1 nM); L404F/ V418L (~7 nM); L404V & L414V (~30 nM); V418A & L404V/ L414V (~70 nM), L404V/ V418L (~350 nM). Our CM protocol removes side-chain placement bias in the VDR by docking a representative conformer from each side-chain population cluster (Pop. A = 73%, Pop. B = 14%, Pop. C = 11%; MK: 63%, 5%, 31%), obtained from dot map calculations for ligand alone (Mizwicki *et al*. PNAS 101, 2004). CM of Pop. B and C MK and 1,25D conformers in the VDR showed that only for MK both Pop. B and C forms are able to bind the VDR with equivalent potential interaction energies (PI_E = -94.2 and -94.6 kcal/mol; 1,25D Pop. B = -107.9; C = -98.7 kcal/mol). The reduced MK selectivity is a consequence of its reduced molecular volume altering the way MK's planar lactone can form noncovalent bonds with the H305 imidazole. In all MK-VDRwt complexes MK lacks optimal vdW contacts with the hydrophobic crown residues, leading to H12 instability and antagonism. This mechanism was confirmed by: a) H305A and H305A/H397F convert MK into a superantagonist, b) H305F and H305F/H397F turn MK into a superagonist and c) formation of a MK-VDR covalent adduct with H397 only occurs when [MK] is $\geq 10^{-5}$M (all verified by PSA). The proposed mechanism is consistent with the enhanced VDR affinity, antagonistic potency and PI_Es of 24R/S-CH_3-MK and 2α,24R/S$(CH_3)_2$-MK analogs. Collectively the data provides a more detailed understanding to VDR structure/function and may represent a new paradigm for sterol and/or protein based drug design (i.e. MK is an attractive compound for treating Paget's disease).

Raloxifene Treatment Modulates ER α Expression in Bone. N. Bravenboer, P. Holzmann*, P. Lips. Endocrinology, VU medical center, Amsterdam, The Netherlands.

Raloxifene is acting as an estrogen agonist in the skeleton, thereby maintaining bone mineral density (BMD) and preventing new vertebral fractures in postmenopausal women. Estrogen receptors (ERs) are proteins that mediate the action of estradiol and a series of natural and synthetic chemicals that mimic estradiol structure. Tissue specific distrubution partly determines the response of tissues to estrogenic compounds. Both ER α and β are present in bone tissue in distinct patterns of expression, whereas ER α is predominantly expressed in cortical bone. We questioned whether raloxifene treatment has any effect on the expression of the ER α in bone. 24 postmenopausal women who participated in the MORE trial were biopsied twice, before and after two years of treatment with either placebo or raloxifene 60 or120 mg/d. All women were provided supplemental calcium (500 mg/day) and vitamin D (400 IU/day). Immunohistochemical detection of ER α was performed on two sections per biopsy. Semi quantitative analysis of the sections was performed by a single investigator, who was blind for the therapy. Ordinal scores for amount of positive osteocytes and osteoblasts were tested using Mann Whitney and Wilcoxon signed rank test. In all biopsies, there was a distinct expression of ER α in some osteocytes in the spongiosa as well as in both cortices. Osteoblasts were rarely positive in both trabecular and cortical bone. Biopsies from the two dosage groups, raloxifene 60 and 120 mg/d, were not different with respect to amount of osteocytes, therefore data from these two groups were combined. The amount of positive osteocytes in trabecular bone decreased after two years raloxifene treatment , while it increased after two years placebo treatment (p=0.026). In cortical bone no differences were observed for the amount of positive osteocytes. Positive osteoblasts were present in 7/24 biopsies at baseline and in 1/10 after placebo treatment and in 2/14 after raloxifene treatment. Although in cortical bone no differences were found in the amount of positive osteocytes, the amount of osteocytes expressing ER α in the trabecular bone decreased after raloxifene treatment while it increased after placebo treatment.

ER Isoform Specific Regulation of TGF-β Inducible Early Gene-1 by Estrogen in Human Osteoblasts. J. R. Hawse[1], M. Subramaniam[1], D. G. Monroe[1], F. J. Secreto[1], K. Rasmussen*[1], S. Khosla[2], M. Oursler[2], T. C. Spelsberg[1]. [1]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA, [2]Endocrine Research Unit, Mayo Clinic, Rochester, MN, USA.

TGF-β inducible early gene-1 (TIEG) is a Krüppel-like transcription factor that plays an important role in mediating TGF-β effects in osteoblasts (OB) and other cells. We have previously shown that estrogen directly regulates the expression of TIEG in human OB. To define this regulation, we have utilized U2OS human osteosarcoma cell lines stably transfected with a doxycycline inducible estrogen receptor (ER) α or β construct. Cells were pretreated with doxycycline for 24 hours followed by treatment with 10 nM estrogen for 2 hours. Total RNA was isolated and real-time RT-PCR analysis was performed to examine the expression of TIEG mRNA. This analysis revealed an approximately 6-fold increase in TIEG in the ERβ cell line with a minimal increase in the ERα cell line. Based on these results, studies were initiated to elucidate the molecular mechanisms of this ER isoform specific regulation. We have identified 2 potential estrogen regulatory elements (EREs) in the first intron of TIEG. One of these sites is a perfect half ERE while the other closely resembles the consensus ERE sequence. Electrophoretic mobility shift assays were performed using each of these sequences and revealed that both ERα and ERβ were capable of binding to these sites. Cold competition assays, using a consensus ERE sequence, indicated that the TIEG half ERE bound both isoforms of the ER much stronger than that of the full-length ERE-like element. To further characterize these two sequences, we cloned an 850 base pair region of TIEG intron 1, spanning these two potential EREs, into a pGL_3 luciferase vector. This construct was transfected into U2OS cells and used to examine estrogen regulation of these sequences *in vivo*. Interestingly, these ERE-like sequences were capable of eliciting a 3-fold increase in luciferase activity following estrogen treatment only when co-transfected with the β isoform of the ER. These results clearly suggest that, although both isoforms of the ER are capable of binding to these ERE-like sequences, only the β isoform is capable of activating TIEG transcription. Chromatin immunoprecipitation assays are underway to verify the binding of both ER isoforms to these elements under *in vivo* conditions and to determine if ER co-regulators play a role in the ERβ specificity of this element.

Loss of Sex-Specific Difference in Bone Size in Leptin Knockout Mice. X. Wang*, C. H. Rundle, A. Srivastava*, J. Tesfai*, E. I. Davis*, J. E. Wergedal, K. H. W. Lau, S. Mohan, D. J. Baylink. MDC, J.L. Pettis VAMC, Loma Linda, CA, USA.

Leptin is an important mediator of body weight and bone metabolism. The obesity of leptin-deficient (*ob/ob*) mice facilitates the study of several fat-related effects of obesity, including hypogonadism. It is well known that the bones of male wild-type mice are larger than female wild-type mice and are the result of androgen actions. Because the effects of androgen and estrogen on bone are mediated in part by different molecular pathways, we asked the question if leptin deficiency exerts differential effects on the bones of male versus female mice.We therefore compared the bones of male and female leptin knockout mice (in C57BL/6 background) with the C57BL/6 wild-type control strain at 10 weeks of age. pQCT measurements in the femoral midshaft using an analysis threshold of 570-214 revealed that the large differences in the periosteal circumference (PC), endosteal circumference (EC) normally observed between male and female wild-type mice were reduced in male leptin knockout mice to values not significantly different from those of female leptin knockout mice (Table 1). The same was true for femur length. Total fat and body weight, as determined by DXA, were not significantly different between male and female leptin knockout mice (Table 1). PC, EC and femur length were not significantly different between female wild-type mice and female leptin mice (Table 1), indicating that the reduction of these parameters in leptin knockout male mice was caused by diminished androgen functions that could be attributed to hypogonadism in leptin knockout male mice. In conclusion, this study suggests that (1) the bone size determination depends on the action of leptin, and (2) the deficiency of leptin action may induce defects in the biological actions of androgen in male mice.

Table 1. C57BL/6-Leptin Knockout Mouse Comparison

Parameter	C57BL/6 Male/Female (%)	Leptin KO Male/Female (%)	C57BL/6 Female/ Leptin KO Female (%)
Femur PC	108.9*	100.0	101.5

Sex Steroids as Predictors of Bone Mineral Density, Bone Size and Prior Osteoporosis-Related Fractures in Elderly Swedish Men- *MrOS Sweden*. D. Mellström[1], A. Eriksson[1], M. Lorentzon[1], E. Orwoll[2], Ö. Ljunggren[3], O. Johnell[4], C. Ohlsson[1]. [1]Center for Bone Research at the Sahlgrenska Academy, Departments of Internal Medicine and Geriatrics, Gothenburg University, Gothenburg, Sweden, [2]Bone and Mineral Unit, Oregon Health and Sciences University, Portland, OR, USA, [3]Department of Medical Sciences, University of Uppsala, Uppsala, Sweden, [4]Department of Orthopaedics, Malmö General Hospital, Malmö, Sweden.

Osteoporosis-related fractures constitute a major health concern not only in women but also in men. Previous studies have indicated that serum levels of estradiol but not of testosterone are associated with bone mineral density (BMD) in elderly men. The aim of the present study was to investigate if levels of free estradiol (FE2) or free testosterone (FT) are associated with BMD, bone size and/or prior osteoporosis-related fractures in a large cohort of elderly Swedish men. In the Swedish part of the MrOS study (n= 3000, average age 75.4 years) bone parameters were measured using DXA and prior fractures after 50 years of age were estimated using standardized questionnaires. Serum levels of testosterone, estradiol and SHBG were measure and FT and FE2 were derived from the mass action equations. Height, weight, age, physical activity, smoking habits and calcium intake were included together with FE2 and FT in regression models for BMD. FE2 (β= 0.120, p<0.0001) but not FT (β= 0.003, NS) was an independent predictor of lumbar spine BMD. Both FE2 and FT were independent predictors of total body (FT β= 0.066, p< 0.001; FE2 β= 0.083, p< 0.001) and trochanter (FTβ = 0.068, p< 0.01; FE2 β= 0.067, p< 0.01) BMD. FT (β= 0.041, p<0.01) but not FE2 (β= 0.023, NS) was an independent predictor of total body bone area. Both FT (β= -0.061, p= 0.001) and FE2 (β= -0.042, p= 0.023) were negative predictors of prior fractures after 50 years of age (n= 497 individuals with reported fracture). Similar results were seen when only fractures at the major osteoporosis-related sites (vertebrae, radius, hip and humerus) were counted (n= 187 individuals with reported fracture, FT β= -0.044, p = 0.018; FE2 β=-0.037, p = 0.046). In conclusion, FE2 is an independent predictor of BMD at most skeletal sites while FT only is an independent predictor of BMD at selected sites. In contrast, FT but not FE2 is an independent predictor of bone area. Both FT and FE2 are predictors of prior osteoporosis-related fractures.

A TAAAA Repeat Polymorphism in the SHBG Gene Is Associated with Hormone Levels and BMD in Elderly Swedish Men - *MrOS Sweden* . A. Eriksson[1], M. Lorentzon[1], E. Orwoll[2], Ö. Ljunggren[3], O. Johnell[4], D. Mellström[1], C. Ohlsson[1]. [1]Center for Bone Research at the Sahlgrenska Academy, Departments of Internal Medicine and Geriatrics, Gothenburg University, Gothenburg, Sweden, [2]Bone and Mineral Unit, Oregon Health and Sciences University, Portland, OR, USA, [3]Department of Medical Sciences, Uppsala University, Uppsala, Sweden, [4]Department of Orthopaedics, Malmö General Hospital, Malmö, Sweden.

Sex hormone binding globulin (SHBG) serves as a transporter of sex steroids in the blood, and thereby regulates free levels of estradiol and testosterone. Free sex steroids in turn regulate skeletal homeostasis. Furthermore, some studies have indicated that SHBG is an independent regulator of bone mineral density (BMD). Recently, a pentanucleotide repeat polymorphism $(TAAAA)_n$ in the 5` promoter region of the SHBG gene has been characterized. The aim of the present study was to investigate if the TAAAA repeat polymorphism is associated with serum levels of SHBG and sex steroids, and BMD in a large cohort of elderly Swedish men. In the Swedish part of the MrOS study (n= 3000, average age 75.4 years) bone parameters were measured using DXA. Serum levels of testosterone, estradiol and SHBG were measured and free testosterone and free estradiol levels were derived from the mass action equations. The TAAAA repeat polymorphism was divided into long (>6 repeats = L) and short (6 repeats = S) variants. The SHBG repeat polymorphism was clearly associated with serum levels of SHBG (r= 0.114, p<0.0001), total testosterone (r=0.100, p<0.0001), free testosterone (r=0.057, p=0.007) and total estradiol (r = 0.065, p=0.002) but not with free estradiol levels (r= 0.032, p=0.12). Subjects with two short alleles had the highest levels of SHBG (SS 48.8 ± 2.0 nmol/l, SL 43.9 ± 0.7 nmol/l, LL 41.4 ± 0.6 nmol/l, p<0.0001), total testosterone (SS 19.2 ± 0.6 nmol/l, SL 17.3 ± 0.3 nmol/l, LL 16.0 ± 0.1 nmol/l, p=0.005) and total estradiol (SS 105.2 ± 3.0 pmol/l, SL 100.0 ± 1.4 pmol/l, LL 95.9 ± 1.1 pmol/l, p=0.005). We next investigated if the SHBG repeat polymorphism was an independent predictor of BMD. Height, weight, age, physical activity, smoking habits and calcium intake were included together with the SHBG repeat polymorphism in regression models for BMD. The SHBG repeat polymorphism was a significant independent predictor of trochanter BMD (β= -0.052, p=0.009) but not a significant predictor of lumbar spine BMD (β= -0.031, p=0.128). In conclusion, a TAAAA repeat polymorphism in the promoter region of the SHBG gene is associated with serum levels of SHBG and trochanter BMD in elderly men.

Phenolic Compounds in Safflower Seeds Reduce Bone Loss in Ovariectomized Rats. W. Lee*[1], Y. Bae*[2], J. Jin*[1], Y. Jung[1], S. Choi*[3], S. Cho*[3], I. Park[1], R. Park*[1], I. Kim*[4], S. Kim[1], J. Choi[1]. [1]Biochemistry, Kyungpook National University, School of Medicine, Skeletal Diseases Genome Research Center, Daegu, Republic of Korea, [2]Oral Anatomy, Kyungpook National University, School of Dentistry, Daegu, Republic of Korea, [3]Food Science and Nutrition, Catholic University, Daegu, Republic of Korea, [4]Biochemistry, Kyungpook National University, School of Medicine, Daegu, Republic of Korea.

We previously reported that safflower seeds attenuated bone loss in ovariectomized rats (Kim *et al*., Calcif Tissue Int., 71:88-94, 2002). In the present study, we investigated whether the phenolic compounds in safflower seeds are responsible for the bone-protecting effects. Female Sprague-Dawley rats (12 week old) were subjected to bilateral ovariectomy (OVX) or sham surgery. Ovariectomized rats were randomly assigned to groups and either fed a diet containing powder of defatted safflower seeds (SP) or phenolic compounds extracted from safflower seeds (SE), or injected with 17β-estradiol (E_2). After 4 weeks, their proximal tibiae were processed for scanning electron microscopy and quantitative bone histomorphometry. In contrast to marked bone loss and marrow fat deposition of the OVX group, both SP and SE groups showed approximately 80% of the bone volume of the sham group and no increase in marrow adiposity. The amount of the osteoid bone, reflecting newly formed bone, increased to 170% of the sham level in the OVX group, but was maintained at almost the sham level both in the SP and SE groups. In an attempt to find out which phenolic compounds exert the beneficial effects, lignans, flavones and serotonin derivatives were isolated from SE and administered to ovariectomized rats. Each phenolic compound significantly reduced the OVX-induced trabecular bone loss, increase in osteoclast numbers and marrow adiposity in the proximal tibiae. The present data provide the first direct *in vivo* evidence that the mixture of phenolic compounds from safflower seeds reduces the bone turnover and bone loss caused by estrogen deficiency.

Follicle-Stimulating Hormone Receptor Deficiency in Female Mice Results in an Osteoporotic Phenotype Characterized by Impairment of Osteoblastic Bone Formation and Stimulation of Osteoclastic Bone Resorption. J. Gao[1], Y. Yang*[2], D. Miao[1], M. R. Sairam*[2], A. C. Karaplis[1], D. Goltzman[1]. [1]Department of Medicine, McGill University, Montreal, PQ, Canada, [2]Molecular Reproduction Research Laboratory, Clinical Research Institute of Montreal, Montreal, PQ, Canada.

Follicle-stimulating hormone receptor (FSHR) knockout mice display impaired ovarian follicular development and infertility in females. FSHR deficiency also causes marked bone loss; however, the mechanism whereby FSHR affects bone remodeling is unclear. In order to investigate whether the effect of FSH on bone is direct or indirect and whether the bone loss in FSHR deficient mice results from the impairment of osteoblastic bone formation or the stimulation of osteoclastic bone resorption, we examined the expression of the FSHR in skeletal tissues and the effect of FSHR deficiency on bone remodeling. We found that the FSHR was undetectable in skeletal tissues as demonstrated by RT-PCR. The skeletal phenotype was normal at 4 weeks of age in the female FSHR knockout mice. By 3 months of age, as determined by contact radiography, Piximus densimetry, micro-CT and histomorphometric analysis, bone mineral density and trabecular bone volume were decreased significantly in the female FSHR knockout mice compared to their sex-matched wild type littermates. To determine whether the alterations of bone volume which were observed were associated with alterations of osteoblastic bone formation, we examined osteoblast number and osteoblast surface by histomorphometry and the alterations in expression of genes related to bone formation using RT-PCR. Both osteoblast number and surface were markedly diminished and expression of genes encoding Cbfa 1, alkaline phosphatase, type I collagen and osteocalcin were all reduced in bones of the female FSHR knockout mice. Following histochemical staining for tartrate resistant acid phosphatase (TRAP), osteoclast surface was quantified. The results showed that the osteoclast surface relative to the bone surface was increased significantly in the female FSHR knockout mice. The level of RANKL mRNA was not significantly increased but the level of OPG mRNA was reduced in bone of the mutants compared to wild-type bone. These results indicate that the effect of FSHR on bone is an indirect one that is likely mediated by sex hormones. FSHR deficiency therefore indirectly caused an osteoporotic phenotype associated with both the impairment of osteoblastic bone formation and the stimulation of osteoclastic bone resorption and which is only manifest after sexual maturation.

Vitamin D Receptor Antagonist ZK 191784 Augments ApoA1 Gene Expression. K. R. Wehmeier*, M. J. Haas*, A. E. Beers*, A. D. Mooradian*. Division of Endocrinology, Department of Internal Medicine, Saint Louis University School of Medicine, St. Louis, MO, USA.

Studies of arteriosclerosis have used in vivo models of vascular calcification created by pharmacologic doses of vitamin D. Investigators have previously demonstrated that human high-density lipoprotein (HDL) inhibits the spontaneous osteogenic differentiation and mineralization of calcifying vascular cells in vitro. Members of the steroid receptor super family are known to alter the transcription of the major apoprotein of HDL, ApoAI. 1α,25-Dihydroxyvitamin D_3 was shown to reduce ApoA1 synthesis in our lab. Interventions that increase HDL cholesterol level significantly reduce the risk of coronary heart disease events. To investigate the effects of a vitamin D receptor (VDR) antagonist ZK 191784 (ZK) on ApoA1 gene expression in a human hepatoma cell line (HepG2), we assessed the effect of ZK on apoAI synthesis and promoter activity. In HepG2 cells transfected with the apoAI reporter gene construct pAI.474.CAT, ZK induced apoAI promoter activity in a dose-dependent manner with a plateau at 10 μM. To determine the time course of ZK on apoAI protein levels, HepG2 cells were incubated with 1 μM ZK for 0, 1, 3, 6, 12 and 24 hours, and apoAI protein levels were measured by Western blotting. ApoAI protein levels in the media were significantly increased only after 24 h. To quantify the effect of ZK dose on apoAI protein levels, HepG2 cells were incubated with increasing amounts of ZK and after 24 h, apoAI protein levels were measured by Western blot analysis. ApoAI protein levels increased significantly at 10 nM, reaching a rapid plateau. To assess the effect of ZK on apoAI promoter activity in the presence or absence of vitamin D (Table 1), HepG2 cells were transfected with the apoAI reporter gene construct, and treated with ZK, and vitamin D (1α,25-dihydroxyvitamin D_3 250 nM) for 24 h. ZK, in a time and dose dependent manner, relieved vitamin D mediated transcriptional repression. These studies suggest that VDR analogs may be important in the regulation of ApoAI synthesis. Further studies are needed to define the implications of VDR ligands on cardiovascular risk.

Effect of ZK on apoAI promoter activity in the presence or absence of vitamin D.

Conditions	CAT Activity (% Acetylation)	% Change (from control)	P (vs. Control)
Control	25.0 ± 0.8	--	--
ZK (0.02 nM)	24.8 ± 0.4	-0.8	N.S.
ZK (0.2 nM)	22.5 ± 1.6	-10.0	N.S.
ZK (2.0- nM)	30.1 ± 0.8	20.4	0.01
Vit. D (100 nM)	15.8 ± 0.7	-36.8	0.001
Vit. D + ZK (0.02 nM)	17.5 ± 1.2	-30.0	0.006
Vit. D + ZK (0.2 nM)	22.4 ± 1.0	-10.4	0.06
Vit. D + ZK (2.0 nM)	27.7 ± 1.0	10.8	N.S.

The Effects of UV-B Light on Serum 25(OH)D in Humans. L. A. G. Armas*[1], R. P. Heaney[1], M. J. Barger-Lux*[1], C. Huerter*[2], R. Lund[3]. [1]Osteoporosis Research Center, Creighton University, Omaha, NE, USA, [2]Dermatology, Creighton University, Omaha, NE, USA, [3]Nephrology, Creighton University, Omaha, NE, USA.

We report results of work to quantify the relationship of skin color and 25(OH)D response to graded doses of UV-B light delivered by a light booth. The subjects (n=48, age 21-49 yr, females = 28, males = 20) were healthy indoor workers with limited non-solar sources of Vitamin D. They were divided into 5 treatment groups based on their self-reported susceptibility to tan or burn (Fitzpatrick skin types I-VI). Data were gathered from January through April. We determined BMI, 25(OH)D, Ca^{2+} and PTH at baseline. We used a portable skin colorimeter that utilizes the CIE L*a*b* color system to measure constitutive skin color of the upper inner arm and facultative skin color of the forearm. The subjects were exposed to UV-B light from a UV light booth 3 times a week for 4 weeks (12 treatments) in graded doses ranging from 40mJ to 80 mJ per treatment . 25(OH)D was drawn weekly during, and 4 weeks after, completion of UV-B treatment. There was a rise in 25(OH)D of 29.9 nmol/L(median; interquartile range 24.3-40.7) during the 4 weeks of UV-B treatment and a fall 4 weeks after UV-B treatment ceased of 3-14% from peak 25(OH)D levels. The L* values of exposed skin did not vary significantly throughout the treatment period. There was a significant correlation between L* readings (a continuous darker-to-lighter scale) of baseline facultative and constitutive skin color and 25(OH)D response per mJ of UV-B light given (r^2=0.535, r^2=0.551) (i.e. the lighter skinned subjects had a greater response). In conclusion, increase in 25(OH)D per mJ of UV-B exposure was related to the "L" value of skin at baseline. This increase in 25(OH)D was achieved without changing "L*" values (i.e. becoming darker).

Cellular Entry of Vitamin D Ligands Together with VDR Affinity Represent the Primary Determinants of Biological Potency. L. A. Zella, N. K. Shevde, J. W. Pike. Biochemistry, University of Wisconsin- Madison, Madison, WI, USA.

Vitamin D superagonists are analogs of 1,25-dihydroxyvitamin D3 (1,25(OH)2D3) that display biologic potencies inconsistent with their relative affinities for the vitamin D receptor (VDR). Mechanisms proposed to account for this interesting feature include differential cellular uptake, altered metabolism and the potential for these ligands to provoke unique VDR conformations capable of unusual coregulator interactions. To define the mechanism responsible for increased biologic potency, we evaluated the ability of three vitamin D superagonists, MC1288, KH1060 and 2MD as well as 1,25(OH)2D3 to induce Cyp24, osteopontin (OPN) and RANKL gene expression in osteoblastic cells *in vitro*. Mouse MC3T3-E1 and/or ST2 cells were treated for 6 hrs with increasing concentrations of each ligand and isolated RNA was analyzed by RT-PCR. As expected, the vitamin D superagonists induced expression of the three target genes with potencies 2 logs greater than that for 1,25(OH)2D3. Interestingly, however, despite a direct correlation between superagonist affinity for VDR and their ED50's, this relationship diverged for 1,25(OH)2D3. This suggested the possibility that "restricted entry" of 1,25(OH)2D3 might be solely responsible for the phenomenon of differential ligand potency. To test this, osteoblasts were treated with ligand in the absence of serum and isolated RNA subsequently analyzed for Cyp24, OPN and RANKL mRNA induction. Surprisingly, this maneuver increased the potency of 1,25(OH)2D3 to a level fully equivalent to that of the superagonists. We then assessed whether the transcriptional effects of serum could be linked directly to VDR activation. We determined the capacity of tritiated 1,25(OH)2D3 and 2MD to bind directly to the VDR in intact cells, the potency of each ligand to induce VDR protein upregulation, and the ability of ligands to promote VDR binding to endogenous Cyp24 and OPN gene promoters using chromatin immunoprecipitation. All studies were carried out in the presence and in the absence of serum. The results revealed that serum impacts each of these VDR-associated activities in a fashion identical to that observed for transcription. In a final experiment, we used serum derived from either wildtype and DBP-null mice to demonstrate that the decrease potency observed for 1,25(OH)2D3 in the presence of serum was due exclusively to DBP. Our studies indicate that in the absence of catabolism, the primary determinants of vitamin D ligand potency are affinity for the VDR and affinity for serum component such as DBP. Our results do not support a molecular mechanism for potency that involves unusual interactions between the VDR and its coregulators on target genes.

Measurement of Specific Vitamin D Binding Protein Capacity and Calculation of Free 1,25-Dihydroxyvitamin D (1,25D). D. Laurie*, M. Gardner*. R&D, IDS Ltd, Boldon, United Kingdom.

A purely mass measurement of vitamin D binding protein (DBP) could give an erroneously elevated indication of functionality if all the DBP can not bind vitamin D. The aim of the study was to demonstrate the utility of the newly developed IDS Vitamin D Binding Protein Capacity (DBPc) reagent pack (AA-36F1). DBPc levels were measured in normal, liver disease (LD) and third trimester pregnancy (3TP) sample groups. This was used with a total 1,25D measure to calculate a 'free' 1,25D level for samples. The IDS DBPc method involved saturating 20µL serum sample with excess 25D (500µL of 1200nM) at 37ºC for 30min. Cold charcoal reagent (100µL) was added after 10min chilling on crushed ice. The mixture was incubated for a further 1hr on the ice to remove unbound or low affinity albumin bound 25D. After centrifugation, a proportion of the supernatant containing the high affinity DBP-bound 25D was measured using the IDS 25-hydroxyvitamin D RIA kit (AA-35F1). Samples (Biochemed, U.S.) were also assayed for total 1,25-dihydroxyvitamin D (1,25D), 25-hydroxyvitamin D (25D) (IDS RIA kits) and albumin (BCG Method, Thermoelectron). DBPc levels were significantly higher in the 3TP and lower in the LD groups compared to the normal group. Levels of total 1,25D followed the changes in DBPc levels. Free 1,25D levels calculated from total 1,25D and DBPc levels were higher in the 3TP group, despite the rise in DBPc values. Rises in DBPc, total and free 1,25D were also seen in the pregnancy compared to the normal group in the referenced study [(1)]. 25D and albumin levels were generally as expected for sample groups with the low 25D levels in the normal group probably a reflection of the season when samples were taken. This study shows that the 3 sample groups tested gave differing DBPc levels using the IDS DBPc reagent pack. From DBPc and total 1,25D measures, it is possible to calculate a potentially physiologically relevant level for 'free' 1,25D in these samples. The IDS DBPc Reagent Pack is effective in measurement of the specific binding capacity of DBP for vitamin D compounds in serum. This might provide a more meaningful indicator of the functionality of DBP in samples in relation to vitamin D physiology than a purely mass DBP measurement.

	Normal (n=60)	LD (n=20)	3TP (n=20)
DBPc (µM)	5.56 (+/-0.61)	4.35* (+/-0.79)	8.16* (+/-0.69)
Total 25D (nM)	34.8 (+/-13.8)	35.4 (+/-12.0)	69.5* (+/-17.4)
Total 1,25D (pM)	99.0 (+/-39.7)	43.8* (+/-20.5)	338* (+/-52.2)

Development of a Rapid LC-Tandem MS Assay for Serum 25-Hydroxyvitamin D_2 and 25-Hydroxyvitamin D_3 and Comparison with Nichols Advantage, CPBA and HPLC Assays on Serum from Patients Treated with Pharmacological Doses of Vitamin D_2. D. P. Jamieson*[1], A. Zhang*[1], J. Mathieu*[1], R. Ray*[1], D. G. Kelling*[2], T. C. Chen[1], M. F. Holick[1]. [1]Vitamin D Research Laboratory, Boston University School of Medicine, Boston, MA, USA, [2]Diabetes Self-Care Program,, NorthEast Medical Center, Concord, NC, USA.

Serum assays for 25-hydroxyvitamin D [25(OH)D] are used to determine the vitamin D status of patients. These assays include radioimmunoassay, competitive protein binding assay (CPBA), and high performance liquid chromatographic assay (HPLC). To date there are only a few Tandem LC Mass Spectrometry (LC-MS/MS) assay methods for the determination of serum 25(OH)D, and most reported methods have low sensitivity and need extensive sample preparation. The LC-MS/MS assay we have developed measures both $25(OH)D_2$ and $25(OH)D_3$ and shows remarkable sensitivity and accuracy with a lower limit of quantification of 2 ng/ml and with coefficients of variance less than 10% over the range from 2 to 200 ng/ml, respectively. The rapid LC-MS/MS method utilizes a unique extraction procedure, and direct sample loading without the need for further sample preparation, allowing for a total analysis time of 6 minutes per sample. To determine the accuracy of the LC-MS/MS assay for detecting both $25(OH)D_2$ and $25(OH)D_3$, as compared to other methods, serum samples were obtained from 80 patients who were treated with pharmacologic doses of vitamin D_2 for a period of several months to years. Samples were analyzed by four different methods including: LC-MS/MS, HPLC, CPBA, and the Nichols Advantage System. For all of the vitamin D_2 treated patient samples, we were able to detect and quantify $25(OH)D_2$ and $25(OH)D_3$ by all four methods. A linear analysis shows no correlation between the levels of $25(OH)D_2$ and under detection in the Nichols Advantage assay. This suggests that the discrepancy is more of a patient specific phenomenon and/or a result of possible metabolite interference.

Do Different Storage Conditions Affect the Measurement of Vitamin D Metabolites? J. L. Berry, P. L. Selby, M. Davies. Vitamin D Research Group, Medicine, Manchester Royal Infirmary, Manchester, United Kingdom.

Assays for vitamin D metabolites can be extremely variable. The UK Vitamin D External Quality Assessment Scheme (DEQAS) has shown that the coefficient of variation (CV) of vitamin D metabolite measurements can vary from 19-28% between laboratories. Many laboratories have specific requirements for storing samples before assay. For example, some insist that samples should be frozen immediately and sent frozen to the assay laboratory, others that samples can be sent unfrozen by first class post. We have examined different storage conditions to see whether this could account for some of the variation in measurement of vitamin D metabolites between laboratories. Whole blood or serum (separated within 30 min of sampling) were left at room temperature (RT) or placed in the fridge (4-6ºC), serum was frozen at -20 °C. Samples were assayed 1, 2 and 7 days post-sampling. A further serum sample was packaged and posted back to our own laboratory then frozen before assay. Whole blood was centrifuged immediately prior to assay. 25-hydroxyvitamin D (25OHD) was measured by HPLC and 1,25-dihydroxyvitamin D (1,25D) by in-house radioimmunoassay. An example from one sample is shown in table 1

Table 1 The effect of different storage conditions on the measurement of vitamin D metabolites

Sample	Storage conditions	Day 1		Day 2		Day 7	
		25OHD ng/ml	1,25D pg/ml	25OHD ng/ml	1,25D pg/ml	25OHD ng/ml	1,25D pg/ml
Serum	RT	8.2	41	8.3	39	8.6	34
	4ºC	8.8	38	9.2	30	8.3	37
	-20 °C	8.5	38	8.9	36	8.2	34
	By post			8.6	39		
	Freeze/Thaw 1			8.7	44		
	Freeze/Thaw 2					8.5	34
Whole Blood	RT	8.3	49	8.6	32	7.1	36
	4ºC	8.9	36	8.4	40	8.3	35

Mean (±SD) 25OHD 8.5±0.4 ng/ml CV 5.1%; 1,25D 37±4 pg/ml CV 11.9%

Mean coefficient of variation from all samples with varying levels of vitamin D metabolites was 5.13±0.06% for 25OHD and 10.8 ±1.0% for 1,25D. This was not significantly different from the normal assay variation for control serum run on the same assays (4.5% for 25OHD and 12.3% for 1,25D). We conclude that different storage conditions do not account for the variation in vitamin D metabolite measurements between laboratories. Furthermore, samples do not need to be frozen before assay.

Assessing Vitamin D Status; the Problem of Assay Variation. M. F. Holick[1], N. C. Binkley[2], D. Jamieson*[1], D. Baran[3], R. A. Petruschke*[3], E. Chen*[3], A. E. de Papp[3]. [1]Boston University School of Medicine, Boston, MA, USA, [2]University of Wisconsin, Madison, WI, USA, [3]Merck & Co., Inc., West Point, PA, USA.

Vitamin D status is best assessed by measuring serum 25-hydroxyvitamin D [25(OH)D]. However, wide variations in commercially available 25(OH)D assay performance have been reported. We recently conducted an observational study to assess the prevalence of vitamin D inadequacy using the Nichols Advantage chemiluminescent system in 1536 North American postmenopausal women receiving osteoporosis therapy. Because of the reported variability in 25(OH)D measurements, we randomly selected a subset of 293 samples from this cohort and re-measured total 25(OH)D by Diasorin radioimmunoassay (RIA) and 25(OH)D_3 and D_2 using liquid chromatography- mass spectrometry (LC-MS).The mean (median) serum 25(OH)D was 30.2 (30) ng/mL using the Nichols Advantage system, 32.7(34) ng/mL using the Diasorin RIA and 29.6 (29.3) ng/mL using LC-MS. The mean (median) serum 25(OH)D_2 as measured by LC-MS was 3.9 (0.8) ng/mL. Significant correlation was found between all three assays for measurement of total 25(OH)D; r = 0.698 between Nichols Advantage and LC-MS, r = 0.789 between Diasorin and LC-MS, and r = 0.748 between Nichols Advantage and Diasorin. At lower serum concentrations, there was good agreement (kappa= 0.7-0.75) between the three assays for determining the prevalence of vitamin D deficiency (<15 ng/mL); 9.6% with Nichols Advantage, 8.2% with Diasorin and 9.9% with LC-MS. More moderate agreement (kappa= 0.49-0.57) was seen at higher cutpoints; the prevalence of vitamin D inadequacy (<30 ng/mL) was 49.2% with Nichols Advantage, 34.5% with Diasorin and 50.5% by LC-MS. Compared to LC-MS, the Diasorin RIA had greater specificity but less sensitivity than the Nichols Advantage system across all cutpoints of serum 25(OH)D concentrations. There was even greater variability among 16 patients in whom vitamin D_2 accounted for more than 50% of their serum 25(OH)D. These results suggest that commercially available 25(OH)D assays perform in a similar manner and are reasonably good for detecting vitamin D inadequacy in a population when compared to a more sensitive chromatographic method. This is likely due in part to the low intake of vitamin D_2 in the North American population. However, variation between assays may exist in individual patients and can be problematic in clinical practice.

Comparison of DiaSorin Immunoassay Methods with LC-MS/MS for the Measurement of 25-OH Vitamin D. J. A. Schmidt[1], J. S. Fenske*[1], K. A. Pieper*[1], K. J. Belisle*[1], M. Eastvold*[2], R. J. Singh*[2]. [1]DiaSorin Inc, Stillwater, MN, USA, [2]Laboratory Medicine & Pathology, Mayo Clinic and Foundation, Rochester, MN, USA.

Vitamin D is an essential component in the regulation of calcium and bone metabolism. Measurement of 25-OH vitamin D is used for the assessment of vitamin D nutritional status. Decreased levels may be seen in dietary deficiency, malabsorption and various disease states. The measurement of 25-OH Vitamin D is growing in importance with the recognition of the involvement of Vitamin D in autoimmune diseases, cancers, and cardiovascular disease as well as bone health. Because both D2 and D3 forms of the vitamin are used to supplement low levels of Vitamin D, and it is important both forms be measured to accurately assess Vitamin D sufficiency. The purpose of this study is to demonstrate the equivalence of immunoassays made by DiaSorin Inc. to LC-tandem mass spectrometry for the determination of 25-OH Vitamin D. Isotope dilution liquid chromatography -tandem mass spectrometry was used to measure 25-OH Vitamin D2 and 25-OH Vitamin D3 in 100 serum samples containing D2 and D3, or D3 alone. The sum of 25-OH Vitamin D2 and 25-OH Vitamin D3 was compared to 25-OH Vitamin D determined by 125-I RIA and by chemiluminescence immunoassay on LIAISON®. Both immunoassays are from DiaSorin Inc., and utilize the same rabbit polyclonal antibody. The immunoassay methods demonstrated good correlations to LC-MS/MS and clinical equivalence in the range from 7-150 ng/mL. Linear regression analysis gave the following equations: RIA = 0.91(LC-MS/MS) + 5.4 ng/mL (r=0.93) and LSN = 1.02(LC-MS/MS) + 2.0 ng/mL (r=0.90). These comparisons show that both the RIA and the LIAISON® methods measure 25-OH Vitamin D2 and 25-OH Vitamin D3 accurately, and that results determined by DiaSorin immunoassays compare very closely to the LC-MS/MS method, which is considered the "gold standard" method for the measurement of 25-OH Vitamin D.

Age-Related Change of Spinal Bone Mineral Density and Accumulated Bone Loss Rate in Korean Women. H. Choi*[1], D. Lee*[2], B. Kim*[3]. [1]Family Medicine, Eulji University Hospital, Daejoen, Republic of Korea, [2]Family Medicine, Samsung Jeil Hospital, Seoul, Republic of Korea, [3]Family Medicine, Ajou University Hospital, Suwon, Republic of Korea.

Objective: We investigated the age-related bone mineral density(BMD), accumulated bone loss rate(ABLR) and the prevalence of osteoporosis at lumbar spine in Korean women. Methods: Using dual energy X-ray absorptiometry(DEXA), lumbar spine BMD(L1-4) were measured in 3,988 pre- and postmenopausal women. We obtain corrected spinal BMD through spinal BMD devide by a square of height. Results : In early postmenopausal age group(51~55 years), the prevalence of osteoporosis was 20.1%, but after 60 years old, more than 60% of women were classified as osteoporosis. In correlation analysis, age was strongly associated negatively with spinal BMD and corrected spinal BMD(r=-0.61, r=-0.45, p<0.001 respectively). After controlling weight and height, age was strongly associated negatively with spinal BMD and corrected spinal BMD(r=-0.54, r=-0.54, p<0.001 respectively). When the data were analyzed by 5-year old age groups, the peak spinal BMD was at the age of 36-40 years, but the peak corrected spinal BMD was at the age of 41-45 years. The bone loss rate was the greatest in 51-55 years. In this age group, the accumulated bone loss rate was 8.5%. In the premenopausal women, the bone loss was not occurred significantly. Conclusion: We conclude that the physiological age was the most important factor that affect the rate of bone loss in women. And our data support the benefit of active intervention being initiated in the late perimenopausal period or as early as possible after the menopause in women identified as having low bone mass at that time.

Middle-Aged Cycling Women Show Aging Effects on Androgens, Osteocalcin, and Hip Bone Density Prior to Menopause. J. L. Lukacs[1], M. Kleerekoper[2], R. Ansbacher*[3], V. Padmanabhan*[3], N. E. Reame*[1]. [1]School of Nursing, University of Michigan, Ann Arbor, MI, USA, [2]School of Medicine, Wayne State University, Detroit, MI, USA, [3]School of Medicine, University of Michigan, Ann Arbor, MI, USA.

To distinguish age effects on bone turnover and mineral density we studied 3 groups of volunteers differing by age and menopause status: 21 cycling young (CY; mean age = 24.5 ± 0.8 yrs), 19 cycling older (CO; mean age 48.9 ± 0.5 yrs) and 19 postmenopausal (PM; mean age 49.0 ± 0.7 yrs, mean yrs PM 2.8 ± 0.5) women. Cycling women were assessed on menstrual cycle day 4 ± 1. Volunteers were not using oral contraceptives or hormone replacement. We assessed estradiol (E_2), testosterone (T), free T, bone turnover with bone alkaline phosphatase isoenzyme (BAP), osteocalcin (OC), and bone mineral density (BMD) at the lumbar spine (L1-L4) and total hip sites with DEXA. As expected CO women had similar estradiol (34 ± 5 vs 24 ± 3 pg/ml), but lower T (0.2 ± 0.02 vs 0.4 ± 0.03 ng/ml, p < 0.0001) and free T (0.5 ± 0.06 vs 0.9 ± 0.07 pg/ml, p < 0.0001) compared to CY. PM women had lower E_2 (7 ± 1 pg/ml) but T (0.2 ± 0.02 ng/ml) and free T (0.5 ± 0.08 pg/ml) did not differ from CO group (p = NS). CO women had lower OC, a marker of bone formation (3.8 ± 0.2 vs 5.7 ± 0.5 ng/ml, p = 0.01), plus lower total hip BMD (1.0038 ± 0.032 vs 1.1126 ± 0.030 gm/cm^2), femoral neck BMD (0.9088 ± 0.032 vs 1.0743 ± 0.035 gm/cm^2) and femoral shaft BMD (1.1879 ± 0.038 vs 1.3058 ± 0.031 gm/cm^2) than the CY group. The rate of bone turnover was higher in PM women (BAP: 128.6 ± 6.6 vs 85.7 ± 5.7 U/L; OC 6.5 ± 0.6 vs 3.8 ± 0.2 ng/ml) compared to CO. Lower BMD at all sites, L1-L4 (-0.26), total hip (-0.5), femoral neck (-0.6), trochanter (-0.39), and shaft (-0.44) was associated with older age (p < 0.05). BMD at hip sites: total hip (r = 0.323), femoral neck (r = 0.4), trochanter (r = 0.26), shaft (r = 0.28) is positively associated with free T (p ≤ 0.05); and femoral neck (r = 0.32, p = 0.01) with T. The data suggest that the age-related decline in androgens may be one factor in lower bone formation and bone density in the hip of mid-life premenopausal women, while the well known increase in rate of bone turnover is evident at menopause.

SU003

Age, Body Weight and a History of Fracture Are Major Predictors of Bone Mineral Density in both Asian Men and Women - Results from Mr and Ms Os Hong Kong, the First Cohort Study in Asians. E. Lau[1], P. Leung*[2], T. Kwok*[3], J. Woo*[4], E. Orwoll*[5], S. Cumming[6]. [1]Hong Kong Osteoporosis Center for Treatment and Research, Hong Kong, Hong Kong Special Administrative Region of China, [2]Department of Orthopaedics and Traumatology, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China, [3]Medicine, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China, [4]Community and Family Medicine, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China, [5]Medicine, Oregon University of Health Sciences, Oregon, OR, USA, [6]Coordinating Center, University California San Francisco, San Francisco, CA, USA.

Little is known about the determinants of bone mineral density in Asian men and women. Mr and Ms Os is the first cohort study designed to do so in Asians. Four thousand men and women aged 65 to 95 were interviewed using a standardized questionnaire. Various physical measurements were performed, and bone mineral density was measured by dual X-ray densitometry.

Predictor (unit)	Percentage change in BMD (g/cm^2)			
	Men		Women	
	Femoral Neck	Total Spine	Femoral Neck	Total Spine
Age (year)	-1.3	2	-3.6	0.4
Body weight (kg, per SD)	7.6	8.1	7.7	9.1
Fracture after 50 years (yes/no)	-1.1	-0.9	-1.7	-1.9
R^2 for regression model	0.25	0.179	0.304	0.223

It can be seen that age, body weight and a history of fracture after 50 years accounted for 25% and 31% of the variation in femoral neck BMD in men and women respectively. Adding other variables such as cigarette smoking, and medical risk factors caused only very slight increase in the r^2. We conclude that age, body weight and a history of fracture were major predicators of BMD in Asian men and women, and these could be applied to identify subjects in whom BMD measurements are truly indicated.

Osteoprotegerin and RANK-L in Extreme Longevity, and their Changes during the Aging Process. G. Passeri[1], C. Galli*[1], A. R. Telera*[1], R. Vescovini*[1], G. M. Macaluso*[2], R. Minelli*[1], R. Delsignore*[1], P. Sansoni*[1], M. Pedrazzoni[1]. [1]Dep. Internal Medicine, Univ. of Parma, Parma, Italy, [2]Chair of Periodontology, Univ. of Parma, Parma, Italy.

RANK-L and its decoy receptor Osteoprotegerin (OPG) are key regulators of bone resorption in vitro and in vivo, and their balance is therefore critical for modulation of osteoclastogenesis and bone remodeling. RANK-L is expressed by osteoblasts, bone marrow stromal cells and activated T lymphocytes, RANK is a transmembrane receptor in cells of osteoclastic lineage, and OPG is produced by osteoblasts. It has been recently demonstrated that bone remodeling, especially bone resorption, is active even in extreme longevity, and in particular in centenarians. We have here evaluated some parameters of bone metabolism, and in particular circulating OPG and RANK-L serum levels, in a group of 44 centenarians (average age 101±1.5 years, 37 females and 7 males, group 1) and in two other groups, averaging approximately 60 (18 females and 2 males, group 2) and 20 years of age (16 females and 4 males, group 3). Centenarians were showing features of secondary hyperparathyroidism, with elevated levels of PTH, serum CTX, significantly lower levels of serum calcium and phosphates, and elevated ALP as compared to the other two groups. Average serum creatinine was 1.2±0.55, 0.86±0.1 and 0.89±0.1 mg/dl, while creatinine clearance was 29, 78 and 95 ml/min in centenarians, 60 and 20 years old subjects respectively. OPG was significantly elevated in centenarians as compared to the other 2 groups (p<0.001). In 60 years old subjects OPG was slightly higher as compared to the youngest group. Circulating RANK-L resulted significantly elevated in 20 years old subjects as compared to the other 2 groups, while no differences were present between 60 years old subjects and centenarians. In conclusion our data confirm a condition of secondary hyperparatiroidism, already demonstrated in extreme longevity, and show an increment in OPG levels in centenarians. This can be considered as a possible, although insufficient, homeostatic mechanism able to limit bone loss. RANK-L serum level may reflect, at least in part, an age dependent different production by circulating T lymphocytes, without considering the membrane bound form expressed by cells of osteoblastic lineage. Therefore it may not mirror the real amount present and active in the bone microenvironment.

Association of Estrogen Receptor Beta Gene Polymorphisms and Rate of Bone Loss in Perimenopausal Women. J. Gu, B. Lai, V. Chan, A. Kung. Medicine, The University of HongKong, Queen Mary Hospital, HongKong, Hong Kong Special Administrative Region of China.

Estrogen deficiency associated with menopause is a major cause of osteoporosis in women. Understanding the pathogenesis of bone loss associated with menopause and early identification of perimenopausal women with rapid bone loss is an effective approach to

help reduce the increasing incidence of osteoporosis. To determine the role of estrogen receptor beta gene (ESR2) and rate of bone loss in perimenopausal women, we studied 12 single nucleotide polymorphisms (SNPs) encompassing the whole ESR2 gene in 269 Southern Chinese women aged 40-60 years (mean age 49.8± 3.6). Bone mineral density (BMD) was measured at a mean interval of 18months (range 12-24 months). The association and risk of rapid bone loss (3% per annum) with ESR2 SNP and SNP haplotype was assessed using chi-square test and logistic regression model. The results showed that allele C carriers at a SNP in the promoter region (nt -1213 TC) was associated with lower risk of rapid bone loss at both the spine and hip (lumbar spine OR=0.47, p=0.023, femoral neck OR=0.47, p=0.017, trochanter: OR=0.053, p=0.041 and total hip OR=0.41, p=0.005). When adjusted for age, height and body weight, all sites remained significant (lumbar spine: OR=0.47, p=0.023, femoral neck: OR=0.47, p =0.017; total hip: OR=0.41, p=0.005). Analysis of the haplotype data revealed similar findings as individual SNP analysis. In conclusion, SNP and SNP haplotype of ESR2 is associated with rate of bone loss in perimenopausal women and may be useful for predicting bone loss during early postmenopausal period.

SU006

A Cross-Sectional Study of Changes in BMD and Bone Turnover Associated with Aging in 888 Volunteer Women in Their Early Adolescence to Middle and Advanced Age. Y. Onoe[1], Y. Miyabara*[1], A. Harada*[2], R. Yoshikata*[1], M. Yoshida*[1], M. Mikumo*[1], T. Kuroda*[1], H. Okano[1], M. Kume*[3], H. Ohta[1]. [1]Obstetrics and Gynecology, Tokyo Wemen's University, Tokyo, Japan, [2]Biostatistics, Tokyo University, Tokyo, Japan, [3]Nursing, Tokyo Wemen's University, Tokyo, Japan.

Bone mineral density (BMD) in women is known to increase in their early adolescence and begin to decrease in their perimenopausal years, and after a certain decrease in BMD, they become eligible for the diagnosis of osteoporosis. While pharmacological interventions are commonly applied to established osteoporosis, there is no consensus regarding prophylaxis against osteoporosis. To establish such prophylactic strategies requires investigating changes in BMD associated with aging in women from adolescence onwards, and optimizing therapeutic interventions for each age group. A cross-sectional study in a broad range of women from early adolescence to middle and advanced age was therefore conducted to address this issue. This study was conducted in female volunteers aged 19 to 60 years. Women with conditions that affect BMD, as well as pregnant or breast-feeding women, were excluded from the study. The subjects were asked about their age and current menstrual status. Additionally, height, body weight, as well as serum calcium, phosphorus, albumin, intact-osteocalcin (OC), cross-linked N-telopeptide of type I collagen (NTX), and bone-alkaline phosphatase (BAP) were measured in these women. The BMD of the lumbar vertebrae 2 to 4 (L 2-4), as well as the total BMD of the proximal femur (BMD of the hip), was also measured in the subjects using QDR 4500. A total of 888 women (mean age, 27.3 ± 8.2) were enrolled in the study between October 2003 and August 2004. The BMD of the L2-4 was confirmed to remain at a certain level (mean: 1.00 ± 0.11 g/cm^2) between the ages of 19 to 40, and then to tend to decrease thereafter. The total BMD of the hip (mean: 0.87 ± 0.10 g/cm^2) was seen to decrease between the ages of 19 to 30, remain stable for a time, and then decrease again thereafter. During this observation period, of the bone metabolic markers examined, NTX was noted to decrease until age 30, and then to increase after age 45, while BAP was shown to decrease until age 25, and then to increase after the age of 48. Our study results indicate that BMD peaks in these women before age 19 and that changes in BMD associated with aging differ between the lumbar vertebrae and femur with the BMD of the femur seen to decrease earlier. The status of bone turnover during this period appears to be independent of changes in BMD, where the bone turnover tends to be lower in younger years, and after a time, begins to increase again, preceded by an increase in bone resorption markers.

SU007

Osteoporosis of Ossicles and Hearing Loss in Mice. K. Matsuo[1], M. Ito[2], K. Ogawa*[3], S. Kanzaki*[3]. [1]Department of Microbiology and Immunology, Keio University School of Medicine, Tokyo, Japan, [2]Department of Radiology, Nagasaki University, Nagasaki, Japan, [3]Department of Otolaryngology, Keio University School of Medicine, Tokyo, Japan.

Hearing loss and osteoporosis are both associated with aging, but whether osteoporosis can directly contribute to impaired auditory function is unclear. Mice lacking osteoprotegerin (OPG$^{-/-}$ mice) develop osteoporosis due to enhanced differentiation of osteoclasts. We therefore isolated the three auditory ossicles, the malleus, incus, and stapes, from the middle ear cavity of adult OPG$^{-/-}$ mice, and compared them with heterozygous controls. All three ossicles in OPG$^{-/-}$ mice showed apparent thinning, especially at the malleal manubrim, malleal processus brevis, and stapedial arch. Furthermore, ossicles from OPG$^{-/-}$ mice stained more extensively positive for tartrate-resistant acid phosphatase (TRAP) activity than those from heterozygous controls indicating elevated osteoclastic bone resorption of ossicles in OPG$^{-/-}$ mice. Radiological analysis using micro CT (μCT40, Scanco Medical, Switzerland) showed that malleal bone thickness was decreased in OPG$^{-/-}$ mice, corresponding to the decrease in tibial bone mineral density measured by quantitative CT (LaTheta, Aloka, Japan). To examine hearing sensitivity in OPG$^{-/-}$ mice, we measured auditory brainstem response (ABR) at 6, 10 and 15 weeks of age. OPG$^{-/-}$ mice showed progressive hearing loss over the frequency range tested (2-20 kHz). At 15 weeks, mutant mice were more than 20 decibels (dB) less sensitive than wild-type controls at the highest frequency of 20 kHz. These data suggest that auditory ossicles are susceptible to bone resorption by osteoclasts and that osteoporosis may be a risk factor for conductive hearing loss.

SU008

Bone Quality in Elderly Community-Dwelling Men Is Significantly Associated to Muscle Strength and to A Creatinine Clearance of Less than 65ml/min. L. C. Dukas*, E. Schacht, H. B. Stähelin*. Acute Geriatric Clinic, Kantonsspital Basel, Basel, Switzerland.

Few studies have investigated the association between muscle strength, life style and biometric factors and bone density in elderly men. Within a randomized controlled study we assessed in an observational survey in 188 independently living community-dwelling men, aged 70 years and older, the association between bone density and calcitropic hormones, creatinine clearance, muscle strength measured as grip strength and some demographic and life style variables. The t-score as measured with ultrasound of the calcaneus was used as measure of bone density. Serum concentrations of calcitropic hormones, grip strength, creatinine clearance (CrCl) and other variables were studied in multivariate controlled linear regression models with the t-score as the dependent variable and/or as dichotomous variables (i.e. CrCl < 65ml/min vs ≥65ml/min). The dependent variable t-score was analyzed as a continuous variable as well as in categories (t-score <-2.5 vs ≥-2.5 to-1 vs ≥-1) Calcitropic hormones (calcidiol, Calcitriol, iPTH) were in multivariate analyses not associated with the t-score as measured by US calcaneus. Decreasing BMI (p<.0001), decreasing CrCl (p=.0) and decreasing muscle strength (p=.032) were significantly associated with decreasing t-scores. Significantly more men with a t-score of -<2.5 had a CrCl of <65ml/min compared to men with higher t-scores (CrCl<65ml/min. and t-score <-2.5 vs ≥-2.5 to -1 vs ≥-1: 60% vs 37.5% vs 27.3%, p=0.034). Men with a t-score of <-2.5 had also significantly lower grip strength muscle strength performance as compared to men with higher t-scores (grip strength performance in kilopounds and t-score -<2.5 vs ≥-2.5 to -1 vs ≥-1: 0.60 ± 0.12kp vs 0.72 ± 0.15kp vs 0.78 ± 0.15kp, p=.004). The use of statins and history of polyarthrosis was inversely associated with lower t-score (p=.029, res. .024) In elderly community-dwelling men a CrCl of <65ml/min. is associated with a significant increased more than doubled risk of having a t-score of <-2.5. A t-score of <-2.5 was also associated with significantly reduced muscle strength. Since Calcitriol has been shown to significantly decrease with a CrCl of <65ml/min., it is highly probable that the decreasing bone density associated with a low CrCl and decreasing muscle strength is due to a common factor, decreasing serum levels of Calcitriol. Therefore, we hypothesize that the low CrCl associated decrease in bone density and muscle strength has to be treated with Calcitriol in order to prevent fall associated osteoporotic fractures.

SU009

Bone Mass and BMC Changes among Pre- and Postmenopausal Women: a 10-y Follow-Up Study. K. Uusi-Rasi, H. Sievänen*, P. Kannus*. UKK Institute, Tampere, Finland.

This prospective, 10-year study evaluated bone mass and changes in BMC of due to exercise and calcium among pre- and postmenopausal women. At baseline, 265 healthy women were divided into groups based on their habitual level of physical activity (PA+ = > 20 min vigorous exercise > twice/wk; PA- = no vigorous exercise) and calcium intake (Ca+ = > 1200 mg/d; Ca- = < 800 mg/d). At 10-year follow-up, measurements were completed for 212 women (80% of the original sample), 102 premenopausal women (mean age 38 ± 2 yrs), and 110 elderly postmenopausal women (mean age 73 ± 2 yrs). Measurements were taken at the proximal femur by DXA. The baseline groups were maintained. Repeated measures ANCOVA was used to analyze the between-group differences in bone mass and in BMC changes, and regression analysis to find predictors of changes. For the postmenopausal women, BMC of the femoral neck averaged 4.9% (95% CI 0.1% to 9.9%) higher in the Ca+ group than in the Ca- group, and 6.8% (1.7% to 12.1%) higher in the PA+ group than in the PA- group. The corresponding differences at the trochanter were 2.2% (-2.5% to 7.1%) and 5.4% (0.4% to 10.6%) for Ca+ and PA+, respectively. For the premenopausal women, the observed BMC values were higher in the Ca+ and PA+ groups compared with Ca- and PA- groups, respectively, although the between-group differences were statistically significant at the trochanter only. In both age groups, BMC at the proximal femur declined similarly between the high and low physical activity groups. However, there was no significant difference in BMC decline between Ca-groups among postmenopausal women, but the premenopausal women with high calcium intake (Ca+) seemed to loose less bone mass than the Ca- group. The mean difference in BMC change at the femoral neck was 1.2% (-0.8% to 3.3%) and at the trochanter 3.8% (1.4% to 6.3%) in favour of the Ca+ group. Regression analysis showed that current breast feeding was a strong predictor of BMC decline at the femoral neck. This unique 10-year follow-up suggested that decrease in BMC occurred both among premenopausal and elderly postmenopausal women, but the initial between-group differences remained. High calcium intake seemed to retard the decrease in BMC at the proximal femur, especially among the premenopausal women.

TGF-β Inducible Early Gene-1 Null Mice Display Weaker Bones with Ultra-Structural Defects Compared to Wild-Type Mice. S. F. Bensamoun[1], M. Subramaniam[2], J. R. Hawse[2], B. Ilharreborde*[1], D. Fraser*[3], M. Oursler[3], P. Amadio*[1], K. N. An*[1], T. C. Spelsberg[2]. [1]Orthopedic Research, Mayo Clinic, Rochester, MN, USA, [2]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA, [3]Endocrine Research Unit, Mayo Clinic, Rochester, MN, USA.

TGF-β inducible early gene-1 (TIEG) is a member of the Krüppel-like transcription factor family originally cloned from human osteoblasts. Previously, we have demonstrated that TIEG plays an important role as a transcriptional repressor involved in TGFβ mediated Smad signaling. To elucidate the function of TIEG in skeletal development, we generated a TIEG knockout (KO) mouse. Osteoblasts isolated from TIEG KO mice display a reduced expression of osteoblast marker genes and defects in mineralization. We have further characterized the skeletal phenotype using mechanical tests (3-point bending) and morphological analyses (light microscopy, micro-CT and pQCT) on the femurs and vertebrae of these animals. The L5 vertebrae and femurs were removed from 7 wild-type, and 7 TIEG KO 3-month old C57 Black/129 female mice. A three-point bending test was performed with the left femur using a slow velocity (0.3mm/s) and load-displacement curves were used to measure the ultimate force. As seen in Table 1, the femurs of TIEG KO mice are significantly weaker when compared to wild-type controls. Cross sections (70μm) were cut in the mid-shaft of each right femur and polished. These sections indicate that the cortical thickness and area are significantly reduced in TIEG KO mice (Table 1). Micro-CT analysis (n=3; resolution= 5.99μm) was performed on the femoral head, vertebrae and lower metaphysis. Interestingly, there is a 42% increase in the femoral head trabecular separation in TIEG KO mice (Table 1). Trends of decreased cortical bone and vertebral bone volume were also observed in these animals. pQCT analysis of 25 tibias from 4-month old wild-type and TIEG KO mice revealed significant decreases in cortical area, thickness, content as well as periosteal and endosteal circumference (Table 1). These studies demonstrate that the loss of TIEG, in our TIEG null mouse model, results in a significant decrease in the size, strength and structure of long bones, supporting a role for this gene in bone modelling/remodelling.

Mechanical and morphological parameters of wild-type and TIEG knockout mice (*P<0.05)

		Wild-Type	TIEG KO
Bending Test	Ultimate Force (N)	31.56 ± 4.00	24.13 ± 3.67 *

Use of ^{3}H-Tetracycline to Assess the Effects of Ovariectomy Stabilization and Diet on Bone Resorption in Rats. J. M. K. Cheong*[1], N. S. Gunaratna*[2], G. P. McCabe*[2], C. M. Weaver[1]. [1]Foods and Nutrition, Purdue University, West Lafayette, IN, USA, [2]Statistics, Purdue University, West Lafayette, IN, USA.

Tritiated tetracycline (^{3}H-TC) can be used to measure bone resorption (BR) in animal models. ^{3}H-TC is absorbed and attached to the apatite of the bone structure and when bone turns over, the label is released into the urine providing a direct measure of BR. Our ultimate goal is to develop use of urinary ^{41}Ca appearance from bone to directly measure BR in humans. Here we used this inexpensive rat model to understand timing of label incorporation and release when BR was manipulated by ovariectomy stabilization and dietary calcium (Ca). Sixty-four ovariectomized (ovx) 6-month old rats were randomized to 1 of 16 groups that differed in terms of (1) ovx stabilization (ovx non-stabilized (ON) or ovx stabilized (OS)), (2) dietary Ca (0.2% or 0.5% Ca), and (3) time of euthanasia (1 week , 1 month, 3 months, or 6 months post ^{3}H-TC dose). The ON group received a single subcutaneous injection of 30 uCi of ^{3}H-TC while ovariectomy was being stabilized while the OS group received the same dose after ovariectomy was stabilized for 3 months. Diet treatment was started at the time of dose. Total skeleton and 48-hour urine and feces were recovered and collected at 1 week, 1 month, 3 months, and 6 months post dose for the assessment of ^{3}H-TC in urine and bone, Ca balance, and percent Ca retention. This study was approved by the Purdue animal care and use committee. Ca balance and Ca percent retention were higher in rats that were fed 0.5% Ca diet than rats fed 0.2% Ca diet. BR as assessed by urinary ^{3}H-TC decreased over time for all time points, but the difference between 3 and 6 months post dose was no longer significant. There was an ovx stabilization effect on BR at 1 week post dose, as reflected by a higher urinary ^{3}H-TC in OS rats. At one month post dose, we find that OS rats have lower values of urinary ^{3}H-TC and that a 0.5% Ca diet leads to lower urinary ^{3}H-TC for OS rats. However, we failed to detect any differences due to ovx stabilization or diet three months post dose or later although Ca balance was persistently higher on higher Ca intakes. We conclude that perturbations in BR by hormonal status and diet are transient effects and best measured in rats at 1 month (1 sigma in rats) post dose.

Aging Decreases the Responsiveness of Bone Marrow Stromal Cells to Insulin-Like Growth Factor-I (IGF-I) through Down-Regulation of IGF-I Signaling Pathways. J. J. Cao, P. S. Kurimoto*, B. Boudignon*, B. P. Halloran. Medicine, UCSF, San Francisco, CA, USA.

Bone development, growth and metabolism are tightly regulated. With advancing age, the osteoprogenitor pool diminishes, while the osteoclast progenitor pool increases and the balance between formation and resorption necessary to maintain bone mass is lost. Coincident with the changes in bone cell activity, the serum concentration of IGF-I decreases with age. Insulin-like growth factor-I (IGF-I) is abundant in bone and can stimulate osteoblast proliferation and promote bone formation. It has been suggested that decreases in serum IGF-I, alterations in IGF-I signaling or both may contribute to age-related bone loss. To determine the effect of IGF-I on bone in animals of different ages and how aging affects IGF-I signaling in bone cells, we examined the effect of IGF-I on bone *in vivo* and bone marrow stromal cells (BMSCs) cultured *in vitro* from 6 week (young), 6 month (adult), and 24 month (old) old mice. Aging markedly increased apoptosis and decreased proliferation of osteoblasts. With aging, the effect of IGF-I on cell proliferation is diminished. While IGF-I receptor expression increased at both the message and protein levels with aging, the phosphorylation of IGF-I receptor, ERK 1/2 (p44/42 MAPK), and Akt in cultured BMSCs was decreased in cells from mice of increasing age. When normalized to cell number, IGF-I binding sites (Scatchard analysis) in adult and old animals were reduced by approximately 75% of that in young. The receptor internalization was similar among all ages but the degree was less in adult and old animals when compared to young. These data suggest that the decrease in bone responsiveness to IGF-I is associated with decreases in IGF-I binding sites and intra-cellular signaling.

The Impact of Feeding Orange on Bone Homeostasis in Orchidectomized Rat Model of Osteoporosis. F. Deyhim*[1], K. Garcia*[1], A. Villarreal*[1], K. Mandadi*[2], R. Rios*[1], B. S. Patil*[3]. [1]Human Sciences, Texas A&M University-Kingsville, Kingsville, TX, USA, [2]Department of Agronomy and Resource Sciences, Texas A&M University-Kingsville, Citrus Center, Kingsville, TX, USA, [3]Vegetable and Fruit Improvement Center, Department of Horticultural Sciences, Texas A&M University, College Station, TX, USA.

Reactive oxidative species could be one of the factors causing osteoporosis. Citrus fruits are known to be a rich source of multitude bioactive compounds, antioxidants, vitamins, minerals and eating citrus fruits may potentially prevent osteoporosis. In a previous study, we observed that daily consumption of orange juice significantly increases 4th lumbar density in male osteoporotic rats. The current study evaluated whether feeding orange pulp in varied concentrations (2.5%, 5%, and 10%) impact 5th lumbar density, femoral density, femoral strength, and plasma antioxidant capacity in male rat model of osteoporosis. Forty-five retired breeder male rats were randomly divided into five treatment groups as follows: 1. Sham (control); 2. Orchidectomy (ORX); 3. ORX+2.5% powdered orange pulp/Kg diet; 4. ORX+5% powdered orange pulp/Kg diet; and 5. ORX+10% powdered orange pulp/Kg diet. The treatment diets were isocaloric and isonitrogenous with similar fiber content. After four months of feeding, all rats were sacrificed, blood was collected for measuring plasma antioxidant capacity while right femur and the 5th lumbar were separated to determine bone mineral density and femoral strength. Orchidectomy depressed ($P<0.05$) plasma antioxidant capacity in the ORX group while feeding orange pulp restored it to the level of the sham group. Orchidectomy decreased ($P<0.05$) femoral and 5th lumbar density, femoral strength, and significantly ($P<0.05$) shortened time induced femoral fracture in the ORX group while feeding orange pulp dose dependently increased ($P<0.05$) femoral and 5th lumbar density to the level of the sham group. Femoral strength and time induced femoral fracture were also significantly ($P<0.05$) increased with all orange pulp dosages compared to the ORX group. In conclusion, feeding orange pulp enhances bone density, bone strength, and delays time induced bone fracture. These effects may be mediated through increasing the plasma antioxidant capacity.

Influence of Calcium Channel Antagonists on Estrogen-Regulated Bone Resorption. L. A. Ashley*, D. L. Brown*, S. G. Combs*, D. A. Dillon*, R. P. Filiatreau*, J. L. Mack*, E. D. Nickel*, C. M. Pendleton*, K. D. Trent*, D. L. DeMoss. Biological Sciences, Morehead State University, Morehead, KY, USA.

Bone metabolism is invariably correlated with calcium transport indicating that calcium channels are a potential point of regulation for skeletal remodeling. Calcium channel antagonists are utilized therapeutically and experimentally to decrease the influx of calcium into cells by blocking voltage-regulated L-type calcium channels. Previous experimental evidence has suggested that calcium antagonists decrease osteoblastic activity, thus decreasing the activity of the bone forming cells at a time when bone formation is already exceeded by bone resorption, exacerbating the situation. Literature also reports a ten-year lag in the age-related rise in cardiovascular mortality in women as compared to men. Therefore, the established principle that bone formation decreases following the attainment of peak bone mass, illustrates the need for a more comprehensive understanding of the action calcium channel antagonists have on bone turnover and an improved understanding of the protective action estrogen exerts on skeletal mass.

Experimentation utilized female Brown Norway Rats six months of age to compare the effects of estrogen and the antagonists on blood pressure and bone turnover from both the amorphous and calcified compartments. In order to evaluate the positive or negative impact of estrogen and various calcium channel antagonists on bone loss, bone resorption parameters were compared between normal females, estrogen-deficient females, females receiving hormone replacement therapy, females receiving calcium channel antagonists (Diltiazem, Nifedipine, Verapamil), or females receiving a combination of the two agents. The models utilized to study bone turnover were the pharmacokinetic loss of the tracer H^3-tetracycline, a compound deposited in the active mineralization front an freely released in urine and the measurement of various bone degradation markers (deoxypyridinoline, pyridinium, and helical peptide) in urine collected throughout the experimental period. Ovariectomized females display an increased turnover rate while those receiving hormone replacement therapy were not significantly different from controls. The physiologic mechanism by which these drugs elicit their action appears to be antagonistic to that of estrogen for the amorphous compartment while synergistic to that of estrogen for the calcified compartment. Data obtained suggest that calcium channel antagonists potentially elicit their actions through alternative mechanisms in each of these highly regulated calcium pools.

Degree of Mineralization in the Cortical Bone of Fibular Shaft Was Higher in Aged Male than in Female Patients. T. Mashiba, S. Mori, N. Gomi*, Y. Kaji*, T. Manabe*. Orthopedic Surgery, Kagawa Medical University, Kagawa, Japan.

Objective We have reported that degree of mineralization in the cortical bone of fibular shaft was increased in female over 70 years old. In this study, the degree of mineralization in the fibular shaft was examined in aged male patients. Sexual difference of cortical bone mineralization between female and male were also evaluated. Patients and Methods Specimens for this study came from fibular mid-shafts of eleven men (60-75 y.o.) who underwent high tibial osteotomy for medial type osteoarthritis of the knee. The collected bones were stored frozen at -80°C until specimens were made. After thawing at room temperature, they were stained en-bloc with 1% basic fuchsin dissolved in ascending concentration of ethanol, defatted with xylene, and embedded in methyl methacrylate. A 125 μm-thick transverse ground section was made for the static histomorphometry and measurement of degree of mineralization of bone (DMB). For DMB measurement, quantitative contact microradiograph was taken and DMB at each osteon was calculated using a computerized microdensitometric method. Measured DMB parameters include mean osteonal DMB and the distribution of osteon based on DMB. Age related changes in static cortical histomorphometric parameters and DMB parameters were evaluated. Results Cortical structural parameters, mean DMB and DMB distribution did not significantly change with age in the fibular shaft of aged male patients. However, when comparing with data form women of almost same age, mean osteonal DMB was significantly higher in men than in women, and DMB distribution was located in narrower range. Discussion We have reported age related structural deterioration of cortical bone, such as bone marrow expansion, cortical thinning and increased cortical porosity and elevated DMB in the fibular shaft of aged women. However, these age related changes were not observed in aged men, indicating that skeletal aging changes after sixty years old is much slower in men than in women probably because of the gender difference of bone remodeling activity. Higher and homogenous DMB distribution in age men demonstrated in this study is compatible with very common findings that bone mineral density measured by DXA is higher in men than in women. This also suggests that because older osteon should have higher DMB, replacement of old into new osteon was suppressed by lower osteonal remodeling activity especially in aged men.

The Role of Age and Body Size in Predicting the 3D Structure of Cortical Porosity at the Human Anterior Femoral Mid-Shaft. D. M. L. Cooper*[1], C. D. L. Thomas*[2], J. G. Clement*[2], B. Hallgrimsson[3]. [1]Archaeology and Medical Science, University of Calgary, Calgary, AB, Canada, [2]School of Dental Science, University of Melbourne, Melbourne, Australia, [3]Cell Biology & Anatomy, University of Calgary, Calgary, AB, Canada.

The 3D structure of cortical bone porosity undergoes continuous change through the process of remodeling. The goal of the current study was to examine the roles of age and body size in predicting the 3D structure of cortical porosity (at the level of osteonal canals) and to assess whether these roles vary between the sexes. The sample included 79 individuals, 28 females and 51 males, spanning 18 to 92 years of age. The mean (+/- SD) ages for the males and females were 55.90 (+/- 20.21) years and 52.61 (+/- 23.56) years, respectively. Anterior femoral midshaft blocks, 5 mm wide and 8 mm long were micro-CT scanned at 7 μm isotropic resolution. Cylindrical volumes of interest, 3 mm in diameter and 3 mm long, adjacent to the periosteal surface, were isolated from the scan data for quantitative analysis of cortical porosity (CaV/TV), mean canal diameter (CaDm), canal number (CaN), mean canal separation (CaSp), and degree of anisotropy (DA). Height and weight were measured at autopsy. Stepwise multiple linear regression was employed to determine the combination of variables (height, weight, and age) that best predict the morphological parameters for each of the sexes. For males, all parameters were significantly predicted ($p<0.05$) by age alone, with adjusted r^2 values of 0.408, 0.275, 0.380, 0.430, and 0.090 for Log CaV/TV, Log CaDm, CaN, CaSp, and DA, respectively. Age was a significant predictor ($p \leq 0.001$) for all parameters in females, however weight was also included in the predictive models for Log CaDm and DA, while height was included for CaN. The best fit adjusted r^2 values for females were 0.722, 0.682, 0.408, 0.525, and 0.440, respectively. The results indicated that 3D parameters of cortical porosity are better predicted for females and that, while age is the most important predictor for both sexes, body size plays a significant role in females. Further, this study revealed that cortical bone, which is generally regarded as more stable than trabecular bone, is extensively affected by systemic bone loss, even at a site as robust as the femoral midshaft.

Recovery of Skeletal Growth and Mineralization from Dietary Calcium Deficiency in Young Pigs. A. J. Smiltneek*, C. E. Pardo*, D. K. Schneider*, T. D. Crenshaw. Animal Sciences, University of Wisconsin -Madison, Madison, WI, USA.

In earlier studies (J Bone Miner Res 18:S184) prepuberal pigs failed to recover skeletal mass following a period of dietary Ca deficiency. A limitation of the earlier study was that pigs were fed diets with Ca at minimum requirements during the recovery period. The objective of the current experiment was to determine the potential for recovery of skeletal mass in young pigs (initial wt. = 9.2 kg, age = 39 d) fed diets with 150% of Ca requirements following a period of Ca depletion. During the depletion period (4 wk), pigs were fed diets with either 150% (excess Ca, n=16) or 70% (deficient Ca, n=16) of the dietary calcium requirement. Subsequently, during a six week recovery period, pigs within each depletion period group were fed diets with excess (150 %) or deficient (70 %) Ca. Pigs were scanned at intervals throughout the trial using dual energy X-ray absorptiometry (DXA, GE Lunar Prodigy software version 8.10.027) using the pediatric scan mode. After a 4-wk depletion period, total body bone mineral content (BMC, g) was reduced ($P \leq 0.001$) by 67% and bone mineral density (BMD, g/cm^2) by 29% in pigs fed deficient vs excess Ca diets. During the recovery period, the change in BMC, g/d was the same within dietary Ca groups regardless of whether pigs were fed deficient or excess Ca during the depletion period. See Table below. However, the daily change in BMD during the recovery period was greater ($P \leq 0.05$) in pigs fed a deficient diet during the depletion period than that of pigs fed excessive Ca during the depletion period . The greater change in BMD implies a potential for recovery of bone mineralization following a period of deficiency if excess dietary Ca is provided.

	Results after 4 wk Depletion - 6 wk Recovery Periods			
Dietary Ca,	BMC, g	ΔBMC, g/d	ΔBMD, g/cm^2	BMD, g/cm^2/d

Atrovastatin Attenuates Cardiovascular Calcification and Osteoporosis in the Experimental Hypercholesterolemic LDLR-/- Mice. N. M. Rajamannan[1], M. Subramaniam[2], F. Caira*[1], S. Stock[1], A. Flores*[1], J. Gocek*[1], T. C. Spelsberg[2]. [1]Cardiology, Northwestern University, Chicago, IL, USA, [2]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA.

Atherosclerosis and osteoprorosis are the leading causes of morbidity and mortality in the aging population in the Unites States. Evidence indicates that hyperlipidemia plays a paradoxical role in these disease processes. However, the hyperlipidemic mechanisms of atherosclerotic calcification and decrease bone mass are not well understood. We have previously shown that cardiovascular calcification expresses an osteoblast phenotype in humans. We hypothesize that hyperlipidemia plays a role in cardiovascular calcification and osteoporosis. We propose to test this hypothesis in an experimental hypercholesterolemia model and further test if statins play a protective role in this process. LDLR-/- mice (n=60) were treated with Group I (n=20) normal diet, Group II (n=20) 1.25% chol diet (w/w), and Group III (n=20) 1.25% (w/w) chol diet+atorv to determine the development of calcification in the hearts and osteoporosis in the bones. The aortic valve and aortas (AVA) was examined for myofibroblast cell proliferation, calcification, and bone matrix markers by immunohistochemistry and RTPCR. Bone formation was assessed by micro Computed Tomography (microCT), calcein injection, osteocalcin, cbfa-1 and osteopontin expression. The cholesterol diet induced complex bone formations by microCT in the calcified AVA with an increase in cellular proliferation, osteopontin, osteocalcin and cbfa-1 expression. Atorvastatin reduced bone formation, cellular proliferation and cbfa-1 levels and calcification in the AVA. Ex vivo analysis of calcein label demonstrated an increase in calcein label (4+) in the hypercholesterolemia AVA and the periosteal femoral bone surface with attenuation of the calcein label (1+) with atorvastatin therapy in the the AVA and the femoral bones. (Calcein Scale =1-4, 4+=severe label, 1+=miminal label). Experimental hypercholesterolemia induces cardiovascular calcification and increased bone turnover which is attenuated by atorvastatin and mediated in part by an osteoblast pathway in the cardiovscular tissues. This model may have future implications in the treatment of cardiovascular calcification and osteoporosis with statin therapy.

	Osteocalcin and Cbfa-1 RNA expression in the AVA		
%GAPDH	Control	Chol	Chol+Atorvastatin
Osteocalcin	0.72	0.75	0.50
Cbfa-1	0	0.83	0.39

Age-Related Loss of Bone Strength in the Spine and Hindlimb of Mice Independently of BMD. A. Parfitt, R. Weinstein, T. Bellido, R. Jilka, C. O'Brien, J. Goellner, S. Kousteni, S. Stewart*, P. Roberson*, S. C. Manolagas. Div. Endocrinol. and Dept. Biostatistics, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. Arkansas Med. Sci., Little Rock, AR, USA.

Age is a far more critical determinant of fracture risk than BMD in humans. Heretofore, this was thought to be the result of changes in balance, visual acuity, and muscle mass, rather than changes in the strength of bone itself. In the studies reported herein, we have tested the hypothesis that there may be age-related factors associated with bone strength which are independent of BMD. To this end, we determined BMD of vertebrae and hindlimbs by DEXA and bone strength by vertebral compression and 3-point bending of femora of female C57BL/6 mice (an animal cohort maintained with support from the NIA at Harlan Inc.) at 8, 16, 25, and 31 months of age (n = 11-12 per group). We report that with advancing age these mice exhibit a progressive loss of bone strength and BMD in both the spine and hindlimbs. Most importantly, the loss of strength is detectable 9 months earlier than the loss of bone mass. Likelihood ratios comparing models with both age and site specific BMD as predictors of strength indicated that for each site (spine and hindlimbs) the two predictor model is significantly better than a model with age or BMD alone ($p < 0.001$), establishing that for both vertebrae and hindlimbs there is a statistically significant age-related impact on strength which is independent of the BMD contribution. In addition, cancellous osteoblast apoptosis increased by 48% in the 25 month old animals and by 99% in the 31 month old animals when compared with the 8 month old mice ($p < 0.001$ and < 0.0005, respectively; by ANOVA); and cortical osteocyte apoptosis increased by 84% in the 25 month old animals when compared with the 8 month old animals ($p < 0.001$). Bone formation rate was decreased by 60% at both 25 and 31 months of age when compared with the 8 month old mice ($p < 0.02$); and it was inversely related to the prevalence of osteoblast apoptosis ($r = -0.46$, $p < 0.04$). These changes were temporally associated with a decrease in glutathione reductase activity and a corresponding increase in the levels of reactive oxygen species in the bone marrow, and an increase in the phosphorylation of the $p66^{shc}$ in vertebrae - an adapter protein that is induced by oxidative stress and is an important determinant of lifespan in mammals. The temporal dissociation of strength and BMD decline with age in this model provides, for the first time, an opportunity to investigate experimentally the contribution of different qualitative influences on bone strength in a mammal.

Spectromicroscopy Shows Oxidative Damage to Collagen. N. Saless[1], B. Frazer*[2], G. E. Lopez Franco[1], G. de Stasio*[2], S. Litscher*[1], R. D. Blank[1]. [1]Medicine, University of Wisconsin, Madison, Madison, WI, USA, [2]Synchrotron Radiation Center, University of Wisconsin, Madison, Madison, WI, USA.

A major effect of aging is the deteriorating bone quality. While multiple factors contribute to the greater fracture risk of the very old, old bone has poorer intrinsic quality than young bone. Collagen is the major protein of the bone and on the molecular scale; it plays a significant role in bone viscoelasticity. Conditions characterized by increased oxidative stress are also associated with skeletal fragility. Oxidative damage to the extra-cellular matrix of bone could account for some of the age-related deterioration of biomechanical performance. Exposure to oxidative stress *in vivo* allows physiologic adaptation to the altered mechanical properties of the bone matrix. In order to study the effects of oxidative damage to the bone matrix in isolation of such a response, we have developed an *ex vivo* protocol testing of paired bones from individual animals, thus eliminating bone mass, bone architecture, and physiological adaptation to an abnormality as confounding factors in interpreting biomechanical performance. Further, we have established a spectromicroscopic assay of carbon bond energies that can spatial information that cannot be obtained biochemically. In pilot experiments, femora were excised from mice. One bone of each pair was incubated overnight in H_2O_2, and the other member of the pair in H_2O. The bones were then tested by 3-point bending to failure, under displacement control. The preliminary data demonstrate a trend toward reduction of post-yield deflection and energy to failure. Spectromicrographic analysis of bone powder (figure) demonstrates the loss of 2 signals, that we believe represent pyridinoline and deoxypyridinoline cross-links. Next steps in characterizing the nature and extent of biomechanical impairment arising from oxidative damage will be to titrate the time and concentration of oxidizing agents to mimic the degree and distribution of oxidative damage encountered in *in vivo* oxidative stress models.

Influence of Bone Osteocalcin Level in Bone Loss Induced by Ovariectomy in Warfarin-Treated Rats. K. Hara, M. Kobayashi, Y. Akiyama. Applied Drug Research Department, Eisai Co., ltd., Tokyo, Japan.

Introduction: We have established bone OC level-reduced rats by warfarin (WF) treatment over the long term. To test the function of OC in bones, the changes in bone parameters after OVX were compared between in WF-treated and normal rats. **Methods:** Female 4-week-old rats were divided into the intact (n=24) and WF treated groups (n=40). Warfarin was orally given to rats at 0.4mg/kg, 3 times a week for 16 weeks. Then, 8 rats in each group were sacrificed (pre) and the remaining WF-treated rats were further divided into 2 groups: the WF-discontinuing group and the WF-continuing group. Each group was divided into sham-operated and OVX groups (n=8) and the operation was performed. After 12 weeks, bone and plasma osteocalcin, bone parameters (pQCT), mechanical properties (three-bending test) in the femurs were measured. **Results:** After 16 weeks of WF treatment (pre), the ratio of γ-carboxyglutamyl (Gla)-OC to total-OC in plasma was 53% of that in the intact group, and OC level in the femoral diaphysis and metaphysis were 14% and 12%, respectively. There were no differences in bone mineral content (BMC) and bone strength between in the intact and WF-treated groups. Twelve weeks after OVX, the ratios of Gla-OC to total-OC in plasma in the WF-discontinuing-sham and the WF-continuing-sham were 100% and 54% of that in the intact sham, respectively. Diaphysial and metaphysial OC levels in the WF-discontinuing-sham were 16% and 36%, and those in the WF-continuing-sham were 11% and 10%, respectively. In the intact group, OVX resulted in a decrease only in metaphysial bone mineral density (BMD), and in the WF-discontinuing group, decreases in metaphysial BMC, BMD and diaphysial BMD were observed. In the WF-continuing group, the parameters above-mentioned, and diaphysial BMD, area, cortical thickness and maximum load (bone strength) were decreased after OVX. Plasma total OC and urinary deoxypyridinoline levels in the OVX rats were both higher than in the sham rats in all groups. **Conclusion:** These data indicated that although low levels of OC in bone did not affect bone parameters directly, low level of OC in bone clearly influenced bone loss after ovariectomy. Therefore, bone OC levels may play an important role in maintaining BMC, BMD or bone strength when bone turnover increases.

Osteoporosis and Calcification of Cardiovascular System. C. Woong Hwan*, S. Hong*. Endoclinology, internal medicine, hanyang university medical center, seoul, Republic of Korea.

Background: Cardiac valve calcification and arteriosclerosis were correlated with congestive heart failure, hypertension and coronary heart disease. And the incidences of these two diseases and osteoporosis were increased with ages. Few studies suggested the correlation of these two diseases and osteoporosis. We observed the correlations of two diseases and osteoporosis. **Method:** We selected 23 patients with cardiac valve calcification (Group A) and 32 controls with normal cardiac valve (Group B) from 164 patients (over 60 years olds) who were checked the echocardiography and the bone mineral density from may 2003 to September 2004. And we also studied the correlation of aortic calcification (n=24) and osteoporosis (n=38) by 3D-QCT in 62 patients. Chronic renal failure patients and calcium metabolic disorder patients were excluded. Cardiac valve calcifications were defined as three or more hyper-echogenic nodules on cardiac valves in parasternal short axis view or post acoustic shadows at the base of posterior leaf of mitral valve. And aortic calcifications were confirmed by CT films. We also checked body weights, serum calcium, phosphate, albumin, alkaline phosphate, and total cholesterol. **Result:** There was no difference of basic characteristics(ages, body weight, serum calcium, and alkaline phosphate) except total cholesterol (174.4±39.1 vs. 202.0±35.7 mg/dL; $P<0.05$) The mean of bone mineral densities (T-score) were deceased in cardiac valve calcification group (L-spine -2.67±1.33 vs. -1.83±1.50; $p<0.05$, Femur -3.38±0.91 vs. -2.11±1.00: <0.001). The odds ratio of osteoporosis (T-score≤-2.5) for cardiac valve calcification is 7.92 (95% CI 2.28-27.4). And the odd ratio of valve calcification for femur Z-score was 1.13 (95% CI 1.05-1.22). And the mean BMD in patients with aortic calcification was significantly lower than the mean BMD in patients without aortic calcification. (61.3 vs 74.0, $p<0.05$) **Conclusion:** Bone mineral density is correlated with valve calcification and vascular calcification. So the dictation of valve or vascular calcification indicates a high probability of osteoporosis.

Histological Analysis on Altered Bone Matrix of Warfarin-Administered Rats. N. Amizuka[1], M. Li*[1], K. Hara[2], M. Kobayashi[2], Y. Akiyama[2], T. Maeda*[1]. [1]Oral Biological Science, Niigata University, Niigata, Japan, [2]Pharmacological Evaluation Section, Eisai Co., Ltd., Tokyo, Japan.

Bone mineral maturation seems to require the participation of osteocalcin. This prompted us to elucidate the ultrastructural role of gla-proteins in early stages of mineralization in bone by employing warfarin-administered rats. Male Wistar rats at 4-week-old, were administered warfarin (0.4 mg/kg, warfarin group), or Ringer's solution (control group), and fixed after 4, 8 and 12 weeks with an aldehyde solution. The extracted tibiae and femora were embedded in paraffin for alkaline phosphatase, osteocalcin and tartrate-resistant acid phosphatase histochemistry, as well as in epoxy resin for ultrastructural observation under transmission electron microscopy (TEM). After 4, 8 and 12 weeks, there were no apparent histological alterations in the warfarin group. Therefore, the warfarin administration at the dosage of 0.4 mg/kg appeared not to affect bone turnover. We next examined if warfarin could affect gla-proteins in bone matrix. The

intense osteocalcin-immunoreactivity at the control bone surface was in contrast to the extremely reduced immunoreactivity in the matching region of the warfarin group. We therefore investigated the ultrastructure of initial mineralization of metaphyseal trabeculae. Mineralized nodules, globular assembly of crystalline particles or ribbon-like structures were seen in the control osteoid. However, the warfarin administration gave rise to dispersed crystalline particles throughout the osteoid without showing typical mineralized nodules. Immunoelectron microscopy verified less association of osteocalcin with those scattered crystalline particles, whereas normal mineralized nodules in control rats accumulated osteocalcin. Thus, gla-proteins appear to play a pivotal role in the assembly of mineralized nodules, rather than affecting bone turnover.

Mineralization of the Rachitic Growth Plate Despite Calcium Deprivation Leading to Hypocalcemia. N. Dion, G. Mailhot*, J. L. Petit*, C. Deschênes*, V. Lascau*, M. Gascon-Barré, L. G. Ste-Marie. Saint-Luc Hospital, CHUM Research Centre, Montréal, PQ, Canada.

Previously, our group used a non-rachitogenic rat model [vitamin D (D)depleted and low calcium (Ca) diet (D-Ca-)] to study endochondral ossification and bone mineralization defects. These rats had growth retardation, hyperosteoidosis and, high serum parathyroid hormone (HPTH) secondary to hypocalcemia and D depletion. When D-Ca- rats were repleted with a high Ca content diet ($Ca+_3$) for 14 days (d), serum Ca and PTH were normalized, hyperosteoidosis was partly corrected but severe hypophosphatemic rickets developed. When $Ca+_3$ rats were abruptly switched to the initial D-Ca- diet, they all died within 5d. When $Ca+_3$ rats were progressively redepleted over a period of 11d there was also a very high mortality rate (80%) but the time-to-mortality curve shifted to the right with a survival rate of 20% after 14d. Surviving rats were found to have hypocalcemia similar to D-Ca-. To investigate at the bone level, the pathophysiological causes leading to the death of $Ca+_3$ rats during redepletion we performed undecalcified bone morphometry on proximal tibiae taken from rats sacrificed after 3d of the rapid redepletion (RR) or after 5, 8, 11 and 14d of the progressive redepletion (PR). In RR compared to $Ca+_3$, Goldner's trichrome, Von Kossa and Alizarin red stainings showed a widened growth plate (GP) with matrix mineralization abnormally occurring within GP cartilage at the hypertrophic chondrocyte zone. During PR, rickets regressed progressively with the primary spongiosa getting enlarged. In addition, hyperosteoidosis returned, being at 14d of PR similar to D-Ca-. Detection of alkaline phosphatase and annexin II, two markers of matrix vesicles (MV) involved in GP mineralization, showed that RR and $Ca+_3$ had a high level of MV markers due to the accumulation of hypertrophic chrondrocytes. In PR rats, MV markers decreased over time being at 14d, at similar levels of D-Ca-. Our data suggest that during Ca redepletion, correction of hypophosphatemia in $Ca+_3$ allowed the return of mineralization at the rachitic GP and increased demand for Ca by the enlarged GP ensued (evidenced by significant matrix mineralization). The little amount of Ca absorbed from the Ca-D- diet associated with an incapacity of the bone to provide sufficient Ca (despite the return of secondary HPTH) could not meet the Ca demand from the GP. This caused a rapid and severe hypocalcemia leading to the death of these animals, most likely by arrhythmia. This hypothesis is further supported by the observation that rats in PR which had a more progressive fall in their serum Ca, exhibited a delay in death rate, a gradual involution of rickets and survival only in animals returning to the D-Ca- phenotype.

The Mineralization of the Bone Matrix and the Elemental Mapping of Calcium, Phosphorus, and Magnesium in the Klotho Mouse. H. Suzuki*[1], N. Amizuka[2], M. Noda*[3], H. Ohshima*[1], T. Maeda*[2]. [1]Department of Oral Biological Science, Niigata University, Division of Anatomy and Cell Biology of the Hard Tissue, Niigata, Japan, [2]Department of Oral Biological Science, Niigata University, Division of Oral Anatomy, Niigata, Japan, [3]Tokyo Medical and Dental University, Medical Research Institute, Tokyo, Japan.

The klotho gene-depleted mouse is known as an animal model for accelerated gerontic state, mimicking osteoporosis, skin atrophy, ectopic calcification, pulmonary emphysema and gonadal dysplasia. To elucidate the influence of klotho-deficiency on bone mineralization, we examined the ultra-structures of osteoblasts and bone matrices, as well as performed the elemental mapping of calcium, phosphorus and magnesium in bone. Under anesthesia, 5-week-old klotho-deficient mice ($klotho^{-/-}$ mice) and their wild-type littermates were perfused with 4% paraformaldehyde. The tibiae and femora were processed for light and electron microscopic observation. Paraffin sections were subject to alkaline phosphatase (ALP) and tartrate resistant acid phosphatase (TRAP) histochemistry. Semi-thin and ultra-thin sections obtained from epoxy resin-embedded specimens were used for detecting mineralization, according to von Kossa's staining method, and for elemental mapping by electron probe micro-analyzer (EPMA), respectively. ALP-positive plump osteoblasts adjacent to the growth plate normally developed cell organelles in the $klotho^{-/-}$ metaphyses. However, this was contrasting with the flattened osteoblasts covering the trabecular bone of the diaphyses, accompanied by small TRAP-positive osteoclasts. The wild-type mice displayed well-mineralized metaphyseal trabeculae parallel to the longitudinal axis of the bone. Alternatively, the $klotho^{-/-}$ mice demonstrated a fine meshwork or patches of mineralized bone in the metaphyses, as well as large non-mineralized area in the diaphyseal bone. Consistently, EPMA verified sporadic distribution of the higher or lower concentrations of calcium and phosphorus in each trabecule. The distribution of magnesium, however, was almost uniform. Thus, the klotho-deficiency appears not only to reduce osteoblastic population, but also to disturb important osteoblastic functions, bone mineralization.

Intracellular Signaling Mechanism of Vasopressin-Induced Na-Dependent Phosphate Transport Activity in Rat Aortic Smooth Muscle Cells. K. Nishiwaki-Yasuda[1], A. Suzuki[1], A. Kakita*[2], Y. Ono*[1], S. Sekiguchi[1], K. Inagaki*[1], T. Matsumoto*[1], S. Imamura*[1], H. Kakizawa*[1], N. Hayakawa*[1], N. Oda*[1], Y. Oiso*[3], M. Itoh*[1]. [1]Division of Endocrinology, Fujita Health University, Toyoake Aichi, Japan, [2]Department of Internal Medicine, Hekinan Municipal Hospital, Hekinan Aichi, Japan, [3]Department of Metabolic Diseases, Nagoya University Graguate School of Medicine, Nagoya Aichi, Japan.

We investigated the effect of arginine vasopressin (AVP) on inorganic phosphate (Pi) transport, which has been reported to be involved in the mechanism of atherosclerosis, and its intracellular signaling mechanism in A-10 rat aortic vascular smooth muscle cells (VSMCs). AVP time- and dose-dependently stimulated Pi transport in A-10 cells. A protein kinase C (PKC) inhibitor calphostin C partially suppressed the stimulatory effect of AVP on Pi transport. AG1478, a selective inhibitor of EGFR tyrosine kinase, suppressed AVP-stimulated Pi-transport. The selective inhibitors of mitogen-activated protein (MAP) kinases, such as ERK and p38, did not affect AVP-induced Pi transport. Both LY294002 and wortmannin, phosphatidylinositol (PI) 3-kinase inhibitors, attenuated AVP-induced Pi transport. A selective inhibitor of S_6 kinase, rapamycin, reduced this effect of AVP, while Akt kinase inhibitor did not. In summary, these results suggest that AVP stimulates Na-dependent Pi transport activity in VSMCs. The mechanism responsible for this effect is not mediated by p38 or ERK MAP kinase, but involves activation of PKC, EGFR tyrosine kinase, PI 3-kinase and S_6 kinase. These findings seem to be important for the targeting the molecule responsible for the progress of atherosclerosis.

Effects of Adrenalectomy and γ_2-MSH Administration on Bone Histomorphometric Change in Leptin-Deficient Ob/Ob Mice. J. K. Yeh, J. F. Evans*, Q. T. Niu*, J. F. Aloia. Metabolism Laboratory, Winthrop-University Hospital, Mineola, NY, USA.

The hypothalamic-pituitary-adrenal axis may be associated with mechanisms involved in the regulation of bone formation and bone linear growth. This study was designed to investigate bone histomorphometric changes induced by adrenalectomy (ADX) in wild-type (W) and ob/ob (Ob) mice. Groups of 30 Ob, 30 W female 4-week old mice were each divided into 3 groups of 10 animals each as Sham-Ob, ADX-Ob, ADX-$_2$-MSH-Ob, Sham-W, ADX-Wγ, and ADX-γ_2-MSH-W. All ADX animals were implanted subcutaneously (s.c.) with a pellet designed to deliver 2.4ug corticosterone per day over 21 days. The ADX-γ_2-MSH treatment groups received 50ug/day acetyl-(lys^9, Nle^3)-γ_2-MSH amide (γ_2-MSH) s.c. over the 21 days. Calcein (8mg/kg) was injected at 10 and 3 days, respectively, before the end of the experimental period. The proximal tibial metaphases were processed undecalcified for quantitative bone histomorphometry. In comparison to Sham-W mice, Sham-Ob mice had shorter tibial length (16.19±0.30mm vs 16.92±0.11mm, $P<0.05$) without a significant difference in growth plate width (99.8±11.8um vs 96.2±14.1um). The trabecular bone volume (TV/BV, %) was lower in the Sham-Ob (8.99±2.46) than that of the Sham-W group (11.59±2.39). ADX resulted in a significant increase in tibial length of Ob mice (16.57±0.33mm, $P<0.05$), a non-significant increase in the W mice (17.1±0.27mm), and a significant decrease in TV/BV in Ob (5.63±1.2, $P<0.05$) and a decrease in W mice (6.04±1.46, $P<0.05$) as compared to the respective Sham group. The bone formation rate (BFR) was significantly higher in the ADX-Ob mice (51.9±12.7 mcm/day vs. 35.5±5.5, $P<0.05$) and non-significantly higher in the ADX-W mice (47.0±11.2 vs. 41.6±3.9, $P=0.167$) as compared to the respective Sham group. Although, γ_2-MSH treatment to the ADX-mice resulted in no significant effect on the TV/BV or on the BFR in both groups, it resulted in an increase in the growth plate width (150.7±18.1um vs. 134.9±17.5, $P=0.06$) and a trend increase in the tibial length (16.83±0.29mm, vs. 16.57±0.33, $P=0.078$) of the ADX-Ob mice. In conclusion, elevated ACTH and depleted corticosterone after ADX enhances linear growth and bone turnover rate. Administration of the melanocortin-3-receptor specific agonist, γ_2-MSH, to the ADX mice further enhances bone linear growth without affecting the bone turnover.

Strontiums Effect on Bone Ultrastructure in Rats: Insights from Laboratory Scanning Small Angle X-Ray Scattering (sSAXS). T. P. K. Hansen*[1], M. H. Bünger[2], F. Besenbacher*[3], B. Langdahl[4], H. Oxlund[5], J. S. Pedersen*[6], H. Birkedal*[6]. [1]Interdisciplinary Nanoscience Center (iNANO), University of Aarhus, Aarhus, Denmark, [2]Interdisciplinary Nanoscience Center (iNANO) & Dept of Endocrinology and Metabolism C, University of Aarhus, Aarhus, Denmark, [3]Interdisciplinary Nanoscience Center (iNANO) & Dept of Physics and Astronomy, University of Aarhus, Aarhus, Denmark, [4]Dept. of Endocrinology and Metabolism C, Aarhus Sygehus, Aarhus, Denmark, [5]Dept. of Anatomy, University of Aarhus, Aarhus, Denmark, [6]Interdisciplinary Nanoscience Center (iNANO) & Dept. of Chemistry, University of Aarhus, Aarhus, Denmark.

Strontium salts (containing Sr^{2+}) have attracted strong interest as a possible anabolic drug for the treatment of osteoporosis. Sr is believed to be incorporated into the inorganic phase of bone by substituting Ca in the apatite crystal lattice. However, detailed knowledge about possible effects of Sr treatment on the ultrastructure of bone is still missing. In the

present work, scanning Small Angle X-ray Scattering (sSAXS) is used for studying the effects of a strontium treatment regime in a rat model. In bone the SAXS signal originates from differences in electron density between the mineral and organic phase and SAXS offers unique information about thickness, orientation and shape of the mineral particles. The effect of Sr on the treatment of ovariectomy induced osteoporosis was studied in 6 month old female Wistar rats. Animals were treated with 4 mmol $SrCl_2$ (aq)/kg/day or placebo in the drinking water for a period of 140 days. All rats were labelled with flourochromes at days 7, 126 and 136. Four ~150 µm thick cross sections (-ov/-Sr, +ov/-Sr , -ov/+Sr and +ov/+Sr) of midshaft femur were studied in detail using fluorescence microscopy and scanning electron microscopy (SEM) including element mapping with energy dispersive X-ray analysis (EDAX) and sSAXS. The new bone, identified by fluorescence microscopy, was found to contain increased levels of Sr by EDAX analysis in the two +Sr animals. The SAXS survey scans, with a ~50 µm lateral resolution, revealed a large variation in the SAXS intensity in the central part of the individual sections, while they were more homogeneous toward the periost in agreement with current models of bone maturation. Qualitatively, the sSAXS results illustrated the osteoinductive behaviour of Sr as seen by comparison of survey scans of the four samples. Detailed SAXS investigations of selected regions were used to determine crystallite orientation, shape and thickness. We will compare +Sr and -Sr bone to bring to light any possible effects of Sr treatment on the crystallite properties and distribution.

Lovastatin Microbead Scaffolds Stimulate Local Bone Formation. G. Rossini*, G. Gutierrez, G. Mundy, I. R. Garrett. OsteoScreen, Ltd, San Antonio, TX, USA.

Statins are inhibitors of the enzyme HMG Co-A reductase, the rate-limiting step in hepatic cholesterol biosynthesis. It is now recognized statins produce a multitude of effects including potential benefits on bone formation which are unrelated to the lowering of serum cholesterol. Statins increase bone formation in vitro by increasing the expression of bone morphogenetic protein-2 (BMP-2), which acts as an autocrine-paracrine factor in osteoblast differentiation. Preclinical animal studies and in vitro studies have revealed the importance of the mode of administration of statins. When statins are administered locally, they markedly stimulate new bone formation1, 2. Statins, therefore, represent the first small-molecular-weight BMP-like molecule that stimulates new bone formation locally. Our hypothesis is that the use of lovastatin impregnated microbead scaffolds made from biodegradable polymers will enhance fracture repair through both the osteoconductive properties of scinted-polymer-microbeads scaffolds and the osteoinductive capabilities of controlled lovastatin release. Microbeads of PLGA polymer containing lovastatin at 10mg/ gm of polymer were made. The raw microbead/lovastatin product was developed for various scaffolds and matrices. 3D scaffolds were prepared by scinting beads together using either heat, microwaving or by proprietary chemical scinting. The resultant matrix scaffold structures were light, porous and showed excellent compressive strength when measured by constant loading rate (3 mm/min) in an MTS Q-test 5 mechanical test machine. Whereas, lovastatin injected over the calvaria of mice at 125ug/day for 5 days did stimulate new bone formation (new bone area 0.13+0.05mm2), the scaffolds releasing lovastatin at 5ug/day placed over the calvaria of mice, increased new bone area by over 400% (scaffold alone 0.06+0.005mm2 and lovastatin scaffold 0.32+0.007mm2). Lovastatin in the serum of these mice was undetectable and no toxicity was evident at the site of implantation. Delivery of anabolic compounds, such as statins, by controlled release microbead scaffold technology provides an extremely effective treatment and repair of bone void defects. This simple but innovative approach has the potential to deliver lovastatin as well as other low-cost anabolic agents to fracture sites to significantly accelerate fracture repair, and has the added potential for use in a wide range of surgical environments.

Analgesic and Chondroprotechtive Effect of Risedronate in Osteoarthritis Assessed by Electroalgometry and Measurement of Collagen Type II Fragments in Urine. T. Fujita[1], M. Ohue*[1], A. Miyauchi*[2], Y. Takagi*[3]. [1]Medicine, Katsuragi Hospital, Kishiwada, Japan, [2]Medicine, National Hospital System Hyogo Chuo Hospital, Hyogo, Japan, [3]National Hospital System Hyogo Chuo Hospital, Hyogo, Japan.

In order to evaluate the effect of risedronate on pain and cartilage metabolism in osteoarthritis, 233 patients with osteoarthritis of the knee were randomly divided into two groups. In Group RC, 2.5 mg risedronate and 900 mg calcium as active absorbable algal calciuym (AAACa) was given daily for 8 months, and only calcium was given in Group C during the same period. Pain on exercise was estimated by subjective visual rating scale (VRS) and electroalgometry (EAM) measuring skin impedance (General Devices, New Jersey) and fragments of cartilage-]specific collagen type II in the second morning urine samples were measured before and during the administration (Nordic Bioscience Diagnostics, Copenhagen). Alleviation of pain induced by walking assessed by the fall of skin impedance was significantly more efficient in RC than in C after 4 month treatment (p=0.0179) and on overall comparison before and after supplementation (p=0.0084). Pain induction by knee bending and lying on bed in addition also gave similar finding (p=0.0088, and 0.0067). Urinary excretion of type II collagen fragments was significantly more pronounced in the third month (p=0.0089) and on overall compasison (p=0.0236). Though the results of VRS and EAM pain evaluation generally correlated significantly, EAM (p=0.0153) but not VRS (p=0.6482) demonstrated a significantly more effective alleviation of exercise-induced pain by RC than C on overall comparison of pre-and post-treatment. Approximate synchronicity between electroalgmetrical pain alleviation and decrease of urinary collagen type II excretion due to cartilage destruction suggests a chondroprotective effect of risedronate leading to pain alleviation. Osteoarthritis characterized by increased cartilage Ca content, hardening, degeneration and wasting in response to physical stress is apparently caused by increased bone resorption induced by calcium deficiency and other causes, with consequent Ca entrance into cartilage. Chondroprotective effect of risedronate may be explained by its inhibition on bone resorption and Ca entrance into cartilage.

Circulating Chondrogenic Precursors. S. A. Kuznetsov, M. H. Mankani, A. Leet, P. Gehron Robey. Craniofacial and Skeletal Diseases Branch, National Institute of Dental and Craniofacial Research, Bethesda, MD, USA.

In cultures of human peripheral blood, macrophages and their derivatives can acquire notoriously diverse morphological and tinctorial phenotypes. Consequently, subsets of these cells frequently have been mistakenly identified as fibroblast-like cells, thus incorrectly suggesting an abundance of connective tissue progenitors in human blood. In fact, when rigorous criteria are applied (ability to form discrete colonies and to undergo multiple passages, precise immunophenotypying, capacity for bone formation upon in vivo transplantation, or display of other phenotypes), true connective tissue precursors are extremely scarce in human blood. Using a number of cell separation techniques and various culture conditions, we were able to identify just three donors out of 62 studied whose blood contained connective tissue colony-forming cells. Out of these three, one was a patient with multiple bone fractures, and another had been subjected to blood mobilization by G-CSF injections. In contrast, blood cells of several animal species, such as mouse, rabbit, and, in particular, guinea pig, demonstrate much more reproducible connective tissue colony formation. Based on this fact, we chose the guinea pig model to study the differentiation potential of adherent strains of circulating cells. Multicolony-derived strains (5 in total) consisted uniformly of spindle-shaped, fibroblast-like cells, positive for the markers of fibroblasts, osteogenic cells, and smooth muscle cells, and negative for the markers of endothelial cells, leukocytes, and macrophages. Following in vivo transplantation, one of the strains formed abundant bone, accompanied by adipocytes and hematopoiesis-supporting stroma, and formed abundant cartilage in pellet cultures in vitro. Out of 22 single colony-derived strains of various morphologies (6 spindle-shaped, fibroblast-like, 4 flat-shaped, fibroblast-like, 11 polygonal, 1 intermediate), only 5 spindle-shaped strains were able to proliferate extensively. None of these formed bone in vivo, while two did form cartilage in pellet cultures. Apparently, there are cells in guinea pig blood capable of both extensive proliferation and differentiation towards cartilage: circulating chondrogenic precursor cells. These cells lack osteogenic potential and therefore represent committed chondrogenic precursors. This is the first time that precursor cells with chondrogenic but not osteogenic potential have been identified. At the same time, our finding of a multicolony-derived strain capable of osteogenesis, chondrogenesis, and stromal tissue formation suggests that circulating multipotential skeletal stem cells do exist.

Basic Calcium Phosphate Crystals Promotes Apoptosis in Bovine Articular Chondrocytes. H. K. Ea*[1], B. Uzan*[1], C. Rey*[2], F. Lioté*[1]. [1]Hospital lariboisière, INSERM 606, Paris, France, [2]CIRIMAT, UMR CNRS 5085, ENSIACET, Toulouse, France.

Basic calcium phosphate (BCP) crystals including octacalcium phosphate (OCP), carbapatite (CA) and hydroxyapatite (HA) are frequently found in articular fluid and are associated with a severe and destructive form of osteoarthritis (OA). These crystals have heterogeneous biological properties and induce different inflammatory responses as demonstrated *in vivo* and *in vitro* studies. Beside inflammatory cytokines and metalloproteases (MMPs) released after synoviocyte stimulation, recent studies have demonstrated that BCP crystals directly activated chondrocytes to produce MMPs and nitric oxide. The aim of this study was to investigate the role of BCP crystals in articular chondrocytes apoptosis, a hallmark feature in OA. Sterile and pyrogen-free OCP, CA and HA crystals were characterized by X-ray diffraction and infrared spectroscopy. Primary bovine articular chondrocytes isolated from calf metatarsal phalangeal joints were cultured in monolayer condition for 7 days. To study apoptosis cells were then replated and cultured in serum-free medium for 4-48 hours. Apoptosis was assessed by caspase 3 activity, Hoescht staining and phosphatidylserine labelling with annexin V-FITC. Chondrocytes viability was evaluated with MTT assay. All three BPC crystals induced articular chondrocyte apoptosis : chromatin condensation and phosphatidylserine externalisation. Caspase 3 activity increased in a dose- and time-dependent fashion for each crystal and this was associated with a dose-dependent decrease in chondrocyte viability. Maximal caspase 3 activity was obtained with the low dose (50 µg/ml) for OCP (+400%) and CA (+400 %) crystals whereas a ten-fold higher dose (500 µg/ml) was necessary with HA crystals to achieve the same effect. Using a transwell system, BCP crystals did not induce caspase 3 activity indicating that BCP crystal-induced apoptosis was not secondary to calcium release. Furthermore, chelating extracellular calcium with EGTA or EDTA, or using a calcium-free medium increased caspase 3 activity as well. Finally caspase 3 activity was associated with increase Bax/Bcl-2 ratio and was markedly diminished in a dose-dependant fashion when chondrocytes were pre-incubated with caspase-8 (Z-IETD-FMK) and caspase-9 (Z-LEHD-FMK) inhibitors, suggesting the involvement of the 2 signal

pathways. Our data showed for the first time that BCP crystals directly promoted chondrocyte apoptosis. This further suggested that they might participate to cartilage destruction in crystal related-joint diseases.

A New Thienoindazole Derivative Promotes Chondrogenic Differentiation in a Sox9-Independent Manner without Inducing Hypertrophy. F. Yano[1], S. Ohba[1], F. Kugimiya[2], T. Ikeda[1], N. Ogata[1], T. Ogasawara[1], T. Takato[1], K. Nakamura[2], H. Kawaguchi[2], U. Chung[1]. [1]Division of Tissue Engineering, Faculty of Medicine, University of Tokyo, Tokyo, Japan, [2]Department of Sensory and Motor System Medicine, Faculty of Medicine, University of Tokyo, Tokyo, Japan.

Aiming at clinical application to cartilage regeneration, we established prechondrogenic ATDC5 cell lines stably expressing green fluorescent protein (GFP) under the control of the chondrocyte-specific fragment of the type II collagen promoter. Using these cells as a monitoring system of chondrogenic differentiation, we screened natural and synthetic compound libraries and discovered that a thienoindazole derivative small compound T-198946 (TM) strongly induced GFP fluorescence in a period as short as 3 days. To clarify its molecular mechanism of action, we treated mouse embryonic stem cells (ESC), undifferentiated mesenchymal C3H10T1/2 cells and bone marrow-derived mesenchymal stromal cells (MSC) with TM and examined markers of chondrocyte differentiation. Real-time RT-PCR analysis revealed that TM treatment up-regulated expression of chondrogenic differentiation markers such as type II collagen, aggrecan and chondromodulin-1, but not that of hypertrophic differentiation markers such as type X collagen and osteopontin. Toluidine blue and Alcian blue stainings of C3H10T1/2 and MSC revealed that TM treatment increased cartilage matrix synthesis in a dose-dependent manner. Furthermore, TM treatment of dedifferentiated primary chondrocytes which were isolated from newborn mouse ribs and passaged three times led to restoration of mRNA expression of chondrogenic differentiation markers and synthesis of cartilage matrix, suggesting that TM promotes redifferentiation of dedifferentiated chondrocytes. Since Sox9 is required during sequential steps of chondrocyte differentiation, we investigated whether Sox9 and its cofactors Sox5 and Sox6 were involved in the action of TM. TM treatment of ESC, C3H10T1/2 and MSC did not significantly alter mRNA level, protein level or phosphorylation of Sox9, whereas it dramatically up-regulated mRNA expression of Sox5 and Sox6. TM treatment of Sox9-deficient ESC up-regulated expression of chondrogenic differentiation markers to the level comparable to that of wild-type ESC. These date suggest that TM induces chondrogenic differentiation in a Sox9-independent manner without inducing hypertrophy. TM may be useful for the regenerative medicine of permanent cartilage.

Connective Tissue Growth Factor (CTGF/CCN2) Reinforces the Molecular Phenotype of Aauricular Chondrocytes *In Vitro*. T. Fujisawa*[1], K. Nakao*[2], T. Hattori*[2], S. Kubota*[2], T. Kuboki*[1], M. Takigawa[2]. [1]Department of Oral and Maxillofacial Rehabilitation, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan, [2]Department of Biochemistry and Molecular Dentistry, Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Okayama, Japan.

Cartilage is an avascular tissue, so once damaged, hyaline and elastic cartilage have limited capacity for self-repair. However, recent advances in tissue engineering technology have brought significant progress in reconstruction of cartilage defects. It is well known that connective tissue growth factor (CTGF/CCN2) is a multifunctional growth factor for chondrocytes, and plays important roles in the control of the proliferation and differentiation of chondrocytes *in vitro*. We have previously reported that CTGF/CCN2 promotes all process of the endochondral ossification, such as cell proliferation, maturation and hypertrophy of growth cartilage cells, however, does not stimulate their hypertrophy or calcification of articular chondrocytes *in vitro*. These results indicate that CTGF/CCN2 may reinforce their own molecular phenotype of chondrocytes derived from different cartilage, such as growth cartilage and articular cartilage. Therefore, in this study, we tried to investigate the effects of CTGF/CCN2 on auricular chondrocytes. Rabbit primary auricular chondrocytes were isolated from their auricular cartilage by enzyme digestion and cultured in alpha-MEM containing 10% FBS. Chondrocytes were cultured in the presence or absence of 50 ng/ml recombinant human CTGF/CCN2. The effect of CTGF/CCN2 on the auricular chondrocytes proliferation was evaluated by MTS assay and [^{3}H] thymidine incorporation, and the proteoglycan synthesis was determined by [^{35}S] sulfate incorporation. The mRNA level of *elastin* was evaluated by real-time PCR analysis, and the accumulation of elastin fibers were visualized by Victoria-blue stain. CTGF/CCN2 stimulated the proliferation of rabbit auricular chondrocytes slightly, DNA synthesis up to 1.8 times and proteoglycan synthesis up to 1.6 times. The gene expression of *elastin* after stimulation with CTGF/CCN2 was increased up to 2.5 fold in comparison with the control condition. In addition, the production of elastin fiber was slightly up-regulated by stimulation with CTGF/CCN2. This is the first report to show that CTGF/CCN2 promotes the phenotypes of the auricular chondrocytes such as *elastin* gene expression and elastin fiber accumulation, which suggests that CTGF/CCN2 may be useful for repair or reconstruction of elastic cartilage, e.g., auricular cartilage.

CTGF Acts as A Downstream Mediator of TGF-β1 in Promoting Condensation And Regulating FN and Sox9 Expression in Mesenchymal Stem Cells. J. J. Song[1], R. A. Aswad*[1], R. A. Kanaan*[2], M. C. Rico[1], T. A. Owen[3], M. F. Barbe[1], F. F. Safadi[1], S. N. Popoff[1]. [1]Anatomy & Cell Biology, Temple University School of Medicine, Philadelphia, PA, USA, [2]Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, USA, [3]Cardiovascular and Metabolic Diseases, Pfizer Global Research and Development-Groton Laboratories, Groton, CT, USA.

Condensation or the aggregation of mesenchymal stem cells (MSCs) precedes chondrocyte differentiation and is required for cartilage formation and subsequent skeletal development. CTGF is a matricellular protein that has been found to be expressed in condensations and the perichondrium by *in situ* hybridization studies. Since TGF-β1 inititates the condensation of MSCs and CTGF is a downstream gene of TGF-β1, this study examined whether CTGF mediates TGF-β1-induced MSC condensation. In addition, the relationship between the expression of CTGF and Sox9, the master transcription factor required for chondrocyte differentiation, was examined. The expression of CTGF, TGF-β1, Sox9, and FN was evaluated by immunohistochemical analysis of developing vertebrae in sections from mouse embryos at E10.5-E12.5. CTGF, TGF-β1 and FN were co-expressed at high levels in condensations, while high levels of Sox9 expression were observed at a later time point in chondrocytes of developing vertebrae, at a time when CTGF expression had shifted to the perichondrium. To model condensation *in vitro*, micromass cultures of C3H10T1/2 mesenchymal stem cell-line (MSC) were used. TGF-β1 stimulation initiated the condensation of MSCs and this effect was concomitant with the up-regulation of CTGF expression. To study the importance of CTGF in condensation, CTGF siRNA (siCTGF) and CTGF antisense oligonucleotide (antisense) were used to silence CTGF expression in TGF-β1 stimulated cultures. Migration and proliferation assays were performed to evaluate the effects of CTGF silencing on MSCs; Western blot and quantitative Real Time RT-PCR analyses were performed to evaluate expression of CTGF, Sox9 and FN in these cultures. CTGF silencing by siCTGF and antisense showed that TGF-β1-induced condensation of MSCs was CTGF dependent. In addition, the up-regulation of FN and suppression of Sox9 expression by TGF-β1 were also found to be mediated by CTGF. The down-regulation of CTGF expression by siRNA significantly decreased the proliferation and rate of migration of MSCs, two events that play a crucial role in condensation. In conclusion, these results demonstrate that CTGF acts as a downstream mediator of TGF-β1 in promoting condensation of MSCs (via proliferation and migration), and in regulating the expression of FN and Sox9 prior to their overt differentiation into chondrocytes.

Expression of Osteoclastogenesis-Related Molecules in Chondrocytes: *In Vivo* And *In Vitro* Evidence. G. Mailhot, A. Mason-Savas*, C. A. Mackay*, P. R. Odgren. Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA.

Commitment of mononuclear precursors to mature osteoclasts relies on two major and interdependent pathways: interaction of csf-1 with its receptor c-fms and binding of RANKL to its receptor RANK. Animals with inactivating mutations in either one of these pathways lack osteoclasts and are severely osteopetrotic. In addition, these osteoclast-deficient mutants display progressive postnatal growth plate dysplasia characterized by loss of columnar organization, increased thickness, decreased vascular invasion and reduced hypertrophic chondrocyte apoptosis. In order to better understand the involvement of osteoclastogenic molecules in postnatal growth plate physiology, in vivo and in vitro studies were carried out using laser microdissected growth plate chondrocytes and a well-characterized chondrocyte culture model. We investigated the presence and expression of these molecules along with others involved in growth plate function and regulation by quantitative PCR, in situ hybridization and immunohistochemistry. In vivo expression of collagen types II and X and aggrecan as well as parathyroid receptor 1, its ligand PTHrP, Patched and Indian hedgehog confirmed the phenotype of the dissected area. Expression of csf-1, RANKL and their receptors is largely confined to hypertrophic zone chondrocytes. Low levels of osteocalcin and TRAP expression excludes extensive bone tissue contamination. In vitro studies confirm the in vivo findings and showed that gene expression follows the course of chondrocyte differentiation. This study shows for the first time that osteoclastogenic molecules are expressed in laser-captured hypertrophic chondrocytes of the growth plate. These results may help explain the growth plate dysplasia in csf-1 or RANKL-related pathway knockout animals. Further studies comparing mutant and wild-type growth plates as well as investigations of signaling events should lead to a better understanding of the role of csf-1 and RANKL in chondrocyte differentiation.

Regulators of G Protein Signaling (RGS) Regulate Chondrocyte Differentiation. C. T. G. Appleton*, C. G. James*, F. Beier. Physiology & Pharmacology, University of Western Ontario, London, ON, Canada.

RGS proteins are known to exhibit negative control of G protein signaling. Our goal was to characterize the functions of RGS (regulator of G-protein signaling) proteins during chondrocyte differentiation, a well-defined process in endochondral bone development. Initially, microarray analyses indicated differential expression of several *Rgs* genes during chondrogenic differentiation; we confirmed this using RT-PCR (James et al., in revision). To investigate biological roles played by the murine *Rgs* genes, we transfected the murine ATDC5 chondrogenic cell line with human *RGS2*, *RGS4*, *RGS5*, *RGS7*, or *RGS10* constructs to overexpress the RGS proteins. Using real time PCR, RT-PCR, alkaline phosphatase activity assays, and staining techniques we assessed changes in the chondrocyte differentiation program. Premature increases in Type II collagen expression were detected in clones overexpressing RGS2, RGS7, or RGS10. These same clones exhibited accelerated hypertrophic differentiation as demonstrated by increases in the hypertrophic chondrocyte marker genes Type X collagen and BSP (bone sialoprotein), and increased levels of alkaline phosphatase activity. FGFR3 and IHH expression was also altered due to RGS protein overexpression. In contrast, RGS4 and RGS5 overexpression accelerated the transition from the proliferative to the pre-hypertrophic chondrocyte, but had no effect on hypertrophic differentiation compared to vector-transfected controls. To investigate how RGS proteins regulate a specific G protein signaling pathway we measured cAMP production by ELISA after stimulation with 10^{-7}M PTHrP. Interestingly, RGS protein overexpression caused an increase in cAMP production in response to stimulation with PTHrP. Finally, preliminary studies using *Rgs2-/-* mice suggest that RGS2 is required for skeletal growth and development. Histological and *in situ* hybridization studies are currently underway to investigate this phenotype in detail. These data show, for the fist time, a role played by RGS proteins in chondrogenic differentiation. Identification of the signaling pathways and downstream targets regulated by RGS proteins will shed further light on the mechanisms controlling chondrocyte physiology and pathophysiology.

B-Raf Is Dispensable for Normal Endochondral Bone Development. S. Provot[1], J. Paruch*[1], A. Chen*[2], A. Silva*[2], H. M. Kronenberg[1]. [1]Endocrine Unit, MGH - Harvard Medical School, Boston, MA, USA, [2]Department of Neurobiology, UCLA - Brain Research Institute, Los angeles, CA, USA.

Parathyroid hormone-related peptide (PTHrP) through its G protein-coupled PTH/PTHrP-receptor (PPR) is a positive regulator of chondrocyte proliferation and a negative regulator of chondrocyte maturation in endochondral bone development. We have previously demonstrated that these effects most likely involve cAMP-dependent signaling pathways. Because it has been suggested that the ability of cAMP to stimulate cell proliferation involves the MAPKKK B-Raf, we hypothesized that PPR's proliferative action in chondrocytes might be mediated by B-Raf. We observed *B-raf* expressed in proliferative but not hypertrophic chondrocytes, and conditionally inactivated this gene in cartilage, using a collagen II promoter-driven cre, and a floxxed *B-raf* allele. Mice lacking B-Raf in cartilage are identical to wild-type mice. Histologic analysis of the *B-raf*-null growth plate showed no difference compared to control littermates, both in prenatal and postnatal animals. *In situ* hybridization analysis with various chondrogenic markers did not reveal any abnormal chondrocyte differentiation. We also found that *B-raf*-null chondrocytes have a similar proliferation rate to that of control littermates. Because B-Raf may have subtle effects in the growth plate, we looked for possible consequences of a lack of B-Raf in settings in which PTHrP signaling has been ectopically activated. Metatarsal explants treated acutely with PTHrP presented both a similar proliferation rate, and a similar delay of chondrocyte maturation, in presence or absence of B-Raf. We verified that B-Raf protein was efficiently removed from primary chondrocytes using Western blot. Lastly, we looked at the expression of the two other members of the Raf family in the growth plate, in order to see whether they could compensate for the lack of B-Raf. We found that *A-raf* is expressed in proliferative chondrocytes and its expression is unchanged in *B-raf*-null chondrocytes, whereas *C-raf* is only expressed in mature hypertrophic chondrocytes. Based on our results, we conclude that B-Raf is dispensable for normal growth plate development and that B-Raf alone is not responsible for PTHrP-induced chondrocyte proliferation. Because *A-raf* expression is identical to that of *B-raf* we speculate that A-Raf might play a redundant function with B-Raf in cartilage.

How Do Hypertrophic Chondrocytes Die? Y. Ahmed*, L. Tatarczuch*, C. N. Pagel*, K. Alkhodair*, A. F. Clarke*, H. M. S. Davies, M. Mirams*, E. J. Mackie. School of Veterinary Science, University of Melbourne, Parkville, Victoria, Australia.

During endochondral ossification, chondrocytes in growth cartilage undergo hypertrophy then die by a process that is morphologically distinct from classical apoptosis but has not been well characterised. The aims of the current study were to document the morphology of dying hypertrophic chondrocytes in different anatomical locations throughout foetal and postnatal growth, and to develop a culture system for studying the molecular mechanisms of physiological death of these cells. Specimens of articular-epiphyseal and physeal growth cartilage (AEGC and PGC, respectively) were collected from the distal femur and distal tibia of horses during foetal and postnatal growth, and examined by transmission electron microscopy. Two types of dying chondrocyte were observed, 'dark' and 'light' chondrocytes. Dark chondrocytes were characterised by a dark nucleus with small, irregular patches of condensed chromatin; their electron dense cytoplasm was gradually being extruded into the extracellular space. Light chondrocytes also contained a condensed nucleus but their cytoplasm and organelles appeared to be undergoing gradual disintegration within a preserved cellular membrane. The proportion of light chondrocytes was higher in foetal than postnatal specimens and greater in AEGC than in PGC. Chondrocytes were isolated by collagenase digestion from epiphyseal cartilage excised from foetal horses. These cells were centrifuged and grown as pellets for up to 28 days under a variety of conditions, then analysed by light and electron microscopy. By day 7, pellets cultured in 0.1% or 10% foetal calf serum (FCS) were organized into a cartilage-like tissue surrounded by a perichondrium-like layer of flattened cells, and contained hypertrophic chondrocytes resembling those seen in vivo. Some light chondrocytes were present at days 7 and 14; dark chondrocytes and a small number of apoptotic cells were present at all stages of culture. The addition of transforming growth factor-β to the culture medium resulted in an increase in the proportion of cells dying as dark chondrocytes. Triiodothyronine added to medium containing 0.1% FCS caused an increase in the proportion of cells dying as light chondrocytes, but had no effect in the presence of 10% FCS. Staurosporine, which induces apoptosis in a variety of cell types, increased the proportion of cells dying as dark chondrocytes, but did not induce apoptosis in pellet culture. This culture system will provide a useful model for studies on the mechanism of physiological death of hypertrophic chondrocytes.

Transient Receptor Potential Vanilloid 4 (TRPV4) Deficiency Alters Chondrocytic Column Formation during Endochondral Ossification in Mice. A. Mizuno[1], N. Amizuka[2], M. Li*[2], M. Suzuki*[1]. [1]Molecular Pharmacology, Jichi Medical School, Tochigi, Japan, [2]Division of Oral Anatomy, Center for Transdisciplinary Research, Niigata University, Niigata, Japan.

Mechanical stress including the gravity is generally believed to affect endochondral ossification. Transient receptor potential vanilloid 4, TRPV4, is a member of TRP family of calcium-permeable cation channels, which can respond to hypotonicity, moderate heat, acidic pH in neurons, keratinocytes, and endothelial cells. The previous investigation on TRPV4 deficient (TRPV4-/-) mice have verified that this molecule serves as mechanosensor *in vivo*. The molecular mechanism of the mechanosensation is, however, still veiled in the research field of bone. The purpose of this study is to investigate the role of TRPV4 during bone development, by employing TRPV4-/- mice. Immunohistochemical staining showed the TRPV4 channel in chondrocytes of the proliferative and the early stage of hypertrophic zones of the wild-type growth plate, consistent with the TRPV4 mRNA in cultured normal chondrocytes and osteoblasts. Furthermore, an electrophysiologic analysis verified the functional TRPV4 in the primary cultured chondrocytes, indicating that the channel on chondrocytes act as a mechanosensor during bone development. Tibiae of 4-week-old TRPV4-/- mice showed the deformed chondrocytic columns and irregularly-shaped primary trabeculae. Staining of type X collagen, a hallmark of the hypertrophic zone, demonstrated the isolated islets of the hypertrophic chondrocytes in the mutant growth plate, indicating non-synchronous differentiation of some chondrocytes. No remarkable alterations were found in osteoblasts and osteoclasts, as well as CD31-positive vascular endothelial cells at the chondro-osseous junction in TRPV4-/- mice. Therefore, the lack of TRPV4 appears to result in a failure of spatially-organized gradient of chondrocytic differentiation, giving rise to the malformation of chondrocytic columns in the growth plate. Electron microscopy furthermore demonstrated the cell nests of chondrocytes, which closely attached each other, as well as dispersed collagen fibrils in all directions, in the TRPV4-/- mice, thereby, suggesting a defective cellular polarity associated with extracellular matrices. These results indicate that TRPV4 appears to be responsible for maintaining normal cellular polarity of chondrocytes, and consequently enable spatially-organized gradient of chondrocytic differentiation. Thus, it is likely that signaling linked to TRPV4 channels plays a crucial role in spatial orientation of chondrocytes during normal endochondral ossification.

Calcitonin Abolishes Collagen-Induced Arthritis. I. MacIntyre, L. Mancini*, M. Perretti*. William Harvey Research Institute, Queen Mary's School of Medicine and Dentistry, London, United Kingdom.

Female Lewis rats (150 ± 20g) on a standard chow pellet diet were injected with bovine nasal collagen II (4 mg/ml) at the base of the tail. Arthritis developed at day 18 to 21. In preliminary experiments, calcitonin had a variable and modest anti-inflammatory effect. In further definitive and extensive experiments rats were given calcitonin (2 μg/kg/day) alone and accompanied by prednisolone (3 mg/rat/day) and in a separate group prednisolone (0.6 mg/rat/day). Prednisolone alone (3 mg/rat/day) suppressed the arthritis while calcitonin alone had little effect in this experiment. However when administered with prednisolone (0.6 mg/rat/day) calcitonin completely abolished the arthritis as judged by paw swelling, incidence and clinical score. These results suggest that in the presence of the lesser prednisolone dosage (itself without effect) calcitonin has a marked anti-inflammatory effect. The synergistic effect of prednisolone might represent suppression of calcitonin receptor down-regulation but this remains to be established. These results might have implications for calcitonin in human subjects with rheumatoid arthritis.

Mechanisms of Parathyroid Hormone (PTH) Inhibition of Extracellular Signal-Regulated Kinases (ERK1/2) in Chondrocytic Cells. L. P. Lai*, J. Mitchell. Pharmacology, University of Toronto, Toronto, ON, Canada.

Indian Hedgehog (Ihh) is produced by growth plate pre-hypertrophic chondrocytes, and is the master regulator of endochondral bone formation. It regulates the rate of proliferation and differentiation of growth plate chondrocytes as well as osteoblast differentiation. Previously, we have shown that parathyroid hormone (PTH) downregulates Ihh mRNA levels in a chondrocytic cell line, CFK-2, and this is mainly mediated by PTH inhibition of extracellular signal-regulated kinases (ERK1/2) activities (Lai, et al., *J. Cell. Physiol.* 203: p177, 2005) . In this study, we investigated the mechanisms by which PTH inhibits ERK1/2 activities in CFK-2 cells. PTH (PTH (1-34)) decreased the phosphorylation levels of c-Raf at ser338 in both time (maximally in 5 min and sustained for 30 min) and concentration (from 10^{-11} to 10^{-7}M) dependent manner. Similarly, PTH was also able to decrease the phosphorylation levels of MEK1 with a similar time frame. On the other hand, PTH induced the expression of MAP kinase phosphatase 1 (MKP-1) in both time (detectable within 30 min and sustained for 90min) and concentration (from 10^{-11} to 10^{-7}M) dependent manner. These data showed that both PTH inhibition of the Raf-MEK pathway and PTH induction of MKP-1 expression can potentially mediate PTH inhibition of ERK1/2 activities in chondrocytes. To further elucidate the signaling pathway, we transiently transfected different mutant constructs in CFK-2 cells, and determined their effects on PTH inhibition of ERK1/2 activities. While a constitutively active mutant of c-Raf alleviated 50% of the PTH-dependent decrease of ERK1/2 phosphorylation, overexpression of the wild type, dominant negative mutant of MKP-1, or construct encoding the si-MKP-1 had no effect. These data demonstrated that PTH inhibition of ERK1/2 activities is mainly mediated by the Raf-MEK pathway. Furthermore, they suggested the central role of Raf-MEK-ERK signaling pathway in mediating PTH downregulation of Ihh in chondrocytes.

Targeted *In Vivo* Measurements of Small Cartilage Defect Volumes in Knee Joint MRI's. R. Vargas-Voracek[1], D. Steines*[1], J. Ryaby[2], S. Liew[1], C. Arnaud[1], P. Hess[1]. [1]Imaging Therapeutics, Inc., Foster City, CA, USA, [2]Orthologic, Corp, Tempe, AZ, USA.

There is clinical need for non-invasive imaging tools that are capable of detecting and evaluating cartilage defects as well as monitoring response to new cartilage repair therapies. Magnetic resonance imaging (MRI) has shown the greatest promise of all such tools motivating studies to determine whether it is accurate and reproducible enough to quantitatively measure the volume and thickness of cartilage tissue. Most work has focused on measurements of large cartilage volumes on *in-vitro* specimens without the effect of inter-scan or operator variability; the latter two effects being of practical clinical relevance. The purpose of this study is to obtain a quantitative assessment of the *in vivo* reproducibility of small and clinically relevant (up to 125mm diameter) cartilage defect measurements from MRI of the knee using image processing tools. We acquired sixteen baseline and short-term follow up knee-MRI scans in the sagittal and coronal planes from eight patients with three-dimensional spoiled gradient-echo (3D SPGR) sequences. The images were 256 by 256 pixels at 0.55mm by 0.55 mm pixel resolution and 1.5 mm slice spacing. Three operators with low, average and high skill levels segmented the cartilage regions from the images using image segmentation tools. Targeted defect volumes were selected and extracted randomly without overlap from the baseline segmented images. Baseline volumes were then compared with volumes extracted from the same location in the corresponding follow-up images. Reproducibility was evaluated by comparing the defect volumes from baseline and follow-up scans through linear regression. For inter-scan reproducibility, results with 270 focal cartilage defect measurements show high measurement correlation (average R^2 of 0.95) between baseline and follow up scans. Intra and inter observer reproducibility showed consistent improvement with increased operator skill (R^2 (low) =0.95, R^2 (high) =0.99, average R^2=0.96). In conclusion, we were able to quantitatively and reproducibly measure targeted small volumes from MRIs. Intra and inter observer reproducibility can be optimized and variability minimized by either increasing operator skill level or improving the automation of the segmentation process. The possibility for improving inter-scan reproducibility with higher MR scan resolution and 3D image processing algorithms further emphasizes the potential usefulness of MRI as a non-invasive tool for *in-vivo* quantitative assessment of cartilage disease, disease progression, and monitoring response to treatment.

Naturally Occurring Selective Estrogen Receptor Modulators, Genistein, may Reduce the Production of Proinflammatory Molecules in Human Chondrocytes. S. Hooshmand*[1], D. Y. Soung[1], S. V. Madihally*[2], L. Devareddy*[1], E. A. Lucas[1], B. H. Arjmandi[1]. [1]Nutritional Sciences, Oklahoma State University, Stillwater, OK, USA, [2]Chemical Engineering, Oklahoma State University, Stillwater, OK, USA.

Previously, we reported that cartilage is an estrogen receptor (ER) positive tissue and that mRNA levels of ERß increase in postmenopausal women with osteoarthritis. Based on our findings and those of other investigators, we hypothesize that local rather than circulating estrogen levels negatively affect chondrocyte metabolism and that selective estrogen receptor modulators (SERM) augment cartilage health. To test the latter part of our hypothesis, we have begun to explore the role of genistein, a naturally occurring SERM with high affinity to bind ERß, in inhibiting the lipopolysaccharide (LPS)-induced cyclooxygenase (COX)-2 but not COX-1 in human chondrocytes (HCH). Cells (PromoCell, Germany) were treated with three levels of genistein (0, 50, and 100 µM). After one hour, the genistein-treated cells were stimulated by one µg/mL LPS for six hours. Cells were then harvested and the cytosolic fraction was isolated for assessing COX-1 and COX-2 protein levels using Western blot. Our preliminary data indicate that the LPS-induced increase in COX-2 protein level is reduced by pretreatment of 100 µM of genistein, whereas COX-1 protein level is not affected by genistein. These findings support our clinical study (*Arjmandi et al. Phymed, 11:567-575, 2004*) that patients with osteoarthritis may benefit from consumption of soy isoflavones.

Intact Caveolae and Caveolin-1 Are Required for 1α,25(OH)$_2$D$_3$ Regulation of the Growth Plate. B. D. Boyan*[1], L. Wang[1], K. Wong*[1], H. Yao*[1], R. E. Guldberg*[1], H. Jo*[2], Z. Schwartz[1]. [1]Georgia Institute of Technology, Atlanta, GA, USA, [2]Emory University Medical School, Atlanta, GA, USA.

1,25-dihydroxyvitamin D3 [1,25(OH)$_2$D$_3$] dependent PKC signaling in rat growth plate chondrocytes is mediated by a plasma membrane associated 1,25(OH)$_2$D$_3$-binding protein, ERp60. Activation of PKC involves rapid increases in phospholipase A_2 and phospholipase C, both of which are found in lipid rafts/caveolae in many cells. Here, we examined the hypothesis that the caveolae microenvironment is required for ERp60 function and that caveolae play an important role in regulating growth plate physiology. Rat costochondral cartilage prehypertrophic/upper hypertrophic zone chondrocytes were examined for caveolae by transmission electron microscopy (TEM) and for caveolae proteins caveolin-1 (Cav-1), -2 and -3. TEM showed that the cells had caveolae and Western blots demonstrated that Cav-1, 2 and 3 were present. Resting zone chondrocytes, which do not exhibit a PKC response to 1,25(OH)$_2$D$_3$, also had Cav-1, 2 and 3 but their caveolae were fewer in number and were structurally larger. Confocal microscopy showed that ERp60 and Cav-1 were in the plasma membrane of growth zone cells, whereas the traditional nuclear vitamin D receptor (VDR) was found primarily in the nuclei. Beta-cyclodextrin (CD) was used to disrupt lipid rafts/caveolae and was found to block 1,25(OH)$_2$D$_3$'s stimulatory effects on PKC, alkaline phosphatase and [^{35}S]-sulfate incorporation. Growth plate chondrocytes from Cav-1$^{-/-}$ mice did not respond to 1α,25(OH)$_2$D$_3$, although wild type C57BL/6 cells exhibited 1,25(OH)$_2$D$_3$-dependent increases in PKC, alkaline phosphatase, and proteoglycan production. Histology of tibial growth plates from 8-week-old male wild type and Cav-1$^{-/-}$ mice showed marked differences. Cav-1$^{-/-}$ growth plates were longer and had more hypertrophic cells in each column. Micro-CT analysis confirmed that the height of the growth plate was greater and showed that the cross-sectional area of the Cav-1$^{-/-}$ growth plates was greater as well. These results indicate that the membrane mediated effects of 1,25(OH)$_2$D$_3$ via ERp60 require caveolae and Cav-1, and demonstrate the consequences of Cav-1 deficiency on growth plate physiology.

Expression of CaMK Iβ mRNA in Growth Plate Chondrocytes and Metaphysial Osteoblasts. M. E. Pedersen*[1], D. Fortunati[1], M. Nielsen*[1], S. H. Brorson*[2], O. P. Løseth*[1], L. S. H. Nissen-Meyer*[1], R. Paro*[3], A. Teti[3], F. P. Reinholt[2], K. M. Gautvik[4], R. Jemtland*[5]. [1]Department of Biochemistry, Institute of Basic Medical Sciences, University of Oslo, Oslo, Norway, [2]Institute of Pathology, National University Hospital, Oslo, Norway, [3]Department of Experimental Medicine, University of L'Aquila, L'Aquila, Italy, [4]Department of Biochemistry, Institute of Basic Medical Sciences University of Oslo, Ullevål University Hospital and Lovisenberg Hospital, Oslo, Norway, [5]Endocrine Section, Dept. of Medicine, National University Hospital, Oslo, Norway.

The family of Ca2+/calmodulin-dependent protein kinases (CaM-kinases) are known to mediate many of the effects of Ca2+ as a second messenger in eukaryotic cells, which includes regulating signaling pathways involved in modulating various cellular functions such as proliferation, differentiation and gene expression.Our group has previously cloned CaMK Iβ, which belongs to the group of multifunctional CaM-kinases thought to be specifically enriched in the brain, from a hypothalamus substraction cDNA library. In the present study, we characterized the localization of cells expressing mRNA for CaMK Iβ in mouse skeletal tissue *in vivo*, using *in situ* hybridization with digoxigenin labeled antisense RNA probes. We also assessed expression of CaMK Iβ mRNA in clonal and normal osteoblasts and chondrocytes of human and rodent origin by Real-Time PCR. *In situ* hybridization of whole embryos demonstrated that CaMK Iβ mRNA was most highly expressed in growth plate hypertrophic chondrocytes of long bones and also in hypertrophic chondrocytes of various other skeletal elements. In mouse hind limbs, expression of CaMK Iβ was sustained at similar high levels throughout the observation period (i.e. from embryonic day 16.5 until postnatal day 10). In addition, positive hybridization signals were detected in a subpopulation of cells with the appearance of osteoblasts situated along trabecular bone surfaces in the metaphysial region. Real-Time PCR of total RNA from primary mouse calvarial osteoblasts, rat UMR 106 osteosarcoma clonal cells and primary human chondrocytes derived from cartilage explants confirmed that CaMK Iβ is expressed in both chondrocytes and osteoblasts *in vitro*. Our data demonstrating unexpectedly high expression of CaMK Iβ in extraneural skeletal tissue, suggest a role for this protein in chondrocyte maturation and in osteoblast development.

Premature Degenerative Joint Disease of the Knee in Mice Lacking Phosphoadenosine-Phosphosulfate Synthetase 2 Activity (Papss2): a Model of Human PAPSS2 Deficiency. A. F. Ford-Hutchinson*[1], Z. Ali*[1], R. A. Seerattan*[2], D. M. L. Cooper*[3], B. Hallgrímsson*[4], P. T. Salo*[2], F. R. Jirik*[1]. [1]Biochemistry and Molecular Biology, University of Calgary, Calgary, AB, Canada, [2]Surgery, University of Calgary, Calgary, AB, Canada, [3]Archaeology and Medical Science, University of Calgary, Calgary, AB, Canada, [4]Cell Biology and Anatomy, University of Calgary, Calgary, AB, Canada.

We investigated whether loss of Papss2 activity, a cause of degenerative joint disease in humans, would similarly lead to degenerative joint disease in mice. Murine brachymorphism (bm) results from an autosomal recessive mutation of the Papss2 gene that encodes 3'-phosphoadenosine 5'-phosphosulfate synthetase 2, one of the principal enzymes required for the sulfation of extracellular matrix molecules in cartilage and other tissues. A form of human spondylo-epimetaphyseal dysplasia has been identified in Pakistani kindred having a mutation of PAPSS2. These individuals have skeletal malformations, including short stature evident at birth, short bowed lower limbs (genu varum), brachydactyly, kyphoscoliosis (Ahmad, 1998). These individuals also demonstrate premature onset of degenerative joint disease. Animals homozygous for the Bm (Papss2) gene mutation on a C57BL/6 background were obtained from the Jackson Laboratory. Knee joints were analyzed by micro-computed tomography (micro-CT) analysis and histology. Compared to control 12-14 month old C57BL/6 mice that demonstrated minimal if any pathology, by 12 months both male and female brachymorph mice exhibited severe degenerative knee joint disease, with cartilage damage being most evident in the patello-femoral and medial compartments. Micro-CT imaging of Bm knees revealed skeletal malformations, including bowing of the fibula and tibia, bone remodeling of the patello-femoral groove, and variable remodeling of the tibial crest and tubercle. Whether brachymorph knee joint degeneration results primarily from a cartilage matrix abnormality (e.g. hyposulfation of proteoglycans), altered biomechanics associated with abnormal bone structure, abnormal muscle packing, or a combination of these features is not clear. The Bm mutant mouse thus represents a novel example of hereditary murine degenerative joint disease, and is also model of human PAPSS2 deficiency-associated arthrosis.

A Murine Epiphyseal Chondrocyte Model of ADAMTS 5- Mediated Aggrecanolysis. M. Stewart[1], A. J. Fosang*[2], C. B. Little*[3], J. D. Sandy*[4]. [1]Veterinary Clinical Medicine, University of Illinois at Urbana-Champaign, Urbana, IL, USA, [2]Paediatrics, University of Melbourne, Parkville, Australia, [3]Raymond Purves Bone and Joint Research laboratories, University of Sydney, St Leonards, Australia, [4]Shriners Hospital, Tampa, FL, USA.

This study assessed the utility of murine epiphyseal chondrocyte cultures for studying aggrecan synthesis and degradation. Distal femoral and proximal humeral epiphyses were collected from 4-day-old WT, NITEGE-null and ADAMTS-5-null mice. Chondrocytes were isolated by collagenase digestion and cultured as non-adherent aggregates in serum-free medium. Cultures were maintained for up to 12 days, with sample collections at 3-day intervals. GAG content in the pericellular and medium compartments was monitored by DMMB assays. Aggrecan expression and degradation were assessed by Western blot analyses of chondroitinase-treated lysates, using antibodies specific for the full-length protein and neoepitopes created by ADAMTS activity. Expression of cartilage-linked ADAMTS genes (TSs 1, 4, 5, 8, 9 and 15) was determined by RT-PCR. Murine epiphyseal chondrocytes synthesized 60-80 ug GAG/million cells/3-days. Approximately 10% of total GAG was retained in the pericellular compartment while 90% was released into the medium. Aggrecan immunoblotting demonstrated spontaneous degradation of the full-length protein with neoepitope expression characteristic of ADAMTS activity. Chondrocytes from mice lacking the NITEGE motif were unable to cleave aggrecan in the amino-terminal interglobular domain, as expected, but exhibited an alternate aggrecanolysis profile. Epiphyseal chondrocytes expressed all six of the cartilage-linked ADAMTSs. However, chondrocytes isolated from mice lacking TS5 secreted full-length aggrecan with no evidence of aggrecan cleavage, indicating that aggrecan degradation in this model is dependent on TS5 activity. In conclusion, the neonatal murine epiphyseal chondrocyte model is a valuable tool for investigating aggrecan synthesis and turnover by ADAMTS proteases. Aggrecanase activity is an inherent property of the model, and does not require stimulation by retinoic acid or inflammatory cytokines. Comparisons of WT and KO chondrocytes emphasize the utility of this culture model for genetic and transgenic approaches to the investigation of aggrecan turnover. These analyses indicate that aggrecan cleavage by epiphyseal chondrocytes requires TS5 activity. Recent studies have shown the importance of TS5 in osteoarthritis. The epiphyseal model represents an ideal vehicle to investigate the pathways that regulate TS5 expression and activity, and test the efficacy of putative antagonists against this protease.

Insight into the Mechanisms of Bone Remodeling in Prostate Cancer Bone Metastasis. M. P. Roudier[1], C. Morissey*[1], I. M. Coleman*[2], L. D. True*[3], C. S. Higano*[4], P. S. Nelson*[2], S. M. Ott[5], R. L. Vessella[1]. [1]GU Cancer Research Lab, University of Washington, Seattle, WA, USA, [2]Fred Hutchinson Cancer Research Center, University of Washington, Seattle, WA, USA, [3]Pathology Dept, University of Washington, Seattle, WA, USA, [4]Oncology Dept, University of Washington, Seattle, WA, USA, [5]Medicine, Metabolism and Endocrinology, University of Washington, Seattle, WA, USA.

We collected bone samples from patients who died of PCa using a rapid autopsy procedure. Bone samples were submitted to bone histomorphometry and to gene expression profile analysis. Mean bone volume per biopsy was 30% and ranged from 3.72% to 72.60% (median 39.70%) of the total tissue volume. There is a wide variation of bone volume from one patient to another and from a biopsy to another in a given patient. Except in 2 patients (where mean bone volume was less than 20%), bone metastases were osteodense. In each bone biopsy, total bone consisted of lamellar bone, woven bone and osteoid. The volume of the lamellar trabecular bone, ranged from 0 % to 27.10% (median 9.4%) of the tissue volume. The volume of woven bone ranged from 0% to 70.3% (median 20%). There was woven bone formation in all patients. In 2 patients with osteolytic pattern, bone biopsies showed an osteoblastic remodeling with woven bone. Increased eroded surface (greater than 7% of the bone surface) was noted in 50% of the osteodense samples. Osteoclast number was increased and not correlated to bisphosphonate treatment. A SAM two-sample unpaired t-test comparing osteolytic metastases with osteoblastic metastases found no genes statistically different between the two groups. However, 347 genes were identified which exhibited >3 fold differences between the average ratios of the two groups and 6 genes were bone related. Among them, IGF-BP3 mRNA levels were higher in osteolytic than osteoblastic metastases. IGF-BP3 has been reported to influence bone remodeling. IGF-BP3 mRNA level decrease in osteoblastic prostate bone metastasis might induce a higher availability of IGF which in turn can increase osteoblast activity. These data suggest that CaP cells influence osteoblast activity by inducing a few known osteoblast signaling pathways. Inhibition of downstream targets should be investigated as it could result in inhibition of the CaP/Osteoblast interaction, which in turn might lead to the development of preventive agents and/or more effective therapies for advanced prostate cancer. The heterogeneity of prostate cancer bone metastases makes gene expression analyses much more difficult than those of the primary tumor.

Unanticipated Development of Cataract and Nephrotic Syndrome in Transgenic Rats Overexpressing Type III Na-Dependent Phosphate Transporter. A. Suzuki[1], K. Nishiwaki-Yasuda[1], J. Caverzasio[2], Y. Ono*[1], S. Sekiguchi[1], S. Nagao*[3], H. Takahashi*[3], M. Matsuyama*[4], K. Yan*[5], R. Kaneko*[6], M. Hirabayashi*[6], P. Ammann[2], R. Rizzoli[2], Y. Oiso*[7], M. Itoh*[1]. [1]Division of Endocrinology, Fujita Health University, Toyoake, Japan, [2]Service of Bone Diseases, University Hospital of Geneva, Geneva, Switzerland, [3]Education and Research Center of Animal Models for Human Diseases, Fujita Health University, Toyoake, Japan, [4]Department of Surgical Pathology, Fujita Health University, Toyoake, Japan, [5]Departmento of Pediatrics, Kyorin University, Tokyo, Japan, [6]National Insitute of Physiological Sciences, Okazaki, Japan, [7]Division of Metabolic Diseases, Nagoya University Graduate School of Medicine, Nagoya, Japan.

Type III sodium-dependent inorganic phosphate (Pi) transporter, Pit-1 (Glvr-1), is a ubiquitous protein. Its expression was found to increase in a subpopulation of hypertrophic chondrocytes suggesting a role in bone development. The aim of the present study was to investigate the effect of Pit-1 overexpression on the development of different organs. Mouse Pit-1 gene was overexpressed under the control of CAG promoter in transgenic (Tg) rats. Na-dependent Pi transport was increased by 2.5-3 fold with no change in alanine uptake in primary cultured osteoblastic cells derived from calvaria of Tg compared with wild type (WT) animals. Skeletal development and body length were normal in Tg animals. Body weight was significantly decreased in Tg compared with WT rats, a difference that was more pronounced in male compared with female animals (8wks WT 378±42 g, Tg 296 ±30 g; 20wks control 551±50 g, Tg 441±30 g). An early onset of cataract development was observed after 2 to 8 wks of age. In addition, male Tg rats developed massive proteinuria at 20 wks of age (Tg 308±177 mg/day, WT 33±20 mg/day,). This effect was associated with lower serum albumin levels (Tg 3.5±0.5 mg/day, WT 4.7±0.1 mg/day) and hyperlipidemia (Tg 237±99 mg/day, WT 99±14 mg/day). Proteinuria was detected at 3 months of age and glomerular deformity assessed by EM images already observed in kidneys of 8 weeks old Tg rats. Survival was much shorter in Tg rats with death already occurring between the 7 and 9 month of age. In conclusion, results presented in this study indicate that Pit-1 overexpression and high cellular Pi transport does not markedly influence skeletal development. However, it is associated with an early onset of cataract and alterations of the glomerular system leading to a nephrotic syndrome.

Identification of the Genes Regulated by Extracellular Inorganic Phosphate in the Early Stage of Chondrocyte Differentiation. M. Kimata*[1], K. Tachikawa*[1], K. Ozono[2], T. Michigami[1]. [1]Department of Environmental Medicine, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan, [2]Department of Pediatrics, Osaka University Graduate School of Medicine, Osaka, Japan.

During endochondral bone formation, extracellular inorganic phosphate (Pi) as well as calcium plays important roles in mineralization and regulation of gene expression. In osteoblasts, it was reported that the expression level of osteopontin was increased in response to extracellular free Pi, suggesting that extracellular Pi might act as a signaling molecule on bone cells. Here we have attempted to identify the genes that respond to extracellular Pi in the early stage of chondrocyte differentiation. To address this issue, we utilized ATDC5 cells, a model for endochondral bone formation. ATDC5 cells were plated in the usual growth media, and 24 hours later, the medium was changed to those containing 1 mM or 10 mM Pi. After 24-hour incubation in 1 mM Pi or 10 mM Pi, total RNA was extracted and subjected to microarray analysis. There was no obvious difference in the viability of the cells between the two groups. The microarray analyses were performed three times, and the genes showing >1.5-fold increase or <0.66-fold decrease in expression on all the three microarrays were selected. Among 4285 genes, 15 genes showed at least 1.5-fold increase in expression when incubated in 10 mM Pi for 24 hours, while 98 genes exhibited <0.66-fold decrease. In the genes up-regulated in response to 10 mM Pi, 47% of them were classified in enzyme by functions, 7% structure, 13% transcription, and 7% apoptosis. On the other hand, in the genes down-regulated in response to 10 mM Pi, 35% of them were categorized in enzyme, 12% structure, 9% transcription, 1% cell cycle, and 4% transporter. The differential expressions of some genes identified were confirmed by reverse transcription-polymerase chain reaction (RT-PCR) analyses. The expression of alkaline phosphatase gene was markedly decreased when cultured in 10 mM Pi compared with the cells cultured in 1 mM Pi. Interestingly, the expressions of BMPs and TGF-β as well as collagens were also decreased within 24 hours in response to 10 mM Pi. The expression of type II collagen gene was also decreased, although a reportor assay demonstrated that the promoter activity of the gene was not suppressed in response to 10 mM Pi, suggesting that mechanism might be involved other than the direct action on the promoter activity. In summary, using ATDC5 cells of proliferation stage, we have identified some genes whose expression was altered in response to high concentration of extracellular Pi. The results suggest that chondrocytes of early stage might have a sensing system for extracellular Pi level.

Tracking the Osteoblast Lineage via the *In Vitro* Differentiation of Murine Embryonic Stem Cells. N. L. Woll*, K. Dunham*, C. Niyibizi*, S. Bronson. Cellular and Molecular Physiology, Penn State College of Medicine, Hershey, PA, USA.

The process of bone formation can be observed in vitro, in the form of a mineralized nodule. Mesenchymal stem cells (MSCs), the immediate precursors to osteoprogenitors are found in the marrow, and likely in numerous other sites throughout the organism. Differentiation of these progenitors, when placed into culture under appropriate conditions, proceeds through characteristic stages of commitment, proliferation, matrix secretion and mineral deposition during a period of 3-4 weeks. We have developed an ESC-derived osteogenic culture system as a model of MSC commitment and differentiation. ESCs were allowed to form embryoid bodies (EBs). EBs were disrupted and plated at concentrations as low as 25 cells/cm2. By 8 days post plating a significant percentage of the colonies had morphology characteristic of other types of osteogenic cultures. By three weeks in culture these colonies go on to form layered nodules. At 21 days cultures were fixed and stained using silver nitrate to identify mineralized colonies, and with methyl green to identify all other colony forming units. Generally 60% of the colonies are layered, mineralized nodules. We have isolated RNA from entire plates and individual colonies at different stages of the differentiation process and have used Quantitative Real Time PCR (QRT-PCR) to investigate the expression of genes characteristic of the osteoblast lineage as well as genes characteristic of other lineages and stem/progenitor cells. Runx2, Osterix, Type I Collagen and Osteocalcin are all transcriptionally upregulated by day 14 and continue to increase in expression out to 21 days. Twist1 and 2 both peak by approximately day 14 and are downregulated by 21 days in culture. Analysis of gene expression in the first week revealed that Brachyury, Twist2, Runx2 and Sox-9 are upregulated by day 4 of the osteogenic culture, with osterix expression increasing by day 7. QRT-PCR analysis of amplified RNA from individual colonies indicates that it is the morphologically osteogenic colonies that are expressing mRNA characteristic of the osteoblast lineage and allows us to further categorize colonies into hematopoietic, osteogenic, adipogenic, myogenic or a mixture of mesenchymal lineages. We have also investigated the impact of exposure to exogenous bone morphogenetic protein 2 (BMP-2) at various points in the differentiation process. Exogenous BMP2 added prior to day 5 of the osteogenic culture disrupts mesenchymal differentiation. We hypothesize that a critical decision point involving the mesenchymal lineages occurs somewhere between day 4 and day 5 of the osteogenic culture.

Defining Embryonic Stem Cell Derived Therapeutic Osteogenic Populations. J. E. DeMarco*[1], J. D. Heaney*[2], N. L. Woll*[1], S. K. Bronson[1]. [1]Cellular and Molecular Physiology, Penn State College of Medicine, Hershey, PA, USA, [2]Case Western Reserve University, Cleveland, OH, USA.

We are initiating a new series of experiments to test the in vivo osteogenic capacity of our murine embryonic stem cell (ESC)-derived osteogenic cultures. Transfer of murine ESCs beneath the kidney capsule or subcutaneously results in a teratoma, reflecting the pluripotent differentiation capacity of embryo-derived stem cells. Conversely, mature osteoblasts while phenotypically stable have restricted proliferative potential and thus limited therapeutic capacity for degenerative, congenital or traumatic bone loss. The goal of these experiments is to determine where in the in vitro differentiation of ESCs to mature osteoblasts we can isolate and transfer a cell population with therapeutic capacity. Cells have been engineered to express EGFP in mature osteoblasts under control of the human osteocalcin gene regulatory sequences contained on a bacterial artificial chromosome (BAC). Progenitors derived from this ESC line will be used to assess the presence of mature, donor-derived osteoblasts in our transplants. Cells will be tested in three different contexts: loading in synthetic scaffolds with subsequent subcutaneous transfer, intravenous injection, and intramedullary injection, with the goal of narrowing down the window of time when cells from osteogenic cultures are capable of engrafting and synthesizing bone matrix. These experiments will provide critical proof of concept for the future use of human ESCs for osteogenic therapies.

Expression of CD24 in Intrervertebral Disk. N. Fujita*[1], T. Miyamoto[1], J. Imai*[2], N. Hosogane*[3], M. Yagi*[1], K. Morita*[3], K. Ninomiya*[1], T. Suzuki*[1], K. Chiba*[3], S. Watanabe*[2], Y. Toyama*[3], T. Suda*[1]. [1]Cell Differentiation, Keio University School of Medicine, shinjuku, Japan, [2]Clinical Informatics, Tokyo Medical and Dental University, Bunkyo, Japan, [3]Orthopaedics Surgery, Keio University School of Medicine, shinjuku, Japan.

Low back pain is one of the most common deseases and constitutes a devastating economic burden on the individual and society. Degeneration of the intervertebral disc (IVD) based on aging is considered as a cause of low back pain, however, the molecular mechanism of IVD degeneration is still unclear. In order to reveal what molecules are expressed in annulus fibrosus (AF) and nucleus pulposus (NP), both of which are the component of IVD, we performed microarray analysis in independent tissues including AF and NP in adult rats. We identified that CD24 was highly expressed in NP compared with other tissues. CD24 is a cell surface glycosyl-phosphatidylinositol-anchored protein. It was reported to be expressed physiologically in pre-B cell, T cell, keratinocyte and renal tubular epithelium. The CD24 expression in NP and its tissue distribution was comfirmed

by real-time PCR analysis and immunohistochemical analysis. The CD24 expression was also detected in notochord from which NP develops and its expression level was not changed in NP between 3 to 40 week old rats, although the expression of chondrogenic extraceller matrix proteins, type2 collagen and aggrecan were reduced as aging. CD24 expression was also detected in the herniated NP as well as the remaining NP in the rat. These results suggested that CD24 is the useful marker to detect the NP and notochordal cells. CD24 was reported to function as a ligand of P-selectin and was expressed in wide variety of malignant tumors such as epithelial ovarian cancer, breast cancer and prostate cancer. We found that CD24 is also expressed in the human chordoma. Chordoma is the common primary malignant neoplasm of the skeletone and is considered to be a notochordal origin. Since the CD24 expression was not detected in chondrosarcomas, CD24 is a new diagnostic marker for chordoma to distinguish from chondrosarcoma. We propose that CD24 is a significant molecular marker for NP, including chordoma.

Enhanced Runx2 Expression Is Accompanied with Degenerative Changes in Canine Intervertebral Disc. H. Ito*[1], Y. Asou[2], S. Takeda[3], Y. Hara*[1], Y. Nezu*[1], Y. Harada*[1], H. Haro*[4], H. Komori*[2], M. Tagawa*[1], K. Shinomiya*[2]. [1]School of Veterinary Medicine, Nippon Veterinary and Animal Science University, Division of Veterinary Surgery, Tokyo, Japan, [2]Tokyo Medical and Dental University, Department of Orthopaedic Surgery, Tokyo, Japan, [3]Tokyo Medical and Dental University, Center of Excellence program for Frontier Research Program on Molecular Destruction and Reconstruction of, Tokyo, Japan, [4]Graduate School of Medicine, University of Yamanashi, Department of Orthopaedic Surgery, Yamanashi, Japan.

Degeneration of the intervertebral disc(IVD) is an underlying etiology in many of spine disorders including intervertebral disc herniation (DH). However, the mechanisms for the degenerative process in the IVD are not well understood. Runx2 is a trancriptional factor that upregurates type X collagen and promotes hypertrophic differentiation of the chondrocyte, both of which are typically observed in degenerated IVD. Therefore, to understand the molecular mechanisms that lead to cartilage degeneration during the progression of disc degeneration, we have investigated the expression of the transcription factor Runx2 in intact or degenerated IVD. Tissue samples were surgically collected from the disc materials of canine disc herniation patients (dachshund, ages 4-7 years, 4-8kg). As control, annulus fibrosus (AF) and the nucleus pulposus (NP) from normal dogs were both collected from young, skeletally mature,beagle dogs (age 1-2 years, 10-12kg). Each sample was divided into two blocks, one for histological analysis, another for RT-PCR analysis. Histological analysis revealed that extruded NP from DH patients showed low proteoglycan content and abundant hypertrophic chondrocyte-like cells. Additionally, immnohistological analysis indicated that the expression of Type II collagen, an essential constituent of the healthy NP, was decreased, whereas the expression of type I and type X collagen, the markers of cartilage degeneration, were enhanced in NP from DH patients. To investigate the contribution of Runx2 in canine bone and cartilage metabolism, complete length of canine Runx2 cDNA sequence was determined with 3'- and 5'-rapid amplification of cDNA ends (RACE) procedure from canine bone tissue. Canine Runx2 cDNA showed over 97% conservation with human RUNX2. Interestingly, RT-PCR analysis demonstrated that Runx2 transcript was specifically expressed in the NP from DH patients, while no expression was detected in control. These results indicate that Runx2 was specifically expressed in herniated IVD, and may contribute to degenerative changes of the IVD.

Betula Platyphylla var. Japonica Inhibits Interleukin-1 α Induced Cartilage Metabolism, Viability, and Morphology in Rabbit Articular Cartilage. D. Kim*[1], J. E. Huh*[2], Y. H. Baek*[2], J. D. Lee*[2], D. Y. Choi*[2], D. S. Park*[2], M. Yoo*[3]. [1]Internal Medicine, Kyung Hee University Hospital, SEOUL, Republic of Korea, [2]Oriental Medicine Research Center for Bone & Joint Disease, Kyung Hee University, SEOUL, Republic of Korea, [3]Orthopedic Surgery, Kyung Hee University Hospital, SEOUL, Republic of Korea.

Articular cartilage is a potential target for drugs designed to inhibit the activity of matrix metalloproteinases (MMPs) to stop or slow the destruction of the proteoglycan and collagen in the cartilage extracellular matrix. Many cartilage protective agents have been developed from natural products. *Betula platyphylla* var. *japonica* (*B. platyphylla*), is one of these natural products, and is widely distributed in Korea, Japan, China, Sahalin, and Siberia. The bark of *B. platyphylla* has been used in folk medicine for the treatment of arthritis, cancer, nephritis, dermatitis, poisoning, and chronic bronchitis. The purpose of this study was to investigate the effects of *B. platyphylla* in inhibiting the release of glycosaminoglycan (GAG), the degradation of collagen, and MMP activity in rabbit articular cartilage explants. The cartilage-protective effects of *B. platyphylla* was evaluated by using GAG degradation assay, collagen degradation assay, colorimetric analysis of MMP activity, measurement of lactate dehydrogenase activity and histological analysis in rabbit cartilage explants culture. Interleukin-1α (IL-1α) rapidly induced GAG, but collagen was much less readily released from cartilage explants. *B. platyphylla* significantly inhibited GAG and collagen release in a concentration-dependent manner. *B. platyphylla* dose-dependently inhibited MMP-3 and MMP-13 expression and activities from IL-1α-treated cartilage explants cultures when tested at concentrations ranging from 0.02 to 0.2 mg/ml. *B. platyphylla* had no harmful effect on chondrocytes viability or cartilage morphology in cartilage explants. Histological analysis indicated that *B. platyphylla* reduced the degradation of the cartilage matrix compared with that of IL-1α-treated cartilage explants. These results indicate that *B. platyphylla* inhibits the degradation of proteoglycan and collagen through the down-regulation of MMP-3 and MMP-13 activities without affecting the viability or morphology of IL-1α-stimulated rabbit articular cartilage explants.

Biological Effects of a Self-Setting Alpha-TCP on Osteogenesis in Combination with Dental Implant Placement. M. Nakadate*[1], N. Amizuka[2], S. Nomura*[1], T. Maeda*[2]. [1]Division of Aging and Fixed Prosthodontics, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan, [2]Division of Oral anatomy, Niigata University Graduate School of Medical and Dental Sciences, Center for Transdisciplinary Research, Niigata, Japan.

This study aimed to evaluate the biological effects of a self-setting alpha-tricalcium phosphate (α-TCP) bone substitute on new bone formation in the concomitant presence of dental implants. 4-weeks-old male Wistar rats had their first and second maxillary molars removed, and dental implants were inserted in the healed extraction area after four weeks. Standardized bone defects surrounding the dental implants were filled with self-setting α-TCP for stabilization. The treated rats were perfused with an aldehyde solution at 1, 2, 4, and 8 weeks post-operatively, and the maxillae were processed for histochemical examination. Bone mineral density (BMD) was measured by peripheral quantitative computed analysis. Bone formation was assessed in two areas: (1) the interface between α-TCP and the implants, and (2) the surface of α-TCP corresponding to the previous alveolar ridge. At the α-TCP/implant interface, new bone formation was showed to progress from the cavity-bottom toward the alveolar ridge. Tartrate-resistant acid phosphatase (TRAPase)-reactive osteoclasts arrived into the narrow α-TCP/implant interface, followed by the migration of alkaline phosphatase (ALPase)-positive osteoblasts that covered thin new bone matrices. Osteopontin-reactive reversal lines on the α-TCP were observed in relation with the invading osteoclasts. On the surface of α-TCP corresponding to the previous alveolar ridge, consistent with the findings at the α-TCP/implant interface, osteoclastic resorption on α-TCP preceded ALPase-positive osteoblastic bone deposition. Moreover, the new formed bone appeared to share the features of compact rather than woven bone, as evidenced by the BMD values (874±140 and 918±104 mg/cm^2 at 4- and 8-weeks, respectively). Thus, bone deposition onto α-TCP was coupled with previous bone resorption, which may give rise to a tissue structure similar to that of compact bone, the gold standard for "bone quality". Our findings suggest that a self-setting α-TCP might be a reliable bone substitute when combined with dental implant placement.

Enhancement of Osteogenesis on NaOH-Treated PLGA Scaffolds. W. Huang, J. Roostaeian*, S. David*, K. Ishida*, G. H. Rudkin*, D. T. Yamaguchi, T. A. Miller*. VA Medical Center of West Los Angeles, Los Angeles, CA, USA.

Chemical etching of scaffolds using NaOH could result in a more hydrophilic surface, increased surface area, altered porosity and pore size, and a greater degree of nanometer roughness. These features might provide a more favorable environment for proliferation and differentiation of bone marrow stromal cells. Treatment of PLGA with NaOH has been shown to enhance osteoblast and chondrocyte function. We assessed the effect of NaOH on oseogenic differentiation by studying rabbit bone marrow stromal cells and mouse pre-osteoblastic MC3T3-E1 cells. PLGA films or scaffolds were treated with 1 N NaOH for 10 minutes. Cells were cultured on NaOH treated PLGA film and scaffolds and their untreated counterparts. NaOH treatment significantly enhanced osteogenic differentiation in both cell types cultured in 3-D scaffolds as measured by increases in mRNA expression of osteocalcin, osteopontin, bone sialoprotein, and Type I collagen. Minimal effect by NaOH was observed on both cell types cultured on 2-D PLGA films. Secretion of alkaline phosphatase was also significantly higher in both cells cultured in treated scaffolds. NaOH treatment also enhanced mineralization of rabbit bone marrow stromal cells cultured in 3-D scaffolds as revealed by von Kossa staining. Treatment of PLGA films with NaOH, however, showed little effect on mineralization of bone marrow stromal cells. These results indicate pretreatment of scaffolds with NaOH stimulates osteogenic differentiation in both undifferentiated bone marrow stromal cells and partially differentiated pre-osteoblastic cells.

Hydroxyl Ions in Bone Mineral Observed By 1D ^{31}P-^{1}H NMR Spectroscopy. Y. Wu[1], J. L. Ackerman*[2], L. Graham*[1], M. J. Glimcher[1]. [1]Orthopaedic Surgery Department, Children's Hospital, Boston, MA, USA, [2]Radiology Department, Massachusetts General Hospital, Boston, MA, USA.

Solid state NMR spectroscopy has recently proved extremely useful in helping to resolve the longstanding controversy over the hydroxyl ion content of bone mineral crystals. Previous 2D ^{1}H-^{31}P heteronuclear correlation NMR methods have detected OH^- ion in bone mineral, but due to their two dimensional nature, these measurements are time consuming (about 24 hrs/spectrum). Here we demonstrate a novel one dimensional solid state ^{31}P-^{1}H reverse cross polarization (CP) NMR method that substantially speeds up the measurement of structural OH^- ion in bone mineral. In the new method, polarization is transferred from ^{31}P to ^{1}H, the reverse of conventional CP. Because the magnetization transfer rate is inversely proportional to the sixth power of the internuclear distance, only those signals arising from protons located within atomic distances of phosphorus will yield

signal, insuring that only mineral crystal proton signals are observed. Experiments were carried out on powdered synthetic HA (hydroxyapatite) and 27 week old chicken bone samples on a 600 Mz Bruker NMR spectrometer. Conventional single pulse proton spectra contain signals from all components of the sample (Fig. 1), but the crystal OH^- and water signals are obscured. Using the new technique (Fig. 2) the matrix signals are completely suppressed and the OH^- and interfacial/crystal water signals from the mineral are readily observed. Peak assignments were determined by comparing CP spectra of bone and HA, and further confirmed by experiments in which the CP contact was turned off, causing these peaks to disappear. One CP spectrum can be obtained in 3 hr for ~ 110 mg of bone specimen powder with good signal to noise ratio. This study further confirms the existence of OH^- in bone mineral crystals and demonstrates that the measurement time can be dramatically reduced by 1D ^{31}P-^{1}H reverse CP experiments.

Oxandrolone Weakly Stimulates Osteoblast Differentiation. L. X. Bi, G. L. Klein, E. G. Mainous, W. L. Buford*, D. N. Herndon*. Depts. of Surgery, Pediatrics and Orthopaedics & Rehabilitation, The University of Texas Medical Branch and Shriners Hopitals for Children, Galveston, TX, USA.

Previous studies have shown that Oxandrolone increases nuclear translocation of androgen receptor and stimulates collagen type I synthesis in vitro (Bi LX et al, JBMR 19: SU489 Suppl. 1, 2004), and in burned children increases lean body mass at 6 mo and bone mineral content at 1 yr post-burn (Murphy KD et al, Surgery 2004;136:219-224). In the present study, we examined expression of osteocalcin and alkaline phosphatase activity (ALP). Human osteoblast cells were cultured in a-minimum essential medium [a-MEM] and 10% fetal bovine serum with or without oxandrolone at the concentration of 5ug, 10ug and 15ug/ml, respectively, for 24 hr. The levels of ALP were assayed using a commercial kit. Expression of osteocalcin (polyclonal antibody, Santa Cruz Biotechnology, Inc. CA) was examined using immunoquantitative assay. ALP activities were elevated (11-20%, $P<0.05$) in oxandrolone-treated group, compared to control group. expression of osteocalcin was increased (12-18%, $P<0.05$) after oxandrolone treatment. While there is a statistically significant increase in both osteocalcin and alkaline phosphatase following oxandrolone stimulation, the increase is small when compared to the magnitude of the dose given. These data suggest that the observed increases in bone mineral content with long-term oxandrolone therapy may be unrelated to direct effects of oxandrolone on osteoblasts.

Neotendon Formation Induced by the Manipulation of Smad8 and BMP2 in Mesenchymal Stem Cells. A. Hoffmann*[1], G. Pelled*[2], G. Turgeman*[2], P. Eberle*[1], Y. Zilberman*[2], H. Shinar*[3], K. Keinan-Adamsky*[3], A. Winkel*[1], S. Shahab*[1], G. Navon*[3], G. Gross*[1], D. Gazit[2]. [1]Signaling and Gene Regulation, Gesellschafter Biotechnologische Forschung (GBF), Braunschweig, Germany, [2]Skeletal Biotech Laboratory, Hebrew University of Jerusalem, Jerusalem, Israel, [3]School of Chemistry, Tel Aviv University, Ramat Aviv, Tel Aviv, Israel.

Members of the Bone Morphogenetic Protein (BMP) family have been shown to have a role in tendon formation in vivo. To date, no specific Smad molecule has been identified to mediate such an effect in mesenchymal stem cells (MSCs). **In this study, we defined a novel mechanism that mediates the differentiation of MSCs into tendon based on the expression of Smad8 and BMP2**. Smad8 and BMP2 were co-transfected to MSCs. The in vitro phenotype of the engineered MSCs was evaluated using RT-PCR, histochemistry and morphology. In addition, the cells were implanted in vivo in ectopic sites and in tendon defects in order to assess their potential in tendon regeneration. 5 weeks post implantation the area of the implantation was isolated and analyzed. Cell survival in the implantation site was non-invasively and quantitatively demonstrated in vivo by the detection of Luciferase bioluminescence. Our results indicated a **tenocytic phenotype** of the engineered MSCs that over expressed the characteristic genes Six1, EphA4 and Scleraxis. Formation of tendon tissue in vivo was confirmed by the finding of dense connective tissue with parallel-organized fibers and spindle shaped cells (A). Electron microscopic analysis showed tightly packed collagen fibers (B). Moreover, we were also able to repair Achilles tendon defects with the engineered MSCs. Bioluminescence imaging monitored cell survival in the operated tendon, and imunohistochemical staining detected the labeled implanted cells in site (C &F). DQF MRI analysis proved that highly ordered collagen fibers were formed in the site of implantation as opposed to the control group (D, E). Since the expression of BMP2 is known to drive MSCs to osteogenic differentiation, we propose that the expression of Smad8 in MSCs induces an inhibition of the BMP2 signaling pathway, resulting in the differentiation of MSCs into tendon cells. This is the first study showing that a specific Smad signaling molecule is involved in tendon formation.

Connective Tissue Growth Factor (CTGF/CCN2) Enhanced Human Bone Marrow Stromal Cell Attachment *In Vitro* and Migration and Survival of the Cells in a Hydroxyapatite Scaffold *In Vivo*. M. ONO*, W. Sonoyama, K. Akiyama*, T. Fujisawa*, T. Nishida, M. Takigawa, T. Kuboki*. Okayama University Graduate School of Medicine, Dentistry and Pharmaceutical Sciences, Japan, Okayama, Japan.

For establishment of bone regeneration in a large scale, adhesion of osteogenic cells (e.g., bone marrow stromal cells: BMSC) to a scaffold, osteoblastic differentiation of the cells and angiogenesis into the scaffold would be necessary. We have previously reported that connective tissue growth factor (CTGF/CCN2) promotes osteoblasts proliferation and differentiation, as well as vascular endothelial cell migration. These results suggest a possibility that CTGF/CCN2 with autologous BMSC transplantation may be useful to accelerate bone formation and to overcome the hypoxia inside of the scaffold. Therefore, we investigated 1) effects of CTGF/CCN2 adsorption to hydroxyapatite (HA) disks on initial human bone marrow stromal cell (hBMSC) attachment in vitro, 2) effect of CTGF/CCN2 addition to a porous hydroxyapatite/hBMSCs hybrid on cells migration and survival of the hBMSCs inside of the hybrid in vivo. The hBMSCs were isolated from human iliac bone marrow of a volunteer and their multipotent (osteoblastic and adipogenic) differentiation abilities were confirmed. Recombinant human CTGF was adsorbed onto HA disks according to Shimo et al. Then the hBMSCs were seeded and allowed to attach onto CTGF-treated disks for 3 hours under a serum-free condition. Disks treated without CTGF were served as control. After removal of non-attached cells, the relative attached cell number was estimated by MTS assay. In addition, the hBMSCs were incubated with or without anti-aVb3 integrin antibody for an hour prior to cell seeding, and the same cell-

attachment-assay was done. Mean value of four wells in each condition was calculated and statistically analyzed by one-way factorial ANOVA followed by Scheffe's multiple comparison tests. Next, hBMSCs were incubated to attach onto porous HA blocks (Pentax Co., Japan) for a week. The porous HA/hBMSCs hybrids were implanted subcutaneously in nude mice (4 week-old) with CTGF (1ug) or distilled water (control). The implants were harvested after 4 weeks for SEM observation. CTGF (100ng/ml) adsorption onto the HA disks significantly enhanced the cell attachment, while the anti-integrin-subunit antibody partially suppressed the enhancement. SEM observation supported that hBMSC-like cells migrated and survived inside of the porous HA scaffold with CTGF application, while without CTGF, no viable cells were observed inside of the scaffold. These results suggested that CTGF enhanced hBMSC attachment onto HA disks in vitro, and migration and survival of the cells inside of the HA scaffold in vivo.

Effects of Ultrasound Stimulation on the Proliferation and Metabolism of Cementoblasts *In Vitro*. D. A. Dalla-Bona[1], E. Tanaka*[1], H. Oka*[2], E. Yamano*[1], N. Kawai*[1], M. Miyauchi*[2], T. Takata[2], K. Tanne*[1]. [1]Department of Orthodontics and Craniofacial Developmental Biology, Hiroshima University Graduate School of Biomedical Sciences, Hiroshima, Japan, [2]Department of Oral Maxillofacial Pathology, Hiroshima University Graduate School of Biomedical Sciences, Hiroshima, Japan.

Root resorption is an adverse outcome of orthodontic tooth movement. Recently, it has been shown that ultrasound (US) stimulation accelerates repair of orthodontically induced root resorption in *in vivo* human study. However, the mechanism by which US achieves these outcomes is not clear. Cementoblast is one of the cells involved in root repair process. The aim of the present study was, thus, to evaluate the effect of US exposure on proliferation and metabolism of cementoblast *in vitro*. Cultured cementoblasts, mouse cementoblastic cell line (OCCM-30), received US exposure (frequency = 1 MHz; intensity = 100, 150 or 400mW/cm^2) or sham exposure for 15 min per day for 4 days, and then assayed for cell proliferation and calcium concentration. Expression levels of osteocalcin (OCN), bone-sialoprotein (BSP), alkaline phosphatase (ALP) and osteopontin (OPN) were analyzed by real time-PCR. Furthermore, we investigated the effects of US exposure on the gene expression of interleukin-1 beta (IL-1ß), interleukin-6 (IL-6), OPG and receptor activator of NF-kappa B ligand (RANKL). US exposure had no effect on cell proliferation. Calcium concentration was statistically increased ($p<0.05$) after US exposure at 100 or 150 mW/cm^2 compared with control. US exposure had no effect on transcripts for OPN, OCN and BSP. In contrast, ALP mRNA levels were significantly ($p<0.05$) increased by US stimulation with 150 mW/cm^2. Expression levels of IL-1 ß, IL-6, OPG and RANKL were not significantly altered by US. These results demonstrate that US alters cementoblast function *in vitro* and may be an important candidate as a medical remedy to accelerate repair of root resorption.

Evaluation of the Efficacy of Vitamin D3 and its Metabolites to Prevent Thiram-Induced Growth Plate Dysplasia in Chickens. N. C. Rath[1], W. E. Huff*[1], G. R. Huff*[1], R. L. Horst*[2]. [1]PPPSRU, USDA, ARS, Fayetteville, AR, USA, [2]NADC, USDA, ARS, Ames, IA, USA.

Tibial dyschondroplasia (TD) is a metabolic disorder in rapidly growing broiler chickens and turkeys that is characterized by the failure of growth plate cartilage to be replaced by bone. Although the natural etiology of the disease is not understood, it has been suggested that diets supplemented with certain vitamin D metabolites could ameliorate TD in birds that were induced TD feeding Ca: P imbalanced diets. We have currently developed an experimental model of TD using tetramethyl thiuram disulfide (thiram), a dithiocarbamate pesticide, which when included in the diet at a concentration of 100 ppm between 1-3 week of age induces TD in more than 90% of chickens. Using this model the objective of our study was to evaluate the ability of vitamin D_3 or its selective metabolites to prevent TD in chickens. Groups of broiler chickens were fed control or diets supplemented with vitamin D_3 or its different metabolites over and above the content of vitamin D_3 in the control diet. The study consisted of birds that were fed *ad libitum* (a) control non supplemented feed, (b) vitamin D_3, 4,000 IU cholecalciferol / kg, (c) HYD™, a 25 $(OH)_2$ D_3 , 63 µg/ kg, (d) low dose 1, 25 $(OH)_2$ D_3: 1 µg /kg, and, (e) high dose 1, 25 $(OH)_2$ D_3: 5 µg /kg, starting from day of hatch. On day 7 feed was withdrawn for a period of 12 h after which each group was divided into two sub groups of 25 birds each. One received its assigned diet while the other received the same diet containing 100 ppm thiram for a period of 48 h. At the end of experimental thiram feeding, all birds in each group received their assigned diets until the day of necropsy on day 15. The birds were weighed, bled prior to necropsy and the tibial growth plates were evaluated for TD index (incidence times severity score) (scores: 0= normal, 1= growth plate width increased more than 2 times, and 2= growth plate size increased more than 3 times). Some growth plates were processed for histological evaluations. In all birds that received thiram treatment, regardless of vitamin D treatment, the body weight was significantly reduced ($p\leq 0.005$) and the TD index remained high (≥ 1.7) as compared to ≤ 0.2 in birds that did not receive thiram. Thiram caused chondrocyte apoptosis and blood capillary atrophy in the hypertrophic zone. It is concluded that extra supplementation of vitamin D or its metabolites do not protect birds against thiram-induced TD.

Effects of Halogenated Hydrocarbons and Electromagnetic Field on Bone Tissue. Z. Valkusz[1], L. Gáspár*[1], M. Radács*[2], A. Juhász*[3], A. Petri*[4], M. Gálfi*[2]. [1]Dept. of Endocrinology, University of Szeged, Szeged, Hungary, [2]Environmental Protection Group, Faculty of Juhász Gyula Teacher Training College, Szeged, Hungary, [3]Department of Psychiatry, University of Szeged, Szeged, Hungary, [4]Department of Surgery, University of Szeged, Szeged, Hungary.

The formation and eventually the functionability of the osteocytes are determined by the modifications of extracellular environment. The structure of bone tissue is changed after hexa-chlorobenzene (HCB) or electromagnetic field (EMF) treatment. The chemical potential of HCB is low, because this agent has nonreactive activities. These facts can cause the main biological effects of HCB: eg. deponation into different organisms and can modify biological food cascades. The biological effects of EMF depend on its energy content, frequency, wave-length. Thus environmental effects (chemical and/or physical) play a very important role among the factors inducing osteoporosis. We have investigated how they effect the bone structure by extremely low doses (eld) of HCB diet, and of eld-EMF chronic treatment. Wistar rats (male, 100-250g/bw.) were treated orally with chlorobenzenes (HCB 0,5 µg/bw. kg) for 30 and 60 days. We administered the compound through gastric tubes. The HCB pretreated rats were then exposed to eld EMF (50 mT, 60Hz) for further 30 days. The investigated were taken from the bone (femur) tissues of treated and control animals. Tissue structure and Ca^{2+} content of the bone, and liver function were estimated by determination of γGT, SGOT, SGPT). Bone structure were investigated by morphometry. As a result of the chronic chlorobenzene treatment (60 days) showed significant changes in the femur. This modification of bone tissue consisted of significant change in the Ca^{2+} content of the bone matrices. After the combined treatment (HCB pretreating + eld-EMF exposition) femur samples showed no differences than that of the control animals. The eld-EMF alone has not caused significant changes according to the examined parameters. From our results we suppose that the EMF treatment can protect the degenerative effects of HCB on bone structure.

gp130-Mediated Signaling Is Important for the Normal Morphogenesis of Meckel's Cartilage and Subsequent Mandibular Development. J. W. Choi*[1], J. T. Kim*[1], J. Y. Choi[2], S. Y. Kim[2], E. K. Park[2], H. I. Shin[1]. [1]Oral Pathology, School of Dentistry, Kyungpook National University, Daegu, Republic of Korea, [2]Skeletal Diseases Genome Research Center, Kyungpook National University, Daegu, Republic of Korea.

gp130-Mediated signaling is involved in both chondrogenesis and osteogenesis, but its direct role in the mechanism of embryonic Meckel's cartilage and associated mandibular development has not yet been elucidated. In this study, we examined the influence of gp130 ablation on the developing mandibular Meckel's cartilage by evaluating the morphological and histological changes as well as the gene expression patterns in developing embryonic *gp130-/-* mice. The ablation of the gp130 gene showed no change in region-specific collagen mRNA expression except for a slight delay in its expression but caused shortened embryonic Meckel's cartilage, delayed hypertrophic chondrocyte maturation and subsequent bony replacement with characteristic bending of the intramandibular Meckel's cartilage. The bending of Meckel's cartilage leads to a narrow mandibular arch at the rostral area with poor cortical plate formation. These findings indicate that gp130-mediated signaling is important for the normal morphogenesis of Meckel's cartilage and subsequent mandibular development.

Both Risedronate and PTH Maintain Bone Mechanical Properties and Matrix Composition in a Mouse Model of Glucocorticoid-Induced Osteoporosis. G. Balooch*[1], W. Yao*[2], R. K. Nalla*[3], J. H. Kinney*[1], M. Balooch*[1], N. E. Lane[2]. [1]University of California, San Francisco, San Francisco, CA, USA, [2]University of California, Davis, Davis, CA, USA, [3]Lawrence Berkeley National Laboratory, Berkeley, CA, USA.

Glucocorticoid-induced osteoporosis (GIOP) commonly results from suppression of bone formation and enhancement of bone resorption, which alters bone structure and induces bone fragility. Bisphosphonates, acting as anti-resorptive agents, and anabolic agents, are effective therapies in the prevention and treatment of GIOP in clinical trials; however, the mechanism by which they increase bone strength is not yet clear. The purpose of this study was to assess if concurrent treatment of mice with GCs + Risedronate (RIS) or GCs + PTH would maintain bone mechanical properties (local and global) and bone mineral concentration (BMC) compared to GC treatment alone. Four groups of mice were randomized to placebo, GC (1.5mg/kg in a slow-release pellet that was s.c. implanted x 21 days), GC + RIS (5µg/kg, sc, 5X/wk) and GC + hPTH (1-34) (40µg/kg, sc, 5X/wk- and treated for 21 days). After sacrifice, the following procedures were done: microCT for trabecular microarchitecture and compression tests of 3rd LVB. The 4th LVB were processed for Elastic Modulus Mapping (EMM), a scanning probe microscopy-based technique that allows high resolution (15nm) mapping of elastic modulus (E) surrounding osteocyte lacunae. In addition, synchrotron x-ray tomography (XTM) analysis was performed on femurs to assess changes in BMC. Finally, EMM and XTM were performed

on iliac crest biopsies from GC and GC+RIS treated subjects. Treatment with GCs reduced BV/TV by 53% and both GC+RIS and GC+PTH treatment prevented loss of BV/TV. Compared to the PL group, E was reduced by 66% and 58% in GC-treated mice ($p<.001$) and humans ($p<.05$), respectively, along the trabeculae perimeter and surrounding the osteocyte lacunae; however, E was maintained with GC+ RIS and GC+ PTH groups. Compression tests of the LVB3 in mice treated with GC+ PTH and GC+RIS revealed a 62% and 88% increase in strength ($p<.001$), 64% and 61% increase in compression modulus ($p<.001$), and 51% and 39% increase in stiffness ($p<.01$), respectively, compared to PL mice. XTM analysis revealed a 45% and 31% reduction in BMC in the trabeculae of both GC-treated mouse ($p<.01$) and human bone ($p<.01$), respectively, while GC+RIS and GC+PTH treatment led to a 33% ($p<.01$) and 48% ($p<.01$) increase in BMC compared to PL, respectively. These results indicate that PTH and RIS treatments in the presence of GCs prevent the deterioration of BMC and both local and global mechanical properties. Therefore, these therapies appear to be effective means in reducing bone fragility in GC treated individuals.

Achieving Bone Augmentation with Hydroxyapatite and a Polylactic Acid Plate: A Histological Study in Rats. T. Kojima*[1], N. Amizuka[2], C. Saito*[1], T. Maeda*[2]. [1]Division of Reconstructive Surgery for Oral and Maxillofacial Region, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan, [2]Division of Oral Anatomy, Niigata University Graduate School of Medical and Dental Sciences, Center for Transdisciplinary Research, Niigata University, Niigata, Japan.

One of the primary goals for bone augmentation is the establishment of compact bone with rigidity, toughness and strength --desirable bone quality--, in addition to the induction of new bone grown up to, or higher than the previous bone surface. We applied a polylactic acid (PLA) plate that is clinically used for osteosynthesis and hydroxyapatite (HA) as the grafting material to surgically-created bone defects, and then, evaluated the histological alterations. Standardized bone defects (ϕ 5mm) in rat calvariae were filled with a compound of atelo-collagen and authentic bovine HA, commercially available as Boneject®, and then covered with a molded PLA plate (DeltaSystem®). The rats were fixed with an aldehyde solution at 1, 2, 4, 8 and 12 weeks post-operation, and the newly-formed bone in the defects was examined for alkaline phosphatase (ALP), tartrate resistant acid phosphatase (TRAP), osteopontin (OPN) and osteocalcin (OCN). One week after surgery, HA particles revealed OPN- and OCN-immunopositivity at their surfaces. At the bottom of the cavity, ALP-positive cells were found covering the HA particles, suggesting that bone proteins *i.e.,* OPN and OCN, may accumulate on HA-surfaces to affect osteoblastic migration and attachment. At 2 weeks, woven bone with many ALP-positive osteoblasts and osteocytes extended from the bottom of pre-existing bone, and surrounded the HA particles. At 4 weeks, the new bone attained at the level of the PLA plate, only separated by a thin fibrous layer without ALP-positivity. ALP-positive osteoblasts and TRAP-positive osteoclasts were abundantly localized at the surfaces of the new bone, indicative of bone remodeling. At 8 and 12 weeks, the new bone encompassing the HA particles increased in width and showed the histological profile of compact bone, which, therefore, seemed to satisfy, al least in part, preferable bone quality. Thus, the combination of HA and a PLA plate appears to promote desirable osteoconduction and bone remodeling, resulting on compact bone formation.

Implication of Connexin43 Gap Junctions in the Responsiveness of HIG-82 Cells to Interleukin1 Beta Treatment. C. Niger*, F. Lima*, J. P. Stains. Orthopaedics, University of Maryland School of Medicine, Baltimore, MD, USA.

Synovial inflammation is one of the changes observed in osteoarthritis (OA) pathophysiology. Current evidences attribute a key role to the matrix metalloproteinases (MMPs), which control the breakdown of the cartilage extracellular matrix, in OA disease progression. Previous studies have shown that cytokines such as interleukin-1 beta (IL1), produced by activated synoviocytes, up-regulate MMP gene expression. Recently, connexin43 (Cx43)-mediated gap junctional intercellular communication between synovial lining cells was also shown to contribute to the etiology of OA. Previously, we have reported that gap junctions play a critical role in regulating signaling and gene transcription in osteoblasts. Accordingly, we set out to examine the role of Cx43 gap junctions in synovial cell responses induced by IL1, to determine if an analogous process occurs in these cells. First, we have shown that treatment of HIG-82 rabbit synovial fibroblast cell line for 16 hours with 100 pg/ml IL1 stimulates Cx43 protein expression 1.6-fold, as determined by western blotting. Further, transient transfection of Cx43 in synovial fibroblasts results in an increase of MMP-1 (1.3-fold), MMP-13 (1.7-fold) and cyclooxygenase-2 (COX-2, 2.24-fold) gene expression by real time PCR, suggesting that gap junctional intercellular communication can mediate regulatory signals of these genes. However, the action of IL1 on Cx43-transfected cells is still under investigation. In addition to a direct effect of IL1 on Cx43 protein expression, we have shown that gap junctions further regulate signaling activated by IL1. IL1-treated HIG-82 cells activate extracellular signal regulated kinase (ERK) and treatment of the cells with the gap junction inhibitor glycyrrhetinic acid decreases the magnitude of the ERK activation, as determined by western blotting. Thus, we propose a model in which low grade inflammation present in the synovial fluid during OA induces Cx43 expression, which leads to up regulation of genes associated with cartilage destruction. Further, Cx43 may propagate and the downstream effects of IL1, as disruption of Cx43 gap junctional communication can attenuate the effects of IL-1b on HIG-82 cells. In conclusion, our results indicate that Cx43-mediated gap junctions enhance transcription of specific genes implicating in osteoarthritis pathophysiology and could represent a target for IL1ß action in promoting the progression of OA.

Twist **Gene Dosage may Contribute to Craniofacial Defects in Endothelin-A Receptor (*Ednra*) Mutant Mice.** M. Abe, D. E. Clouthier*. Department of Molecular, Cellular and Craniofacial Biology, Birth Defects Center, Univ. of Louisville, Louisville, KY, USA.

Much of the bone, cartilage, and connective tissue of face and neck is derived from cephalic neural crest cells (NCCs). Multiple signaling molecules are involved in the precise patterning and differentiation of NCCs, one of which is endothelin-1 (Edn1), whose binding to the endothelin-A receptor (Ednra) on neural crest cells induces multiple signaling cascades. Targeted inactivation of either *Edn1-/-* or *Ednra-/-* results in severe craniofacial defects in lower jaw and middle ear structures, including homeotic transformation of the mandible into an upper jaw-like structure. This correlates with changes in gene expression in the mandibular portion of the first arch (from which the lower jaw arises), including loss of distal gene expression involved in mandible development and an up-regulation of gene expression normally associated with more proximal arch gene expression. One gene whose expression is upregulated in *Ednra-/-* embryos encodes the basic helix-loop-helix (bHLH) transcription factor Twist. A recent study shows that *Twist* and the bHLH molecule *Hand2* functionally antagonize each other in limb development. Since *Hand2* expression is down-regulated in *Ednra-/-* embryos, it is possible that an upregulation of *Twist* in addition to loss of *Hand2* might contribute to the observed facial defects. To address this point, we crossed *Twist* mutant mice onto the *Ednra-/-* background and then examined the phenotypic consequences. We find that midline clefting frequently observed in the lower jaw of E18.5 *Ednra-/-* embryos is not present in E18.5 *Ednra-/-;Twist+/-* embryos. Further, tongue formation is partially rescued and soft tissue is more abundant around the lower incisors. These findings suggest that alterations in bHLH levels (and the types of heterodimers and homodimers subsequently formed) may play a role in the mis-patterning of NCCs observed in *Ednra-/-* embryos.

Hyaluronan Inhibits MMP-1 and -3 Productions Induced by IL-1 beta in Rheumatoid Synovial Fibroblast via ICAM-1. T. Hiramitsu*[1], T. Yasuda*[2], H. Ito[1], M. Shimizu*[1], T. Nakamura*[1]. [1]Department of Orthopaedic Surgery, Kyoto University, Graduate School of Medicine, Kyoto, Japan, [2]Department of Sports Medicine, Tenri University, Faculty of Health, Budo, and Sports Studies, Tenri, Japan.

In rheumatoid arthritis (RA), it is well known that rheumatoid synovial fibroblasts (RSFs) produce metalloproteinases (MMPs) stimulated by cytokines such as inteleukin-1β (IL-1β), which causes joint destruction in those patients. As one of the treatments, it has been reported that hyaluronan (HA) injection into RA joints has clinically beneficial effects, but how it works remained to be clarified. We have previously shown that HA inhibits IL-1β actions in RSFs via CD44, one of HA receptors, but that CD44 only mediates the HA effects partially, which led us to speculate that other receptors of HA do as well. Thus, we investigated whether HA affected matrix metalloproteinase (MMP) -1 and -3 productions induced by IL-1β in RSFs and whether intercellular adhesion molecule-1 (ICAM-1), one of HA cell surface receptors, was involved in the HA effects. Human rheumatoid synovial tissues were obtained from patients with rheumatoid arthritis (RA) at total knee replacement surgery. RSFs were isolated from the rheumatoid synovial tissues by enzymatic digestion and were cultured in monolayer. RSFs of 3 - 7 passages were examined. The confluent cells were incubated for 48 hours with IL-1β at 2 ng/ml, IL-1β plus HA at the various concentrations, IL-1β plus HA after the pretreatment of anti ICAM-1 antibody at the various concentrations, or without any treatment. MMP-1 and MMP-3 secretions were analyzed by immunoblotting of the conditioned media. Immunofluorescent cytochemistry was performed to evaluate HA binding to ICAM-1. MMP-1 and MMP-3 were markedly produced by 2 ng/ml IL-1β stimulation, and HA at more than 2 mg/ml significantly inhibited MMP-1 and MMP-3 productions induced by IL-1β in a dose dependent manner. Moreover the pretreatment with anti ICAM-1 antibody at 50 μg/ml significantly attenuated HA effect for IL-1β action on RSFs. Immunofluorescent cytochemistry demonstrated that, indeed, HA bound to RSFs, and that the pretreatment with anti ICAM-1 antibody partially prevented HA from binding to RSFs. It also showed that anti ICAM-1 antibody hardly bound to RSFs after the pretreatment with HA. Therefore HA bound to RSF, at least partially, via ICAM-1. Taken together, we conclude that HA suppresses IL-1β action on RSFs via ICAM-1.

Regulation of the Expression of MMP-13 by Reactive Oxygen Species in Chondrogenic ATDC5 Cells. K. Morita*[1], T. Miyamoto[2], H. Takaishi*[1], M. Yagi*[2], N. Fujita*[2], K. Ninomiya*[2], T. Suzuki*[2], Y. Toyama*[1], T. Suda*[2]. [1]Orthopaedic Surgery, School of Medicine, Keio university, Tokyo, Japan, [2]Cell Differentiation, School of Medicine, Keio university, Tokyo, Japan.

The matrix metalloproteinases (MMPs) are the extracellular matrix (ECM) degrading proteins, and play crucial roles in many pathological and physiological processes, including cell growth, differentiation, tissue remodeling and destruction. MMPs are consisted of 25 subtypes in vertebrates. Among them, MMP-13 (also known as collagenase-3) plays a central role of degrading proteoglycans and collagens of cartilage ECM, and it is reported to be involved in destruction of articular cartilage in osteoarthritis (OA) and rheumatoid arthritis (RA). Recently, it has been shown that reactive oxygen species (ROS) of joint fluid was increased in OA and RA. In this study we analyzed the induction of MMP-13 expression by ROS in chondrogenic ATDC5 cells. The expression of MMP-13 was upregulated by hydrogen peroxide (H2O2) and buthionine sulfoximine (BSO) as ROS in ATDC5 cells, and this induction was abolished by addition of anti-oxidant, N-acetylcysteine (NAC). To detect the intracellular signal transduction mechanism of this induction, phosphorylation of mitogen-activated protein kinase (MAPK), such as p38, extracellular signal-regulated kinase (ERK) 1/2 and c-Jun N- terninal kinase (JNK), by H2O2 was investigated. Phosphorylation of p38 and ERK1/2 were rapidly induced by H2O2, while JNK was not. The phosphorylation of p38 and ERK1/2 by H2O2 were inhibited by NAC, resulting in inhibition of the induction of MMP-13. Furthermore, MAPK specific inhibitors, SB203580 (p38 inhibitor) and U0126 (ERK inhibitor) inhibited the MMP-13 expression, while SP600125 (JNK inhibitor) did not, indicating that p38 and ERK1/2 pathways were involved in MMP-13 induction by ROS in chondrogenic ATDC5 cells. These results suggest that ROS might be involved in cartilage degradation of OA and RA by inducing MMP-13 expression via p38 and ERK1/2 pathways.

Assembly and Reorganization of Bone Extracellular Matrix Proteins Imaged in Living Osteoblasts. P. Sivakumar[1], Q. Chen[1], B. J. Rongish*[2], A. Czirok*[2], V. P. Divakara*[1], V. Dusevich*[1], S. L. Dallas[1]. [1]Univ. of Missouri, Kansas City, MO, USA, [2]Univ. of Kansas Med Cntr, Kansas City, KS, USA.

Fibronectin (FN) is an extracellular matrix (ECM) glycoprotein critical for cell adhesion, migration and survival. Osteoblast-like cells lacking the gene for FN show impaired mineralization and fail to assemble multiple bone ECM components, including type I collagen (Col I), fibrillin-1, decorin, biglycan and latent TGF-beta binding protein-1 (LTBP1). To gain further insights into the mechanisms of assembly of FN and its spatial and temporal interactions with other bone ECM proteins, we have performed dynamic imaging in living osteoblasts using fluorescent probes for ECM components. We have also developed computational techniques to analyze cell and ECM fibril kinetics. Dual imaging of FN together with LTBP1 or Col I indicated that these proteins were initially co-assembled onto similar fibrils in the ECM of primary osteoblasts (FRC). These fibrils were highly elastic and continually underwent large dynamic movements in response to cell motion. Motile cells appeared to actively participate in ECM assembly by moving or shunting “globules” or "packets" of fibrillar material onto growing fibrils. The cells also reorganized the assembled ECM by shunting fibrillar material and/or exchanging material between fibrils. In mature FRC cultures, LTBP1 and Col I were found in fibrils that were distinct from FN, suggesting ECM reorganization or partitioning. These distinct fibrillar networks showed different dynamic properties in response to cell movement. A more detailed dynamic imaging analysis of FN assembly revealed that FN was initially incorporated onto the cell surface as small spots/patches, resembling focal adhesions, which then progressively coalesced to form fibrils. Individual fibrils received contributions from multiple cells. Pulse-chase analysis using alexa488-green followed by alexa555-red labeled FN showed that newly incorporated FN first assembled into spots/patches on the cell surface, which then redistributed to become co-localized with pre-existing fibrils. Quantitative analysis showed that redistribution was maximal after 12h and was inhibited by jasplakinolide, an actin destabilizing agent, suggesting that cell motility is critical for FN redistribution. Vector displacement mapping showed that the motions of cells and fibrils were significantly correlated. Our data suggest novel mechanisms by which motile cells may participate in the assembly and reorganization of bone ECM proteins and confirms a key role for FN in the assembly of Col I. These findings have important implications in normal bone physiology as well as diseases associated with defective collagen assembly.

Homocysteine Modification of Matrix Proteins - a Potential Mechanism of Osteoporosis and other Diseases of "Normal" Aging. C. Prince[1], C. Krumdieck*[2]. [1]University of Alabama at Birmingham, Birmingham, AL, USA, [2]Nutrition Sciences, University of Alabama at Birmingham, Birmingham, AL, USA.

Five years ago we recognized that several diseases common to late life (presbyopia, occlusive vascular disease, osteoporosis and cognitive decline) have parallels with manifestations of homocystinuria (ectopia lentis, occlusive vascular disease, osteoporosis, and mental retardation)(1). We proposed that these manifestations, which occur at a young age in homocystinuria (in which plasma homocysteine (Hcy) is often >100M), develop only after many years of exposure to moderately elevated levels of plasma Hcy. For example, osteoporosis is detectable by radiographs in 80% of untreated homocystinuric patients by age 30(2). Recently, Sato et al(3), among others, have shown that prolonged, moderately elevated Hcy (~20-30 M) is likely to have a causal role in the development of osteoporosis, and should, by extension, play a similar role in the other diseases of aging. Because of a lack of change in bone mineral density, Sato, et al.,(3) speculated that the mechanism underlying their observed association may involve interference in collagen crosslinking resulting in the formation of an altered bone matrix. Indeed, collagen crosslinking may be affected, but similarities in connective tissue pathologies of homocystinuria, Marfan syndrome, sulfite oxidase deficiency and molybdenum cofactor deficiency are informative as to mechanism of action. Marfan syndrome is caused by mutations in the fibrillin-1 gene that disrupt disulfide bonds in epidermal growth factor-like repeats of the fibrillin molecule, while Hcy has the capacity to break and rearrange disulfide bonds in similar protein domains (4). (Similarly, the sulfite anion, which accumulates in sulfite oxidase and molybdenum cofactor deficiencies, also reacts avidly with protein thiols breaking disulfide bridges). Thus, post-translational “homocysteinylation” of fibrillin-1 and other disulfide rich proteins, with disruption of critical disulfide bonds, may play a causal role in many connective tissue disorders often associated with “normal” aging, including, but not limited to, osteoporosis. In support of this hypothesis, we have preliminary data which show that human adult bone matrix protein extracts release high levels of Hcy on reductive cleavage.

Non-Enzymatic Glycations of Bone Collagen Modify Osteoclastic Activity. U. Valcourt*, B. Merle*, E. Gineyts*, P. D. Delmas, P. Garnero. INSERM Research Unit 403 - Hôpital E. Herriot, Lyon, France.

Type I collagen, the major organic component of the bone matrix, undergoes a series of enzymatic and non-enzymatic posttranslational modifications that are altered with ageing and osteoporosis. Among these, advanced glycation end products (AGEs), which are formed by a non-enzymatic reaction between amino groups of proteins and sugars, can modify both the biological properties of affected structural proteins and cellular activity, through their interaction with specific cell-membrane receptors including RAGE. Pentosidine -one of the most investigated AGEs- has been shown to markedly increase with age in human bone and to be associated with alterations of bone biomechanical properties, although the influence of AGEs on bone remodelling is unknown. The aim of our study was to investigate whether the bone content in AGEs modifies osteoclastic activity. We used an in vitro model of bone resorption based on the seeding of rabbit unfractionated bone cells enriched in osteoclasts on 3-month-old calf cortical bone or ivory slices incubated with or without ribose (0.2 M for 45 days), a mediator of AGEs formation. Bone resorption was evaluated by measuring the number and the area of the resorption cavities on the slices and the release in the culture media of the type I collagen degradation products, CTX and helical peptide (ELISA), and hydroxyproline (HPLC). The bone content of pentosidine in bone or ivory slices incubated with ribose was 0.75±0.1 mol/mol of collagen and not detectable in untreated specimens. When osteoclasts were cultured for 3 days on AGE-modified matrices, there was little variation of the total area of bone resorbed, whereas the number of pits increased (from +19% to +42%). Consequently, the area of bone resorbed per cavity was decreased (from -23% to -43%). At 8 days the total area of bone resorbed also decreased. Inhibition of bone resorption was also supported at 8 days by a marked and consistent reduction of the release of collagen fragments in the culture media as judged by CTX (average: -92%), helical peptide (-90%) and hydroxyproline (-68%) concentrations. The content of AGEs in bone matrix influences osteoclast-mediated bone resorption in vitro. These findings suggest that the extent of non-enzymatic posttranslational modifications of type I collagen could play a role in the alterations of bone remodelling associated with aging and metabolic bone diseases including osteoporosis. The molecular mechanisms by which AGEs modulate osteoclast activity remain to be determined.

OA-Derived Peptides Stimulate Osteoblast Adhesion, Spreading, Migration and Differentiation. I. Arango-Hisijara*, J. M. Reyes*, J. LeGates*, S. N. Popoff, F. F. Safadi. Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, USA.

Osteoactivin (OA) plays an important role in the regulation of osteoblast differentiation and function. In a previous study, OA-derived peptides termed the OA-D peptide that has the RGD domain and the OA-E peptide that has glutamic acid (E) in the place of aspartic acid (D) stimulated osteoblast differentiation in an RGD-independent manner. In this study, we examined the role of both peptides as extracellular matrices on osteoblast adhesion, migration and differentiation. MC3T3-E1 osteoblast-like cells were plated on a polystyrene non-tissue culture plate coated with either peptides at various concentrations (5-20 µg/well), cells adhered to poly-L-lysine served as control, an adhesion assay was then performed. Both peptides stimulate osteoblast adhesion in a dose-dependent manner with more profound effect using the RGE peptide. These data suggest that OA stimulates osteoblast adhesion in an RGD-independent manner. We next examined the formation of focal adhesion in osteoblasts adhered to OA peptides. Cells were plated in dishes pre-coated with either OA-D or OA-E peptides and incubated at different time points (0-18 hours). The phosphorylated focal adhesion kinase (p-FAK) was evaluated by Western blot

analysis. p-FAK was increased reaching maximum at 2 hours in cells adhered to OA-E when compared to control. We next examined osteoblast migration in response to OA peptides. Cells were plated in chamber slides pre-coated with either peptide OA-D or OA-E, cells were then wounded with pipette tips and wound healing was evaluated. Osteoblasts migration was enhanced in cells adhered to OA peptides when compared to control. Osteoblast adhesion to OA peptides also stimulated the formation of focal adhesion and cytoskeletal re-organization as determined by immunofluorescent staining for vinculin and TRITC-conjugated phalloidan, respectively. These results indicate that OA derived peptides play a role in osteoblast spreading, formation of focal adhesion and actin cytoskeletal re-organization and migration. We next examined the effect of OA peptides as an extracellular matrix on osteoblast differentiation. Primary osteoblast cultures were plated in dishes pre-coated with OA peptides or Poly-L-Lysine and examined for their differentiation using alkaline phospahtase staining. Osteoblasts that adhered to OA-peptides differentiated faster than cells adhered to Poly-L-Lysine. Collectively, this might explain, in part, the role of OA-derived peptides in stimulating osteoblast differentiation and function.

Periostin-Like-Factor: A Putative Anabolic Factor in Bone Formation. S. Zhu*, F. Safadi, J. Litvin*. Anatomy and cell Biology, Temple University, Philadelphia, PA, USA.

We have identified a new isoform of periostin, referred to as Periostin-like-factor (PLF). PLF was identified in the developing mouse heart. It is also expressed in bone and vascular smooth muscle cells. Our findings show that (1) PLF is a secreted protein, (2) PLF promotes and accelerates osteoblast differentiation in vitro and (3) PLF promotes bone formation in vivo. The effect of PLF over-expression in osteoblasts in vitro was assessed by alkaline phosphatase staining, von kossa staining to evaluate nodule formation and mineralization and by RT-PCR to evaluate the expression of osteoblast-specific differentiation markers. Over-expression of PLF in primary osteoblasts accelerated alkaline phosphatase expression and resulted in nodule formation after only eight days in culture. These findings were compared to those obtained from untreated cells or cells infected with control adenovirus expressing GFP or LacZ. In vivo, over-expression of PLF in the bone marrow cavity of six-week-old rats induced bone formation within the marrow cavity.Therefore, we conclude that PLF mediates osteoblast differentiation in vitro and bone formation in vivo.

CTGF-Derived Peptide (CTGF-P) Stimulates Osteoblast Adhesion, Spreading and Differentiation. I. Arango-Hisijara*[1], R. A. Kanaan*[2], F. F. Safadi[1], S. N. Popoff[1]. [1]Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, USA, [2]Department of Orthopedics, University of Pennsylvania School of Medicine, Philadelphia, PA, USA.

Connective tissue growth factor (CTGF/CCN2) is a member of the CCN family of secreted proteins that regulates multiple cellular functions In previous studies we showed that recombinant CTGF protein (rCTGF) stimulated osteoblast proliferation and differentiation in vitro, supported by the osteogenic effect in vivo. Our recent studies showed that the rCTGF stimulates osteoblast adhesion in a dose dependent manner, and that αv β5 integrin is the adhesion receptor for CTGF in osteoblasts. In this study, we examined the role of a C terminus CTGF-derived peptide (CTGF-P) in osteoblast adhesion, migration and differentiation. MC3T3-E1 osteoblast-like cells were plated in a polystyrene non-tissue culture plate coated with CTGF-P at various concentrations (2-50 μg/well), an adhesion assay was then performed. CTGF-P stimulated osteoblast adhesion in a dose-dependent manner. We next examined the formation of focal adhesion in osteoblasts adhered to CTGF-P. Cells were plated in dishes pre-coated with CTGF-P peptide or Poly-L-Lysine, as control, and incubated at different time points (0-30 minutes). The phosphorylated focal adhesion kinase (p-FAK) was evaluated by Western blot analysis. p-FAK was increased reaching maximum at 10 min in cells adhered to CTGF-P when compared to control. We next examined whether this adhesive property of CTGF is mediated through the extracellular signal regulated kinase (ERK) pathway, osteoblasts were plated in dishes pre-coated with CTGF-P and incubated at different time points (0-2 hours). The phosphorylated-ERK (p-ERK) was evaluated by Western blot analysis. p-ERK was increased reaching maximum at 1 hour in cells adhered to CTGF-P, suggesting that MAPK family is involve in regulating osteoblast adhesion to CTGF. Osteoblast adhesion to CTGF-P also stimulated the formation of focal adhesion and cytoskeletal re-organization determined by immunofluorescent staining for vinculin and TRITC-conjugated phalloidan, respectively. We next examined the effect of CTGF-P as an extracellular matrix on osteoblast differentiation. Primary osteoblast cultures were plated in dishes pre-coated with CTGF-P or Poly-L-Lysine and examined for their differentiation using alkaline phospahtase staining. Osteoblasts adhered to CTGF-P differentiated faster than cells adhered to Poly-L-Lysine. These results clearly show that CTGF-P plays a role in osteoblast adhesion and spreading through ERK signaling pathway and this might lead to enhance osteoblast differentiation.

MicroRNA (miRNA) Binding Sites in the Osteonectin 3' Untranslated Region (UTR) Regulate Expression. C. Kessler*, A. M. Delany. Center for Molecular Medicine, University of Connecticut Health Center, Farmington, CT, USA.

Abundant in bone, osteonectin or SPARC (secreted protein acidic and rich in cysteine) is a "matricellular" glycoprotein that functions more as a regulator of cell behavior than as structural component of the matrix. It is associated with conditions of active matrix remodeling and cellular stress in multiple organ systems ranging from skin, bone, muscle, brain, and adipose. Cells regulate their expression of osteonectin in response to normal and pathogenic stimuli, causing changes in cell behavior that are critical for biological response. However, the mechanisms regulating osteonectin are largely unknown. Modulation of osteonectin RNA stability is likely to play a key role in its regulation, and determinants of RNA stability are often found in the 3' UTR. We sought to define sequence motifs and trans-acting factors regulating osteonectin RNA stability in murine osteoblasts, using chimeric luciferase-osteonectin 3' UTR reporter constructs. The mouse osteonectin 3' UTR is ~ 1 kilobase, and use of the full length osteonectin 3' UTR as the 3' UTR for the luciferase gene (in the constitutive reporter pGL3-control) decreases luciferase activity by 90-95%. Insertion of the first 220 bases of the UTR (997-1217) 3' to luciferase has a similar effect, whereas insertion of the latter 831 bases of the osteonectin 3' UTR causes a 1.5 to 2 fold increase in luciferase activity. These data indicate that the proximal portion of the osteonectin 3' UTR contains a dominant motif for regulation of RNA stability and/or translation. This region of the UTR can form a stem-loop structure, and it demonstrates specific binding to osteoblast cytoplasmic proteins in RNA mobility shift assays. Further, it contains overlapping potential binding sites for miRNAs 29a, 29c, and 96, which are conserved across the mouse, human, rat, cow and dog osteonectin transcripts. miRNAs are a class of endogenous noncoding ~22 base RNAs that regulate gene expression by pairing with mRNAs and specifying cleavage or repression of translation. Deletion of the 27 base overlapping miRNA binding sites in the luciferase-osteonectin 3' UTR chimera increases activity by ~7 fold, verifying the regulatory nature of these sites. A second site in the proximal UTR, homologous to a well characterized SNP in the human osteonectin gene (human 998 G/C) and upstream of the miRNA sites, also has regulatory activity in our assays. In conclusion, we've defined a powerful regulatory motif in the proximal portion of the osteonectin 3' UTR, likely a target for miRNA regulation. We hypothesize that a specific array of miRNAs modulates osteonectin RNA stability and/or translation in normal differentiation and in disease states.

Osteopontin Deficient Mice Show Delayed Healing during Distraction Osteogenesis. Z. S. Alaql*[1], K. A. Jacobsen[2], T. A. Einhorn[2], L. Gerstenfeld[2], R. S. Carvalho[1]. [1]Department of Orthodontics, Boston University School of Dental Medicine, Boston, MA, USA, [2]Department of Orthopaedic Research Laboratory, Boston University School of Medicine, Boston, MA, USA.

Osteopontin (OPN) is a phosophoprotein found in the extracellular matrices of mineralized tissues and is believed to play a role in the remodeling of these matrices. OPN is also one of a limited number of genes that respond to mechanical strain. Distraction osteogenesis represents a unique *in vivo* surgical method of applied mechanical tension that induces new bone formation and therefore represents an ideal model to assess the multiple functional roles of osteopontin. Tibia distraction osteogenesis was carried out using a monolateral fixator on male transgenic mice lacking osteopontin (C57B1/6 OPN -/-) and their background strain (C57B1/6). The tibiae were harvested at defined times over a 31 day time course and bone formation was evaluated radiographically and by assessment of mRNA expression for matrix genes. In the absence of OPN bone repair failed to reach completion relative to the controls. Surprisingly, when bone repair began in the distraction gap in the OPN-/- mice it was initiated in the center of the gap while in the control bones bridging proceeded from the proximal and distal edges of the osteotomy. Assessment of the multiple mRNAs associated with osteoblastic activity (BSP, OC, Col1A1) all showed compensatory (30% to 115%) elevation of their expression in OPN -/- mice through out the time course relative to controls. Interestingly, multiple mRNAs encoding numerous matrix metaloproteinases (MMPS) that are associated with bone remodeling were also over-expressed (15%-45%) throughout the time course of distraction in the OPN deficient mice. These observations suggest a crucial role for OPN in this model of bone formation. They show that osteopontin plays a clear structural role in relating the spatial orientation of new trabecular bone formation. Furthermore, they suggest that insufficiencies in the expression of one matrix component lead to alteration in the expression of others and may affect the normal balance between bone formation and turnover.

Wnt Induced Secreted Protein 1 (WISP-1) Splice Variants and Possible Relationship with BMP Signalling. C. A. Inkson*, S. Wadhwa*, P. Gehron Robey, M. F. Young. NIDCR, NIH, Bethesda, MD, USA.

Wnt induced secreted protein 1 (WISP-1/CCN4) is a member of the cysteine rich CCN protein family, some of which members have been shown to modulate bone and joint development and repair. Expression of WISP-1 was recently identified in bone, and experiments by others implicated WISP-1 in the fracture healing process. We have now identified multiple splice variants of WISP-1 in human bone. RNA was collected from cultures of human trabecular bone cells and bone marrow stromal cells with differing degrees

of differentiation, and used for RT-PCR analysis of CCN family members. WISP-1 and connective tissue growth factor (CTGF/CCN2) had notably increased expression in the more mature trabecular bone cells, as judged by levels of bone sialoprotein (BSP) expression. Other WISPs (CCNs 5 and 6) had lower levels of expression in these samples. In contrast to full length WISP-1 which was constitutively expressed, we observed a smaller WISP-1 variant with up-regulated expression during osteoblastic differentiation. Sequence analysis revealed that the smaller variant corresponds to a previously reported oncogenic WISP-1va, which is a result of exon splicing. We performed gene and protein alignment of the WISP-1 variants with other CCN family members using the web based Clustalw (1.82) program. Both WISP-1 and WISP-1va were the most homologous to CTGF. However, WISP-1va protein is lacking the Von Willebrand factor type C-like domain (VWFc). This variable domain contains a cysteine rich (CR) consensus motif found in chordin-like molecules, and also holds the putative site of the BMP/TGF binding capacity of CTGF. We also analysed another cysteine rich region found at the c-terminal of CCN proteins. This motif is analogous to the cysteine knot region of other BMP antagonists such as noggin, twisted gastrulation (Tsg) and the Dan family. Both WISP-1 and WISP-1va possess the cysteine knot region, but do not resemble these BMP anatagonists in any other way. Others have previously shown that overexpression of WISP-1 in osteoblast-like cells can exaggerate the effect of BMP-4 induced differentiation. However, little is known of the molecular mechanisms involved in this process. It is plausible that like CTGF, WISP-1 could modulate TGF-β1 superfamily members and their functions in bone. In light of our observations of a WISP-1 variant lacking in the domain responsible for such putative activity, we hypothesize that that in addition to being a wnt inducible gene, alternative expression of WISP-1 variants may differentially regulate BMP induced osteoblastic differentiation.

Targeting and Immobilization of Bioactive Peptides on Mineralized Tooth Matrices. J. Song*, A. Wlodarska*, H. Ko*, W. Grzesik. Anatomy, School of dental Medicine, Univ. Pennsylvania, Philadelphia, PA, USA.

The need to enhance healing and/or regenerate structurally and functionally competent tooth root cementum appears to be critically important for successful restoration of peridodontal attachment. Since cementum deposition needs to be confined to the tooth root surface, there is a need for targeting and stably integrating biologically active molecules to this location. We have developed a new method for targeting and covalently binding synthetic peptides to the surface of mineralized biological matrices. This method utilizes poly-glutamic acid stretch ((pE))to target peptides to mineral and a glutamine-containing transglutaminase (TG) substrate sequence to allow formation of a covalent bond between the peptide and the organic matrix. In this study, as biologically active model molecule we have employed the integrin-binding motif, RGD. Using synthetic peptides containing TG substrate sequence, pE and RGD we have evaluated the effects of their immobilizing on tooth root dentin on the adhesion of human cementoblastic cell in vitro. Tooth root dentin was treated with synthetic peptides containing the TG substrate sequence, mineral binding motif (pE) and cell attachment motif RGD and the transglutaminase consensus motif (glutamine) and transglutaminase. Untreated dentin slices as well as slices treated with peptide or TG only were employed as controls. Prepared dentin substrates were used as a substrate for cell attachment assay employing Human Cementum-Derived Cells (HCDC), a model of cementoblastic cells for cell attachment assays throughout all experiments. The cementoblastic phenotype of the cellular strains used was confirmed during previous studies in an in vivo transplantation assay. HCDC were seeded onto dentin substrates and cell adhesion was evaluated quantitatively (cell number) and qualitatively (cell morphology) as a function of time and peptide concentration. Cementoblastic adhesion (both cell attachment and spreading) was significantly increased on the surface of dentin that contained covalently bound peptides compared to all controls. However, dentin treated with TG alone also showed an effect on cementoblastic attachment (an effect that was expected), although to a lesser degree. Cellular spreading was pronounced best on dentin with peptides immobilized on. These effects were dependent on the dose of the peptide employed. Transglutaminase-catalyzed covalent binding of bioactive peptides targeted to mineralized collagenous dentin matrix via the polyglutamate motif can be readily achieved. If further confirmed in an in vivo assay, it may be of clinical use in periodontal regeneration.

Involvement of RhoE and Regulator of G-protein Signaling Protein (RGS) 2 in the Response of Human Periodontal Ligament Cells to Mechanical Stress. R. M. Santos de Araujo, Y. Oba, K. Moriyama. Department of Orthodontics and Dentofacial Orthopedic, Institute of Health Biosciences, University of Tokushima, Tokushima, Japan.

The periodontal ligament (PDL) is though to play a critical role as a transducer of mechanical signals into biological response including alveolar bone remodeling. However, the intracellular signaling pathways in the PDL cells in response to mechanical stress are still unclear. Using a cDNA microarray approach for gene expression induced in PDL cells under compressive force, we recently identified the monomeric G-protein RhoE and regulator of G-protein signaling protein (RGS) 2, which catalyzes the hydrolization of GTP (active form) to GDP (inactive form). The purpose of this study is to investigate the involvement of RhoE and RGS2 in the PDL cells under compressive force. Human PDL cells isolated from extracted premolars for orthodontic treatment were suspended into a collagen solution at a concentration of 1 x 10^6 cells/ml and the collagen gels were molded in 24-well plates. The gels containing PDL cells were transferred to 6-well culture plates with fresh media and then subjected to 6.0 g/cm^2 of compressive force for 1, 3, 6, 12, 24, 48 and 72 hours. The quantitative PCR and Western blotting analyses demonstrated that the expressions of RhoE and RGS2 were time-dependently increased by compressive force compared with control groups. The compressive force also significantly increased the production of intracellular cAMP, which plays an important role in G protein signaling, in the PDL cells in a time-dependent manner. To examine the involvement of RGS2 in the cAMP production induced by compressive force, the cells were treated with dideoxyadenosine (DDA), an inhibitor of adenylyl cyclase activity, at 1, 10, and 20 μM. Western blotting analysis showed that the RGS2 expression induced by compressive force was suppressed by DDA in a dose dependent manner. Transfection of PDL cells with antisense S-oligonucletotide (10 μM) to RGS2 enhanced the intracellular cAMP production under compressive forces. These results suggest that RhoE and RGS2 participate in the cellular responses to mechanical stress mediating cAMP in PDL cells.

Contributions of Cortical and Trabecular Architecture to Biomechanical Properties of Human Vertebrae. J. P. Roux*[1], Z. Merabet*[1], M. E. Arlot[1], F. Duboeuf*[1], P. D. Delmas[1], M. L. Bouxsein[2]. [1]INSERM Unit 403, C. Bernard University, Lyon, France, [2]Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA.

Vertebral fractures are common in elderly persons, yet the mechanisms of injury underlying these fractures remain obscure. Whereas there is clear evidence for a strong influence of the quantity of bone (i.e., bone mass or BMD) on the mechanical behavior of vertebrae, there are less data addressing the relative influence of cortical and trabecular microarchitecture. Thus, the aim of this study was to determine the relative contributions of bone mass, trabecular microarchitecture and cortical thickness to the mechanical behavior of human lumbar vertebrae. We obtained 19 L3 vertebrae (10 men and 9 women, aged 26 -93 yrs), and assessed BMD (g/cm^2) of the vertebral body by lateral DXA; vBMD (g/cm^3, as BMC / directly measured vertebral body volume); 3D trabecular microarchitecture (BV/TV, trabecular thickness, degree of anisotropy, and structure model index) and thickness of the anterior cortex by μCT (35 μm voxel size, Skyscan). Then, compressive stiffness and failure load were measured, and apparent modulus and ultimate strength computed using the minimal cross-sectional area of the vertebral body. Bivariate regression analysis showed that BMD was strongly correlated to compressive stiffness (r=0.86) and failure load (r=0.82). Except for trabecular thickness, all trabecular parameters (r = 0.50-0.76, p=0.03-0.0002) and anterior cortex thickness (r = 0.58-0.65, p=0.01-0.003) were also strongly correlated with mechanical behavior. The quantity of bone (ie; BV/TV, BMD or BMC) explained 42 to 74% of variability in mechanical properties. Trabecular architectural features were strongly correlated with BMD and BV/TV (r = 0.58 to 0.95), and thus did not improve prediction of mechanical properties over that provided by BMD. Conversely, anterior cortical thickness was not correlated with trabecular architecture and weakly with BMD (r = 0.52). Accordingly, the combination of BMD or BV/TV with anterior cortical thickness significantly improved the prediction of mechanical properties, with the combination explaining 58 to 80% of variability in mechanical properties. Our data imply that measurements of cortical thickness may enhance predictions of vertebral fragility, and that therapies which improve both vertebral cortical as well as trabecular bone properties may provide a greater reduction in fracture risk.

Mechanical Significance of Human Mandibular Bone Structure Assessed by a Remodeling Simulation. K. Tezuka[1], A. Kawaguchi*[2], A. Takahashi*[3], T. Takeda*[2], Y. Wada*[3], M. Kikuchi*[3]. [1]PRESTO, Graduate School of Medicine, Gifu University, Gifu, Japan, [2]Graduate School of Medicine, Gifu University, Gifu, Japan, [3]Department of Science and Technology, Tokyo University of Science, Noda, Japan.

Bone is continuously being remodeled by bone-forming osteoblasts and -resorbing osteoclasts. These 2 types of cells are tightly linked and adapt the shape of bone to the local stress. Wolff proposed a theory that the trabecular architecture of bone matches the stress trajectories. Additionally, computer-aided strategies have made it possible to calculate the stress distribution in bone tissue and investigate how bone remodeling can adapt the structure of bone to voluntary mechanical stress. Recently, we proposed a simple bone remodeling model, iBone, based on a reaction-diffusion system. We have applied this model to calculate structures of human mandibular bone adapted to various biting conditions. A three-dimensional 14-year old female mandible bone model consisting of approximately 1.4 million elements was used for the analysis. The locations and directions of muscles, and their forces were predicted from the CT images. Incisor, right or left group, and right or left molar biting conditions were simulated by fixing corresponding teeth. Considering the complexity of occlusion, we used comprehensive analysis approach to survey various biting conditions. Approximately 40 different loading conditions were tested. Remodeling simulation was performed by 10 sets of finite element analysis, reaction-diffusion calculation, and remodeling simulation for each loading condition. Simulations indicated that angles of the tooth movement had substantial effects on internal structure of the model bone. Fixing teeth in a plain allowing upper-forward movement caused significant stress in most part of the model, and produced internal structures similar to that of real bone. However, some locations, such as lingual side of mentum, did not bear significant stress in this condition. On the other hand, conditions allowing the tooth movement toward upper-backward direction caused stress accumulation at the lingual side of mentum and induced bone formation in this location. Very interestingly, the real bone structure looked like a sum of these different structures, and these results suggested that mandible bone seemed to have a sophisticated structure which can resist to a wide range of loading conditions. Combination of remodeling simulation with comprehensive

mechanical analysis may become a powerful tool to analyze structural significance of living bone, and potentially be used for medical diagnosis and treatment of various bone disorder based on the high-resolution CT images.

Directed Bone Removal Causes Significant Changes in Biomechanical Properties Over Uniform Erosion. H. Hong*, G. Gross*, B. Borah*, R. Phipps, T. E. Dufresne*. P&G Pharmaceuticals, Mason, OH, USA.

Increased rates of bone turnover, as observed in many postmenopausal women, are associated with loss of bone mass, deterioration of trabecular architecture, decrease in mineralization and increase in local stress risers caused by osteoclastic resorption. These factors, among others, are determinants of bone quality and may compromise bone strength leading to increased risk of fracture. The objective of the study was to use finite element modeling (FEM) to investigate the effects of removing bone selectively from high stress regions compared to uniform surface erosion of the bone to test whether loss of specific localized regions would result in large changes in biomechanical integrity. FEM analysis was performed on a 3D μCT image of a female iliac crest trabecular bone obtained with a Scanco μCT40 scanner at 16 micron resolution over a 3.5 mm^3 volume of interest. The brick elements of the bone were assigned a single material property of 18 GPa with a Poisson's Ratio of 0.3. A simple compression test along the long axis was performed with a fixed force of 18 N. The resulting stress distribution was calculated using the Scanco FEM solver. FEM analysis was then repeated under the following conditions: (a) the top 5% highest stressed voxels were removed [5% localized erosion,(5% LE)], (b) the top 10% of the highest stressed voxels were removed [10% localized erosion,(10% LE)] and (c) a 5% uniform erosion was performed towards the center of the original model data [5% uniform erosion,(5% UE)]. The results of this analysis are shown in Figure 1. The stress distribution of the 5% UE case is very similar to the original. However, in the 5% LE case, there was more heterogeneity, with an increased percentage of high stress voxels. As discussed by Weinans et al [1], this broader distribution can be considered to be a compromised architecture, with a larger percentage of elements approaching their failure threshold. The results of the 10% LE case indicates that the trend continues with higher levels of localized bone loss. This data suggests that directed bone loss in high stress regions can have deleterious effects on the biomechanical properties of bone. Therefore, preservation of trabecular bone with anti-resorptive therapies could have a larger impact on bone integrity than suggested by changes in BMD.

The Effects of Rowing Versus Running on Skeletal Homeostasis. M. Walcott*[1], K. E. Ackerman[2], S. Hurwitz*[1], N. Glass[1], M. S. LeBoff[1]. [1]Medicine, Brigham and Women's Hospital, Boston, MA, USA, [2]Internal Medicine, Hospital of the University of Pennsylvania, Philadelphia, PA, USA.

Attainment of peak bone mass is affected by exercise, nutrition, and reproductive function. To understand how to best maximize bone mass in young adulthood, we studied the effects of rowing versus running on skeletal homeostasis in 123 women between the ages of 18 and 32. Bone Mineral Density (BMD) by dual x-ray absorptiometry (hip, spine, whole body), bone turnover markers (osteocalcin, N-telopeptides) and serum 25 (OH) vitamin D were measured on 68 elite female rowers (Olympic and top collegiate) and 55 elite female distance runners (top collegiate and marathoners). In addition the athletes completed food frequency and athletic training questionnaires. The rowers were divided into two standard groups: openweight rowers (>130lbs, n=55) and lightweight rowers (<130lbs, n=13). The runners and rowers did not differ significantly in prevalence of amenorrhea, oral contraceptive use, or incidence of stress fractures. The lightweight rowers had equivalent body mass index as the runners (p=0.14). Although the caloric intake was the same, compared with runners, lightweight rowers consumed significantly fewer ($p<0.05$) vitamins and minerals including calcium, vitamin D, and B vitamins. The rowers had significantly higher bone density at the lumbar spine compared with the runners (p=0.0001). The runners had increased bone density at the hip compared with the lightweight rowers, but not at the lumbar spine. In addition, only the hip BMD was significantly different in openweight versus lightweight rowers.

	Runners n=55	Light Row n=13	Run vs Row p-value	Run vs L Row p-value
Fem. Neck BMD (g/cm2)	0.90±0.1*	0.78±0.2	0.91	0.02
Troch BMD (g/cm2)	0.80±0.1	0.73±0.1	0.52	0.02
Total Hip BMD (g/cm2)	1.06±0.1	0.98±0.1	0.32	0.02
L Spine BMD (g/cm2)	1.01±0.1	1.05±0.1	0.0001	0.39
Osteocalcin (ng/ml)	7.1±2.3	4.26±1.7	0.001	0.0001
NTX (nM BCE/mM Cr)	45.4 ±23.3	39.0±21.1	0.85	0.37
Vitamin D (ng/ml)	31.76±9.4	37.43±8.9	0.01	0.05

*mean ± stdev

Osteocalcin, N-Telopeptide, and serum vitamin D levels (DiaSorin RIA, Stillwater, MN) were normal in all groups, but differences were noted between groups. Osteocalcin levels were significantly lower in the lightweight rowers than the other groups, while that of the runners was significantly higher than any other group. Vitamin D was significantly lower in the runners than the rowers. Runners, whose sport provides repetitive impact on the hip, had higher BMD at the hip compared with lightweight rowers, who are comparable in size. Openweight and lightweight rowers, despite differences in size, had similar spine BMD, likely a result of the forces applied on their backs during rowing and possibly conferring long-term benefit in protection against spine fractures.

Differentiated Chondrogenic Cell Line ATDC5 Cells Up-regulates Type II, X Collagen and Aggrecan mRNA Expression in Response to Mechanical Strain. H. Horizono*, I. Owan, F. Kanaya*. Orthopedic Surgery, University of the Ryukyus, Okinawa, Japan.

Mechanical strain is an important factor to regulate chondrocyte proliferation and differentiation. Response of chondrocyte to mechanical strain could be differentiation dependent. Chondrogenic ATDC5 cells differentiate into hypertrophic chondrocytes in response to insulin, and regulates type II, X collagen, aggrecan, ALP, and PTH/PTHrP receptor mRNA expression. In the present study, we examined whether ATDC5 cells respond to mechanical strain in differentiation specific manner. ATDC5 cells were cultured on plastic plates at 1×10^6 cell/plate in the medium of F12/DMEM containing 5% FBS and 10 μg/ml insulin. ATDC5 cells were stained with toluidine-blue to observe the morphologic change. We utilized an in vitro cell loading system using four-point bending. The magnitude of strain was 4200 μstrain and the frequency was 0.5 Hz. To assess the effects of mechanical strain on ATDC5 cells, the expression of type II, X collgaen, aggrecan, ALP, and PTH/PTHrP receptor mRNAs were determined using northern blot analysis. Six to 24 hours after beginning of loading on day 4 through day 28, total RNA was extracted and hybridized with various cDNA probe. ATDC5 cells initiated chondrogenic differentiation as reported before. Type II collagen mRNA expression was firstly observed on day 4, type X collagen and aggrecan on day 14. The effects of mechanical strain were not observed on day 4 or 7, but mechanical strain up-regulates type II, X collagen, and aggrecan mRNA in a time-dependent manner thereafter. However, there were no increase in ALP and PTH/PTHrP receptor expression. These results indicate that differentiated, but not undifferentiated ATDC5 cells up-regulates type II, X collagen, and aggrecan transcripts in response to mechanical strain.

Prediction of Ultimate Stress in Femoral Cortical Bone by Quantitative Computed Tomography. L. Duchemin*[1], V. Bousson*[2], C. Raossanaly*[1], C. Bergot*[2], J. Laredo[2], W. Skalli*[1], D. Mitton*[1]. [1]Laboratoire de Biomécanique, ENSAM - UMR CNRS 8005, Paris, France, [2]Laboratoire de Radiologie Expérimentale, CNRS UMR 7052, Paris, France.

The purpose of this study was to assess a relationship between QCT grey levels and ultimate mechanical properties of femoral cortical bone, in order to develop a personalized fracture risk predicting Finite Element model of the proximal femur. 13 human femoral mid-diaphysis segments were collected, within 10 days post-mortem, from 2 males and 11 females aged from 54 to 101 years (mean 81.8), cleaned of soft tissue and frozen at -20°C. Segments were investigated using a CT-scan device (Somatom Plus 4 Siemens - 140 kV, 139 mAs, 0.25 mm pixels, 1.25 mm slices thickness). Cylinders were divided in 4 quadrants (posterior, anterior, medial and lateral) and 3 cortical parallelepipedic samples were obtained from each quadrant, using a micrometric low speed diamond saw (BUELHER Isomet) : two for compression (about 3x3x5mm) and one for traction (about 3x3x25mm). The long axis of the specimens corresponded to the diaphyseal axis. After removal of unusable specimens, 87 compression and 46 traction specimens were considered. Mechanical testing was performed on a universal testing system (INSTRON 5500-R). Each sample was tested destructively at a displacement rate of 0.6 mm/min after a pre-loading, and a pre-conditioning process of 3 cycles. Ultimate stress value was calculated as the maximal load divided by the cross sectional area of the specimen, measured on each specimen using a caliper. Ultimate stress values ranged from 10 to 98 MPa (mean value 54 +/- 21 MPa) in traction and from 36 to 151 MPa (mean value 107 +/- 30 MPa) in compression. Significant correlations were found between ultimate stress values and CT-scan Hounsfield Units in traction ($r = 0.75$, $p<0.001$) and in compression ($r = 0.85$, $p<0.001$).Considering the old age of the donors and the high number of females, ultimate stress values obtained in this study are coherent with previous values found in the literature. Good correlations between CT-scan data and maximal stresses, obtained on a large number of specimens and donors, will be useful for the individual prediction of femoral fracture for the elderly patients.

Low-Intensity Pulsed Ultrasound and New Bone Formation within Interconnected Porous Calcium Hydroxyapatite Ceramics. T. Iwai*, N. Tsumaki, J. Murai*, A. Myoui, H. Yoshikawa. Department of Orthopaedic Surgery, Osaka University Graduate School of Medicine, Suita, Japan.

Micromechanical strain caused by ultrasound transmission through the body can promote bone formation in a manner comparable to the bone responses to mechanical stress postulated by Wolff's law. Clinical investigations and animal studies have shown that low-intensity pulsed ultrasound (LIPU) accelerate repair process of pseudoarthroses, delayed unions, non-unions, and distraction gaps generated in hemicallotasis. Recently developed fully open interconnected porous calcium hydroxyapatite ceramics (IP-CHA) show good osteoconductivities by allowing cells to enter into the pores deeply. Although IP-CHA can be a bone graft substitute in a variety of clinical settings, newly formed bone within the pores often matures very slowly. The effects of LIPU on formation of new bone within the pores of IP-CHA was explored in this study. **Methods:** Because ultrasound produces micromechanical strain, there are possibilities that LIPU could weaken IP-CHA mechanically by introducing cracks on thin walls of IP-CHA. To examine these possibilities, we applied LIPU to IP-CHA immersed in water for 48 hours and performed compression tests. Then animal studies were done using New Zealand white rabbits. After drill holes of 4 mm in diameter were made in the femoral condyles of both limbs, size-matched cylindrical blocks of IP-CHA were implanted. The right limb was subjected to LIPU treatment for 20 minutes daily, while the left limb was untreated as the control. After 2 weeks of treatment, rabbits were sacrificed and IP-CHA implants were harvested. After scanning of implants by micro-CT, volumes of newly formed bone within IP-CHA were measured using image analysis software. **Results:** Mean compressive strength of IP-CHA immersed in water without LIPU application was 10.38 ± 0.90 Mpa (n = 12). That of IP-CHA receiving LIPU application for 48 hrs was 9.86 ± 0.77 Mpa (n = 12). There was not significant difference (P = 0.14), suggesting that LIPU application may not weaken IP-CHA itself. Following animal studies showed that mean volumes of the newly formed bone were 9.89 ± 5.05 (n = 3) for IP-CHA implants treated with LIPU and 19.21 ± 4.64 (n = 4) for those without LIPU treatment. These results suggest that LIPU application may substantially accelerate maturation of bone which is newly formed within the pores of IP-CHA. The use of LIPU in combination with IP-CHA may be one of options in treating bone defects.

Modeling Fluid Flow and Tracer Transport in Haversian Bone. G. C. Goulet*[1], N. Hamilton*[1], D. Coombe*[2], D. Tran*[2], R. Zernicke[3]. [1]Mechanical Engineering, University of Calgary, Calgary, AB, Canada, [2]Computer Modelling Group, Calgary, AB, Canada, [3]Mechanical Engineering & Faculties of Kinesiology and Medicine, University of Calgary, Calgary, AB, Canada.

Intrinsic fluid flow likely plays a major role in the initiation of bone adaptation, but the underlying mechanisms remain unclear (Knothe Tate, 2003). To better understand fluid flow characteristics in bone, a model was developed to recreate idealized fluid flow in cortical loaded bone at the osteonal level. This model was implemented in STARS, an advanced process fluid flow simulator that contains a coupled mechanical displacement simulator. Bone was modeled at the osteonal level with a radial grid to approximate an osteon. High porosity regions were added to simulate the presence of the Haversian canal at the center of the osteon and lacunae, in which osteocytes are encased within the solid bone matrix. Multiple cycles of 0.1% axial strain were applied at physiologically relevant frequencies (0.8 Hz - step loads). Interactive molecular transport was modeled with tracers with molecular weights equivalent to glucose and lactate, and placed initially in the Haversian canal and osteocyte lacunae, respectively. As the simulation progressed, the tracers were transported through the model by diffusion and load-induced convection. The possibility of osteocyte-induced glucose to lactate reactive conversion was considered. Immediately after compressive load application, fluid flowed from the high porosity regions into the low porosity bone matrix. Following that initial flow, the fluid flowed back from the solid matrix into the lacunae and Haversian canal. The largest load-induced fluid velocities were found in regions surrounding the modeled lacunae. If osteocytes triggered the remodeling process based on the cells sensing fluid flow (cf. Cowin & Weinbaum, 1998), then the model showed that the signal for load transduction was especially strong in their vicinity. The loading-enhanced fluid flow also had the effect of increasing the nutrient supply and waste removal potential to and from the osteocytes. Thus, these simulations provided evidence that cyclical loading could contribute to bone health by enhancing intrinsic fluid flow.

Mechanobiological Regulation of Molecular Expression and Tissue Phenotype during Bone Healing. K. T. S. Palomares*[1], T. A. Einhorn[2], L. C. Gerstenfeld[2], E. F. Morgan[3]. [1]Department of Biomedical Engineering, Boston University, Boston, MA, USA, [2]Department of Orthopaedic Surgery, Boston University School of Medicine, Boston, MA, USA, [3]Department of Aerospace and Mechanical Engineering, Boston University, Boston, MA, USA.

A growing body of evidence indicates that mechanical cues modulate the development and repair of skeletal tissues by regulating gene expression and cell differentiation. Several studies have shown that the mechanical environment plays a crucial role during the bone repair process which involves mechano-sensitive, pluripotent mesenchymal cells. The overall goal of this project was to purposefully modulate the bone repair process by using an applied, cyclic bending motion in order to promote cartilage, rather than bone formation. A mid-diaphyseal, transverse osteotomy was created in each of 64 (32 experimental and 32 control) rat femora and was stabilized with a custom-designed external fixator. Experimental animals were subjected to daily bending stimulation of the osteotomy gap; this stimulation consisted of 60° (±30°) of cyclic angular displacement applied at 1 Hz for 15 minutes daily for 1, 2 or 4 weeks following a 10-day latency period. Control animals were subjected to continuous rigid fixation. Tissue phenotypes and expression of specific mRNA levels were analyzed at each timepoint using histological analyses, ribonuclease protection assays, and cDNA microarrays. Statistical analyses included analyses of variance (ANOVA) and Tukey *post hoc* tests. Bending stimulation substantially altered the bone healing response at both tissue and molecular levels. Stimulated specimens exhibited an increase with time in the amount of cartilage present within and surrounding the osteotomy gap, whereas control specimens demonstrated complete bony bridging at 42 days. Molecular analyses revealed corresponding temporal alterations in the chondrogenic and osteogenic mRNA expression patterns. As compared to expression patterns in the control animals, expression of collagen types II and X persisted until later timepoints (days 17-24), the peak in the expression levels of osteopontin and osteocalcin occurred later (days 24-38), and the expression levels of bone morphogenetic protein-3, which has been shown to be down-regulated during bone formation, was higher at all timepoints. These results indicate that manipulation of the local mechanical environment can directly alter skeletal tissue repair, and they further suggest the potential of using applied mechanical stimulation to elucidate novel mechanisms of cartilage repair. Such insights into cartilage repair may substantially benefit treatment strategies for degenerative joint diseases such as osteoarthritis.

Directional Sensitivity of Rodent Long Bone Cortical Strength to Collagen Denaturation. M. Barrero*, L. Gubago*, D. J. Adams. Orthopaedic Surgery, University of Connecticut Health Center, Farmington, CT, USA.

The small size of rodent long bones precludes the application of most formal mechanical property testing techniques, requiring structural bending tests to measure cortical bone tissue strength in the longitudinal direction. Because whole bone tests exhibit variation and inaccuracy, alternative tests are desirable. We developed a test technique for measuring the circumferential strength of rodent diaphyseal cortex using open-ring specimens cut from multiple long bone cross-sections. The purpose of this study was to measure the longitudinal versus circumferential sensitivity of long bone cortical strength to thermally induced collagen denaturation. 50 diaphyseal open-ring specimens were cut from left and right femora (5 per femur) of 6 month old Sprague-Dawley rats. The radius was isolated for 3-point bend tests, and cross-section area moment of inertia was measured from microCT images. Control specimens were tested to establish baseline cortical strength in the circumferential (open-ring) and longitudinal directions (whole bone bending). Treatment specimens were subjected to controlled thermal denaturation of collagen prior to testing, using dry oven heat exposure for 4 hours at either 90°C (control for drying and rehydration) or 150°C (to break hydrogen bonds in calcified collagen). Cortical tissue strengths were compared between groups using unpaired t-tests. Whole bone tests demonstrated an average longitudinal cortical tissue strength of 199 ± 48 MPa, exhibiting 24% variation in the measurement. Collagen denaturation reduced longitudinal strength by 61.2% to 77 ± 55 MPa ($p < 0.0001$), but with 71% variation. Open-ring tests

demonstrated an average circumferential cortical tissue strength of 54 ± 13 MPa, exhibiting 23% variation. Collagen denaturation reduced circumferential strength by 43.3% to 31 ± 6 MPa ($p < 0.0001$), with only 21% variation.Cortical bone strength was reduced approximately 50% due to heat-induced collagen denaturation at 150°C, whereas others have found significant reductions in mechanical properties of bovine bone only when heated beyond 150°C for the same 4 hour exposure. Despite the predominant orientation of collagen, documented higher strength, and larger reduction in strength with collagen denaturation in the longitudinal direction, circumferential strength also was reduced substantially. Open-ring specimens demonstrated considerably less variation in strength measurements following collagen denaturation than whole bone bending tests. With the ability to obtain multiple specimens per long bone with relative ease, the open-ring test may provide increased statistical power for hypothesis testing in rodent skeletal research.

Direct Effects of Bisphosphonates on Primary Bone Tumor Cells *In Vitro*. U. C. Stumpf*[1], S. Goettig*[2], M. Schoenherr*[1], C. Eberhardt*[1], W. J. Fassbender[3], R. Henschler*[2], A. A. Kurth*[1]. [1]Orthopedic Surgery, University Hospital, Frankfurt, Germany, [2]German Red Cross Blood Center, Institute of Transfusion Medicine and Immune Hematology, Frankfurt, Germany, [3]Department of Internal Medicine, Hospital Zum Heiligen Geist, Kempen, Germany.

Regardless the survival rate of 80% there is still a significant number of non-responders to the chemotherapeutical treatment of osteo- and Ewing`s sarcomas who develop metastasis and finally die. Bisphosphonates are known to induce apoptosis in different cell types such as osteoclasts and breast cancer cells. Direct effects of bisphosphonates on primary bone tumors are not resolved. Therefore we tested and compared the effects the bisphosphonates Clodronate (CL) and Ibandronate (IB) could have on human sarcoma cells in order to evaluate their different potency in vitro. Two human osteosarcoma cell lines (SAOS 2 and 791 TM HOS) and two human Ewings´s sarcoma cell lines (RD-ES and TC 71) were treated with CL (2 mM, 1mM-10^{-7} M) and IB (10^{-3} M-10^{-7} M) for 24, 48 and 72 h. Cell apoptosis was evaluated by fluorescent flow cytometric analysis: quantification via FACS and PI staining. After 72 h staining with trypan blue and cell counting of dead cells was done. CL-treated cultures of SAOS show after 72 h of incubation in a concentration 2 mM and 10^{-3} M 12,6 % and 8,7 % apoptopic cells, respectively. HOS cell cultures show already after 48h in the range of 2 mM and 10^{-3} M apoptosis <10 % of the cells, after 72 h and the concentration of 10^{-3} M there are 10-25 % apoptotic cells. Ewing`s sarcoma cell cultures were evaluated after 72 h treated with CL: RD-ES cells show at 2mM 10-25 % apoptosis. TC-71 show at 2mM Clodronate < 10% of apoptosis. 10^{-3} M IB solution causes on SAOS cells after 48 h <10% and after 72 h 10-25% apoptotic cells. HOS cells show after 48 h in the range of 10^{-3} M 10-25 % and at 10^{-4} M < 10 % apoptopic cells; after 72 h in both concentrations of IB solution apoptotic cells increased to > 40 %. RDES cells which were incubated with IB showed at 10^{-3} M (5,1%) - 10^{-5} M (12,3 %) clear parts of the culture in s-phase of cell cycle. TC 71 show at concentration of 10^{-3} M and 10^{-4} M IB 10- 25 % and of 10^{-5} M and 10^{-6} M < 10 % of apoptopic cells, respectively. We could demonstrate that the bisphosphonates CL and IB have time- and dose-related direct effects on the investigated primary bone tumor cells. Both induce apoptosis and inhibition of cell proliferation in different ranges, but with IB a much better effect with lower concentration was found. If similar findings are observed in vivo, the use of IB may also be indicated as an adjuvant to existing chemotherapeutic protocols.

Expression of RANKL, OPG, PTHrP and OCIL in Multiple Myeloma Are Influenced by the Tumor Cells' Proximity to Bone. V. Kartsogiannis[1], C. Ly*[1], H. Zhou[2], O. Gallagher*[3], C. Buckle*[3], E. De Leenheer*[3], K. Vanderkerken*[4], K. W. Ng[5], T. J. Martin[1], M. T. Gillespie[1], P. I. Croucher[3]. [1]Bone, Joint and Cancer Unit, St.Vincent's Institute, Fitzroy, VIC, Australia, [2]Bone Biology Unit, ANZAC Research Institute, Concord, NSW, Australia, [3]Academic Unit of Bone Biology, Division of Clinical Sciences, University of Sheffield Medical School, Sheffield, United Kingdom, [4]Department of Hematology and Immunology, Free University Brussels, Brussels, Belgium, [5]Department of Endocrinology, St.Vincent's Hospital, Fitzroy, VIC, Australia.

Multiple myeloma is characterized by the development of lytic bone lesions mediated by increased osteoclastic bone resorption. A number of molecules have been implicated in promoting the increase in osteoclastic resorption including RANKL and macrophage protein-1 alpha. While the RANKL/RANK/OPG system may indeed play a critical role in the osteolysis in myeloma, other molecules may also contribute. One novel family of osteoclast inhibitors, named OCILs (Osteoclast Inhibitory Lectins) may also be effective in altering the progression of multiple myeloma since they are effective in blocking RANKL-, TNFα-induced and TGFβ-primed osteoclast formation. Using in situ hybridization and immunohistochemistry, mRNA and protein expression of OCIL was examined in the 5T2MM murine model of myeloma. OCIL was shown to be expressed by 5T2MM myeloma cells residing in bone. Approximately 80% of myeloma cells within the marrow cavity expressed OCIL. Myeloma cells residing closer to the growth plate, or those contained well within the bone environment, exhibited higher levels of OCIL mRNA and protein than the population of myeloma cells outside the bone. We therefore examined the mRNA and protein expression for other key factors in myeloma including RANKL, OPG and PTHrP. Similar to OCIL, the expression of each of these was elevated when myeloma cells were in proximity to bone but not outside of bone. OPG mRNA and protein were expressed in only a limited number of myeloma cells. Furthermore, quantitative RT-PCR analysis, also revealed a consistent expression of OCIL in the 5T2MM and 5T33MM myeloma cell lines as well as the murine bone marrow endothelial cell lines, STR10 and STR12. These results demonstrate that murine myeloma cells express OCIL and raise questions about the potential role of OCIL in the progression of myeloma as well as the role of the bone microenvironment to influence the expression of other candidate molecules (RANKL, OPG and PTHrP) in the development of osteolytic bone disease.

Vitamin D Deficiency Occurs with High Frequency in Acute Leukemia. M. E. Cabanillas, D. A. Thomas*, A. O. Hoff, M. C. Foudray*, G. N. Mattiuzzi*, H. M. Kantarjian*, C. Escalante*, R. F. Gagel. General Internal Medicine, MD Anderson Cancer Center, Houston, TX, USA.

Background: Acute lymphoblastic leukemia (ALL) and lymphoblastic lymphoma (LL) are conditions associated with rapid clonal expansion of cells of the B and T-cell lymphocytic lineage. In pediatric patients osteopenia and lytic bone abnormalities have been found with some frequency but prior reports have documented no abnormalities of parathyroid or vitamin D (VD) function. There has been no systematic evaluation of calcium metabolism in adults with this disorder. **Methods:** As part of a prospective study of bone loss in ALL & LL during chemotherapy with hyperCVAD, serum 25OHD3 (Quest Diagnostics), calcium (Ca^{++}) and bone density were measured. Most patients had intact PTH (iPTH) measurements. **Results:** Ten men and 13 women were prospectively evaluated in this updated report. Median age was 49 (r: 18-71). Seventeen pts had ALL, 6 had LL. Low 25OHD3 levels (<20ng/ml) were found in 15/23 (65%), while an additional 4/23 pts (17%) had low normal levels (20-25ng/ml). Evidence of secondary hyperparathyroidism (high iPTH [>65 pg/mL] and 25OHD3 ≤25ng/ml) was seen in 11/17 (65%) of pts (see graph). Five of these pts had secondary hyperparathyroidism characterized by high iPTH levels with low ionized Ca^{++}. Baseline skeletal abnormalities were seen in 13/17 (93%) (osteopenia: 11/17, osteoporosis: 1/17, vertebral fracture: 1/17, lytic bone lesions: 1/17, and osteosclerosis: 2/17). Mean SD lumbar spine BMD T and Z scores were -0.6 (range -2.9-2.2) and -0.04 (range -2.7-3.5), respectively. Although these abnormalities occurred in both diseases, the pts with the most striking abnormalities had B-ALL. **Conclusions:** 1) Abnormalities of vitamin D and calcium metabolism occur in adult ALL and LL with surprising frequency, indicating that evaluation for this possibility should be performed routinely. 2) The etiology of these abnormalities is unclear and may be related to absorptive abnormalities in leukemic patients or inadequate UV exposure because of illness. 3) Vitamin D inhibits clonogenic growth of leukemic B-cells *in vitro* and is a differentiating agent in leukemic myeloid cell lines. It is therefore possible that VD deficiency may contribute to the pathogenesis of this neoplastic disorder.

Evidence that Interferon Signaling Is Required for 2-ME-Mediated Osteosarcoma Cell Death. A. Maran[1], K. L. Shogren*[1], M. Zhang*[1], M. J. Yaszemski*[1], R. T. Turner[2]. [1]Orthopedic Research, Mayo Clinic, Rochester, MN, USA, [2]Nutrition and Exercise Science, Oregon State University, Corvallis, OR, USA.

2-Methoxyestradiol (2-ME) is a metabolite of estradiol that leads to induction of interferon-β gene expression and apoptosis in human osteosarcoma cells. Interferons exert pleiotropic effects and have been shown to be involved in the anti-viral, anti-growth and anti-cancer activities in a number of systems through the stimulation of one or more responsive genes. However, no cause and effect relationship has been established between interferon signaling and 2ME-induced osteosarcoma cell death. Therefore, we have investigated the requirement of the interferon pathway for 2-ME-induced cell death in MG63 human osteosarcoma cells. 2-ME treatment induced interferon-β gene expression and increased interferon-β promoter-dependent reporter gene activity in osteosarcoma cells but not in normal primary human osteoblasts. Normal cells are resistant to 2-ME. In addition, 17 β-estradiol and metabolites (2-, 4- and 16α-hydroxyestradiol), none of which induce cell death have no effect on interferon gene expression and promoter activity in MG63 cells. RNA-dependent protein kinase (PKR), a downstream mediator of interferon signaling, is induced in MG63 cells by 2ME. Blockage of the downstream signal through a dominant negative mutant interferon-regulated protein, PKR prevents 2-ME-mediated cytotoxicity. Taken together these data demonstrate a close association between induction of interferon signaling, induction of PKR and cell death in MG63 cells.

Imaging Tumor Burden by [^{18}F]FDG-PET and Osteoblast Activity by [^{99m}Tc]MDP-SPECT/CT in the 5TGM1 Mouse Model of Myeloma Bone Disease. B. O. Oyajobi[1], B. Goins*[2], A. Gupta*[1], C. Zavaleta*[2], B. Grubbs*[1], C. Wideman*[1], Z. Wang*[2], I. R. Garrett[3], W. Phillips*[2], G. R. Mundy[1]. [1]Cell & Structural Biology, Univ Texas Hlth Sci Ctr, San Antonio, TX, USA, [2]Radiology, Univ Texas Hlth Sci Ctr, San Antonio, TX, USA, [3]OsteoScreen Ltd, San Antonio, TX, USA.

The high morbidity and mortality rates associated with multiple myeloma (MM) are due to complications resulting from its effects on the skeleton. These complications including pathological fractures reflect, in part, tumor-induced osteolysis as well as failure of new bone formation. Lack of suitable preclinical models of MM bone disease that closely reflect changes seen in humans has hampered development of novel anti-myeloma agents. Standard histological techniques, which are the gold standards for monitoring tumor progression and osteoblast function, are labor-intensive and invasive and therefore limit the use of mouse models for rapidly assessing efficacy of new treatment modalities. To remedy these shortcomings, we have applied state-of-the-art small animal nuclear imaging modalities [positron emission tomography (PET) and single photon emission computed tomography (SPECT/CT)], similar to those utilized clinically, to the murine 5TGM1 myeloma bone disease model. PET scans performed using [^{18}F]-fluorodeoxyglucose (FDG) provide functional measurements of tumor burden and preliminary studies demonstrate accumulation of FDG in tumors in the skeleton. To demonstrate the feasibility of using SPECT to assess osteoblast function in myeloma-bearing mice, we performed scintigraphic scans after administration of [^{99m}Tc]-hydroxymethylene diphosphonate (MDP) and found that overall skeletal uptake was reduced in tumor-bearing mice. Biodistribution studies confirmed that uptake was suppressed in all bones of 5TGM1-bearing mice in comparison to soft tissues from same mice or to bones of non-tumor bearing mice. Consistent with these findings, cancellous bone volumes and bone formation rates, determined by dynamic bone histomorphometry, are significantly reduced in the 5TGM1 model. These data suggest utility of (i) PET in real-time, longitudinal monitoring of tumor growth and spread or regression in response to therapy within skeletons of individual live animals; (ii) SPECT/CT in concurrent spatial localization of increased osteoblastic activity in response to investigative bone anabolic therapy. Together, these novel imaging capabilities increase the utility of the 5TGM1 model beyond what would otherwise be possible using two-dimensional radiography and bone histomorphometry, and should have a substantial impact not only on identifying novel anti-myeloma therapies, but also in studies to gain mechanistic insights to these therapies.

RANKL Expression Is Regulated in Oral Squamous Cell Carcinoma. F. Li*[1], M. Liu*[1], N. D'Silva*[2], K. L. Kirkwood[1]. [1]Periodontics/Prevention/ Geriatrics, University of Michigan, Ann Arbor, MI, USA, [2]Oral Med/Path/ Surgery, University of Michigan, Ann Arbor, MI, USA.

Invasion of oral squamous cell carcinoma (SCC) into bone is a result of osteoclastic activity. RANKL is a key cytokine involved in osteoclastogeneisis and mediates bone invasion of a variety of malignant tumors. The purpose of the present study was to determine if established oral SCC cell lines express RANKL in response to osteotrophic cytokines and hormones in vitro and in vivo. Several different oral SCC cell lines were treated with cytokines/hormones (IL-1β, TNFα, IL-6/IL-6sR, PTH, or 1,25-di(OH)$_2$VitD$_3$) for 16-18 hours. Total RNA was isolated and RANKL expression was determined by real-time PCR (ABI 7900 Real-Time System). To determine if osteotrophic cytokines/ hormones affected RANKL proximal promoter function, UMSCC11B, an oral SCC cell line, was transfected with the human proximal promoter containing 1974-bp of 5'-flanking sequence of the RANKL gene in reporter plasmid, pGL3-Basic. Stable cell lines were established by co-transfection with the pcDNA3.1-neo. Luciferase (Luc) reporter activity was assessed following osteotrophic cytokines/hormone cell treatment using a luminometer (Molecular Devices) with normalized total cytoplasmic protein. To determine if RANKL promoter activity in oral SCC was active in vivo, UMSCC11B-RANKL-Luc cells were injected into the tibia (1x10^7 cells; n=6) or floor of the mouth (3 or 5 x10^{7}cells; n=3 each) of athymic (nu/nu SCID) mice. In vivo real-time RANKL promoter activity was assessed by bio-luminescence following intraperitoneal injection of D-luciferin substrate (Xenogen IVIS imaging system) over a 4 week period. Results from real-time PCR indicated UM-SCC -(11A and 22B) express RANKL mRNA upon TNFα stimulation whereas UMSCC 11B, 74A and 74B respond to IL-1β, VitD$_3$, PTH, and IL-6. UMSCC11B cells stably transfected with -RANKL-Luc, exhibited a 2-3 fold increase in Luc activity following 18-hr treatment with VitD$_3$, PTH and IL-6, in agreement with real-time PCR results. In vivo RANKL promoter activation data from UMSCC11B-RANKL-Luc injected cells indicates that both the tibia and floor of the mouth model exhibit increased Luc activity over time in most animals injected. The data indicate that SCC tumors produce RANKL in response to osteotrophic cytokines and hormones, consistent with the ability of SCC to invade bone through local extension of the tumor.

Alpha-Calmodulin Kinase II (α-CaMKII) Is Critical for Cell Cycle Progression in Osteosarcoma. V. Saini*[1], A. Zayzafoon*[2], G. P. Siegal*[2], J. M. McDonald[2], M. Zayzafoon[2]. [1]The Department of Physiology and Biophysics, The University of Alabama at Birmingham, Birmingham, AL, USA, [2]The Department of Pathology, The University of Alabama at Birmingham, Birmingham, AL, USA.

Osteosarcoma is the most frequent primary malignant bone tumor in children and adolescents and is characterized by its abnormal cell proliferation. Overexpression of *c-fos* and subsequent alterations in the cell cycle have been suggested to be involved in the neoplastic transformation of osteoblasts. We have previously shown that α-CaMKII is expressed in osteoblasts and regulates *c-fos* expression and osteoblast differentiation. In this study we examined the role of α-CaMKII in the growth and neoplastic progression of osteosarcoma. We used multiple well-characterized human osteosarcoma cell lines, HOS, SaOS-2, MG-63 as well as primary human osteosarcoma tissue derived from patients. Immunofluorescence and Western blotting analyses show that α-CaMKII is expressed in all osteosarcoma cell lines and in human tumor tissue tested. The phosphorylated form of α-CaMKII has distinctive punctate perinuclear localization. Pharmacologic inhibition of CaM and CaMKII by 10μM TFP and KN93, respectively, significantly reduced the mRNA levels of *c-fos*, the osteoblastic gene markers *alkaline phosphatase*, *collagen I*, *osteocalcin* and the metastatic marker *metalloproteinase-13*. TFP and KN93 treatment also inhibited proliferation (80%, P<0.01) of osteosarcoma cell lines as determined by an MTT assay and cell counting. Similarly, a dramatic decrease in the number and size of colonies formed by osteosarcoma cells grown in growth factor reduced Matrigel supplemented with 10μM TFP or KN93 was observed. The pharmacologic inhibition of CaMKII decreases levels of the cyclins, specifically cyclins D1, D2 and D3. This decrease is more pronounced in the nuclear fraction as compared to the cytoplasmic fraction indicating that the inhibition of CaMKII inhibits proliferation of osteosarcoma cells by decreasing the nuclear localization of cyclins. Taken together, our results demonstrate that the inhibition of α-CaMKII in osteosarcoma decreases proliferation by inhibiting the nuclear translocation of cyclin D and promoting cell cycle arrest.

Inhibition of Primary Bone Tumor Cell Proliferation by a Hedgehog Pathway-Inhibitor. J. Warzecha*[1], C. Brünning*[1], S. Goettig*[2], R. Henschler*[2], A. A. Kurth*[1]. [1]Orthopaedic Surgery, University Hospital Frankfurt, Frankfurt, Germany, [2]Institute of Transfusion Medicine and Immune Hematology, University Hospital Frankfurt, Frankfurt, Germany.

Osteosarcomas (OS) and Chondrosarcomas (CS) are the most frequent primary malignant bone tumors in humans. Even though OS are chemosensitive, about 30% of patients remain poor responder and have a bad long term prognosis. In CS there is a resistance to conventional forms of treatment such as chemotherapy and radiation, resulting in a high recurrence rate.The Hedgehog (Hh) signalling pathway has been shown to regulate crucial pathways of proliferation and differentiation during embryonic development. Moreover, in adult tissues the Hedgehog (Hh) signalling pathway controls stem cell behaviour. There is evidence that uncontrolled activation of this pathway results in specific types of cancer. Furthermore in certain types of cancer - such as medulloblastoma -inhibition of Hh signalling is able to suppress tumour growth and induces apoptosis of neoplastic cells. We investigated whether the novel agent Cyclopamine causes growth inhibition in osteosarcoma and chondrosarcoma cells. Using different cell proliferation assays, including BrdU-incorporation and assessment of XXT metabolism, we are able to demonstrate that cyclopamine exhibits considerable in vitro efficacy against the chondrosarcoma cell line SW-1353 and the osteosarcoma cell line HOS. Assessment of the altered proliferative activity reveals a reduction of the cell count by 50% for SW 1353 and by 90% for HOS upon incubation with cyclopamine. In conclusion, our results provide first evidence for the important role of Hh-signalling in the proliferative activity of malignant osteochondrogenic tumor cells and distinguish Hh-inhibition by cyclopamine as a potential molecular target in the treatment of these tumors.

Myeloma Cell-Derived MIP-1 Suppresses Dendritic Cell Maturation and Induces Aberrant Osteoclastogenesis from Immature Dendritic Cells. T. Hashimoto*[1], M. Abe[1], M. Hiasa*[2], J. Asano*[1], Y. Tanaka*[1], E. Sekimoto*[1], S. Ozaki*[1], S. Kido[1], D. Inoue[1], T. Matsumoto[1]. [1]Department of Medicine and Bioregulatory Sciences, University of Tokushima Graduate School, Tokushima, Japan, [2]Department of Orthodontics, University of Tokushima Graduate School, Tokushima, Japan.

Multiple myeloma (MM) is characterized by devastating bone destruction and immune suppression in which impaired dendritic cell (DC) function plays a role. We have demonstrated that MM cells reciprocally reduce myeloid DC formation along with enhanced osteoclast (OC) formation from their common progenitor, monocytes. MM-derived osteoclastogenic macrophage inflammatory protein (MIP) -1alpha and beta turned out to play critical roles in OC induction and suppression of myeloid DC differentiation from monocytes. We also found that CD83+ mature DC formation from immature DCs was almost completely suppressed by co-existing MM cells, suggesting suppression of DC function. Such immature DCs have also been shown to endow with the propensity to differentiate into OCs upon the stimulation with M-CSF and RANK ligand. In order to

further clarify the effects of MIP-1 as well as MM cells on DC differentiation and function, we first investigated the function of immature DCs after the treatment of TNF-alpha in the presence or absence of RPMI8226 cells or MIP-1. When thus treated DCs were irradiated and co-cultured with anti-CD3-treated autologous CD8+ T cells, interferon-gamma production from the T cells was substantially reduced by the DCs pretreated with MIP-1 or RPMI8226 cells, indicating defective function of these DCs. However, MIP-1 as well as MM conditioned media were able to induce the formation of TRAP+ - multinucleated cells from immature myeloid DCs in the presence of soluble RANK ligand, although MIP-1 or MM conditioned media alone showed only minor effects. Consistently, antibodies against MIP-1 alpha and beta in combination abrogated the MM conditioned media effects, suggesting an additional role for MM cell-derived MIP-1 in enhanced osteoclastogenesis in MM. From these results, MM cell-derived MIP-1 not only triggers the reciprocal induction of OC and myeloid DC differentiation from monocytes but also acts on immature DCs to suppress functional maturation of DCs and induce aberrant differentiation into OCs. Therefore, inhibition of MIP-1 actions may enhance anti-tumor immunity and protection against infection through restoration of impaired DC function along with prevention of bone destruction in MM.

Identifying Targets anti-Myeloma by Characterizing the Plasma Cell Specific Unfolded Protein Response. L. Oliva, E. Benasciutti, R. Sitia*, S. Cenci. DiBiT, San Raffaele Scientific Institute, MILANO, Italy.

Multiple Myeloma (MM) is a frequent, severe, and still incurable hematological malignancy that originates from the clonal expansion of plasma cells and causes massive bone destruction. Recently, a new class of drugs, proteasome inhibitors (PI), proved effective in MM therapy, and are currently in phase 4 clinical trial. The anti-tumour effect of these drugs owes to their ability to prime apoptosis selectively in MM cells, via undetermined mechanisms. The normal counterpart of MM, plasma cells, the factories of soluble Ig, are subject to intense ER stress and rely on the adaptive unfolded protein response (UPR) for their differentiation and activity. PI induce a robust UPR, providing a framework to understand their peculiar efficacy on MM cells. To explore the molecular bases of such therapeutic effect, we first asked whether plasma cell differentiation confers apoptotic sensitivity to PI on different models (in vitro, from the murine inducible B lymphoma I.29μ+, and ex vivo, from primary mouse B cells). Our findings reveal that plasma cell differentiation generates apoptotic sensitivity to PI at late stages of differentiation, in correlation with Ig production and activation of a robust UPR activation. The selective toxicity of PI on plasma cells was then confirmed ex vivo in plasma cells from LPS-injected mice. Moreover, we found that PI treatment in vivo significantly reduces the title of circulating Ig in OVA-immunized mice. These data demonstrate that proteasomes regulate plasma cell lifespan and the resulting duration of the humoral response. The UPR is a key inducer of apoptosis in many diseases. To gain insights on the mechanisms that trigger death in plasma cells, we investigated the ordered unfolding of the B cell-specific UPR over time by assessing histone post-translational modifications and cofactor recruitment to UPR target genes by chromatin immunoprecipitation. Our data reveal that: 1) the plasma cell-specific UPR, unlike that induced by pharmacological ER stressors, is accompanied by profound chromatin remodelling at UPR genes (e.g. XBP-1, CHOP and BiP); 2) plasma cell differentiation activates a potentially protective heat shock response (HSR); 3) histone acetylation at target genes correlates with recruitment to gene promoters of the key UPR transcriptional coactivator XBP-1. Our findings link the molecular bases of sensitivity of MM to PI to the Ig-secreting phenotype, and reveal that chromatin remodelling is involved in the plasma cell UPR. Altogether, our data, by characterizing plasma cell differentiation, may help identify potential targets and design more specific therapeutic tools against MM.

SERMs-Induced Myeloma Cell Apoptosis: A Study of NF-κB Inhibition and Gene Expression Signature. S. Olivier*[1], P. Close*[2], E. Castermans*[3], L. de Leval*[4], S. Tabruyn*[5], A. Chariot*[2], M. Malaise*[1], M. Merville*[2], V. Bours*[2], N. Franchimont[1]. [1]Rheumatology, University of Liège, Liège, Belgium, [2]Clinical Chemistry and Human Genetics,, University of Liège, Liège, Belgium, [3]Hematology, University of Liège, Liège, Belgium, [4]Pathology, University of Liège, Liège, Belgium, [5]Molecular Biology and Genetic Engineering, University of Liège, Liège, Belgium.

As multiple myeloma (MM) remains associated with a poor prognosis, novel drugs affecting specific signalling pathways are needed. Osteolytic lesions remain a critical morbidity factor in MM and drugs that would target both myeloma cell growth and osteoclast development would be of great interest. The efficacy of selective estrogen receptor modulators for the treatment of MM and its associated bone lesions is not well documented. We demonstrated that two SERMs, raloxifene and tamoxifen, decreased JJN-3 myeloma cell viability and induced caspase-dependent apoptosis. Moreover, raloxifene inhibited constitutive NF-κB activation in myeloma cells by removing p65 from its binding sites through ERα interaction with p65. In contrast to myeloma cells, raloxifene had no effect on NF-κB activity in osteoblasts. Importantly, micro-array analysis showed that raloxifene treatment decreased the expression of known NF-κB-regulated genes involved in myeloma cell survival and myeloma bone disease (e.g. *c-myc, mip-1a, hgf, pac1,…*) and induced the expression of a subset of gene regulating cellular cycle (e.g. *p21, gadd34, cyclin G2,…*). As raloxifene inhibits *mip-1a* synthesis in JJN3 and *mip-1a* is a factor known to influence osteoclast development, raloxifene may be an interesting drug to test for the prevention or treatment of MM osteolytic lesions. In conclusion, raloxifene induces myeloma cell apoptosis most likely by an NF-κB dependent mechanism. These findings also provide a transcriptional profile of raloxifene treatment on JJN-3 cells, therefore offering the framework for future studies of SERMs therapy in MM.

Impaired Proteasomal Capacity and ER Stress as Therapeutic Targets against Multiple Myeloma. S. Cenci[1], A. Mezghrani*[1], P. Cascio*[2], L. Oliva[1], A. Orsi*[1], E. Ruffato*[1], E. Pasqualetto*[1], R. Sitia*[1]. [1]DIBIT, San Raffaele Scientific Institute and University Vita-Salute San Raffaele, Milano, Italy, [2]Dept. of Morphophysiology, University of Turin, Turin, Italy.

Multiple Myeloma (MM) is an aggressive, debilitating and deadly hematological malignancy, arising from the clonal expansion of plasma cells at multiple sites in the bone marrow. Recently, MM proved sensitive to a new class of drugs, proteasome inhibitors (PI), currently in phase 4 clinical trial. Understanding the molecular bases by which PI induce apoptosis selectively in MM cells promises to help identify novel molecular strategies to combat MM. We explored the mechanisms underlying sensitivity of MM to PI on plasma cells differentiated in vitro from the murine B lymphoma I.29μ+ and ex vivo from primary mouse B cells. We found that in both models apoptotic sensitivity to PI directly correlates with the Ig-synthetic load. Surprisingly, as apoptosis increases, the relative amount of proteasomal subunits and the resulting proteolytic activity decrease dramatically, thus denying the demand for a higher degradative capacity when antibody production becomes maximal. Pulse-chase assays confirmed that proteasomes are overloaded in differentiating plasma cells. The excessive load for the reduced proteolytic capacity causes accumulation of poly-ubiquitinated proteins and stabilization of endogenous proteasomal substrates such as the UPR mediator Xbp1, the NF-kB inhibitor Ik-Balpha, and the pro-apoptotic Bcl-2 relatives Bim and Bax, two proteins critical in limiting B lymphocyte lifespan and activity. Accumulation of these proteins critically exaggerates endoplasmic reticulum (ER) stress, thus predisposing plasma cells to apoptosis upon treatment with PI. Importantly, a similar scenario can be reproduced in HeLa cells, a non-B tumoral line, by driving Ig heavy chain over-expression under an inducible promoter, leading to proteasomal overload, apoptotic sensitivity to proteasome inhibitors, and eventually spontaneous apoptosis, establishing a cause-effect relationship between synthetic load and cell death. Our results unveil a novel developmental program enabling plasma cells to count the integral of produced Ig, linking death to protein production, thus ending the humoral immune response upon accomplishment of its goal. Based on our data, we propose that the high efficacy of PI against MM is due, to a significant extent, to overloading the cell's degradative capacity, a key component of the stress response, already challenged by misfolded chains generated as a side product of intense Ig synthesis. This model provides a framework for attempting to achieve tumour cell destruction through modulation of stress in MM.

Microarray Analysis of Differential Gene Expression in OSCC Cell Lines. C. B. Knight*, D. Richardson*, M. MacDougall*, M. Thornhill*. UTHSCSA Dental School, San Antonio, TX, USA.

Oral squamous cell carcinoma (OSCC) has a high rate of morbidity and mortality despite advances in treatments. Increases in OSCC death rates are primarily due to distant metastases (40-50%). While local control over the disease has improved, much work remains to elucidate the underlying mechanisms of primary invasion and distant spread in order to develop effective therapies for patients with advanced disease. Our laboratory evaluated multiple commercially available OSCC cell lines for their ability to bind and transmigrate across endothelial cells under physiological conditions of flow, *in vitro*. Two cell lines, SCC-4 and CAL-27, demonstrated dramatic differences in this ability. SCC-4 and CAL-27 were both derived from primary OSCC tumors on the tongue of male patients in their fifth decade of life. Interestingly, SCC-4 cells are incapable of binding and transmigrating through endothelial cells; in contrast, CAL-27 cells have the ability to tether and to transmigrate across endothelial cells under physiological conditions of flow, *in vitro*. Our hypothesis is that there are specific gene products in OSCC that enable these tumor cells to invade tissues within the oral cavity. Purpose: Our goal is to characterize differential gene expression patterns in SCC-4 and CAL-27 OSCC cell lines to identify potential regulators of tumor development and metastases. Methods: Differential gene expression was screened using Affymetrix human genome U133 gene array. To confirm these results, semi-quantitative reverse transcriptase polymerase chain reaction (SQ-RTPCR) and quantitative real time PCR (QRT-PCR) were performed on selected transcripts. Results: 39,000 transcripts were tested, in triplicate, by gene array. 110 genes had statistically significant changes in expression levels in CAL-27 cells compared to SCC-4 cells. 76 genes were up-regulated and 38 genes were down-regulated. Dramatic increases in gene expression levels of S100A2, tumor associated calcium signal transducers 1 and 2 (TACSTD1 & 2), and plasminogen activator urokinase (PLAU) were detected. This data also confirmed increased gene expression of osteonectin (OSN) and tenascin-C(TNC) in CAL-27 cells. Each of these proteins is correlated with aggressive tumor phenotypes in various types of cancer. However, their precise role in invasion has yet to be determined. Conclusion: Microarray analysis of differential gene expression in OSCC cell lines exhibiting different abilities to transmigrate across endothelial cells, *in vitro*, is useful for identifying candidate biomarkers for aggressive OSCC tumors.

Roles of Hepatocyte Growth Factor in Bone Metastasis of a Mouse Mammary Cancer Cell Line, BALB/c-MC. K. Ono[1], S. Kamiya*[1], T. Akatsu[2], N. Kugai*[2], M. Li*[3], N. Amizuka[3], K. Matsumoto*[4], T. Nakamura*[4], S. Wada[1]. [1]Department of Clinical sciences, Josai International University, Togane, Japan, [2]Department of General Medicine, National Defense Medical College, Tokorozawa, Japan, [3]Niigata University, Niigata, Japan, [4]Osaka University, Suita, Japan.

Since several kinds of cancer metastasize to skeletal tissue, it has been recognized that bone microenvironment supports the growth of certain cancer cells. Once metastasize, some tumors stimulate osteoclastogenesis and expand in the hard tissue. Hepatocyte growth factor (HGF) is a molecule produced mainly by cells of mesenchymal origin, though the factor was also expressed by some cancer cells. In this study, we investigated the roles of HGF in bone metastasis using a mammary cancer cell line, BALB/c-MC. When mice were inoculated with BALB/c-MC, osteolytic lesions were recognized in tibiae as well as femur by histological examination and 3 D μCT (Scanco μCT40). Immunoreactivity for HGF was found in the stroma surrounding the metastatic lesions. CD31 (a marker of neovascularization)-positive blood vessels corresponded well to the loci showing HGF immunoreactivity. In contrast, expression of VEGF which is noted as a potent angiogenic factor for tumor neovascularization was not detected. To identify the cells of HGF production, we examined the secretion in the culture media. Concentration of HGF was elevated in osteoblasts (3.13 ± 0.25 ng/ml), while undetectable (< 0.4 ng/ml) in BALB/c-MC or bone marrow cells. The production of HGF by osteoblasts was significantly increased in response to PGE2. Addition of HGF (10 ng/ml) to BALB/c-MC cultures increased the number of cells 2 times during 6 days of cultures. In the invasion chamber assay, addition of HGF into the bottom wells facilitated motility and invasive potency of BALB/c-MC. By western blot analysis, c-Met/HGF receptor was identified in BALB/c-MC. When BALB/c-MC was cocultured in the upper chamber with osteoblasts in the bottom half, the number of infiltrating BALB/c-MC was increased 3 times compared with that in the cultures without osteoblasts. Addition of 240 nM NK4, an inhibitor of HGF, abolished accelerated invasive potency of the cells. Based upon these in vitro findings, we suppose that in certain types of bone metastasis osteoblasts would decoy cancer cells from sinusoidal capillary into bone marrow space and facilitate tumor proliferation through the actions of HGF. These observations would provide a basis to recognize a developing process of skeletal metastasis and explore therapeutic procedure for management of the disease. Since NK4 completely abolished the enhanced invasive potency of cancer cells, HGF inhibitors could be an alternative to prevent progress of bone metastasis.

Alendronate Prevents Femoral Neck Bone Loss in Postmenopausal Women with Breast Cancer Following Tamoxifen Withdrawal. J. Fleischer, A. Cohen, M. Johnson*, I. Brown, A. Joe*, D. J. McMahon, S. J. Silverberg. Medicine, Columbia University P & S, New York, NY, USA.

Postmenopausal women in the United States are at increased risk for both osteoporosis and breast cancer. Tamoxifen (TMX), a selective estrogen receptor modulator, has been used for many years to treat breast cancer. TMX has anti-estrogenic effects in the breast, but acts as an estrogen agonist in the skeleton, where it increases lumbar spine (LS) BMD and attenuates bone loss associated with the chemotherapy induced premature menopause. TMX is currently approved for 5 years of treatment. Since women withdrawn from estrogen experience a rapid decline in BMD, we hypothesized that women who stop taking TMX after 5 years would also experience this rapid decline. We therefore initiated a randomized, double blind, placebo controlled trial to determine whether alendronate 70 mg weekly prevents bone loss associated with the discontinuation of TMX. Eligible subjects were postmenopausal women with breast cancer who had no bone metastases. Patient accrual was limited by the introduction of aromatase inhibitors, which reduce estrogen levels and are now routinely begun in those discontinuing TMX at our center. After TMX withdrawal, 11 subjects (58 ± 8 [± SD] years old; 11 ± 7 years past menopause) were randomized to alendronate (ALN) or placebo (PLB) for 1 year along with calcium and vitamin D. T-scores were: LS -1.1 ± 1.2; total hip (TH) -0.4 ± 1.0; femoral neck (FN) -0.7 ± 1.0; and distal radius (DR) -0.3 ± 1.2. There were no differences in age or baseline BMD measurements between groups. After one year, FN BMD decreased in patients on PLB, but were stable in those receiving ALN (ALN +0.1% vs. PLB -5.2%; p=0.02). The effect on BMD did not differ by treatment at the LS (ALN: +2.0% vs. PLB: -1.6%; p= 0.19), the TH (ALN: +0.48% vs. PLB: -1.26%; p= 0.36), or DR (ALN: -1.4% vs. PLB : +1.0%; p= 0.10). In summary, TMX withdrawal was associated with a 5.2% decline in BMD at the femoral neck, which appeared to be prevented by weekly alendronate. This difference was evident despite the small sample size. These data suggest that in postmenopausal women with breast cancer completing TMX: 1) an evaluation of skeletal health is warranted; 2) bisphosphonate therapy may be an appropriate treatment to prevent bone loss. The current trend of placing patients on aromatase inhibitors following or even before TMX treatment raises even greater concern for the skeletal integrity of these at risk women.

PTHrP Derived Peptides without Amino Termini Can Be Identified in Prostate Cells. L. Deftos[1], C. Chalberg*[1], T. Downs*[2], S. Tu*[1], D. W. Burton[1]. [1]Medicine, Veterans Administration San Diego Healthcare System (VASDHS) and University of California, San Diego, San Diego, CA, USA, [2]Surgery, VASDHS and UCSD, San Diego, CA, USA.

PTHrP is robustly expressed in prostate cancer, where its three isoforms may be processed into distinct peptides by endoproteolytic cleavage. The resulting peptides mediate unique biological effects, including growth regulation, tumor progression, and metastases. The PTHrP 1-34 peptide is the most biologically characterized form, but potential non-amino terminal peptides of PTHrP (NTPs) can independently exert biological effects. To identify the presence of prostatic NTPs, we used 2-site immunoassays, immunoaffinity chromatography, westerns, and mass spectrometry. We evaluated extracts of human prostate cell lines and DU 145 cells that were stably transformed with PTHrP1-141 and mutant PTHrP1-141(1-32 region deleted) expression plasmids by two-site PTHrP immunoassays specific for PTHrP1-141, 38-141 and 67-141. The wild type PC-3 and LNCaP cells expressed PTHrP38-141 and 67-141, but no 1-141 was detectable (P 38-141>1-141 (pmol/ml), consistent with endoproteolytic processing events. As expected, the mutant PTHrP1-141(1-32 region deleted) cells expressed PTHrP38-141 and 67-141, but not the intact 1-141 ($P < 0.05$). We also evaluated fresh extracts of patient prostate cancer tissues and primary cultures using a similar approach. The two-site PTHrP immunoassays demonstrated significant increases ($P < 0.05$) in the expression for the 67-141 species compared to the 38-141 and 1-141 species in the prostate cancer tissues, 10, 8.5 and 0.5 pmol/ml, respectively. We further characterized the conditioned medium from DU 145 cells stably transformed with a PTHrP1-173 expression plasmid and profiled on a Ciphergen Protein G array pre-bound with anti-PTHrP. Several putative PTHrP processed peptides were identified in the secreted media using Time-of-Flight mass spectrometry. The masses of the identified PTHrP peptides from the Protein G array were 3144.9, 4109.4 and 5168.4 daltons, which are consistent with PTHrP15-40, 14-48 and 23-68, respectively. Taken together, these findings are supportive of the presence of non-amino terminal PTHrP peptides in prostate cancer cells and indicate endoproteolytic processing sites within the 1-37 and 38-64 regions of PTHrP that may or may not involve basic residues.

Design, Syntheses and Biological Activities of Less Calcemic, Prohormone- and Hormone-like 19-Nor-Vitamin D_3 Analogs for Prostate Cancer Treatment. A. Kittaka*[1], M. Arai*[1], R. Tsutsumi*[1], T. Sakaki*[2], N. Urushino*[3], K. Inouye*[3], S. Ito*[4], K. Takeyama*[4], S. Kato[4], M. F. Holick[5], T. C. Chen[5]. [1]Faculty of Pharmaceutical Sciences, Teikyo University, Kanagawa, Japan, [2]Faculty of Engineering, Toyama Prefectural University, Toyama, Japan, [3]Graduate School of Agriculture, Kyoto University, Kyoto, Japan, [4]The Institute of Molecular and Cellular Bioscience, University of Tokyo, Tokyo, Japan, [5]Endocrinology, Boston University School of Medicine, Boston, MA, USA.

1α,25-Dihydroxyvitamin D_3 (1,25D) is known to inhibit the proliferation and invasiveness of prostate cancer cells. Furthermore, prostate cells possess 1α-hydroxylase (1α-OHase), and can convert 25-hydroxyvitamin D_3 (25D) to 1,25D to inhibit their proliferation. Since 25D and 19-nor-1,25D are known to be less calcemic than 1,25D when administered systemically, we were interested in knowing whether 19-nor-25D and 2-substituted analogs of 19-nor-1,25D would exert potent antiproliferative activity toward prostate cells and therefore could be used as chemopreventive agents without causing hypercalcemic side effects. Synthesis of 19-nor-25D and 2-substituted analogs of 19-nor-1,25D, including 2-allyl-, 2-propyl-, 2-hydroxypropyl-, and 2-phenylcarbamoyl,3-deoxy-19-nor-1,25D were achieved by our new coupling method utilizing Julia-type olefination principle. In addition, a high-throughput analyzing system using a combination of fluorescence and micro-titer-plate has been developed to detect ligand-induced protein/protein interactions between vitamin D receptor (VDR) and coactivators (TIF2 or SRC-1). This system will be used to examine the selectivity of 2-substituted-19-nor-vitmtamin D_3 derivatives. Our results showed that 19-nor-25D had potent antiproliferative activity in prostate cells possessing high levels of 1α-OHase activity (e.g., PZ-HPV-7), but not in those lacking the enzyme (e.g. LNCaP cells). Moreover, 19-nor-25D was shown to be hydroxylated at the 1α position to form 19-nor-1,25D in a reconstituted cell-free system. The results suggest that 19-nor-25D must be converted to 19-nor-1,25D by endogenous 1α-OHase before exerting its antiproliferative activity. Among the 2-substituted analogs of 19-nor-1,25D, we found that a substitution with 2-phenylcarbamoyl group eliminated the antiproliferative activity, whereas substitution with 2-allyl, 2-propyl and 2-hydroxypropyl groups maintained the antiproliferative potency. We conclude that 19-nor-25D and 2-substituted analogs of 19-nor-1,25D can be effective chemopreventive agents for prostate cancer.

Osteocyte Stimulation of Chemotaxis and Invasiveness of Breast Cancer: A Proteomic Analysis. P. A. Veno[1], J. Zhao*[1], J. Guthrie*[2], S. Ko*[1], L. F. Bonewald[1], M. R. Dallas*[1], S. L. Dallas[1]. [1]Univ. of Missouri, Kansas City, MO, USA, [2]Midwest Research Institute, Kansas City, MO, USA.

Breast cancer frequently metastasizes to bone, causing bone destruction with complications of hypercalcemia, pain, fracture, and nerve compression. It is well established that osteoblasts and osteoclasts are critical for growth of breast cancer in the bone microenvironment and its associated bone destruction. However, even though osteocytes are the most abundant cells in bone, little is currently known concerning the potential role of osteocytes in breast cancer-associated bone disease. We hypothesized that osteocytes play an important role in breast cancer metastasis to bone and influence the behavior of the tumor in the bone metastatic site. To test this, we first examined the effects of conditioned media from the osteocyte-like cell line, MLO-Y4, on chemotaxis, invasiveness and proliferation of MDA-231 human breast cancer cells. Conditioned media from MLO-Y4 cells was chemotactic for MDA-231 cells and enhanced invasiveness as determined using the transwell migration assay and matrigel invasion chambers. MLO-Y4 conditioned media also stimulated production of matrix metalloproteinases 2 and 9 (MMP2 and MMP9) by MDA-231 cells, suggesting a role for these proteases in invasion. None of these effects were due to increased cancer cell numbers, as MLO-Y4 conditioned media had no effect on MDA-231 proliferation. To identify proteins and pathways that may mediate breast cancer cell responses to osteocyte-derived factors, a proteomics approach was used. Whole cell lysates from MDA-231 cells treated with 50% MLO-Y4 conditioned media for 24 hrs were compared to untreated control MDA-231 cultures by 2D gel electrophoresis. Differentially expressed protein spots were identified by peptide mass mapping with MALDI-TOF and/or by peptide sequencing (MS/MS). 19 differentially expressed or potentially modified protein spots were identified. One subset with increased expression included several proteins involved in cytoskeletal reorganization such as profilin, coactosin-like protein 1, GTP binding protein-rhoC, consistent with increased chemotaxis and invasion. Proteins involved in resistance to hypoxia and with angiogenesis, such as phosphoglycerate mutase and phosphoglycerate kinase, were also increased. Calcyclin, a calcium-binding protein that has been associated with malignant tumors, was also upregulated. This protein has been shown to act as a calcium sensor in osteoblasts and has been associated with bone formation. These data suggest that in addition to osteoblasts and osteoclasts, osteocytes may play an important role in the vicious cycle of cancer growth and bone destruction in metastatic lesions.

Zoledronic Acid and PTH Increase Bone Mass and Mechanical Strength Following Radiation Therapy for Osteolytic Bone Metastases. S. A. Arrington[1], J. E. Schoonmaker*[1], K. A. Mann*[1], T. Sledz*[2], G. Willick*[3], T. A. Damron*[1], M. J. Allen[1]. [1]Orthopedic Surgery, SUNY Upstate Medical University, Syracuse, NY, USA, [2]Micro Photonics, Allentown, PA, USA, [3]Biological Sciences, NRC, Ottawa, ON, Canada.

The specific aim of this study was to quantify the effects of a clinically proven bisphosphonate (zoledronic acid, ZA; Novartis Pharma AG, Basel) on bone mass, microarchitecture, and mechanical properties following radiation therapy for an osteolytic bone lesion. Additionally, we sought to determine if the beneficial effects of ZA could be further enhanced by concurrent use of an anabolic agent, PTH 1-34, following irradiation. The right distal femora of 22 female nude mice were injected with $1x10^5$ F10 human breast cancer cells. Mice were then divided into four groups: non-irradiated (0Gy, n=4), 20Gy only (20Gy, n=6), 20Gy plus ZA (ZA, n=6), and 20Gy plus PTH and ZA (PTH/ZA, n=6). The left non-operated limb of the 0Gy mice served as the control (n=4). Radiation therapy was administered to the right femur 3 weeks post-tumor inoculation. ZA (100µg/kg SC) was administered once weekly for 6 weeks starting three days before irradiation and PTH (80µg/kg SC) was administered 5 days a week for 4 weeks starting the day after irradiation. X-rays and DEXA scans were obtained at 3, 6 and 9 weeks post-tumor inoculation. Mice were euthanized at 9 weeks or earlier if severe lameness or pathology occurred. Hind limbs were explanted, scanned by micro-CT (10.46µm resolution) and mechanically tested through the intact knee joint. ANOVA and Fisher's PLSD were performed to analyze comparisons between groups. Bone mineral density significantly increased in both the ZA (19%, p=0.0109) and PTH/ZA (34%, p=0.0001) groups compared to treatment with 20Gy only. A 3-fold increase in fractional trabecular bone volume was measured in the PTH/ZA group compared to the 20Gy only group (p=0.003). Mechanical strength increased 115% in the ZA group (p=0.0133) and 92% in the PTH/ZA group (p=0.0645) compared to 20Gy only. Neither treatment with ZA or PTH/ZA completely restored mechanical strength to its normal value. These results clearly demonstrate that ZA used as an adjuvant to radiation leads to clinically relevant increases in mechanical strength. The combination of an anti-resorptive drug (ZA) along with an anabolic agent (PTH 1-34) as adjuvants to radiation therapy also significantly increase bone mass and trabecular bone volume. These results indicate that increased BMD and BV/TV do not restore the limb to its normal strength. Future work will include evaluation of bone quality and strength with altering the dosing and timing of adjuvant therapies.

Targeting Cathepsin K in Prostate Cancer Skeletal Metastasis *In Vivo*. Y. Lu[1], E. Keller[2], J. Dai[2], J. Escara-Wilke*[2], E. Corey[3], Z. Yao*[4], J. Zimmermann*[5], J. Zhang[1]. [1]Department of Medicine, University of Pittsburgh, Pittsburgh, PA, USA, [2]Department of Urology, University of Michigan, Ann Arbor, MI, USA, [3]Department of Urology, University of Washington, Seattle, WA, USA, [4]Department of Immunology, Tianjin Medical University, Tianjin, China, [5]Novartis Pharma Ltd, Basel, Switzerland.

Prostate cancer (CaP) frequently metastasizes to bone causing a mixture of osteoblastic and osteolytic lesions. The tumor invasion process is facilitated by proteolytic cascade involving multiple proteases, including matrix metalloproteinases (MMPs), serine proteases (uPA, plasmin), and cysteine proteases including cathepsin K (CatK). CatK degrades collagen I, and expresses predominantly in osteoclasts. Recently CatK expression has been shown in breast and prostate cancer cells. Importantly, its expression level is higher in CaP bone metastatic sites than primary tumor or normal prostate tissues. The role of CatK in CaP skeletal metastasis, however, has not been studied. In this study, we hypothesized that CatK contributes to CaP-induced osteoclast activity at bone metastatic sites, and inhibition of CatK by its selective inhibitor may prevent the CaP establishment and diminish the CaP progression in bone. Accordingly, we first confirmed the expression of CatK in LNCaP, C4-2B, and PC3 CaP cell lines. Then, we observed the inhibitory effect of CatK inhibitor on the CaP cell invasion suggesting the role of CaK in CaP tumor invasion. Finally, we injected C4-2B cells into the tibiae of SCID mice and then the animals (10 per group) received either vehicle or Cat K inhibitor (high or low dose) either at the time of tumor cells injection (tumor establishment model) or 4 weeks after tumor cells were injected (tumor progression model). In the tumor establishment model, CatK inhibitor significantly prevented the establishment of mixed osteolytic/osteoblastic tibia tumors as were observed in vehicle-treated animals; and in the progression model, CatK inhibitor diminished tumor-induced bone lesions, as demonstrated by radiograph, histology and bone histomorphometry. CatK inhibitor also decreased serum PSA levels in both animal models indicating decreased tumor burden. We concluded that CatK inhibitor is an effective drug to prevent the establishment and diminish progression of CaP growth in bone.

PTHrP Peptides Regulate Expression of Osteoblast Stimulating Factors by Prostate Cancer Cells. D. W. Burton, S. Tu*, C. Chalberg*, K. C. Smith*, L. J. Deftos. Medicine, Veterans Administration San Diego Healthcare System and University of California, San Diego, CA, USA.

Prostate cancer metastasis to bone is associated with increased osteoblast activity. The osteoblastic phenotype of metastatic prostate cancer lesions results largely from the actions of several stimulatory factors produced by prostate cancer cells. Since PTHrP is robustly expressed by prostate cancer cells, we evaluated 7 human prostate cancer cell lines, including DU 145, LNCaP, PC-3, Dupro-1, PPC-1, 267B1 and 267B1-XR for changes in the expression of several prostate derived osteoblast regulating factors, including OPG, RANKL, TGF-beta, ornithine decarboxylase (ODC), IL-6 and IL-8, after treatment with PTHrP peptides and expression plasmids. In general, OPG expression was increased by treatment with PTHrP1-34 and 38-64, and was decreased by PTHrP109-138. PTHrP140-173 stimulated OPG levels in PC-3 and PPC-1 cells but inhibited OPG levels in Dupro-1 cells. RANKL expression was inhibited by PTHrP140-173 in most of the cell lines. PTHrP140-173 treatment increased IL-6 expression in 267B1 cells, but decreased the IL-8 levels in the 267B1 and LNCaP cells. We further studied the intracrine effects of PTHrP by transfecting the DU 145 cells with full-length PTHrP and mutant (without the 1-32 amino acid region) expression plasmids. Cells transfected with full-length PTHrP1-139, 1-141, and 1-173 stimulated RANK, RANKL, IL-6, IL-8 and ODC levels and inhibited OPG. Deletion of the 1-32 region from the PTHrP plasmids prevented the maximal increases in IL-6 and IL-8 expression levels, indicating that the 1-32 region was critical for these changes. Conversely, deletion of the 1-32 region had no significant effects on the increased RANK, RANKL and ODC levels compared to controls, indicating that a non-amino terminal PTHrP region was responsible for the increases. There were also differences in cytokine levels of the PTHrP1-173 transfected cells compared to the PTHrP1-139 and 1-141 transfected cells, indicating a biological function for the 140-173 region. It is evident that PTHrP and the peptides derived from its processing can have multiple and varying biological effects in different tissues and in different preparations of the same tissue. So careful studies are required to gain insight into the mechanisms that lead to the formation of bone lesions by prostate cancer cells, to understand the predilection of prostate cancer to spread to bone, and to develop of more effective therapies for advanced prostate cancer. Our studies also confirm the biological activities of non-amino terminal PTHrP forms.

The Use of ^{18}F-FDG and ^{18}F-fluoride PET/CT Scans to Longitudinally Assess Biologic Behavior of Metastatic Osteolytic, Osteoblastic, and Mixed Lesions in a Prostate Cancer Model. W. Hsu, M. Jo*, B. T. Feeley, L. Krenek*, S. Gamradt*, D. Stout*, A. Chatziioannou*, J. R. Lieberman. Orthopaedic Surgery, UCLA Medical Center, Los Angeles, CA, USA.

Introduction The development of an imaging method that can assess the biologic activity of bone metastases *in vivo* would be advantageous in providing an objective assessment of the efficacy of different treatment modalities. The aim of our study was to evaluate the use of PET/CT scanning in the characterization of osteolytic, osteoblastic, and mixed cell prostate cancer lines in an established murine tibial injection model. **Materials and Methods** 1 x 10^5 cells of human prostate cancer cell lines PC-3, LAPC-9, and C42B were injected into the left tibia of 8-week old male SCID mice via a previously published protocol. Three animals were used for three consecutive time points for each cell line. Tail-vein injections using 250 uci of either ^{18}F-FDG and ^{18}F-fluoride ion tracer were then performed under a high-flow hood. All PET/CT images were analyzed using Amide®, Version 0.7.154. For ^{18}F-Fluoride ion and ^{18}F-FDG scans, regions of interest (ROIs) were drawn over the injected left tibia and contralateral control tibia using a standardized isocontour value for both sides. Lesion size was calculated by subtracting the size of right control tibial ROI from that of the left. **Results** ^{18}F-fluoride PET/CT scans detected greater uptake at consecutive time points for all cell lines. LAPC9 and PC-3 tumors exhibited greater bone turnover than C42B lesions. A progressively larger lesion was demonstrated by ^{18}F-fluoride scans for LAPC9 cells. In addition, a small lesion was measured using PET scan at the 4-wk time point that was undetectable using plain radiographs. ^{18}F-FDG PET/CT scans also demonstrated greater signal uptake for all cell lines at successive time points (figure 1). **Discussion** Our results indicate that using novel ROI drawing protocols and software analysis on PET/CT imaging, biologic activity, and osteoblastic and osteolytic lesion sizes can be detected at early time points and quantified longitudinally. This "real time" technique may prove to be superior to tumor burden measurements in the assessment of treatment modalities. Furthermore, by using *in vivo* imaging methods, the animals required for statistical power in further studies could be reduced.

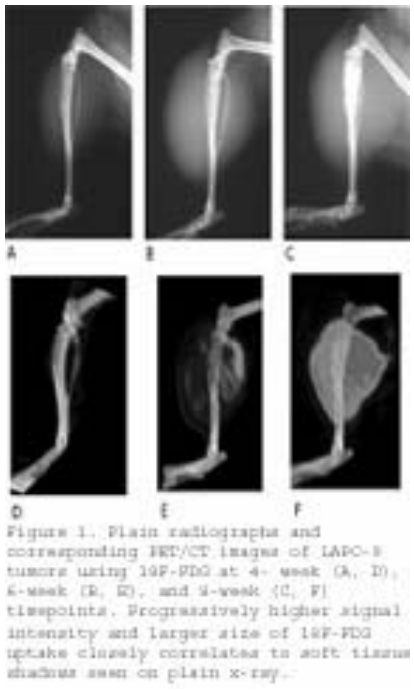

Figure 1. Plain radiographs and corresponding PET/CT images of LAPC-9 tumors using 18F-FDG at 4- week (A, D), 6-week (B, E), and 8-week (C, F) timepoints. Progressively higher signal intensity and larger size of 18F-FDG uptake closely correlates to soft tissue shadows seen on plain x-ray.

The Utility of Measuring Non-Isomerised C-Telopeptides of Type I Collagen (α-CTX) for Early Detection of the Skeletal Metastasis in Patients with Diagnosed Breast or Prostate Cancer. D. Leeming*[1], M. Koizumi*[2], C. Christiansen[3], P. Qvist[1], L. Tanko*[3], I. Byrjalsen*[1]. [1]Nordic Bioscience, Herlev, Denmark, [2]Cancer Institute Hospital, Tokyo, Japan, [3]Centre for Clinical & Basic Research, Ballerup, Denmark.

Skeletal metastases represent a serious complication of carcinoma of the breast or prostate, with direct implications for pain, fracture and overall prognosis. Early detection of such metastases is a prerequisite of timely intervention aiming the prevention of such complications. To date, bone scintigraphy remains the method of choice for diagnosis and monitoring of bone metastases. Biochemical markers provide useful support in first-line diagnostic approach and surveillance of these patients. We evaluated a novel biochemical marker of bone resorption, i.e. the non-isomerised C-telopeptide of type I collagen (α-CTX), for the detection of osteolytic tumour activity and thus the presence of bone metastases in patients with breast and prostate cancer. Morning urine samples were collected from 132 newly diagnosed cancer patients visiting the Cancer Institute Hospital, Tokyo, from October 2002 until April 2004. The study population included 90 women with breast cancer (45 with bone metastases) and 42 men with prostate cancer (17 with bone metastasis). Number of metastases was determined by scintigraphy, and those with >75% of their skeleton affected were excluded from the study (n=8). The urinary concentration of α-CTX was assessed by the ALPHA CrossLaps ELISA (Nordic Bioscience Diagnostics, Herlev, Denmark). The coefficient of long-term intra-individual variation in α-CTX was determined using fasting urine specimens from 115 generally healthy postmenopausal women collected at 4 consecutive time points over a two-year observation period. Regression analysis revealed a statistically significant correlation between α-CTX and the number of bone metastases ($r=0.64$, $p<0.0001$). Using this model, the average increases in α-CTX associated with the presence of one, two, or three skeletal metastases were estimated to be 37, 56 and 73%, respectively. Long-term intra-individual variation and least significant change (LSC) in the background population were estimated to be 20.4% and 40.0%, respectively. These initial observations suggest that measurement of α-CTX carries notable potentials for the early detection of skeletal involvement in patients with breast and prostate cancer. Longitudinal studies monitoring cancer patients with scintigraphy and biomarkers such as PSA and the herein introduced α-CTX are needed to define the relative utility of these diagnostic options for the early detection of skeletal metastases.

Convergence of AR & BMP Signaling Pathways on β-catenin. K. H. Emami*[1], L. G. Brown*[1], K. D. Brubaker*[2], R. L. Vessella*[1], E. Corey[1]. [1]Urology, University of Washington, Seattle, WA, USA, [2]Bloomsburg Unversity, Bloomsburg, WA, USA.

A major challenge in prostate cancer (CaP) research is understanding why CaP cells survive and proliferate in bone. Involvement of β-catenin as a coactivator modulated by androgen receptor (AR) as well as the BMP and Wnt signaling pathways, suggests involvement of a multiprotein signaling complexes in CaP growth in the bone environment. The objective of this study was to evaluate the effects of BMP-7 on the AR and Wnt (TCF/β-catenin) signaling network. Our preliminary data have shown that β-catenin is present in the nuclei of LNCaP, C4-2 and LAPC4 cells, and associates with AR. Treatment with BMP-7 dramatically increased association between AR and β-catenin. Interactions of these transcription factors with Smad1, was also enhanced upon BMP-7 treatment which led to increased AR transcriptional activity in LNCaP cells. Overexpression of AR in PC-3 CaP cells along with nuclear β-cateninS33F led to a reduction in TCF/β-catenin promoter activity. Similarly, abolishing AR expression in LNCaP cells led to increases in TCF/β-catenin activity in these cells. Competition between TCF/β-catenin and AR/β-catenin pathways in CaP cells was further demonstrated by growing cells in an androgen-free environment. The activity of AR was low and the activity of TCF/β-catenin pathway was the highest in the absence of the ligand (DHT), while in the presence of 1 nM DHT, AR activity was the highest and TCF/β-catenin showed the lowest activity. Interestingly, the effect of BMP-7 on TCF/β-catenin signaling was dependent on co-transfection of β-cateninS33F, suggesting that endogenous -catenin is in association with AR as opposed to TCF-4 in CaP cells. TCF/β-catenin transcriptional activity was undetectable in CaP cells and CaP cells treated with BMP-7. However overexpression of β-cateninS33F increased TCF/β-catenin transcriptional activities and treatment with BMP-7 further increased these activities. In conclusion, our data show that BMP signaling can interact with both the AR and TCF/β-catenin signaling pathways. We hypothesize that BMP-7 treatment enhances the AR or the TCF/β-catenin pathway, depending on the β-catenin status of the cell. We speculate that in the bone environment BMPs play a role in adaptation and proliferation of CaP cells in bone by activation of the AR and Wnt pathways. Further investigation of the effects of BMPs on CaP cells is warranted to delineate the signal-transduction network alterations in CaP cells and to elucidate further the role of BMPs in CaP bone metastases.

Does the Human Kallikrein Prostate Specific Antigen (PSA) Contribute to the Prostate Cancer Osteoblastic Response? J. S. Lai, E. Corey, L. G. Brown*, R. L. Vessella*. Urology, University of Washington, Seattle, WA, USA.

Metastatic prostate cancer has the propensity to elicit an osteoblastic response when in bone, in contrast to nearly all other tumors metastatic to bone which are mainly osteolytic. An obvious difference between prostate cancer and these other tumors is the expression of prostate associated serine proteases, including PSA. Our hypothesis is that PSA, as an active enzyme within the bone microenvironment, helps promote the osteoblastic response. We first blocked PSA proteolytic activity *in vivo*. LuCaP 23.1, a prostate cancer xenograft which produces high levels of PSA and causes an osteoblastic reaction in bone, and the neutralizing monoclonal antibody 17-1A3 developed by our laboratory were used in these experiments. Administration of 17-1A3 did not cause significant changes in bone mineral density or in trabecular bone volume. The percentage of free PSA was increased in animals treated with the 17-1A3 antibody, (26.11±0.59 *vs.* 6.17±0.80, $P<0.0001$), suggesting that the antibody exhibited neutralizing activity. Interestingly, tumor volume was significantly lower in the 17-1A3-treated animals as determined by bone histomorphometry (26.05±1.62 *vs.* 35.67±3.51, $P=0.031$). To further explore an association of PSA with the osteoblastic response, we overexpressed PSA in Chinese hamster ovary (CHO) cells using the Tet-on inducible system. *In vitro*, PSA-transfected CHO cells treated with tetracycline had up to 6 times higher levels of PSA when compared to LNCaP cells (161.97±6.67 *vs.* 26.75±0.825 ng/ml/10^5 cells, $P=0.0025$). When TREx-CHO/PSA cells were injected

subcutaneously, high serum PSA levels were observed in the induced animals (~1ng/ml/mm^3 tumor), and the PSA expression did not affect tumor growth in this model. To evaluate the effects of PSA overexpression on bone, TREx-CHO/PSA cells were injected intra-tibially. Immunohistochemical and bone histomorphometric analyses of bone response and effects on tumors will be presented.

Multiple Pathways Involved in the Interaction between Prostate Cancer Cells and Osteoblasts during Bone Metastases. J. Wang*, A. S. Levenson*, J. C. Jarrett*, R. L. Satcher. Department of Orthopaedic Surgery, Northwestern University, Chicago, IL, USA.

The interaction between prostate cancer cells and osteoblasts is critical to progression of bone metastasis. The molecular mechanism on the bi-directional interaction is poorly understood through conventional co-culture methods, because they only allow soluble interaction but exclude physical contact. By using our novel heterotypic co-culture system, we previous found that both physical contact and soluble factors contributed to metastasis progression. This study is to investigate the signal pathways between prostate cancer cells and osteoblasts in bone metastases. In the heterotypic co-culture system, fluorescence-labeled prostate cancer cells were mixed and co-cultured with osteoblasts. Two types of cells were then re-separated through fluorescence-activated cell sorting. Gene expression profiles and kinase signaling were studied by using pathway-focused gene arrays, RT-PCR and Western blot. The results showed that extracellular protease were up-regulated in both prostate cancer cells and osteoblasts, including MMP-2, MMP-9, uPA and cathepsin K. The protease activation contributed to modification of extracellular matrix components and cell adhesion molecules, such as collagen III, collagen IV, collagen X, collagen XII, fibronectin, integrin α1, integrin α2 in prostate cancer cells and collagen VIII, collagen IX, VCAM-1 in osteoblasts. Some other bone matrix proteins (biglycan, decorin, osteopontin) were also modified during the interaction. TGFβ-BMP superfamily pathway was activated in both types of cells. In prostate cancer cells, TGFβ receptor 1 and downstream signal transduction molecule smad 9 were up-regulated. In contrast, TGFβ receptor 1, TGFβ receptor 3 and smad 6 were down-regulated in osteoblasts. In addition, colony-stimulating factors (CSF) were also involved in the interaction, including CSF1, CSF2 and CSF-1 receptor. MAP kinase signal transduction pathway was activated in prostate cancer cells. Among the cascade members, MMK4/JNKK1 was down-regulated while mta-1 and raf-1 were up-regulated. In conclusion, the interaction between prostate cancer cells and osteoblasts modified extracellular matrix protein/protease and growth factors. It in turn activated protein kinase signaling through various growth factors receptors and cell adhesion molecules. It suggested that multiple signal pathways were activated in prostate cancer bone metastasis. Blockage of various pathways simultaneously may be necessary to interference the progression of tumor metastases.

Enhanced Expression of E-selectin on Bone-Derived Vascular Endothelial Cells: Potential Role in Breast Cancer Metastasis. C. V. Gay, L. A. Makuch*, D. L. Geffel*, D. M. Sosnoski*. Biochemistry and Molecular Biology, The Pennsylvania State University, University Park, PA, USA.

Breast cancer cells frequently metastasize to the ends of long bones, ribs and vertebrae, structures which contain a rich microvasculature in close juxtaposition to metabolically active trabecular bone surfaces. This study focuses on the effects of osteoblast secretions on the expression of surface adhesive proteins by skeletal vascular endothelial cells. Vascular endothelial cells were isolated from trabecular bone regions and from the central marrow cavity (which lacks trabecular bone) from long bones of 7 week old Swiss Webster mice. Both types of endothelial cells were placed in culture for 7 days, then exposed 24 hrs to conditioned media (CM) from MC3T3-E1 osteoblasts. CM from two different stages of osteoblast development were tested: (1) from immature MC3T3-E1 cells cultured 5-7 days and (2) from mature MC3T3-E1 cells cultured 28-30 days. The immature osteoblasts were in a state of rapid proliferation; the mature osteoblasts formed a matrix that mineralized. Following exposure to the conditioned media, the vascular cells were exposed to specific antibodies to p-selectin, e-selectin, ICAM-1 or VCAM-1, cell surface adhesive proteins to which breast cancer cells are known to bind. To visualize surface staining, fluorescent secondary antibody was applied followed by confocal microscopy. Of the four proteins evaluated, e-selectin was consistently found on more (~30%) cell surfaces of bone-derived vascular endothelial cells (BVECs) when exposed to the immature osteoblast CM. Vascular endothelial cells from marrow (MVECs) did not show this response to either immature CM or mature CM. RNA has been isolated from both BVECs and MVECs using Qiagen RNeasy; BVECs contained ~3-fold more total RNA than MVECs, an indication that BVECs are more metabolically active. Finally, secretions from immature and mature OBs were found to be chemotactic for a breast cancer cell line, MDA-MB-231, with the mature OB cell secretion being ~ 2-fold more effective as a chemoattractant. Collectively, these studies suggest that 1) the BVEC blood vessels near immature bone cells express more surface adhesive protein, i.e. e-selectin, that could enhance entrapment of breast cancer cells, and 2) once cancer cells have undergone extravasation into marrow adjacent to bone they could be attracted to nearby bone surfaces, particularly sites of bone formation where mature osteoblasts are found. This combination of factors may contribute to the uniqueness of bony sites and therefore to breast cancer cell adhesion and subsequent tumor growth.

Effects of Alendronate on Bone Mineral Density in Men with Prostate Cancer Treated with Androgen Deprivation Therapy. J. M. Bruder[1], D. Katselnik*[1], N. Wing*[1], J. Z. Ma*[2]. [1]Medicine, University of Texas HSC at SA, San Antonio, TX, USA, [2]Psychiatry, University of Texas HSC at SA, San Antonio, TX, USA.

It is known that bone mineral density (BMD) is low in men with prostate cancer receiving androgen deprivation therapy (ADT). Recent studies have demonstrated the efficacy of intravenous bisphosphonates in preventing this bone loss, however, the effectiveness of oral bisphosphonates has not been studied in this population. Therefore we reviewed the charts of patients with prostate cancer receiving ADT referred from the VA Urology Clinic for BMD testing and identified 47 patients with baseline and follow up BMD measurements (mean $\pm$ SD = 18 $\pm$ 7 months). As part of routine care, all were receiving calcium supplements and a multivitamin. Twenty-two men (47%) were also receiving alendronate 70 mg po every week. BMDs were measured at the spine (L1-L4), total hip, trochanter, femoral neck, and radius. To account for the variability in recall, changes in BMD measurements were converted to percent change per year. The most significant difference between groups was seen at the femoral neck. There was a decrease of 2.17 $\pm$ 0.7 % per year in the untreated patients but a 0.32 $\pm$ 0.6 % increase per year in the alendronate treated patients (p 0.0086). Statistically significant differences ($p<0.05$) in the 2 groups were also seen at the L1-L4 spine (-1.29 $\pm$ 0.7 % vs + 1.41 $\pm$ 0.7%), total hip (-0.94 $\pm$ 0.6 % vs + 0.97 $\pm$ 0.5 %) trochanter (- 2.01 $\pm$ 0.7 % vs + 0.79 $\pm$ 0.8 %). In the four other sites measured at the radius (proximal, mid, ultra distal and total), there were no statistically significant differences ($p > 0.05$). These findings confirm that bone loss occurs in men receiving ADT at all sites measured. The use of alendronate can prevent bone loss at the spine and hip, but does not seem to have the same protective effect at the radius. Further study will be required to determine why the radius does not seem to adequately respond to alendronate therapy.

Gene Expression Associated with Prostate Cancer Bone Metastasis. C. Morrissey[1], I. M. Coleman*[2], M. P. Roudier*[1], E. Corey[1], T. S. Kim*[2], L. G. Brown*[1], J. Hahn*[1], C. S. Higano*[1], L. D. True*[1], P. S. Nelson*[2], R. L. Vessella*[3]. [1]Urology, University of Washington, Seattle, WA, USA, [2]Fred Hutchinson Cancer Research Center, Seattle, WA, USA, [3]Urology, University of Washington and Puget Sound VA Medical Center, Seattle, WA, USA.

One of the two major sites of metastases of prostate cancer is bone, but the mechanisms and key factors involved in the propensity of prostate cells to go to bone, proliferate in the bone environment and promote an osteoblastic response are not understood. Our objective is to elucidate phenotypic differences between soft-tissue metastases and bone metastases of prostate cancer. Soft tissue and bone metastasis samples were obtained from patients expiring from advanced prostate cancer within 2-6 hours of death under the auspices of our Rapid Autopsy Program. First, we grossly microdissected metastatic foci from frozen samples and performed expression analysis using a 7K Prostate Expression Data Base (PEDB) and 18k human cDNA microarray chips. Examples of phenotypic changes associated with bone metastases included altered expression of Factor XIIIA, EBP50 and Bone Sialoprotein. To minimize or eliminate the potential of contamination of tumor cells with stromal and bone cells we have mastered laser capture microdissection of tumor cells. cDNA array analysis of these samples showed that 65 genes were upregulated in bone metastases vs. non-osseous metastases, while 41 genes were down regulated (q-value < 1). We are now combining and comparing the cDNA array results from these 2 experiments. Because of the rate of false positive and false negative results from cDNA analyses we will validate the phenotypic changes in two ways. First, the immunohistochemical analyses of markers associated with bone metastases will be performed using a tissue microarray from 30 individuals containing prostate cancer metastases to lymph node (N=46), liver (N=19), and bone (N=104). Secondly, we will elucidate *in vitro* the potential of the bone environment to cause the phenotypic changes detected in patient specimens. In this model PC-3 and C4-2B cells are co-cultured with mouse osteoblasts (MC3T3-E1) at different stages of differentiation. Real-time PCR, immunohistochemistry and cDNA arrays will be used to evaluate altered gene expression of selected candidates. In conclusion we have resources and techniques in place to obtain critical information about key factors associated with the propensity of prostate cancer to metastasize to bone and to yield an osteoblastic response. Results of these validation studies will be presented.

Morphological Study for a Mechanism of Osteolysis by the Human Breast Cancer Cell MDA-MB-231. H. Nakamura*[1], T. Hiraga[2], T. Ninomiya*[3], A. Hosoya*[1], M. Yamaki*[3], Y. Arai*[3], T. Yoneda[2], H. Ozawa*[3]. [1]Oral Histology, Matsumoto Dental University, Shiojiri, Japan, [2]Biochemistry, Osaka University Graduate School of Dentistry, Suita, Japan, [3]Institute for Oral Science, Matsumoto Dental University, Shiojiri, Japan.

We investigated osteolytic bone metastasis induced by the human breast cancer cell MDA-MB-231 using morphological and immunohistochemical methods. To clarify the mechanism of osteolysis, we used an experimental animal model in which inoculation of MDA-MB-231 cells into the left cardiac ventricle of female nude mice causes osteolytic lesions in bone. Four weeks after the cell inoculation, metastatic tumor cells occupied bone marrow cavity and bone trabeculae were extensively destroyed. On the bone surfaces

facing tumor cells, there existed many TRAP- and cathepsin K-positive multinucleated osteoclasts. Of note, TRAP-positive mononuclear and multinuclear cells were also observed in the tumor nests. Immunohistochemical and electron microscopical examinations revealed that these TRAP-positive cells were in direct contact with RANKL-positive stromal cells. Furthermore, we found that MDA-MB-231 cells colonized in bone expressed PTHrP in their cytoplasm. This evidence suggests that tumor-producing PTHrP upregulates RANKL expression in bone marrow stromal cells, which in turn stimulates osteoclast differentiation, leading to the progression of osteolytic bone metastases. On the other hand, it has been reported that bone metastasis was reduced in osteopontin (OPN)-deficient mice. We also examined the localization of OPN, CD44 and hyaluronan in tumor nests. MDA-MB-231 cells showed CD44 -positive reactivity on their plasma membrane. OPN and hyaluronan, ligands for CD44, localized in the extracellular matrix around stromal cells and tumor cells. Immunoelectron microscopy demonstrated that OPN was localized in the Golgi apparatus of stromal cells and in the extracellular matrix between stromal cells and tumor cells. Western blotting using tumor lysate indicated that tumor nests contained OPN and CD44. These results suggest that CD44-OPN interaction may play an important role in initial step of metastasis in bone. RANK-RANKL interaction may be involved in the differentiation and activation of osteoclasts in osteolytic bone metastasis

Repeatability and Sensitivity of Vertebral Morphometry Studies Using the Norland Scanner. J. M. Wang[1], J. C. Liu*[2], T. V. Sanchez[3]. [1]Research and Development, Norland--a CooperSurgical Company, Beijing, China, [2]Department of Nuclear Medicine, PLA 304th Hospital, Beijing, China, [3]Research and Development, Norland--a CooperSurgical Company, Socorro, NM, USA.

The use of DXA equipment to do vertebral morphometry assessments has generated recent interest in the community--this study examines the repeatability of Norland based vertebral morphometry studies and compares those studies to film based morphometry studies. Thirty subjects between 22 and 85 years of age underwent Lateral Spine X-ray Film studies and scans of the T8-L4 spine in lateral recumbancy using the Ruler Tool on Research Scan studies obtained on a Norland XR-36 fitted with Illuminatus software. Additionally, six of these subjects between 22 and 45 years of age undertook a total of four repeated DXA studies--with repositioning--to examine procedural repeatability. Examining the repeatability of DXA-measured anterior, mid and posterior vertebral body height ratios (A_h/P_h , M_h/P_h , P_h/A_h , M_h/A_h) showed repeatability was consistently below 4% for studies of the T8 to L4 region and compares well with the 5% repeatability reported in the literature. When the 1,080 anterior, mid and posterior vertebral body height ratios (A_h/P_h , M_h/P_h , P_h/A_h , M_h/A_h) measured by DXA were compared with morphometric study of Lateral Spine X-ray Film, results proved highly correlated (r = 0.99). Further, when--based on vertebral body height ratios--Lateral Spine X-ray Film demonstrated 11 subjects had evidence of deformity those subjects also showed indications of a deformity by DXA. In conclusion, this study demonstrates that vertebral morphometry studies done with the Norland system are repeatable and that those studies show strong agreement with Lateral Spine X-ray Film studies.

Fat Mass Loss in Obese Subjects Treated with Carnitine: A Whole Body DXA Evaluation. C. V. Albanese[1], M. Danti*[1], I. Preziosa*[2], A. Laviano*[2], R. Passariello*[1]. [1]Department of Radiologic Science, Univerity of Rome, Rome, Italy, [2]Departement of Clinical Medicine, Univerity of Rome, Rome, Italy.

Purpose: Carnitine (CAR) is involved in fatty acid oxidation and its supplementation may facilitate body weight (BW) loss in dieting obese patients. Similarly, calcium (Ca) supplementation appears to influence BW loss by increasing in fatty acid oxidation.We, therefore, hypothesised that CAR and/or Ca supplementation in dieting overweight/obese patients may boost BW loss. **Material and methods:** patients with a body mass index (BMI) ranging 25-35were considered for the study for a period of six months. They were randomly assigned to 4 groups. Group 1:hypocaloric diet(4800 kJ/d for females and 5600kJ/d for males; Ca:900mg/d); group 2:hypocaloric diet(isocaloric with group 1;Ca:1500mg/d); group3:hypocaloric diet (isocaloric with group1;Ca:900 mg/d)+CAR 4g/d; group 4: hypocaloric diet (isocaloric with group;Ca:1500 mg/d)+CAR 4g/d. BW and BMI were monthly measured. Results are expressed as mean± SD.Total and regional fat mass and lean mass was evaluated by whole body DXA. **Results:** At present,44 patients have been enrolled and completed 3 months of follow-up. In all groups BW significantly decreased, and % BW vs. baseline is:94.5±4.7(Group 1; n=11), 94.4±3.1(Group 2; n=11),94.3±3.2(Group 3; n=12),94.3±3.2 (Group 4; n=10).The protocol also included analysis of body composition via DXA basal and at 6 months. However, the number of patients in each group who completed the 6-month follow-up does not allow statistical analysis. Thus, we pooled patients from groups 1 and 2(no CAR) and compared their body composition analysis at 6 months with that of the pool of patients from groups 3 and4(CAR).Data analysis shows a trend toward increased fat mass loss in patients receiving CAR vs patients not supplemented(-4.7% vs -2.7%, respectively). By pooling patients from groups 2 and 4(high Ca)and then comparing their body composition analysis with that of patients from groups 1 and 3 (normal Ca),Ca supplementation does not appear to induce any effect on fat mass loss(-3.2%vs-5%, respectively). **Conclusions:**CAR/or Ca supplementation seem to enhance BW loss in dieting overweight/obese patients.The results also appears to suggest that CAR supplementation may facilitate fat mass loss.Whole body DXA was able to discriminate between total and regional fat and lean mass in such subjects with high degree of accuracy and diagnostic sensibility.

Allometric Scaling of Bone Mineral Content at Various Skeletal Sites in Boy and Girls: Accounting for Bone Size and other Confounding Variables. M. Burrows*[1], J. R. Welsman*[1], D. Simpson*[2]. [1]Childrens Health and Exercise Research Centre, University of Exeter, Exeter, United Kingdom, [2]Nuclear Medicine, Kent and Canterbury Hospital, Canterbury, United Kingdom.

There is debate regarding appropriate methods of controlling for bone size when interpreting bone mass in children. Traditionally bone mineral density is calculated by dividing bone mineral content (BMC) by projected bone area (Ap) but this may not accurately reflect bone volume at specific sites. In addition, bone size is not the only confounding variable associated with BMC. This study assessed the effects of age, sex, A_p and selected anthropometric variables on the interpretation of BMC in children, 38 boys and 94 girls (aged 10.5 ± 3.7). BMC (g), body fat (%), and projected bone area (A_p, cm^2) at the Femoral neck (FN), Trochanter (T) and Total body (TB) were measured using DEXA (GE Lunar, Prodigy). Stature (cms) and body mass (kg) were also recorded. Log-linear regression was used to examine whether age and selected anthropometric variables were predictors of BMC, alongside A_p across the skeletal sites in boys and girls. Significant predictors of FN BMC, T BMC and TB BMC in the boys and girls are shown in Tables 1 and 2 respectively. All coefficients for A_p were significantly different from that predicted by geometric similarity (1.5). In boys, the positive effect of body mass combined with the negative coefficient for body fat indicate that lean body mass is a key determinant of BMC alongside A_p. For girls body fatness was not associated with BMC at any site and the influence of other anthropometric predictors was not consistent across sites as seen in the boys. These results suggest that the predicted exponent of 1.5 does not hold true across skeletal sites and for accurate interpretation of BMC at different sites individual exponents need to be utilised in children. In addition, it may not be adequate to interpret BMC in children according to A_p alone.

Table 1. Log-linear regression results for the boys

Assessment of Total Body Percent Fat from Spine and Femur DXA Measurements in Chinese Women and Men. H. Xu*[1], Q. Zhou*[2], Y. Zhang*[3], J. Gong*[1], W. K. Wacker*[4], L. S. Weynand*[4], F. Chen*[3], K. G. Faulkner[4], S. Lin*[3]. [1]Nuclear Medicine, Ji Nan University 1st Hospital, Guangzhou, China, [2]GE Healthcare, Shanghai, China, [3]Peking Union Medical College Hospital, Peking Union Medical College, Chinese Academy of Medical Science, Beijng, China, [4]GE Healthcare, Madison, WI, USA.

In the past, body composition studies with DXA have required total body scans to measure total body %fat. Recently, estimation of total body %fat from spine and femur DXA scans has been validated for American adult males and females (JBMR 2004;19; Suppl 1:S363). We determined whether regional body composition estimates from spine and femur DXA scans, along with height, weight and body mass index (BMI), in Chinese women and men could be used to predict total body %fat. We examined results from 748 female Chinese subjects (mean age 52 ± 15; range 20-90 years), and 138 male Chinese subjects (mean age 52 ± 17; range 20-84 years) whose spine, femur, and total body were measured concurrently with a Lunar Prodigy densitometer (GE Healthcare) at one of two centers. Regression models of female and male total body %fat as functions of BMI and spine and femur soft tissue thickness and %fat were developed. Five female subjects were excluded as statistical outliers; no male subjects were excluded. Strong correlation between measured and predicted total body %fat was observed (r=0.95 for females, r=0.96 for males). Regression of measured with predicted total body %fat gave a slope and intercept not significantly different from one and zero, respectively, for both females and males (Figures 1,2). The standard errors for the measured values are 2.3 %fat for females and 2.4 %fat for males.We conclude that data obtained from spine and femur scans, in combination with anthropometric information, provide a good estimate of total body fat and fat-free

body composition in the Chinese population. On systems that do not offer total body measurements, regional body composition information derived from spine and femur scans can be used to estimate total body fat percentage.

Long-Term *In Vivo* QCT Scanning of Nasal Turbinates in Cynomolgus Monkeys. A. Varela, I. A. Moreau*, M. Sabourin*, C. Chevrier*, J. Jolette*, S. Y. Smith. Charles River Laboratories Preclinical Services•CTBR, Senneville, PQ, Canada.

The purpose of this study was to assess the long-term reproducibility of quantitative computed tomography (QCT) scanning of nasal turbinates (NT) in cynomolgus monkeys. It is important to precisely evaluate the safety of inhalation or intranasal administration of bone active drugs in chronic studies. QCT scanning also offers a unique opportunity to identify abnormalities for further histologic assessments that may go undetected. QCT scans were obtained of NT for 6 females aged 6 to 9 years, at baseline, 3, 6 and 9 months. For comparison, scans were obtained at larger and more traditional sites at mid L4 and the distal femur (metaphysis [met] and diaphysis [dia]). QCT NT scans were normally obtained posterior to the second premolar (anterior site) and mid first molar (posterior site). The pattern of the turbinates and sinuses, and the anatomy of the maxilla and orbits were used as landmarks for positioning. For analysis, separate regions of interest were placed manually around the left and right middle turbinate, inferior turbinate and nasal septum at each site. Precision was calculated for area as the coefficient of variation (%CV) over the 4 scanning occasions for each animal. CV% was also determined for BMC and BMD but these parameters were expected to be more variable in monkeys that may not have attained peak bone mass. There were no differences observed between right and left NT therefore both were included as separate observations for the purpose of assessing precision. The %CV for the NT (inferior, middle and septum) at anterior and posterior sites was similar for area and ranged from 3.7±1.4 to 7.6±6.6%. As expected, the CV% for BMC and BMD were more variable and ranged from 3.8±1.6 to 11.7±7.8%. In comparison, the overall %CV obtained for total area at the femur met was 3.3±2.0%, the dia was 2.2±2.7%, and mid L4 was 1.4±0.5%. Precision of NT scanning was acceptable but reflected the limitation of the equipment to detect low amounts of mineral in a small area. The area under evaluation for NT was: 15.8±3.5 to 22.7±6.9 mm^2, compared to larger areas at the femur: 126±20 mm^2 (met) and 39±4 mm^2 (dia), and L4: 117±17 mm^2. The amount of mineral (BMC) in the NT differed markedly from the other sites, contributing to the level of precision attainable: NT: 2.3±0.7 to 5.7±2.2 mg/mm; femur met: 64.3±10.2 mg/mm, dia: 49.6±5.2 mg/mm; L4: 52.6±8.8 mg/mm. QCT detected abnormalities of the NT which may otherwise have gone undetected, permitting a more complete histologic evaluation.The long-term reproducibility of in vivo QCT scanning of NT was considered acceptable supporting safety assessments at this site to monitor the chronic intranasal administration of bone active drugs.

Osteoporosis in Chinese American Women: Determinants of Bone Mass. M. Donovan[1], R. Babbar[2], A. Opotowsky[3], F. Nabizadeh[4], A. Rohira*[5], W. Chung*[2], J. Chiang*[2], A. Mediratta*[2], D. McMahon[1], G. Liu*[2], J. P. Bilezikian[1]. [1]Medicine, College of Physicians and Surgeons, Columbia University, New York, NY, USA, [2]Medicine, NYU Downtown Hospital, New York, NY, USA, [3]Medicine, Brigham and Women's Hospital, Boston, MA, USA, [4]Obstetrics and Gynecology, NYU Downtown Hospital, New York, NY, USA, [5]Medicine, Cabrini Medical Center, New York, NY, USA.

Asian women have lower bone mineral density (BMD) than Caucasian women. Chinese women, however, have a lower hip fracture rate than Caucasian women. The relationship between BMD and fracture risk, thus, may differ for Caucasian and Chinese women, which may have implications for diagnosis and treatment of osteoporosis (OP). The purpose of this study is 3- fold: (1) to identify determinants of BMD in Chinese American women; (2) to develop a referent BMD database among Chinese American women; (3) to compare these data to that of Caucasian women in the US. Four hundred Chinese American women, in New York City, age 20-90, are being recruited. Along with DXA of the total hip (TH) and lumbar spine (LS), demographic, familial, nutritional, and behavioral data are being obtained using a questionnaire. To date, 359 women have been recruited. In this cohort, 94 % are foreign born and mean (±SEM) age at emigration was 31±.8 yrs. Mean residence in the US is 14.2±.6 yrs. Mean BMI is 23.3±.2 kg/m^2. Mean age of menarche and menopause are 13.6±.1 and 50.1±.4 yrs respectively. Mean # of pregnancies and live births are 2.3±.1 and 1.6±.1 respectively. Seventy-five percent engage in weekly physical activity. Among this cohort, 4.4% were ever-smokers with mean pack-yrs 38±26. Thirty five percent imbibe alcohol, consuming 14±2.5 grams of alcohol weekly. Daily calcium intake is 612±17 mg. Peak BMD (PBMD) in Chinese American women is lower at the TH (.906±.13 *vs* .942±.12, p<.0001) and LS (1.013±.13 *vs* 1.047±.11, p<.0001) compared to Caucasian women. In contrast to Caucasian women who reach PBMD in the third decade, PBMD is not achieved until the fifth decade (ages 40-49). Determinants of BMD are being evaluated using multiple regression. When we used this newly established Chinese American database, the OP detection rate in our Chinese American cohort ≥age 50 was 51% lower than when we used the Hologic Caucasian database (p<.001). If fracture risk is considered in relation to peak BMD for a specific population, and not BMD in absolute terms (g/cm^2), then use of a Caucasian reference for diagnosis of OP leads to an overestimate of fracture risk among Chinese Americans. These observations may explain discrepancies between T-scores and fracture incidence among Chinese Americans. This study provides a race and geographically-specific BMD database that has clinical relevance to a Chinese American population.

SU130

Co-Morbidity of Decreased Bone Mineral Density (BMD) and Increased Cholesterol Levels among Women Aged 65 Years and Older: Results from NHANES III. J. P. Bilezikian[1], M. Davidson*[2], S. Hendrix*[3], L. Liu*[4], M. Louie*[5]. [1]College of Physicians and Surgeons, Columbia University, New York, NY, USA, [2]Rush University Medical Center, Chicago, IL, USA, [3]Wayne State University Health Center, Detroit, MI, USA, [4]Pfizer, Inc., New York, NY, USA, [5]Weill Medical College of Cornell University, New York, NY, USA.

Low bone mineral density (BMD) is known to be prevalent among women aged 65 years and older, but the co-prevalence of low BMD and increased total and low density lipoprotein (LDL-C) cholesterol levels in this population has not been previously explored. The purpose of this study was to assess the co-prevalence of low BMD and high total and LDL-C cholesterol levels among women aged 65 years and older in the United States. We analyzed BMD and cholesterol data from the third National Health and Nutrition Examination Survey (NHANES III), conducted by the Centers for Disease Control (CDC) from 1988-1994. NHANES data are weighted to be representative nationally. All women aged 65 years and older who participated in the survey were identified for this study. Based on central BMD measurements, these women were classified into three groups as defined by World Health Organization (WHO) criteria for BMD T-scores: normal (>-1.0), osteopenic (-1.0 to -2.5), and osteoporotic (<-2.5). We also examined total and LDL-C cholesterol levels among the study cohort. Among the 19.0 million women aged 65 and older estimated from this national database, 9.6 million (50%) were found to be osteopenic, 3.9 million (21%) were found to be osteoporotic, and 5.5 million (29%) had normal BMD. Seventy-three percent of the osteopenic individuals had total cholesterol (TC) levels of 200mg/dl or greater and 63% had LDL-C levels of 130mg/dl or greater. Among women with osteoporosis, 63% had high TC and 53% had increased LDL-C levels. Among women with normal BMD, 78% had elevated TC and 61% had increased LDL-C. The NHANES III analysis indicates that greater than 70% of all American women aged 65 and older have either osteopenia or osteoporosis, and the majority of these women also have high total and LDL-C cholesterol levels. The fact that the percentage of normal subjects and osteopenic/ osteoporotic subjects who have elevated TC and LDL-C is similar raises questions about the relationship between coronary artery disease and bone loss in postmenopausal women. Nevertheless, the presence of high TC and LDL-C amongst patients with osteopenia/ osteoporosis presents a significant comorbidity profile that may have important clinical implications.

Body Composition Reference Values in Normal Chinese Women. S. Lin*[1], Q. Zhou*[2], Y. Chen*[3], X. Lin*[4], Q. Yang*[3], R. Chen*[1], H. S. Barden*[5], Y. Zhang*[1], F. Chen*[1], K. G. Faulkner[5]. [1]Obstetric and Gynecology, Peking Union Medical College Hospital, Peking Union Medical College, Chinese Academy of Medical Science, Beijng, China, [2]GE Healthcare, Shanghai, China, [3]Jinan Maternity And Child Care Hospital, Jinan, China, [4]Guangdong Zhongshan Obstetric and Gynecology Hospital, Zhongshan, China, [5]GE Healthcare, Madison, WI, USA.

Dual-energy X-ray absorptiometry (DXA) is used increasingly as a rapid, precise and accurate method for measurement of regional and total body composition in both clinical and research settings. Numerous clinical conditions affect body composition, including, obesity, eating disorders, malabsorption disorders, sex hormone disorders, growth hormone deficiency, diseases that cause muscle wasting and liver and heart disease. We measured body composition with DXA (GE Lunar Prodigy) in 268 normal Chinese females aged 20 to 75 years. In addition to the traditional measurements of total body bone mineral content (BMC), lean mass (LM), fat mass (FM), and %Fat, we measured android (waist) and gynoid (hip) %Fat.

Age (years)	n	Height (cm)	Weight (kg)	BMC (g)	Lean (g)	Fat (g)	%Fat	Android (%Fat)	Gynoid (%Fat)
20-29	53	160.4	54.2	2260	34723	16124	30.5	34.2	40.4
30-39	57	159.2	56.8	2328	35869	17527	33.4	36.8	40.9
40-49	50	159.9	61.2	2367	37021	20533	35.7	40.1	43.1
50-59	48	157.2	60.2	2134	35297	21249	36.9	43.9	44.0
60-69	45	155.6	58.6	1925	34947	19969	36.7	44.1	41.9
70-79	15	154.4	62.3	1927	35593	23329	40.3	45.1	44.0

Results showed LM and BMC peaked during the 5th decade, followed by a decline of 19% and 4% for BMC and LM, respectively by age 75 years. Total body FM and %Fat, as well as android and gynoid %Fat showed a general increase with age throughout the age range studied. FM increased 38.4% from young adult age (20-39 yr) values to age 70-79 years, while %Fat increased from 32% at young adult age to 40% at age 70-79 years. Total and regional fat measurements generally continued to increase with age, while lean mass and BMC peaked in the decade of 40-49 years in these Chinese women. Comparison of patients to an appropriate reference group is important because average body composition may vary substantially between populations.

SU132

Precision of Total Body BMD and Body Composition Using the GE Lunar Prodigy Densitometer. R. Chen*[1], Q. Yang*[2], F. Chen*[1], Y. Chen*[2], S. Lin*[1]. [1]Peking Union Medical College Hospital, Peking Union Medical College, Chinese Academy of Medical Science, Beijng, China, [2]Jinan Maternity And Child Care Hospital, Jinan, China.

Total Body BMD and body composition measuredwith dual-energy x-ray absorptiometry (DXA) are utilized increasingly to evaluate a variety of clinical conditions, as well as for nutritional, exercise, and epidemiological research. Total body scans with DXA provide measurements of total body and regional body composition, including bone mineral content (BMC), bone mineral density (BMD), lean tissue mass (lean), fat tissue mass (fat), and % fat. Monitoring changes in BMD and body composition associated with disease and/or the effects of therapy contributes to a thorough patient evaluation. Minimizing precision error allows detection of smaller changes in BMD and body composition. Ten volunteers were scanned with a GE Lunar Prodigy densitometer 5 times each day for 2 days, with the time interval between not exceeding 4 days. Subjects moved off and onto the scanner between each scan. Subjects fasted for at least 6 hours prior to each scan, and there were no known cases of illness that could have affected BMD or body composition over the short term. All scans were acquired and analyzed by the same experienced operator. Precision was calculated using the root-mean-square methodology. Total body precision was 1.2% for fat, 0.7% for lean, 1.2% for % fat, 1.1% for BMC and 0.5% for BMD. As expected, precision errors were generally greater at the regional (arms, legs, and trunk) measurement sites.

Total Body Precision (% Coefficient of Variation)					
	Fat Mass	%Fat	Lean Mass	BMC	BMD
Arms	3.5	2.4	1.4	1.5	1.0
Legs	2.3	1.1	1.8	0.9	0.8
Trunk	2.7	2.1	1.6	2.8	1.0
Total	1.2	1.2	0.7	1.1	0.5

The Advantage of Mechanical Response Tissue Analyzer in Detecting Decreased Mineralization of Cortical Bone versus DEXA and QUS. L. D. Moreno[1], C. Chan*[2], C. Wynnyckyj*[1], S. Waldman*[3], M. Grynpas[1], A. Cheung[2]. [1]SLRI, Mount Sinai Hospital, Toronto, ON, Canada, [2]University Health Network, Toronto General Hospital, Toronto, ON, Canada, [3]Department of Mechanical Engineering, Queen's University, Toronto, ON, Canada.

Dual energy absorptiometry (DEXA) and quantitative ultrasound (QUS) are the most commonly used technologies for evaluating fracture risk. However neither method provides a direct mechanical measurement of bone. A promising candidate for such a device is the Mechanical Response Tissue Analyzer (MRTA). The objective of our study was to investigate whether MRTA measurements of bone stiffness is a better tool in predicting bone quality change due to mineral loss, compared to DEXA and QUS. The emu was chosen as a new animal model for this study. Tibias of 24 male and female emus ages 2-5 years old, were used for the study. The ends of the bones were cut and the bone marrow removed. Bone mineral density (BMD), stiffness (EI) and the speed of sound (SOS) were measured for all the bones. Also determined was the flexural stiffness; bones were loaded in the elastic region in four-point bending at 0.04 mm/s using mechanical machine (Instron 8511). After the first set of measurements the bones were partially demineralized from the inside out. A pump was used to drive the fluid from the bottom to the top of the bones that were in the vertical position, and were kept moist with saline through out the demineralization process of the endocortical surface. After partial demineralization, BMD, EI, SOS and the flexural stiffness were again determined and compared with the values obtained before demineralization. The coefficient of correlation between the stiffness as determined mechanically and the measurements from the different devices are shown in the table below. From all the devices the ultrasound measurements showed the weakest correlation. After demineralization, DEXA measurements showed a decrease of 6.13% demineralization, the QUS showed a decrease of 1.24% in SOS, and the stiffness (EI) measured from the MRTA and the flexural stiffness showed an 11.73% and 11.78% decrease, respectively. From all the medical devices the MRTA measurements was the one that show the highest differences after partial demineralization. This study suggests that the MRTA has better discriminatory power than DEXA and QUS in determining decrease mineralization in cortical bone.

	BMD (DEXA)	SOS (QUS)	EI (MRTA)
Flexural stiffness (Instron)	0.83 (p<0.0001)	0.38 (p=0.07)	0.93 (p<0.0001)
EI (MRTA)	0.72 (p<0.0001)	0.34 (p=0.1)	
SOS (QUS)	0.51 (p<0.0001)

The Effect of Precision on T-scores for Diagnosing Osteoporosis. K. G. Faulkner, L. S. Weynand*, W. K. Wacker*, H. S. Barden. GE Healthcare, Madison, WI, USA.

Effective use of serial DXA measurements for monitoring BMD change requires the minimization of precision error. However, even a single BMD result is subject to both offset (accuracy) errors and variability (precision) errors, which will influence the T-score and potential diagnosis of osteoporosis. In this investigation, we determined the influence of precision error on the T-score for the diagnosis of osteoporosis. Precision has been shown to depend on the experience of the operator, type of DXA system used, and the skeletal site measured. For this study, reported precision errors for expert DXA centers [1] and clinical DXA centers [2] were used. Using the Lunar Prodigy, expert precision error (g/cm^2) in women (mean age 63 ± 9 years) was 0.010 at the L1-L4 spine, 0.013 at the femoral neck, and 0.008 for the total hip region (1). At clinical centers using the Lunar Prodigy, precision error in women (mean age 61± 10 years) was reported as 0.014 at the L1-L4 spine, 0.025 at the femoral neck, and 0.012 at the total hip (2). Assuming BMD is normally distributed, the 95% confidence interval (CI) for a single T-score measurement can be estimated using the following equation: 95% CI = T-score ± 1.96 (Precision/ Population SD). Population SD from the reference database for the Lunar Prodigy is 0.12 g/cm^2 at the spine, femoral neck, and total hip. Using this model, the 95% CI for T-scores at each skeletal site are shown in Table 1.

Table 1: 95% CI for T-scores based on Expert and Clinical Precision

	Spine	Neck	Total Hip
Expert	±0.16	±0.21	±0.13
Clinical	±0.23	±0.41	±0.20

We conclude that clinical DXA T-scores have 95% confidence limits of ±0.2 at the spine and total hip and ±0.4 at the femoral neck. T-scores variations of ±0.2 or less at the spine or total hip and ±0.4 at the femoral neck should not be considered significant when diagnosing osteoporosis. Minimizing precision error can increase confidence in T-scores by reducing the confidence limits to less than ±0.2 at the spine and total femur and to ±0.2 at the femoral neck.

Monitoring Antiresorptive Therapy with Dual Femur. P. K. Burke[1], G. N. Burke*[1], H. S. Barden[2], K. G. Faulkner[2]. [1]Osteoporosis Diagnostic and Treatment Center, Richmond, VA, USA, [2]GE Healthcare, Madison, WI, USA.

Monitoring patients with dual-energy x-ray absorptiometry (DXA) helps physicians assess treatment efficacy in preventing further bone loss and increased fracture risk. Minimizing DXA precision error reduces the least significant measurement change (LSC) required to detect a biological change in patient BMD. Larger increases in bone mineral density (BMD) with antiresorptive therapy are typically observed at the spine, compared to the femur, due to a higher proportion of high-turnover, cancellous bone at this site. However, spine assessment may be compromised in older patients due to osteophytes and other degenerative changes that occur with aging. We compared DXA measurements (Lunar Prodigy, GE Healthcare) of single femur, dual femur, and lumbar spine (L1-L4) for evaluation of treatment efficacy in 309 postmenopausal women (mean age of 65.8 ± 9.9 yrs) on antiresorptive therapy. Changes in BMD were evaluated after an average of 2.1 years of therapy. Femur results were reported for left femur neck (FN), total femur (TF), and dual TF. There was no significant difference in average BMD change (0.8% increase) between left TF and dual TF (p=0.63) or between FN and TF (p=0.82). A larger BMD increase (2.4%) was seen at the spine. Using this center's precision error and 95% confidence levels, the LSC was determined to be 3.9% for FN, 2.5% for single TF, 2.0% for dual TF, and 2.6% for spine. A significant increase in BMD was seen in 21% of subjects at FN, 27% at single TF, 31% at dual TF, and 48% at the spine. A significant decrease in BMD was observed in 9% of subjects at FN, 13% at single TF, 14% at dual TF, and 14% at the spine. About 77% of the women who had a significant positive or negative change at FN, TF or dual TF did not have a corresponding significant change at the spine. We conclude that a) there was no significant difference in the average BMD change for femur neck, single total and dual total femur after 2 years of antiresorptive therapy, b) the number of subjects with a significant positive change was larger (although, not significantly) for dual (n=97) than for single (n=84) total femur, c) more than 25% of patients with a significant positive change at the single or dual total femur did not show a significant positive change at the spine, and d) dual total femur identified an additional 51 subjects with a significant BMD change compared to measurement of spine alone.

	Left Neck	Left Total Femur	Dual Total Femur	Spine
CV (LSC)	1.40% (3.9%)	0.90% (2.5%)	0.72% (2.0%)	0.92% (2.6%)
Average BMD Change	0.8%	0.8%	0.8%	2.4%
Subjects (%) with Significant + Change	65 (21%)*	84 (27%)*	97 (31%)*	148 (48%)*
Subjects (%) with Significant - Change	27 (9%)	41 (13%)	42 (14%)	42 (14%)
Subjects (%) with Sig. + Change Femur Only	17 (26%)	22 (26%)	27 (28%)	
Subjects (%) with Sig. - Change Femur Only	14 (52%)	24 (59%)	24 (57%)	

* p=0.003 (neck vs dual total); p=0.25 (single total vs. dual total); p=<0.0001 (single total vs. spine); p=<0.0001 (dual total vs. spine)

Changes in Total Body Composition with HIV Treatment. T. O. Chernova[1], H. S. Barden[2], N. I. Sazonova*[1]. [1]Russian Academy of Medical Sciences, Moscow, Russian Federation, [2]GE Healthcare, Madison, WI, USA.

Infection with the human immunodeficiency virus (HIV) is associated with a variety of metabolic and endocrine disorders, including progressive weight loss and hypogonadism that may affect body composition and bone density. Wasting syndrome associated with HIV infection results in loss of lean mass, and sometimes fat mass. Recently available highly active antiretroviral therapy (HAART) also is associated with alterations in body composition, fat distribution (lipodystrophy), and may be associated with osteopenia. Lipodystrophy is characterized by wasting of subcutaneous fat, peripheral fat loss, and accumulation of central or visceral fat. Dual-energy x-ray absorptiometry (DXA) allows study of total body and regional changes in soft tissue distribution, bone mineral content (BMC), and bone mineral density (BMD) in HIV-infected patients. We used DXA (Lunar Prodigy, GE Healthcare) to measure total body BMD and body composition in two small groups of Russian male subjects with HIV: Group 1 (n = 8, age 28.7 ± 10.1 yrs) measured at baseline; and Group 2 (n = 10, age 30.5 ± 4.2 yrs) measured at baseline and after treatment with HAART for 4 months. Expected BMD was determined by comparing results with Lunar Northern European reference data. Results showed slightly lower total body BMD than expected, with the largest deficits in the legs (-1.6%) in Group 1 and in the trunk (-5%) in group 2. The largest change with therapy for Group 2 occurred with fat mass, with average total body fat mass increasing 14%. This change appeared to be distributed evenly throughout the body. Total body lean mass showed a modest gain of 2%, while BMC and BMD both decreased overall by about 1%. We conclude that BMD was not substantially different from expected reference values at baseline and that BMC and BMD loss during the short therapy period of 4 months was minimal (~1%). The largest change with therapy was a surprising 14% increase in total body fat, evenly distributed among all regions of interest.

	Difference (%) from Expected BMD			
	Arms	Legs	Trunk	Total
Group 1 (n = 8)	2.4%	-1.6%	1.9%	-0.7%
Group 2 (n = 10)	-0.8%	-1.6%	-5.0%	-0.2%
Percent Change with Therapy				
Group 2	Arms	Legs	Trunk	Total
BMC	-2.6%	-1.2%	-0.3%	-1.0%
Fat Mass	17.3%	14.0%	15.3%	14.3%
Lean Mass	-0.2%	2.7%	2.3%	2.1%
BMD	-2.7%	-1.8%	-0.2%	-1.2%

Poblational Screening with Accudexa. Relationship with Hip Frature Incidence. M. Ciria[1], M. Coll*[1], I. González*[2], J. Fernandez*[3], L. Perez-Edo[1], J. Blanch[1], P. Benito*[1], X. García-Miguel*[1]. [1]Rheumatology, Institut Municipal d'Asisténcia Sanitària, Barcelona, Spain, [2]Primary Care, Institut Catalá de Salut, Barcelona, Spain, [3]Primary care, Institut Catalá de la Salut, Barcelona, Spain.

To assess the incidence of hip fracture in a poblational screening with pheripherical densitometrical equipment (Accudexa) on medium phallanx and FRACTURE questionnaire, in comparison with a non-screened population. We performed a randomized, poblational-based prospective study. The universe were women higher than 65 years-old from an urban Primary Care unit. A randomized screening of half of the population was done, by their family physician in the Primary Care Unit. A structurated questionnaire was done, including anthropometrical data, calcium intake, tobacco and alcohol habit, osteopenic drugs, age of menarchia and menopausia, and previous use of antiresorptive drugs. The FRACTURE questionnaire was calculated without bone mineral density. A densitometrical study of the second phallanx of the non-dominating hand was done. Women with high risk of hip fracture were those with an Accudexa T-score < -2.5 SD or T-score <-1.6 SD and FRACTURE higher than 4 units. All women with high risk of hip fracture started therapy with risedronate once weekly. Patients with hip fractures being admitted in the reference hospital were compiled. Statistical analysis with Chi-square was done. Results: screening group: 1.650 women, screened: 789. Denied to enter in the study: 7%. Control group: 1990. Basal features of both groups were similar. Number of women identified as hip fracture high risk: 284 women. Hip fracture in first year: 14 (3 in screened group and 11 in control group, p=0.072). Hip fracture in second year: 13 (5 in screened group and 8 in control group, p=0.62). Four of the 8 women with hip fracture in the screening group declined their participation in the study and were not screened. Conclusions: The incidence of hip fracture in the screened population in the first year of following tends to be lower than the control group. This phenomenon disappears in the second year. Possibly, the change of incidence in the second year could be almost explained by a low compliance treatment. The Accudexa equipment, along with the FRACTURE questionnaire, helps to detect population with risk of hip fracture and to prescribe antiresorptive drugs if necessary.

Cross-Calibration of a Pencil-Beam and a Fan-Beam DXA (600 subjects): Identification of Factors Determining Differences between BMD Measurements. B. Sutter[1], O. Legrand*[1], G. Weryha[2]. [1]Nuclear Medicine, Institut Calot, Berck sur Mer, France, [2]Endocrinology, CHU, Vandoeuvre les Nancy, France.

Follow-up of individual patients who are receiving treatment for osteoporosis leads to difficulties when a newer model replaces an old DXA system. We report the results of an in vivo cross-calibration study performed between a HOLOGIC® QDR 1000/W pencil-beam and a HOLOGIC® 4500 ACCLAIM fan-beam Dual X-ray Absorptiometer. Phantom quality control measurements were comparable for the two devices (QDR 1000/W: 990.4 +/- 4.1 mg/cm²; ACCLAIM 989.2 +/- 2.5 mg/cm², 10 measurements). Lumbar spine and hip DXA scans were performed same day in 600 patients attending long-term BMD monitoring: female 512, male 88, age 62.0 +/- 10.0 years, Body Mass Index (BMI) 26.0 +/- 4.1 kg/m². Lumbar spine BMD measurements on the two systems agreed closely: r²=0.978. ACCLAIM values were 1.4 % higher than those on the QDR 1000/W (mean difference 11.7 +/- 22.3 mg/cm²). Difference correlated positively with age and negatively with bone density. On an other hand, the 121 subjects with a difference over 4% are significatively older, with a higher BMI and a lower BMD. Femoral neck and total BMD (586 subjects) also correlated closely between the two systems: r²=0.937 for femoral neck, r²=0.956 for total femur. We found an overestimation of BMD with ACCLAIM: +40.2 +/- 27.1 mg/cm² for femoral neck (+5.5%), +19.5 +/- 3.0 mg/cm² for Total femur (+2.8%). Difference positively correlated with BMI (femoral neck & Total femur) and BMD (Total femur). The 197 patients with a femoral neck BMD difference over 5% are significatively older, with a higher BMI and a lower BMD. In summary, despite a close correlation between the pencil beam and fan beam devices, we found an overestimation with fan beam measurements, especially for femoral (neck and total femur) which could not be predicted with quality phantom measurement. Additionally, difference significatively correlated with age, BMI, and BMD values.

Risk-Equivalent Cutoff Levels for DXA Measurements Based Exclusively on Total Femur. C. C. Glüer[1], R. Eastell[2], D. M. Reid[3], C. Roux[4], D. Felsenberg[5]. [1]UK SH, Kiel, Germany, [2]University of Sheffield, Sheffield, United Kingdom, [3]University of Aberdeen, Aberdeen, United Kingdom, [4]René Descartes University, Paris, France, [5]Charité, Berlin, Germany.

The current efforts to develop risk based intervention criteria for osteoporosis treatment requires the definition of cutoff levels at well defined levels of absolute fracture risk. Currently the WHO-criterion of a minimum T-Score < -2.5 for spine and total femur measurements is commonly used both for diagnosis and as an intervention threshold. To facilitate diagnosis and risk assessment the definition of cutoff levels based exclusively on total femur measurements has been proposed. We investigated which cutoff level would be risk-equivalent to the current WHO criterion if measurements were only carried out at a single site, the total femur. Gradients of risk for spine and hip fractures for DXA measurements at the spine and total femur are well established. The gradient of risk for the current approach can be estimated from population-based distributions of spine and hip results. Thus the relative risk for a minimum T-score of -2.5 can be calculated and subsequently the equivalent T-score for a total femur measurement can be derived. We used DXA data of 2374 women (age 55-79, mean age 67) examined in OPUS, a population based multi center study. The gradients of risk per standard deviation of the population variance (sRR) are 1.5 and 2.4 for hip fractures based on spine or total femur measurements respectively and 1.9 for spine fractures for either measurement site (Cummings, JAMA 2002). As gold standard we therefore calculated relative risk of hip fracture from total femur results; gold standard relative risk for spine fractures was calculated as the average of spine and total femur result. We then fitted the result of minimum T-Score of spine and total femur results to gold standard risk levels and observed sRR=2.0. A total femur measurement with its higher sRR of 2.4 reaches the risk level of T=-2.5 already at a T-Score of -2.0. Similarly, the -2.5 level for vertebral fractures for an sRR=1.8 is reached at a T-Score of -2.2 if measurements are only based on total femur results. Equal weighting of both results leads to a risk-equivalent threshold of -2.1 for total femur measurements. Levels of risk equivalency and prevalence equivalency vary with age. Prevalence of subjects below the two criteria was similar (15%) for women above age 65. We conclude, that for a typical population aged 55-79 a T-Score of -2.1 at the total femur is risk-equivalent to the current -2.5 T-Score criterion for DXA of the spine and the hip; the impact of age, however, may necessitate the use of Z-Score criteria which allow to separate density associated components of fracture risk from age effects.

Parity Influence on Femur Geometry. S. Di Gregorio*[1], L. M. Del Rio[1], S. N. Zeni[2], J. Rosales*[1]. [1]Densitometría, Cetir Centre Medic, Barcelona, Spain, [2]Sección Osteopatías Médicas, Hospital de Clínicas. UBA, Buenos Aires, Argentina.

Reproductive history could affect bone mass in postmenopausal population. We found in a previous study that hip fracture prevalence in multiparous women was lower than in nullipaous and is associated to a hight bone mineral density (BMD). Although there are a general concern that hip fracture is related to proximal femur geometrical parameters, there are few data about the impact of parity on femur geometry. We recruited a total of 1074 post-menopausal women for the study (from 39 to 89 years). A standarized interview was employed to obtain information about life style, fracture prevalence and reproductive history. Patients were divided into four group according to the number of pregnancies: G0: 150 nulliparous (60 ±8 year), G1: 566 with one or two pregnancies (59±8 years), G2: 303 with three or four pregnancies (61 ±7years) and G3: 54 grand multiparous -five or more pregnancies- (63 ±8years). Femoral hip (total, neck and trochanter) was measured by DXA (GE-Lunar Prodigy V8.1). The bone status and femur geometry was assessed by using the femur strength analysis program (Lunar GE). Results: The first step analysis was performed comparing nulliparous vs all parous women inpendendently of pregnancies number: there was statistical difference in body weight (61 vs 65 kg $p < 0.0001$) and in BMD at total hip (0.847 vs. 0.884 $p<0.001$) ; trochanter (0.658 vs. 0.686, $p=0.006$)and femoral neck (0.809 vs. 0.830, $p=0.045$). We didn't find differences between geometry parameters. When the impact of pregnancies number was taken into account the BMD results showed a similar tendency was observed in BMD areas. Sectional cross area (CSA) , ($p=0.019$), as well as the femoral neck angle ($p=0.02$) and length ($p=0.01$) were larger in women with one or two pregnancies ($p=0.019$; $p=0.02$ and $p =.001$ respectively . Pearson test showed a positive correlation between body weight and the following geometrical parameters: CSA: G0: R: 0.317 $p <0001$; G1: R:0.345 $p < 0.001$; G2: R =.324 $p <0.001$; G 3: R: 0.413 $p < 0.002$; CSMI: G 0: 0.347: p 0.001; G1: R: 0.337; p 0.001; G2: R:0.427 p: < 0.001; G3: NS. Conclusion: pregnancy has an influence on proximal femur geometry and BMD, perhaps due to a macro-architectural adaptation that could affect biomechanical characterist of bone.

The Effect of Alendronate on Bone Alkaline Phosphatase Vs. Total Alkaline Phosphatase: The Fracture Intervention Trial. D. C. Bauer[1], P. Garnero[2], L. Palermo*[1], P. Delmas[3]. [1]Epidemiology and Biostatistics, UCSF, San Francisco, CA, USA, [2]Synarc, Lyon, France, [3]INSERM 403, Lyon, France.

Among alendronate-treated women in the Fracture Intervention Trial (FIT), greater 1-year reductions in markers of bone turnover were associated with fewer spine and non-spine fractures (Bauer et al, JBMR, 2004). The utility of less specific skeletal biomarkers, such as total alkaline phosphatase, has not been reported. We measured both bone specific alkaline phosphatase (Bone ALP, Hybritech) and total alkaline phosphatase (TAP, Nichols) at baseline and after 1 year of alendronate (ALN), 5 mg/d, in 3044 participants in the Fracture Intervention Trial. TAP was measured as a component of routine "safety labs". Total hip BMD (Hologic) was measured at baseline and after a mean follow-up of 3.6 years. Among ALN-treated women, 252 women had non-spine fractures and 119 had incident vertebral fractures on paired lateral spine x-rays during follow-up. We used age-adjusted logistic and hazard models to examine the independent relationships between 1-year change in Bone ALP or TAP and subsequent spine and non-spine fracture. These analyses are by intention to treat, and are limited to ALN-treated subjects. At baseline, Bone ALP and TAP were modestly correlated (r=0.67). After 1 year of ALN, the mean (SD) change in Bone ALP was -4.8 (4.0) ng/ml (-32.6%), while the mean change in TAP was -14.0 (16.0) mg/dl (-15.3%). The correlations between the 1-year change in Bone ALP or TAP and long-term changes in hip BMD were similar (r=0.28 and r=0.24, respectively). Greater reductions in both Bone ALP and TAP were associated with fewer incident spine fractures (Figure, 4th quartile represents largest reductions). Each additional SD reduction in the 1-year absolute change in Bone ALP was associated with a 28% reduction (95% CI: 12%, 40%) in spine fracture risk, while each SD reduction in the change in TAP was associated with a 22% reduction (95% CI: 8%, 33%). One-year changes in Bone ALP were also associated with a reduced risk of non-spine fracture (RH per SD=0.84, CI: 0.74, 0.96), but 1-year changes in TAP were not (RH per SD=0.98, CI: 0.87, 1.10). We conclude that among ALN-treated women, 1-year changes in both Bone ALP and TAP are associated greater increases in BMD and fewer incident vertebral fractures, but only changes in Bone ALP are associated with non-spine fracture risk.

Serum Cathepsin K Levels Reflect Osteoclastic Activity in Women with Postmenopausal Osteoporosis and Patients with Paget's Disease. C. Meier[1], U. Meinhardt*[2], M. E. Kraenzlin[1], J. R. Greenfield*[2], T. V. Nguyen[2], C. R. Dunstan[3], M. J. Seibel[3]. [1]Clinic for Endocrinology, University Hospital Basel, Switzerland, [2]Garvan Institute of Medical Research, University of NSW, Sydney, Australia, [3]ANZAC Research Institute, University of Sydney, Sydney, Australia.

Cathepsin K, a cysteine protease, plays an essential role in osteoclast-mediated collagen degradation. Recently, an immunoassay to quantify cathepsin K in serum has been developed. We assessed the usefulness of serum cathepsin K as a marker of bone turnover

in cross-sectional and longitudinal studies of patients with metabolic bone disease. The study cohort consisted of 40 healthy controls (13 premenopausal women [age, 30.6±6.6 yrs (mean±SD)]; 11 postmenopausal women [64.1±8.3 yrs]; 16 men [41.6±12.4 yrs]), 21 women with postmenopausal osteoporosis (66.1±7.9 yrs) and 10 patients with Paget's disease of bone (67.1±11.6 yrs). Patients were started on oral or intravenous bisphosphonate treatment and were followed prospectively over 6 months. Circulating cathepsin K levels were determined by a specific sandwich enzyme immunoassay (Biomedica, Austria). In addition, serum carboxyterminal cross-linked telopeptide of type I collagen (βCTX-I) and bone-specific alkaline phosphatase (BALP) were measured for comparison. Serum cathepsin K levels were similar in the three healthy control groups with a mean (±SD) level of 3.1 (±1.7) pmol/L. When compared to healthy controls, mean cathepsin K levels were significantly elevated in women with postmenopausal osteoporosis (11.3 ± 13.1 pmol/L, p=0.01) and in patients with Paget's disease of bone (6.2 ± 4.4 pmol/L, p=0.04). In postmenopausal osteoporotic women, both oral and intravenous bisphosphonate treatment resulted in a significant reduction in serum cathepsin K levels with a nadir at one month (-33.9 % vs. baseline; p=0.01) and stable suppression thereafter. The magnitude of these changes was intermediate to those seen with βCTX-I and BALP. In patients with mild Paget's disease (baseline BALP, 73.3±50.4 U/L), cathepsin K tended to decrease during bisphosphonate treatment (mean % change after one month: -30.3%). Serum cathepsin K levels appear to reflect osteoclastic activity in patients with postmenopausal osteoporosis and Paget's disease and may hold promise as a direct cellular marker of osteoclast activity.

The Effect of Discontinuation of Long-Term Oral Low Dose Hormone Therapy to Skeletal and Metabolic Markers and Bone Mineral Density. J. Haapalahti[1], J. Heikkinen*[2], J. Ramberg*[1], J. Risteli[3], R. Vaheri*[4]. [1]R&D, Orion Diagnostica Oy, Oulu, Finland, [2]Deaconess Institute, Oulu, Finland, [3]Clinical Chemistry, University of Oulu, Oulu, Finland, [4]Orion Group Orion Pharma, Espoo, Finland.

It has been earlier established that oral hormone replacement therapy (HRT) may modify levels of biochemical markers such as total testosterone (T), sensitive C-reactive protein (s-CRP) and intact aminoterminal propeptide of type I procollagen (PINP). The aim of this study was to elucidate the effect of discontinuation of long-term oral low dose hormone replacement on these biomarkers and lumbar spine bone mineral density (BMD). Serum samples taken from 35 healthy postmenopausal women (mean age at inclusion 55.9 years) were retrospectively analysed at baseline before starting HRT with a continuous-combined low-dose 1mg estradiol valerate/2.5mg medroxyprogesterone acetate product (Indivina®, Orion Pharma, Finland) from samples taken at 12-month and 108-month time points after treatment start and one year after discontinuation. T (nmol/l), PINP (microg/l) and s-CRP (mg/l) were measured using commercially available methods (Orion Diagnostica Oy, Espoo, Finland). For s-CRP 12-month analysis was not available. BMD was measured at the same time points using DEXA (g/cm^2). At 12 months BMD was significantly increased (+2.4%, p<0.001) and PINP decreased (-29.5%, p=0.0012). At 108 months increase from baseline was found in T (+18.4%, p=0.012) and BMD (+9.5%, p<0.0001) and decrease in PINP (-22.7%, p=0.004). At one year after discontinuation of HRT BMD had significantly decreased from end-of-treatment values (-2.3%, p<0.001) and PINP had increased (+109%, p<0.0001). No change was found in s-CRP (p=0.672). When HRT-users were divided into subgroups of low and high bone turnover, based on PINP with cut-off of 40 microg/l at baseline, it was found that at 12 months increase in BMD and decrease in PINP were significant in "high bone turnover" group only (p<0.0001 for both). Discontinuation more strongly affected PINP levels in women with "low bone turnover" at baseline. It can be concluded that discontinuation of long-term oral low dose hormone replacement within one year restores mildly elevated levels of T to baseline level but does not affect s-CRP level, whereas BMD and PINP are clearly affected. Biochemical marker of bone turnover PINP shows theranostic potential in prediction of skeletal response to HRT at both initiation and discontinuation of oral HRT.

Serum Cathepsin K Measurements: Repeatability, Intra-Subject and Postprandial Variability. U. J. Meinhardt*[1], C. Meier[2], T. V. Nguyen[3], J. R. Greenfield*[4], C. R. Dunstan*[5], C. Kraenzlin[2], M. J. Seibel[5]. [1]Pituitary Research Unit, Garvan Institute of Medical Research, Sydney, Australia, [2]University Hospital, Basel, Switzerland, [3]Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia, [4]Diabetes and Obesity Program, Garvan Institute of Medical Research, Sydney, Australia, [5]University of Sydney, ANZAC Research Institute, Sydney, Australia.

Cathepsin K, a cysteine protease, plays a major role in bone matrix degradation. Recently, an enzyme-linked immunosorbant assay for cathepsin K measurement in serum and cell culture (Cathepsin K ELISA BI-20432, Biomedica, Austria) was developed using a polyclonal sheep antibody. In this study we assessed the repeatability and intra-subject and postprandial variability of cathepsin K measurements in human sera. Serum samples from nine healthy postmenopausal women aged 65.9 ± 6.5 years (mean ± SD) were collected a) in the fasting state on two occasions separated by 1 - 4 weeks, and b) 120, 240 and 360 minutes after a standard breakfast (1385 Kcal, 37g protein, 88g fat, 104g carbohydrate). Samples were kept frozen at - 20 °C up to 6 months and at - 80°C up to 12 months before being analysed in batch duplicates by a single investigator. Measurement of sera obtained on two separate occasions yielded mean (±SD) cathepsin K values of 3.20 ± 1.41 pmol/L and 2.65 ± 1.29 pmol/L, respectively, with no statistical difference between the two sets of data (p = 0.39). Mixed-effect analysis of variance suggested that the intra-subject variance of cathepsin K was 1.81 ± 0.90 pmol/L^2 of which biological and inter-assay variance accounted for 68 % (1.28 ± 0.87 pmol/L^2) and analytical variance accounted for 32 % (0.58 ± 0.28 pmol/L^2). The postprandial cathepsin K levels at baseline, 120, 240 and 360 minutes were 2.65 ± 1.29, 2.79 ± 1.07, 2.37 ± 1.00 and 2.75 ± 0.96 pmol/L, respectively; no statistically significant difference was observed between these results (p = 0.79). Cathepsin K levels did not appear to be affected by haemolysis of the blood sample (2.73 ± 1.15 vs. 2.28 ± 1.24 pmol/L, respectively, p= 0.12, n = 5). We conclude that serum cathepsin K levels as measured by the Biomedica assay show good intra-subject repeatability and low postprandial variability.

Solid Bone Matrix of Rat Femur Imaged by Water and Fat Suppressed Proton Magnetic Resonance Imaging. Y. Wu*[1], J. L. Ackerman*[2], G. Dai*[2], D. A. Chelsler*[2], M. Hrovat*[3], B. D. Snyder*[4], A. Nazarian*[4], M. J. Glimcher[1]. [1]Orthopaedic Surgery Department, Children's Hospital, Boston, MA, USA, [2]Radiology Department, Massachusetts General Hospital, Boston, MA, USA, [3]Mirtech, Inc, Boston, MA, USA, [4]Orthopedic Biomechanics Lab, Beth Israel Deaconess Medical Center, Boston, MA, USA.

One of the crucial parameters to assess bone quality is the degree of bone mineralization (DM), conventionally defined as the weight of bone mineral in unit volume of bone matrix. A closely related definition of DM is the ratio of bone mineral density (BMD) divided by bone matrix density. Micro-CT (μCT) has gained popularity in bone and mineral research on small rat bone specimens (< 18 mm) due to its high spatial resolution, but as an X-ray based method, μCT of bone can only reflect the mineral content, not the solid matrix content (mostly collagen). Here we explore the feasibility of water and fat suppressed projection magnetic resonance imaging (WASPI) to image the solid matrix content of rat bone specimens, in order to determine matrix density. The MRI experiments were carried out with a 33 cm ID 4.7 T Bruker MR scanner and home made 1.5 cm ID RF coil. A typical measurement time for 1838 projections was 31 min, which yielded a 3D image data set of 64X64X64 with field of view: 20 mm and spatial resolution: 0.63 mm. Figure 1 shows one slice from the full 3D data set of the normal (no water or fat suppression) ^{1}H projection MR image of a rat femur, in which the soft tissue surrounding bone and the water and fat in the medullary cavity are shown clearly while the bone is dark . Figure 2 is the WASPI image of the same rat bone specimen. The signal from the medullary cavity (water and fat) has been largely suppressed, along with the water and fat signal inside bone tissues; the solid matrix is well visualized. In this study, the solid matrix of rat bone was imaged directly by MRI for the first time to the best of our knowledge. This method provides a means to measure bone matrix density in small animals.

Association of 13 Serum Biochemical Markers with Bone Metastases in Women with Breast Cancer. N. Voorzanger-Rousselot*[1], F. Juillet*[1], J. Zimmermann*[2], V. Cretet*[1], E. Mareau*[1], T. Kalebic*[2], P. Garnero[1]. [1]Synarc, Lyon, France, [2]Novartis Pharma, East Hanover, NJ, USA.

Background: Bone metastasis (M) is a frequent complication of breast cancer (BC). Diagnosis of M from BC is challenging and relies mainly on bone scintigraphy, which lacks specificity. Alternatively, serum biochemical markers may be useful to detect bone metastases, although when used alone, they lack sensitivity. The aim of this study was to analyze the value of combining systemic markers of bone turnover, inflammation, and angiogenesis to identify M from BC. Patients and methods: Eighteen women with BC and M (BC, M+, mean age: 56 yr), 19 women with BC and no M (BC, M-, mean age 52) and 15 healthy women (mean age 59 yr) were included. Thirteen serum markers were measured: bone alkaline phosphatase (BAP) and N-propeptide type I collagen (PINP) as markers of bone formation; CTX-I, ICTP as markers of bone resorption, tartrate resistant acid phosphatase 5b (TRAP5b) and osteoprotegerin (OPG) as markers of osteoclastic activity; matrix-metalloproteases (MMP), 2, 7 and 9, the tissue inhibitor of MMP (TIMP-1), IL-6, TGFβ and VEGF. We performed backward multivariable analyses to identify independent markers which were then included in a discriminative model for classifying patients. Results: All bone turnover markers were higher in patients with BC M+ than in healthy women (p<0.01-0001) and patients with BC, M-(p<0.01-0001, except for CTX-I). OPG, MMP-2, 7,9, TIMP-1 and VEGF were also significantly higher in BC, M+ than healthy women (p<0.01-0.0001) and BC, M- (p<0.05-0.0001 except OPG). Serum TGFβ was decreased in BC, M+ compared to healthy women (p=0.05) and there was no difference between groups in IL-6 levels. Patients with BC, M- had similar levels than healthy women except for higher levels of CTX (p=0.001), MMP-2 and 9 (p=0.03). When each marker was considered individually, the diagnostic value was highest and similar for TRAP5b, MMP-2 and MMP-7, with 79-84% of patients being correctly classified. In multiple variable model, only ICTP, TRAP 5b, MMP-2 and 9, TGFβ, and VEGF remained independently associated with bone metastases. This combination of markers correctly identified 94% of patients with and without bone metastases. Conclusion: Combination of serum markers of bone resorption, MMPs, growth and angiogenic factors improve the diagnosis of bone metastases from breast cancer.

Comparison of the Clinical Performance of Six Different Serum Tartrate-Resistant Acid Phosphatase Assays for Monitoring Alendronate Treatment. K. M. Fagerlund*[1], A. J. Janckila[2], H. Ylipahkala*[1], S. L. Alatalo*[3], L. T. Yam*[2], H. K. Väänänen*[1], J. M. Halleen[4]. [1]Institute of Biomedicine, Department of Anatomy, University of Turku, Turku, Finland, [2]Veterans Affairs Medical Center, Louisville, KY, USA, [3]Finnish Red Cross Blood Service, Helsinki, Finland, [4]Pharmatest Service Ltd, Turku, Finland.

Two isoforms of tartrate-resistant acid phosphatase (TRACP) circulate in human blood, TRACP 5a derived from inflammatory macrophages and TRACP 5b derived from bone-resorbing osteoclasts. We have studied the clinical performance of six different serum TRACP assays and compared them with other commonly used markers of bone turnover, including serum CTX, PINP, BAP, OC and urinary DPD, for monitoring alendronate treatment. This double-blinded study included 137 healthy postmenopausal women that were randomly assigned into two groups, one receiving 5 mg alendronate daily (n = 70), and the other receiving placebo (n = 67). The TRACP assays were as follows: 1) A pH-selective in-house immunoassay measuring TRACP 5b activity (also available commercially as BoneTRAP® assay, SBA-Sciences, Oulu, Finland); 2) An immunoassay measuring total TRACP activity (TRAP5, Biovendor, Brno, Czech Republic); 3) An immunoassay using naphthol-ASBI-phosphate as a selective substrate for TRACP 5b (ASBI); 4) An immunoassay measuring TRACP 5a activity; 5) An immunoassay measuring total TRACP protein amount; 6) An immunoassay measuring TRACP 5a protein amount. All bone markers were assessed at baseline and at 3 months after start of treatment. Alendronate treatment decreased significantly serum TRACP measured by the BoneTRAP® assay, TRAP5 assay and ASBI assay, the largest decrease being observed with the BoneTRAP® assay. These three TRACP methods correlated significantly with the other bone markers measured, highest r-values being observed with the BoneTRAP® assay. TRACP protein, 5a activity and 5a protein were not affected by alendronate treatment and did not correlate with the other TRACP methods or with the other bone markers measured. Sensitivity, area under ROC curves and signal-to-noise ratio were higher for the BoneTRAP® assay than for the other TRACP methods. These results demonstrate that serum TRACP 5a is not associated with bone turnover and TRACP 5b specific methods should be used in assessing bone resorption.

The Type I Collagen Related Biochemical Markers of Bone Resorption, ICTP and CTX-Reflect Different Biological Pathways in Patients with Breast Cancer and Bone Metastases. P. Garnero[1], N. Voorzanger-Rousselot*[1], J. Zimmermann*[2], T. Kalebic*[2]. [1]Synarc, Lyon, France, [2]Novartis Pharma, East Hanover, NJ, USA.

Background: Bone resorption generates type I collagen fragments such as ICTP and CTX that can be quantified in serum using specific ELISAs. In vitro studies have shown that ICTP and CTX are released from bone matrix by different enzymatic pathways namely matrix-metalloproteases (MMP) for ICTP and cathepsin K for CTX (JBMR, 2003). The aim of this study was to analyze the respective sensitivity of ICTP and CTX to detect bone metastases (BM) in patients with breast cancer (BC) and to analyze their association with circulating levels of MMPs and markers of osteoclastic activity Patients and methods: Eighteen women with breast cancer and bone metastases (BC, M+, mean age: 56 yr), 19 women with BC and no bone metastases (BC, M-, mean age 52) and 15 healthy women (mean age 59 yr) were included. Serum levels of ICTP, CTX, MMP-2, MMP-7, MMP-9, TIMP-1, tartrate resistant acid phosphatase 5b (TRAP5b) and osteoprotegerin (OPG) were measured by specific ELISAs. Results: Serum ICTP was increased by a median 2 fold (p<0.0001) in patients with BC, M+ compared to both healthy women and patients with BC, M-. Serum CTX was increased by 8 fold in patients with BC, M+ compared to healthy women (p=0.004), and by 20% (p=0.08) compared to: BC, M-. MMP-2, MMP-7, MMP-9, TIMP-1 (p<0.01-0.0001), TRAP5b (p<0.005) and OPG (p0.07-0.001) were also higher in patients with BC, M+ compared to healthy women and patients with BC, M-. When all patients were analyzed together, ICTP strongly correlated with MMP-2 (r=0.60, p<0.0001), MMP-7 (r=0.67, p<0.001), TIMP-1 (r=0.60, p <0.0001) and to a lesser extent MMP-9 (p=0.27, p=0.05). In contrast serum CTX did not significantly correlated with MMPs, except slightly with MMP-7 (r=0.36, p=0.02) and TIMP-1 (r=0.42, p=0.004). Both ICTP and CTX correlated significantly with the markers of osteoclastic activity, TRAP 5b (r=0.66, p<0.0001 and r=0.47, p=0.006 for ICTP and CTX, respectively) and OPG (r=0.63, p<0.0001 and r=0.35, p=0.019). Conclusion: A significant increase in ICTP and CTX has been found associated with osteoclastic activity. Consistently with prior in vitro observations, circulating ICTP -but not CTX- correlates with MMPs driven type I collagen degradation. Osteolysis from breast cancer involved both MMPs and cathepsin K, mediated pathways which can be evaluated by serum ICTP and CTX, respectively

Lack of Hepatic Metabolism of C-Telopeptides of Type I Collagen. P. Qvist[1], K. Petersen*[2], J. Jespersen[3], N. Vinberg*[4], C. Christiansen[5]. [1]Nordic Bioscience, Herlev, Denmark, [2]Department of Obstetrics and Gynecology, Odense University Hospital, Odense, Denmark, [3]Department of Clinical Biochemistry, University of Southern Denmark, Ribe, Denmark, [4]Isotope Agency, Rigshospitalet, Copenhagen, Denmark, [5]Centre for Clincal & Basic Research, Ballerup, Denmark.

Bone biochemical markers have been used in dynamic studies of bone metabolism, and for accurate interpretation of measured marker levels it is essential to have information of extra-skeletal metabolism. Therefore the objective of the present study was to investigate if the circulating C-telopeptides of type I collagen (CTX) was subject to hepatic extraction. Eight, non-obese females between 22 and 32 years of age without previous history of diabetes, arterial or venous thrombosis, or hepatic diseases, participated in the study. Under local anaesthesia and fluoroscopy, a pre-shaped F 7 catheter was inserted through the right femoral vein and the tip of the catheter located in a large right liver vein; a 15-cm F4 catheter was inserted into the femoral artery. A constant-rate infusion of Tc-99m mebrofenin was given intravenously through an arm-vein, approximately 20 MBq over 2.5 hours. In order to measure splanchnic plasma flow, four sets of samples from the artery and the liver vein were obtained at 20-min intervals after one hour of infusion. Simultaneously, samples were obtained for measurements of CTX and PINP. Plasma volume was calculated by injection of approximately 300 kBq I-125 albumine and subsequently obtaining serial arterial blood samples post injection. The study was performed while the participants were in the resting, fasting steady state, and therefore the volume of distribution, splanchnic plasma flow and extraction were assumed to be constant during the period of investigation. No change in plasma level of CTX could be detected over the liver. In contrast, PINP decreased from an average of 52.9 ng/ml in the artery to 42.4 ng/ml in the vein, corresponding to a 19.8% reduction. Therefore it can be concluded that C-telopeptides of type I collagen (CTX) is not subject to hepatic metabolism.

The Discovery of New Biomarkers for the Diagnosis of Osteoporosis: Is SELDI the Answer? S. Bhattacharyya*[1], E. Siegel*[2], S. Jennings*[3], S. Khosla[4], L. J. Suva[1]. [1]Department of Orthopaedic Surgery, Center for Orthopaedic Research, UAMS, Little Rock, AR, USA, [2]Department of Biometry, UAMS, Little Rock, AR, USA, [3]Department of Applied Science, University Arkansas at Little Rock, Little Rock, AR, USA, [4]Endocrine Research Unit, Mayo Clinic College of Medicine, Rochester, MN, USA.

Proteomic pattern analysis leading to the discovery of novel biomarkers has emerged as an effective method for the early diagnosis of many diseases, such as ovarian, breast and pancreas cancer. However, there is little information regarding the utility of this approach for the diagnosis of diseases other than cancer. In this study surface enhanced laser desorption ionization time-of-flight (SELDI-TOF) mass spectrometry was used to screen for potential biomarkers in the serum of 58 postmenopausal women, clinically diagnosed with or without high bone turnover and osteoporosis. The diagnosis and follow-up of this disease is currently reliant on annual bone mineral density measurements and the measurement of unreliable biochemical markers. Accurate biochemical markers of skeletal activity would potentially provide a means of evaluating the skeleton and help in the diagnosis and follow-up of the disease. Serum samples from 28 osteoporotic and 30 age-matched unaffected women were fractionated based on charge (6 fractions) and SELDI spectra collected from each fraction of each patient, in duplicate, and in three molecular weight ranges, generating a total of 2436 spectra, with an average of 15,000 data points per spectra. All spectral data were normalized, standardized and subjected to multivariate statistical analysis and data mining procedures

ultimately leading to the detection of eight peaks (MW ranging from 3.1-7.1kDa) that optimally separated the two groups with a high degree of significance ($p<0.05$). In addition, multiple correlations of the diagnostic SELDI profiles from these patients with clinical parameters such as BMD and t-score strongly support the diagnostic significance of the identified SELDI peaks. This unique discriminatory profile represents a diagnostic fingerprint of the multiple biomarkers that distinguishes post-menopausal osteoporosis from normal post-menopausal, non-osteoporotic controls.

Potential Cost-Effective Use of Bone Turnover Markers to Select Osteopenic Post-Menopausal Women for Alendronate Therapy. J. T. Schousboe[1], K. E. Ensrud[2], D. C. Bauer[3], J. A. Nyman*[4], R. L. Kane*[4], L. J. Melton[5]. [1]Park Nicollet Clinic & University of Minnesota, Minneapolis, MN, USA, [2]VAMC & University of Minnesota, Minneapolis, MN, USA, [3]UCSF, San Francisco, CA, USA, [4]University of Minnesota, Minneapolis, MN, USA, [5]Mayo Clinic, Rochester, MN, USA.

A substantial proportion of fractures (Fx) occur in post-menopausal women without osteoporosis (T-score ≤ -2.5). High bone turnover, a risk factor for incident Fx independent of bone density, may be useful in identifying osteopenic older women at increased fx risk who may derive a greater Fx risk reduction with alendronate therapy. We used a Markov model with 8 health states to estimate the cost-effectiveness of serum C-telopeptide (CTx) and tartrate resistant acid phosphatase (TRACP5b) to identify osteopenic (T-score -2.0) older post-menopausal women with high bone turnover and treat them with alendronate to prevent incident fractures. Fracture rates, Fx direct costs, and long-term care costs after hip Fx were derived from comprehensive population-based data of Rochester, MN. We compared 5 years of alendronate Rx to no initial Rx, included 5 years of additional alendronate Rx following an incident Fx for both strategies, and assumed a relative risk of vertebral Fx on alendronate Rx of 0.54 vs. No Rx for the base case analysis. We assumed relative risks of 1.53 and 1.0 for incident vertebral and non-vertebral Fx, respectively, for those in the top quartile of CTx vs. the bottom 3 quartiles, and relative risks of 2.21 and 1.54 for incident vertebral and non-vertebral Fx, respectively, for those in the top quartile of TRACP5b vs. the bottom 3 quartiles.

Table: Lifetime costs per quality adjusted life year (QALY) gained for a 70-year-old woman with a T-score of -2.0, by quartile of specific marker under different assumptions of non-vertebral Fx reduction benefit from alendronate(Aln).

Condition	Relative Risk of Non-Vertebral Fx, Aln Rx vs. No Rx	Serum CTx	Serum TRACP5b
Marker in Bottom 3 Quartiles	1.0	$114, 370	$131,866
Marker in Top Quartile	1.0	$77,093	$69,011
Marker in Top Quartile	0.8	$50,660	$40,613

If the societal willingness to pay (WTP) per QALY gained is $100,000, obtaining a serum CTx or TRACP5b in post-menopausal women with a T-score of -2.0, followed by alendronate Rx for those in the top quartile, is cost-effective. If the societal WTP is only $50,000 per QALY gained, this strategy is still cost-effective if alendronate lowers the risk of non-vertebral Fx in osteopenic women with high bone turnover by 20% or more.

Validation of Cross-Linked N-Telopeptides of Type I Collagen (NTx) in Cynomolgus Monkey Serum. J. Mayer*, S. Desranleau*, S. Y. Smith, P. Oldfield. Charles River Laboratories Preclinical Services•CTBR, Senneville, PQ, Canada.

The assay to detect N-terminal telopeptides of type I collagen (NTx), which reflects the rate of bone resorption, was validated in cynomolgus monkey serum. The validation included parameters such as specificity, linearity, range of quantification, intra-assay precision and accuracy. In addition, the stability of NTx in cynomolgus monkey serum at 4°C, at room temperature, after three freeze and thaw cycles, and long-term storage stability at approximately -20°C was assessed.The NTx assay in serum is performed using the Osteomark NTx Serum ELISA kit (Wampole Laboratories). The wells of the plate are pre-coated with synthetic NTx antigen to which the conjugated antibody and diluted samples are added and incubated. The wells are washed followed by the addition of a chromogenic substrate, and after a further incubation period the reaction is stopped with sulfuric acid and the absorbance at 450 is measured. The lower limit of quantitation (LLOQ) of the assay is 2.85 BCE. The method has been shown to be specific for the determination of the NTx in cynomolgus monkey serum. Accuracy and precision are summarized as follows:

NTx (nM BCE)	Intra-Assay (n = 6)	
	CV (%)	Recovery (%)
2.85	14.5	105.1
6.34	7.8	97.3
9.51	4.1	106.8
15.84	3.3	105.3
31.69	1.1	100.0

NTx was shown to be stable in cynomolgus monkey serum after three freeze-thaw cycles, at room temperature for 4 hours, at 4°C for 22 hours and at -20°C for at least 63 days.The NTx ELISA assay in cynomolgus monkey serum in conjunction with other available markers of bone turnover in serum and urine, provides a comprehensive panel to monitor the response to ovariectomy procedures and/or treatments with bone active agents in this species.

Disclosures: ***S.Y. Smith****, None.*

Biomarker Discovery in Osteoarthritis. S. Bhattacharyya*[1], E. Siegel*[1], D. M. Findlay[2], N. L. Fazzalari*[3], M. Chehade*[2], S. Neale*[2], G. Wittert*[4], L. J. Suva[1]. [1]Center for Orthopedic Research, University of Arkansas for Medical Sciences, Little Rock, AR, USA, [2]Department of Orthopaedics and Trauma, University of Adelaide, Adelaide, Australia, [3]Division of Tissue Pathology, Insititute of Medical and Veterinary Science, Adelaide, Australia, [4]Department of Medicine and Florey Adelaide Male Aging Study, University of Adelaide, Adelaide, Australia.

Osteoarthritis (OA) is the most common joint disorder, producing pain and disability that leads eventually to the destruction of articular cartilage. Although many of the risk factors for OA have been defined (genetic factors, BMI, female sex), the etiology of this disease is poorly understood. Recent data, from examination of bone in OA, from MRI and from circulating bone markers, suggest a role for subchondral bone in initiation and progression of OA. Sensitive disease markers, which will permit diagnosis of OA during the early pre-radiologic stages, and which facilitate monitoring of disease progression, are urgently required. In this study, surface enhanced laser desorption/ionization time-of-flight-mass spectroscopy (SELDI TOF MS) was used to screen for specific serum biomarkers in end-stage OA patients presenting for hip replacement surgery. Serum samples from 31 OA patients (median age of 67 years) and 30 age-matched unaffected patients (median age of 64.5 years) were fractionated based on charge (6 fractions) and SELDI spectra were collected from fraction 1 of each patient, in triplicate, and in three molecular weight ranges [1.5-10 kDa(low), 6.5-30 kDa(mid) & 25-150 kDa(high)]. All spectral data were normalized, standardized and subjected to multivariate statistical analysis and data mining procedures, ultimately leading to the detection of a number of peaks that optimally separated the two groups. Multiple peaks were identified from each mass range and combined across all three mass ranges in each patient sample. Twenty-two specific peaks were identified that could discriminate between the two sample sets; 10 peaks (m/z 2-9 kDa), 7 peaks (m/z 7-16 kDa) and 5 peaks (m/z 31-71 kDa) were significantly different ($p<0.05$) between the two groups. This profile represents a diagnostic fingerprint of the multiple biomarkers that discriminates OA from normal controls. Ongoing analyses involve the correlation of the SELDI profile with patient characteristics. This study has potentially identified a panel of biomarkers that represents a diagnostic fingerprint of risk factors and/or predictors of OA progression, which we will now seek to validate in patients earlier in disease progression. The identification of validated biomarkers will greatly accelerate therapeutic development for this major public health concern.

Serum C-Terminal Telopeptide of Type I Collagen in Osteoporotic Patients with Vertebral and Hip Fracture. S. B. Hong[1], E. Kim*[1], S. Han*[2], M. Nam*[1], K. Moon*[3], B. Lee*[4], Y. Kim*[1]. [1]Internal medicine, Inha University, Incheon, Republic of Korea, [2]Emergency Medicine, Inha University, Incheon, Republic of Korea, [3]Orthopedics, Inha University, Incheon, Republic of Korea, [4]Gynecology, Inha University, Incheon, Republic of Korea.

Introduction: Bone quality including bone turnover rate have been identified important. Biochemical marker of bone turnover is useful in diagnosis and monitoring response to treatment. However high within-person variability complicate their use. We investigated whether the bone mineral density and bone turnover marker(serum C-terminal telopeptide;cTx and osteocalcin) were associated with fracture in the the patients with femur fracture and vertebral fracture, and also whether sampling time affect the level of cTx. Methods: From January 2004 to December 2004, we had enrolled prospectively 42 patients who visited the emergency department due to fragility fracture in the elderly. 30 patient diagnosed femur fracture(Fx) and 12, vertebral fracture(Vx). Bone mineral densities (BMD) of the lumbar spine and femur were examined. Total calcium, phosphate, alkaline phosphatase, osteocalcin, s-CTx were measured. The patients of femur fracture were divided into two subgroups according to the presence of vertebral fracture.Results: All BMDs of the patients showed osteoporosis. The CTx level increased in the morning than random sampling, but show correlation($r=0.63$, $p<0.01$). The s-CTx levels were higher than control($p<0.05$). The group of Fx with Vx was older than Fx only group, and had lower BMD. There were no significant differences in markers between the subgroups. But the incidence of trochanteric fracture was higher in Fx with Vx than Fx only group.Conclusion: Fx in the elderly was associated with osteoporosis, specially in Fx with Vx. The bone turnover markers and BMD are useful to know the degree of osteoporosis in Fx. so we suggest that they are helpful for planning of treatment and prevention of fragility fracture in the elderly.

Effect of a Fracture on Bone Turnover Markers in Daily Clinical Practice. E. van der Veer*, K. Koerts*, L. Wagenmakers*, J. Hoving*, J. Hegeman*, J. Slaets*, G. Willemsen*, J. van Nieuwpoort*, H. ten Duis*, H. Kreeftenberg*. University Medical Center Groningen, GRONINGEN, The Netherlands.

Can we use bone markers to assess bone turnover when a fracture interferes with baseline values? An important goal of our Fracture- and Osteoporosis Clinic (FO) is case-finding by measuring BMD by DEXA in patients aged 50 years and older after presentation with a low energy fracture. Blood was drawn during the first visit and six weeks later, for osteocalcin, PINP and sCTx. The Z-score for these bone markers was

obtained by using a reference group (n=300) with normal BMD of lumbar spine and femur and normal vitamin-D levels. PINP and sCTx were raised at the day of fracture, mean Z-score 0.48 and 1.21 respectively. Levels above 2 SD were found in 14.6 % and 29.3 %. Not all patients visited the FO on the day of fracture, so we plotted the influence of fracture against time, see table. It is obvious that during the first week PINP and sCTx levels are hardly increased, thereafter they are significant higher. Osteocalcin levels were not significant influenced by the fracture.

Table, Mean of bone turnover markers of patients (n=326), sampled at their first visit in the Fracture policlinic

first visit at day after fracture	patients n	PINP ug/L	PINP Zscore	PINP % patients > 2 SD	sCTx pg/ml	sCTx Zscore	sCTx % patients > 2 SD	Osteocalcin ug/L	Osteocalcin Zscore	Osteocalcin % patients > 2 SD
0	123	46,9	0,48	14,6%	310	1,21	29,3%	13,5	0,08	6,6%
1 - 2	48	45,7	0,39	10,4%	304	1,14	25,0%	12,0	-0,33	7,0%
3 - 4	40	47,4	0,62	20,0%	354	1,70	32,5%	14,6	0,49	10,8%
5 - 7	33	47,5	0,62	18,2%	349	1,65	33,3%	12,2	-0,23	3,2%
8 - 14	34	64,4	1,70	38,2%	380	2,02	41,2%	14,0	0,20	17,9%
15 - 28	48	61,2	1,53	35,4%	405	2,30	35,4%	13,8	0,32	17,9%

Paired t-tests between blood samples of the first and and second visit showed that all bone markers increased. First visit samples of patients obtained after the first week were excluded. For PINP the change of the Z-score was from 0.50 to 1.88 SD ($p < 0.0001$), for sCTx from 1.50 to 2.04 SD ($p< 0.001$) and for osteocalcin from - 0.07 to 0.59 SD ($p< 0.0001$). The Z-score of PINP in osteoporotic patients increased more than in patients with normal or osteopenic BMD (2.23 SD vs 1.53 SD, $p= 0.0359$). *Conclusion:* During the first days after a fracture bone turnover markers reflect the situation before. In comparison with a healthy reference group collagen turnover markers were already elevated at the day of the fracture. Using the day of fracture as baseline PINP and sCTx were significantly increased at day 7, and osteocalcin at 6 weeks. PINP increase was highest in osteoporotic patients. It is recommended to use Z-scores for bone markers for follow up in individual fracture patients in daily clinical practice.

SU156

Effect of Depot Medroxyprogesterone Acetate on Markers of Bone Turnover. J. S. Walsh, R. Eastell, N. F. Peel. Academic Unit of Bone Metabolism, University of Sheffield, Sheffield, United Kingdom.

We have previously shown that Depo-Provera (depot medroxyprogesterone acetate, DMPA) use is associated with a bone mineral density deficit at the spine and proximal femur in women who commence usage before age 20, but not in women who commence usage over age 34. This study aims to identify the effect of Depo-Provera on bone turnover, and whether it is age-specific. We measured serum procollagen type I amino-terminal propeptide (PINP) and urine collagen type I crosslinked N-telopeptide (NTX) in 200 women; 100 Depo-Provera users of more than 12 months duration, and 100 individually matched controls, ages 18-25 (Depo-Provera started before 20y) and 35-45 (Depo-Provera started after 34y). Controls were matched by age, postcode, height, body mass index and smoking habit. We included controls using the combined oral contraceptive as there is good evidence that it has no effect on bone density in estrogen-replete women. Paired t-test of log10 transformed data showed that both markers were higher in Depo-Provera users than their controls, and both markers were higher in the younger age group, consistent with active bone modelling.

	PINP mg/l			**NTX/Cr** nmol/mmol		
	DMPA users	**controls**	**p value**	**DMPA users**	**controls**	**p value**
18-25y	76.4	51.1	<0.001	58.9	50.0	0.007
35-45y	39.9	31.7	0.004	39.4	31.2	0.018

The differences between groups persisted when users of the combined oral contraceptive were excluded. We conclude that Depo-Provera increases bone turnover, associated with decreased bone density in younger users. This age-specific effect may be due to greater susceptibility of actively modelling and remodelling bone to estrogen deficiency.

Disclosures: ***J.S. Walsh****, None.*

SU157

Correlation between Serum and Salivary Concentration of Biochemical Markers of Bone Turnover. S. N. Zeni. Sección Osteopatías Médicas, Hospital de Clínicas, University of Buenos Aires, Buenos Aires, Argentina.

It has been suggested that periodontal disease is a typical early manifestation of osteoporosis; association between them was established in both humans and animals 30 years ago. Proper management of osteoporosis involves early diagnosis of the disease, which includes complementary tests such as assessment of biochemical markers of bone turnover. Currently, remodeling is assessed by serum and urinary biomarkers; however, there is little information concerning presence of these biomarkers in human saliva. The purpose of this study was to determinate whether salivary concentration of bone markers correlated with serum concentration. At the moment of the study 10 young non-pregnant healthy women (aged: 21±2 years) with a self-reported history of medical and dental care were recruited at the school of dentistry, Buenos Aires University, who volunteered for this purpose. In addition, 10 normal adult Wistar rats (300±5g) were studied. Fasting serum (s) and total saliva (sal) were analyzed for bone alkaline phosphatase (b-AL: UL/L) and Carboxy terminal telopeptide of collagen type I (CTX). The b-AL was assessed using a colorimetric method (Wiener Lab) after bone isoenzyme precipitation with wheat-germ lectin, and CTX was measured employing a commercial kit (Crosslaps one step and rat-CTX, respectively. Osteometer Bio Tech, Denmark).Although results were obtained from a small population, data suggest bone markers can be measured in saliva. Significant correlation was observed between saliva and serum concentration of both markers (b-AL: 0.78 and CTX: 0.89). However, whereas sal b-AL was slightly lower (approximately two fold), sal CTX was ten fold lower than that of serum concentration. Although further studies are necessary, this correlation suggests that a simpler and less invasive method exists to assess bone turnover than measurement of serum or urine samples. Since dental visits are more often than medical check-ups, performing routine assay of salivary biomarkers of bone disease in conjunction with delivering routine dental care could allow earlier diagnosis of metabolic bone diseases. Grant M099 UBA.

Reference Range for Bone Turnover Markers in Healthy Premenopausal Women; a Comparison of Oral Contraceptive Users and Non-Users. A. E. de Papp[1], R. Kagan*[2], A. Buinewicz*[1], C. Mullen*[1], E. Chen*[1], M. P. Caulfield*[3], R. E. Reitz*[3]. [1]Merck & Co., Inc., West Point, PA, USA, [2]Foundation for Osteoporosis Research and Education, Oakland, CA, USA, [3]Quest Diagnostics Nichols Institute, San Juan Capistrano, CA, USA.

Biochemical markers (BCMs) of bone turnover reflect whole body bone resorption and formation activity. Commercial BCM assays are used in clinical trials and clinical practice to assess antiresorptive and anabolic efficacy. There are few published premenopausal BCM reference ranges using newer automated assays. A cross-sectional observational study was conducted of 237 healthy premenopausal women (119 combination oral contraceptive [OC] users and 118 non-OC users), with regular cyclic menses and normal bone density determined by central DEXA. A single fasting blood sample was obtained to assess serum chemistry, serum C-telopeptide (CTx) (Elecsys 1010/2010, Roche Diagnostics), serum bone-specific alkaline phosphatase (BSAP) (Access Ostase, Beckman Coulter, Inc.), and serum N-terminal propeptide of type 1 procollagen (P1NP) (Orion Diagnostics). A second morning-void urine sample was collected for analysis of urine N-telopeptide of type 1 collagen (NTx) corrected for creatinine (Cr) (VITROS, Ortho-Clinical Diagnostics). Laboratory values were measured at a central laboratory (Quest Diagnostics). The mean subject age was 37 years (range 28-45), 77.6% were Caucasian. Among OC users, the mean duration of contraceptive use was 10 years. Mean (standard deviation, SD) BCM values among OC users were NTx, 19 (14.3) nmol/mmol; CTx, 251.0 (127.6) pg/mL; BSAP, 8.0 (2.8) µg/L; and P1NP, 33.0 (13.7) µg/L. Among non-OC users, mean values were; NTx, 30.0 (16.4) nmol/mmol; CTx, 304.0 (137.0) pg/mL; BSAP, 9.8 (2.8) µg/L; and P1NP, 45.0 (16.6) µg/L. Table reference ranges (geometric mean ± 2 SD) are based on log transformation with back transformation, except for NTx. Overall, BCM values in our study were generally consistent with those previously reported by the manufacturers for healthy premenopausal women. The mean values of all BCMs tested were significantly lower among OC users than nonusers. We believe that the values obtained from this well characterized population could represent reference ranges for these BCMs of bone turnover in premenopausal women. It is uncertain if these ranges are relevant to untreated or treated postmenopausal women.

Biomarker	OC Users n	OC Users Reference Range	Non-OC Users n	Non-OC Users Reference Range
NTx (nmol/mmol)*	104	3 - 60	98	4 - 64
CTx (pg/mL)	82	80 - 614	96	113 - 675
BSAP (ug/L)	111	4.1 - 14.2	100	5.4 - 16.4
P1NP (ug/L)	81	13 - 68	100	21-85

*Based on mid 95% range of normal values for NTx

Levels of Biochemical Markers of Bone Turnover in Postmenopausal Osteoporotic Women: Comparison to a Premenopausal Reference Range. M. C. Hochberg[1], D. Hosking*[2], H. Bone[3], R. A. Petruschke*[4], M. Melton[4], N. Verbruggen*[4], E. Chen*[4], A. E. de Papp[4]. [1]University of Maryland School of Medicine, Baltimore, MD, USA, [2]Nottinghm City Hospital, Nottingham, United Kingdom, [3]Michigan Bone and Mineral Clinic, Detroit, MI, USA, [4]Merck & Co., Inc., West Point, PA, USA.

Biochemical markers (BCMs) of bone turnover are used in clinical practice and clinical trials to assess bone resorption and formation and treatment effects. Typically, BCM levels in postmenopausal women are higher than those in healthy premenopausal women, although differences have not been adequately characterized. A cross-sectional study in 237 healthy premenopausal women (mean age 37 years [range, 28-45 years]; 78% white), with regular cyclic menses and normal bone mineral density (BMD) evaluated BCMs using newer commercial assays. Reference ranges for BCMs were established from 98 non-oral contraceptive users. A fasting blood sample was obtained to assess serum C-telopeptide of type 1 collagen (CTx), bone specific alkaline phosphatase (BSAP), and serum N terminal propeptide of type 1 procollagen (P1NP). Second morning void urine was collected to analyze urine N-telopeptide of type 1 collagen (NTx) corrected for creatinine (Cr). Data for serum CTx, BSAP, and P1NP, and urine NTx in postmenopausal osteoporotic women (T-score ≤-2.0 at least one site) were obtained using pre-treatment samples from two clinical trials of identical design (Study 1 in USA, N=1053; Study 2 international, N=936). Study 1 patients had a mean age of 65 years (range 26-98) and averaged 19 years postmenopausal; mean total hip BMD T-score was -1.8. Study 2 patients had a mean age of 64 years (range 43-90) and averaged 17 years postmenopausal; mean total hip BMD T-score was -1.7. Results are shown in the Table. As expected,

postmenopausal median BCM values were higher than premenopausal medians. However, there was substantial overlap in the distributions; the majority of postmenopausal women had pretreatment BCM values that fell within the premenopausal range. In both untreated postmenopausal populations, the lower end of the 95% range fell below the lower end of the 95% range of premenopausal women for P1NP and CTx. Further research is needed to determine whether there is an optimal target range for each BCM during antiresorptive therapy, or if alternative targets such as percent reduction from baseline might be preferable.

Biochemical Marker	Premenopausal (N=98) Median (95% range)	Postmenopausal Study 1 (N=1053) Median (95% range)	Postmenopausal Study 2 (N=936) Median (95% range)
NTX nmol/mmol	29.5 (4-64)	43 (18.0-103.0)	43 (14.0-101.0)
CTx pg/mL	273 (124-637)	364 (110-832)	389 (91-949)
BSAP ug/L	9.4 (5.9-16.9)	14.1 (6.8-29.4)	14.5 (7.2-29.2)
P1NP ug/L	41.5 (23-93)	47.0 (19-102)	50.0 (20-104)

Ranges in table are 2.5 - 97.5 percentiles

Serum CTX and P1NP by Roche Elecsys as Theranostics in the Treatment of Osteoporosis. E. T. Leary[1], T. H. Carlson*[1], C. Wu*[1], T. K. Aggoune*[1], V. Luzzi*[2], A. P. Foster*[3]. [1]Pacific Biometrics, Inc., Seattle, WA, USA, [2]Core Laboratory for Clinical Studies, Washington University, St. Louis, MO, USA, [3]Roche Diagnostics, Indianapolis, IN, USA.

Theranostics are diagnostic companion products to therapeutics in predicting risks of disease, diagnosing disease, stratifying patients and monitoring therapeutic response. Emerging data from osteoporosis clinical trials suggest the value of bone markers in fracture risk prediction in addition to treatment monitoring. We investigated serum beta-CrossLaps (CTX), a bone resorption marker, and total serum N-terminal propeptide of type I procollagen (P1NP), a bone formation marker, analyzed as a panel using the Elecsys 2010 immunoanalyzer (Roche Diagnostics, IN) for their robustness and performance as candidate theranostics. Sample stability and imprecision of CTX and P1NP were previously reported. Total imprecision for CTX was <6% CV and <4.5% CV for P1NP. CTX was stable in serum and heparin plasma for 8 hr at room temp, 1 d at 4° C; in K_3 EDTA plasma for 1 d at room temp and 7 d at -4° C. All sample types were stable for > 2 yr at -70° C. P1NP was stable 1 d at room temp, 14 d at 4° C and >3yr at -70° C. Long term consistency in sample, assays and response to therapy was evaluated in 57 women with osteoporosis on antiresorptive therapy. Bone marker values measured immediately after 3 month-treatment period were compared with those measured after 3 years of sample storage at -70° C. Regression comparison of CTX measured 3 years apart was y = 0.85 x + 0.016, R^2 = 0.97. Regression comparison for P1NP was y = 0.95 x - 6.53, R^2 = 0.98. % Change of CTX and P1NP from baseline after 3 month of treatment in samples measured 3 yr apart was similar. Reference ranges in healthy individuals, age 25-83 years, without osteoporosis were determined in 273 Caucasian and 320 African American women, and 272 Caucasian and 281 African American men. Differences in reference ranges among subgroups based on age and ethnicity were small. Overall, African American women have greater CTX and P1NP than Caucasian women ($p<0.05$).). In men, there was no difference for CTX between ages and ethnic groups. For P1NP, an age dependency was observed in both Caucasian and African American men ($p<0.05$). In conclusion, serum CTX and P1NP measured as a panel on the Roche Elecsys may be suitable as theranostics in the treatment of osteoporosis. The preferred sample type is EDTA plasma collected in the fasting state within a controlled time window to minimizes CTX variation. There is large overlap in reference values for CTX and P1NP among subgroups. Establishing common reference ranges, based on the healthy state, that are independent of age and ethnic group, may be desirable.

The Ratio of Osteoclast Activity/Osteoclast Number (CTX/TRACP 5b) Is a Useful Parameter in Rat Orchidectomy Model. J. P. Rissanen[1], J. J. Reponen*[1], R. Hirsinummi*[2], L. Ravanti*[2], P. J. Kallio*[2], J. M. Halleen[1]. [1]Pharmatest Services Ltd, Turku, Finland, [2]Orion Pharma, Turku, Finland.

C-terminal cross-linked telopeptides of type I collagen (CTX) are released from bone collagen during bone resorption, and serum CTX is a useful marker of osteoclast activity. It has been shown recently that serum tartrate-resistant acid phosphatase isoform 5b (TRACP 5b) reflects osteoclast number. We have studied the use of serum CTX and TRACP 5b in rat orchidectomy (ORX) model. Three-month old Sprague-Dawley rats were randomly divided into 3 groups (n = 12 in each group) according to body weight as follows: 1) Sham-operated rats receiving vehicle; 2) ORX rats receiving vehicle; 3) ORX rats receiving testosterone propionate (TP). TP was administered daily by subcutaneous injections at a dose of 0.6 mg/kg/day. Fasting blood samples were collected before the operation and at days 5, 14, 28 and 56 after the operation. Serum CTX (RatLaps®, Nordic Bioscience, Herlev, Denmark) and serum TRACP 5b (RatTRAP®, SBA-Sciences, Oulu, Finland) were measured using commercially available immunoassays. Prostate weight was significantly decreased by ORX and the decrease was completely prevented by TP, demonstrating that the operations and dosing were performed successfully. ORX increased serum CTX and decreased serum TRACP 5b values at all timepoints. TP increased TRACP 5b values to sham-level at all timepoints. However, serum CTX values were slightly decreased at day 5, slightly increased at day 14, not affected at day 28 and significantly decreased below the sham-level at day 56. A resorption index was calculated by dividing the CTX values by the TRACP 5b values, demonstrating the mean activity of a single osteoclast. ORX increased significantly the resorption index at all timepoints, the difference being most pronounced at day 5. TP decreased significantly the resorption index towards the sham-level at all timepoints, the difference being most pronounced at day 56 when the values decreased substantially below the sham-level. These results suggest that ORX increased resorption at all timepoints as shown by the increased CTX values, and because of the bone loss caused by ORX, the absolute number of osteoclasts was decreased at all timepoints as shown by the decreased TRACP 5b values. TP prevented the decrease in osteoclast number at all timepoints, which resulted as an increase in bone resorption during the first 4 weeks. After that, TP substantially decreased bone resorption by other mechanisms than affecting osteoclast number. These results demonstrate that the resorption index (CTX/TRACP 5b) is a useful tool in rat ORX model, showing more significant effects than can be observed with either CTX or TRACP 5b alone.

Stability of Tartrate-Resistant Acid Phosphatase Isoform 5b (TRACP 5b) in Human Serum Samples. J. M. Halleen[1], L. Wahlberg*[2], P. Saloranta*[2], S. Rasi*[2]. [1]Pharmatest Services Ltd, Turku, Finland, [2]SBA Sciences, Oulu, Finland.

Osteoclasts secrete tartrate-resistant acid phosphatase isoform 5b (TRACP 5b) into the blood circulation, and serum TRACP 5b is considered a useful marker of osteoclast number and bone resorption. Serum TRACP 5b activity is elevated in conditions of increased bone turnover and decreased during antiresorptive treatment. We have studied stability of TRACP 5b in human serum samples. A panel of 6 serum samples was stored at different conditions, and serum TRACP 5b activity was measured before and after the storage periods using the BoneTRAP®-assay (SBA-Sciences, Oulu, Finland). TRACP 5b activity was stable for 2 days both at 37°C and at room temperature (20 - 25°C), 3 days at 4°C, 1 month at -20°C and several years at -70°C. Several freeze-thaw cycles from -70°C performed at consecutive days showed no effect on TRACP 5b activity levels. However, a rapid decrease of serum TRACP 5b activity levels was detected during long-term storage of serum samples at -20°C and -70°C when one freeze-thaw cycle was performed before starting the storage period. Approximately 50% of the enzyme activity was lost already after 4 days storage at -20°C. We conclude that serum TRACP 5b activity is relatively stable when samples are incubated at temperatures of 4°C or above, allowing the performance of routine laboratory measurements to freshly collected samples without problems. Storage of serum samples at -20°C should be avoided for periods longer than one month. Long-term storage of serum samples should be performed at -70°C, where TRACP 5b activity is stable for several years. Although TRACP 5b activity survives several consecutive freeze-thaw cycles, long-term stability of the enzyme in frozen serum samples is decreased already after one freeze-thaw cycle. Extreme care should be used in cool transportation of frozen serum samples, and thawing of the samples during transportation should be avoided. It is recommended to send serum samples unfrozen at 4°C rather than frozen if it can not be guaranteed that the samples are not thawn during transportation.

N-MID Osteocalcin Measured by Roche Elecsys Is a Stable Analyte. E. T. Leary, C. Wu*, M. K. McLaughlin*, T. H. Carlson*. Pacific Biometrics, Inc., Seattle, WA, USA.

There is a lingering impression that analysis of osteocalcin (OC) is problematic because of OC instability in patient samples. This perception persists despite contrary data from assays that measure both the intact OC (amino acid 1-49) and the main N-terminal fragment (amino acid 1-43). We have demonstrated in a variety of studies that N-MID OC measured by the Elecsys analyzer (Roche Diagnostics, Indianapolis, IN) is stable (Leary, et al, Clin Chem 2000; 46:A145; Carlson, et al, Clin Chem 2004; 50:A109, Leary, et al, JBMR 2004; 19:S240). The purpose of this work was to consolidate and extend information on N-MID OC stability using the Elecsys 2010. Imprecision and sample stability of OC were previously reported in different sample types including commercial control materials, human serum, heparinized plasma and EDTA plasma. Long term total imprecision was 5.7% CV in the 10 - 69 ng/mL range. Short-term OC stability was evaluated in all three sample types after 0, 4, 8, 24, 48, 72, 96, and 168 hours at room temperature and 4 ºC. EDTA plasma was stable for at least 3 d and serum and heparin plasma stable for > 8 hr (recovery within 10%). In a separate study of six sera, OC recovery averaged 85.1% after 14 days at 4 ºC. Long term OC stability was evaluated in paired sets of serum, heparinized plasma and EDTA plasma. Measurements made within 8 hr of sample collection and after 1, 3, 6, 12, 18 and 24 months of storage at -70 ºC demonstrated recovery within 10% of baseline values at all time points. No trending was observed. Stability at -70 ºC in all three sample types may be extended to 3 to 4 yr based on clinical samples reanalyzed after 3 years of storage (slope = 0.964, intercept = -0.699 and R^2 = 0.924) and renal dialysis patient samples (all 3 sample types) reanalyzed after 4 years of storage (slopes = 0.92 to 1.01, intercepts = 7.2 to +1.3 ; all R^2 >0.98). Stability of twice-thawed samples was evaluated in 21 frozen sera (4.2 to 134.6 ng/mL). After the initial analysis, the samples were refrozen and thawed for reanalysis after 3 months using same lot of reagents. Linear regression comparison gave slope = 1.00, intercept = -0.197 and R^2 = 0.991. In conclusion, OC measured by the Elecsys N-MID OC assay is a stable analyte and does not require special sample handling precaution. Furthermore, OC may be analyzed in twice-thawed samples and samples stored at -70 ºC for up to 4 years.

Bone Turnover Is Reduced at 18 Months after a Single Intravenous Dose of Zoledronic Acid. G. J. Paz-Filho*[1], C. A. M. Kulak[1], J. P. Bilezikian[2], M. J. Seibel[3], V. Z. C. Borba[1]. [1]Serviço de Endocrinologia e Metabologia da UFPR (SEMPR), Curitiba, Brazil, [2]Department of Medicine, College of Physicians & Surgeons, Columbia University, New York, USA., New York, NY, USA, [3]Internal medicine, ANZAC Research Institute, The University of Sydney, Sydney, Australia., Sidney, Australia.

Zoledronic acid (ZOL) is a highly potent bisphosphonate, which has been shown to inhibit bone resorption for up to 12 months after a single intravenous dose (1). The exact dosing period of this agent is yet unknown. In the present investigation we evaluated changes in bone turnover at 12 (T12) and 18 (T18) months after a single injection of 4 mg of ZOL (T0) in 29 patients (24 female; age 61.2 ± 15 years) with low BMD. Lumbar spine, femoral neck and total hip BMD as well as serum CTX-I, a bone resorption marker, and serum BALP, a bone formation marker, were measured concurrently. Results: Median CTX levels were 0.183 ng/ml at T0 (range: 0.01 - 0.69), 0.039 ng/ml (0.01 - 0.37) at T12 ($p<0.001$ vs. T0) and 0.108 ng/ml (0.012 - 0.42) at T18 ($p>0.05$ vs T0). There was no significant change in median BALP levels at any time point. The median percent increase in BMD (vs. T0) at the lumbar spine was 3.3% (-9.5 to +26.6) at T12 and 5.1% (-5.9 to +21.93) at T18. At the femoral neck, the corresponding changes were 2.1% (-4.7 to +83.3) and 0.13% (-6.8 to +116.2), and at the total hip 2.5% (-5.2 to +68.3) and 1.14% (-6.2 to +7.5), with $p>0.05$ in the same site, at T0, T12 and T18. Changes in hip BMD and serum CTX correlated inversely at T12 ($r= -0.509$, $p=0.01$), but no correlations were found between other skeletal sites and bone markers at T12 and T18. In conclusion, bone resorption rates, as assessed by serum CTX-I, were suppressed at 12 months and remained below baseline at 18 months after a single dose of 4mg zoledronate. The increase in BMD was most evident at 12 months. These results demonstrate that a single application of 4mg of ZOL inhibits bone resorption effectively for 12 months, with the effect still being observed at 18 months. Therefore, a dosing interval of 12-18 months may be appropriate in patients with low BMD to inhibit bone resorption.

41Ca and Accelerator Mass Spectrometry to Monitor Calcium Metabolism in End Stage Renal Disease Patients. R. L. Fitzgerald*[1], D. J. Hillegonds*[2], D. W. Burton*[1], T. L. Griffin*[1], S. Mullaney*[1], J. S. Vogel*[2], L. J. Deftos[1], D. A. Herold*[1]. [1]VAMC/UCSD, San Diego, CA, USA, [2]Lawrence Livermore National Laboratories, Livermore, CA, USA.

Background: Stable (^{42}Ca and ^{44}Ca) and short-lived radioactive isotopes (^{45}Ca and ^{47}Ca) of Ca have been used to study calcium metabolism for years. The advantage of combining a marker such as ^{41}Ca (low noise) with a technique with attomole sensitivity, such as accelerator mass spectrometry, is that excellent signal/noise can be obtained from ng quantities of isotopes administered. Our hypothesis is that bones can be labeled *in vivo* with ^{41}Ca and that after an equilibration period, the ratios of ^{41}Ca/Ca in serum will indicate the status of bone resorption. We describe the development of an intravenous ^{41}Ca dose suitable for humans, analytical method validation for measuring ^{41}Ca /Ca isotope ratios in biological samples, and experiments with eight human volunteers dosed with 10 nCi of ^{41}Ca. **Methods:** Using sterile techniques ^{41}Ca was formulated and aliquotted into individual vials. The ^{41}Ca doses were tested for sterility and endotoxins according to USP guidelines. Purity as checked by inductively coupled plasma mass spectrometry. Measurement of ^{41}Ca /Ca ratios in serum were made by accelerator mass spectrometry after isolating calcium with three precipitation steps and a cation exchange column. Four healthy controls and four end stage renal disease patients on hemodialysis were dosed with 10 nCi of ^{41}Ca and distribution kinetics were determined over 168 days. **Results:** The dosing solution was chemically and radiologically pure, contained < 0.1 endotoxin unit per mL (Eu/mL) and passed USP sterility tests. The analytical method for quantification of the ^{41}Ca/Ca ratios was linear from 6×10^{-14} to 9.1×10^{-10}. The run to run precision of the method was 3 % and 2 % at 9.1×10^{-11} and 9.1×10^{-9} respectively. The area under the curve (AUC), representing the time course of ^{41}Ca in the central compartment, was significantly less for end stage renal disease patients as compared with control subjects ($p < 0.005$). **Conclusions:** The calculated overall radiation dose commitment of 0.06 μSv for the first year following a 10 nCi dose of ^{41}Ca is a factor 30,000 times smaller than the total dose from natural radiation. The biological risks associated with this low level radiation exposure are to small too quantify. The ^{41}Ca dose was administered to eight volunteers without adverse effects. Accelerator mass spectrometry was used to measure isotope ratios that span 5 orders of magnitude with excellent precision in the range observed after administration of 10 nCi ^{41}Ca. For the first time, we show that ^{41}Ca can be used to monitor differences in bone turnover between normal subjects and ESRD patients.

Prospective Evaluation of Risk of Vertebral Fractures Using Quantitative Ultrasound Measurements and Bone Mineral Density in a Population-Based Sample of Postmenopausal Women: Results of the Basel Osteoporosis Study. F. C. Hartl[1], H. Didier[2], R. Holländer*[1], M. Kraenzlin[3], C. Gückel*[4], M. Krieg[5], C. Buitrago*[4], R. Theiler*[6], A. Tyndall*[1]. [1]Rheumatology, University, Basel, Switzerland, [2]Nuclear Medicine Division, University, Geneva, Switzerland, [3]Endocrinology, University, Basel, Switzerland, [4]Radiology, University, Basel, Switzerland, [5]Internal Medicine, University, Lausanne, Switzerland, [6]Rheumatology, University, Zürich, Switzerland.

The aim of our study was to investigate the ability of quantitative ultrasound (QUS) and dual x-ray absorptiometry (DXA) to predict vertebral fractures in a population based sample of postmenopausal women. Five hundred women (age 65- 75 years) were prospectively followed for at least 3 years. Lateral spine x-rays in all subjects (lumbar and thoracic) at baseline and follow-up were used to assess incident vertebral fractures. In addition bone measurements using DXA at the spine and hip (GE-Lunar expert), QUS measurements at the calcaneus (GE-Lunar Achilles and Hologic Sahara) and the proximal phalanges (Igea Bone Profiler) were performed. Follow-up information was available for 433 women, representing 89% of subjects found eligible at baseline. Spine x-rays were reviewed for incident vertebral fractures (height loss of at least 20%) by 2 independent radiologists. Appropriate statistical analysis was done. A total of 24 individuals (5.5%) had documented incident vertebral fracture. Baseline characteristics between fracture group (n=24) and controls (n=409) were similar for age, weight and body mass index (BMI), but not for height (height controls: 159.8 cm, height fractured subjects: 157.3 cm, p=0.03). Mean values for the different bone measurements for the fracture group and controls were significantly different ($p< 0.05$) except for ultrasound measurements at the proximal phalanges (BP SOS p=0.21, BP UBPI p=0.29). Age and height adjusted relative risks (RR) for vertebral fracture are shown in table below with their respective 95% Confidence interval:

		RR	Min	max
Heel Achilles	BUA	1,82	1,1	2,9
	SOS	2,73	1,6	4,8
	Stiffness	2,37	1,4	4,0
Heel Sahara	BUA	2,25	1,3	3,8
	SOS	3,14	1,6	6,0
	Stiffness	2,86	1,6	5,3
Finger BP	SOS	1,08	0,7	1,6
	UBPI	0,98	0,6	1,5
Spine - BMD	L1-L4	2,11	1,2	3,6
	Neck	1,83	1,1	3,1
Femur - BMD	Ward	2,31	1,3	4,1
	Troch	1,46	0,9	2,3
	Total Hip	1,80	1,1	3,0

In conclusion, quantitative ultrasound measurements of the calcaneus are significant predictors of vertebral fracture equally well as DXA at lumbar spine, femoral neck and total hip. The predictive value of a bone measurement using Igea Bone Profiler at the proximal phalanges cannot be confirmed.

Differences in Bone Ultrasound between Infants and Children. S. Winder*, G. Chan, T. McNaught*. Pediatrics, University of Utah, Salt Lake City, UT, USA.

The growth and development of bones during the pediatric age period are important. It is the foundation of the highest calcium accretion in ones life. Optimizing the bone quality in infants may provide long time benefits and may be a prerequisite for the prevention of osteoporosis. The purpose of this study is to evaluate the bone quality of two different pediatric age groups. One hundred and twelve children aged from 4 months to 12 years were studied and stratified into a infant group (aged less than 3 years) and a school aged group (aged 5 to 12 years). Gender and anthropometric measurements were recorded. Dietary intake of calcium was evaluated in the school-aged group. The speed of sound (SOS) was measured using a commercially available bone sonometer (Sunlight Omnisense) at the midshaft tibia or distal 1/3 radius. Fifty males and 62 females were studied; 10 males and 12 females in the infant group, 40 males and 50 females in the other group. There was no difference in SOS between males and females in the infant group. In the school-aged group, SOS was greater in males than the females, 3605Â± 81 vs. 3567Â± 88 m/s ($P=0.04$). There was a non-linear relation between age and weight and SOS ($r=0.3$). However, only in the infant group there was a positive association of the midshaft SOS and their age($r=0.90$, $P<0.001$) while in the school aged group there was no relationship between their age and SOS ($r=0.15$, NS). There was a non-linear relation between the midshaft SOS and calcium intake ($P<0.01$). There were no differences between males and females in their weight, height, or calcium intakes. In conclusion, the bone quality as measured by SOS in pediatric subjects is different and needs to be age-adjusted. This finding may have implications for nutritional interventions and bone assessment for children.

Fracture Index Validation in a Population-Based Sample of Swiss Elderly Women Using a QUS Device. O. Lamy, M. Krieg*. Internal Medicine, University Hospital, Lausanne, Switzerland.

Background : Due to the magnitude of osteoporosis and its related morbidity and mortality, the identification of high risk individuals for fracture is essential. The Fracture Index (6 questions), an assessment tool with or without DEXA measurement, was shown to be predictive of hip fracture, as well as vertebral and nonvertebral fractures in postmenopausal women (D. Black et al. Osteoporosis Int 2001). The Swiss Evaluation of the Methods of Measurement of Osteoporotic Fracture Risk (SEMOF) study is a prospective multicenter study which compares 3 QUS devices for the assessment of fracture risk in a population-based sample of Swiss elderly women. The aim of the study was to validate the Fracture Index in the SEMOF study, including QUS in place of DEXA measurement. **Method** : Among the 7062 women age 70 years or older (75.2 ± 3.1), 607 clinical fractures were reported. According to the Fracture Index scoring, women were divided in quintiles. A linear increase of fracture risk was assumed during the follow-up (conservative approach). The follow-up duration varied from 953 to 1121 days, according to the quintile group and the type of fracture. **Results** : 495, 1679, 1264, 2276, and 1348 women were included respectively in quintile one to five. The total number of clinical fractures was 21, 88, 85, 205 and 208, respectively. The annualised incidence of clinical fracture per 1000 women increased from 14.1, 18.3, 23.7, 32.8, to 59.1 with the quintile one to five. The total number of hip fracture was 0, 9, 13, 25 and 43 corresponding to an annualised incidence per 1000 women of 0.0, 1.8, 0.8, 3.8, and 11.4. **Conclusion** : The Fracture Index is a very simple tool that identified women at high risk for fracture, and may defined a threshold for treatment. The use of QUS device in place of DEXA seem very attractive. The risk of fracture observed in our Swiss cohort was lower than in the SOF or EPIDOS studies. It may be in part explained by the shorter follow-up period or by the younger age of women. Another explanation may be the difference of fracture risk related to different population or country.

Quantitative Ultrasound (QUS) Measurements of the Calcaneus in a Portuguese Population: Normative Data. H. Canhao*[1], R. Ferreira*[2], L. Costa*[2], J. Romeu*[3], J. Branco*[4], H. Barros*[2]. [1]Hygiene and Epidemiology,, University of Porto Medical School, Lisboa, Portugal, [2]Hygiene and Epidemiology,, University of Porto Medical School, Porto, Portugal, [3]Rheumatology, Hospital Santa Maria, Lisboa, Portugal, [4]Rheumatology, Hospital Egas Moniz, Lisboa, Portugal.

Background: Quantitative Ultrasound (QUS) of the calcaneus is a safe and reliable method to evaluate skeletal status. However, few normative data were published and none for the Portuguese population. Aims: To estimate QUS parameters describing a representative sample of an adult Portuguese population. Methods: Cross-sectional evaluation of 1482 consecutive subjects (1010 females and 472 males), aged from 18 to 92 years, selected as part of the EpiPorto study, using random digits dialling, among the non-institutionalised population of Porto, Portugal. Information was obtained on demographic, social, clinical and behavioural characteristics using a standard protocol. Calcaneus QUS (Shara Clinical Sonometer, Hologic) parameters were obtained: Broadband Ultrasound Attenuation (BUA) and Speed of Sound (SOS), Qualitative Ultrasound Index (QUI) and Estimated Bone Mineral Density (EBMD). Results: Short-term in vivo precision was 5,5% for BUA and 0.4% for SOS, while in vitro precision was 3.23% for BUA and 0.15% for SOS. The table describes age and sex calcaneus QUS parameters. Significant sex differences were found after 39 years for BUA and after 59 for SOS. A significant age decrease was observed for every parameter, both in males and females. Conclusion: Our data are similar to others obtained in south European countries. These normative values are crucial since there are no previous Portuguese data and the method is increasingly used because of its safety, portability, low cost, simplicity, and capacity to reflect qualitative aspects of bone tissue.

Age / N (%)	BUA (Mean±SD)	SOS (Mean±SD)	QUI (Mean±SD)	EBMD (Mean±SD)

Determinants of Bone Quantitative Ultrasound Parameters in an Adult Portuguese Population. H. Canhao*[1], R. Ferreira*[2], L. Costa*[2], J. Branco*[3], H. Barros*[2]. [1]Hygiene and Epidemiology, Rheumatology, University of Porto Medical School / Hospital Santa Maria, Lisboa, Portugal, [2]Hygiene and Epidemiology,, University of Porto Medical School, Porto, Portugal, [3]Rheumatology, Hospital Egas Moniz, Lisboa, Portugal.

Background: Quantitative Ultrasound (QUS) of the calcaneus is a safe and reliable method to evaluate skeletal status. However, few data are available on the determinants of QUS parameters. Objectives: To estimate the effect of demographic, social, behavioural and anthropometric factors in QUS parameters. Methods: Cross-sectional evaluation of 1482 consecutive subjects (1010 females and 472 males), aged 18 to 92 years, selected as part of the EpiPorto study, using random digit dialling, among the non-institutionalised population of Porto, Portugal. Information was obtained on demographic, social, clinical and behavioural characteristics using a standard protocol. Calcaneus QUS (Sahara Clinical Sonometer, Hologic) parameters were obtained: Broadband Ultrasound Attenuation (BUA, dB/MHz) and Speed of Sound (SOS, m/s), Quantitative Ultrasound Index (QUI) and Estimated Bone Mineral Density (EBMD g/cm2). Comparisons according to exposure levels were done using the Kruskal-Wallis test and the multivariate effect on QUS parameters was estimated by multivariate regression. Results: QUS values were significantly different in males and females ($p<0.01$) and analysis was performed separately by gender. In women, the multivariate model showed that age and duration of the reproductive period (years) were independent predictors of BUA and SOS. Education and body mass index (BMI, kg/m2) significantly influenced BUA level, and smoking status had an effect on SOS. Physical activity, energy, calcium, vitamin D and ethanol intake, age at menarche and number of pregnancies showed no significant effect on QUS parameters. In men, age was found to be significantly associated with BUA and SOS. The multivariate model showed that BMI and calcium intake were significant BUA determinants. SOS was also significantly associated with BMI, total caloric and calcium intake. Physical activity, vitamin D or alcohol intake had no significant effect on male QUS parameters. Conclusion: This study favours the hypothesis that BUA and SOS reflect specific bone characteristics influenced by a different set of independent determinants.

Bone Surface Topology Mapping and its Role in Trabecular Bone Quality Assessment Using Scanning Confocal Ultrasound. Y. Xia, W. Lin*, Y. Qin. Biomedical Engineering, Stony Brook University, Stony Brook, NY, USA.

Quantitative ultrasound (QUS) measurement has been used for assessing bone quality, i.e., density and strength, non-invasively, in which ultrasound velocity (UV) is one of the primary acoustic properties that directly relates to bone quality evaluation. The calculation of UV requires the tissue thickness information in the pathway of wave propagation. It is extremely difficult to extract this information *in vivo*, because of (1) the irregular shape of human bone; (2) surrounded soft tissue around bone, e.g., at site of calcaneus and (3) hard to measure topology by direct measurement. The objective of this study was to identify 3D surface topology of bone for accurate calculation of UV. Scanning confocal ultrasound was performed at surface of bone, in which the reflected wave from surface was utilized to determine the 3-D topology at both medial and lateral sides. The thickness of bone, which is delineated by the bone surfaces, can be calculated from the distance between two bone surfaces. 25 human calcanei have been measured with the surface mapping technique. Wave velocity was calculated from region of interesting (ROI) based on the thickness determined by this technique. To evaluate the accuracy of UV and its capability in predicting bone's density and strength properties, micro-CT (~20 micron resolution) and DEXA scanning was performed on intact calcaneus with parameters extracted from the similar ROI as UV calculation. Mechanical test was performed on the rectangular trabecular bone specimen extracted from the calcaneus. The irregular surfaces of calcaneus can be clearly depicted using surface mapping (Figure 1) and UV determined by using this new technique was highly correlated to bone mineral density (BMD) (r = 0.75), bone volume fraction (BV/TV) (r=0.66) and bone modulus (r = 0.69). This is higher than the prediction capability of UV without using this technique, corresponding correlation coefficients were r=0.59 for BMD, r=0.46 for BV/TV, and r=0.58 for modulus. These results suggest that surface topology mapping using scanning ultrasound is capable of determining calcaneus bone thickness accurately and hence enhancing the accuracy of UV measurement. It is a non-invasive method and no significant hardware modification is necessary, which have potentials and can be easily incorporated into future *in vivo* clinical application.

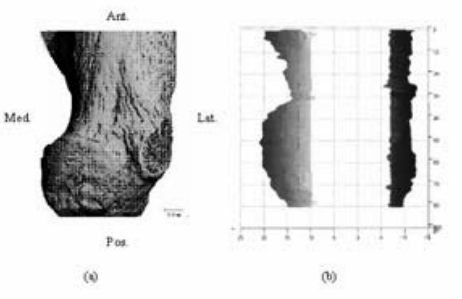

Fig.1 Bottom view of (a) calcaneus 3D surfaces measured by micro-CT with Medial (Med.), Lateral (Lat.), Anterior (Ant.) and Posterior (Pos.) positions as marked, and (b) 3D ultrasound reconstructed surfaces by surface mapping technique.

New Ultrasound Device for Bone Assessment. J. J. Kaufman[1], G. Luo*[1], R. S. Siffert*[2]. [1]CyberLogic, Inc., New York, NY, USA, [2]Department of Orthopedics, Mount Sinai School of Medicine, New York, NY, USA.

The objectives of this study were to design and fabricate a novel ultrasound device that estimates a new set of parameters - known as net time delay (*NTD*) and mean time duration (*MTD*) - and to examine in both computer simulations and clinically the relationship of the ultrasound parameters to bone mineral density (*BMD*) as determined with x-ray absorptiometry at the same anatomical site. The new device, known as the *QRT™ 2000* - for *Q*uantitative *R*eal-*T*ime -- is entirely self-contained, portable, and handheld - being powered by 4 "AA" rechargeable batteries - and permits near real-time evaluation of the ultrasound parameters and their on-line display to the user. In the simulation study, 3D micro-CT images of 10 human calcaneal trabecular bone cores were further processed using morphological image processing to obtain 36 "samples" in various states of porosity and micro-architecture. Ultrasound simulations in through transmission along the medial-lateral direction of each core were carried out using computational software (*Wave3000 Pro*, CyberLogic, Inc.). A linear regression to estimate bone mass from the simulated values of the ultrasound parameters produced an R-squared value of 0.985. In a clinical IRB-approved study the *QRT™ 2000* was used to measure 85 adult women (age range: 21 - 82 years) at the heel. *BMD* at the calcaneus was measured at the same time using *DEXA* (*PIXI*, GE). A linear regression - using the *NTD*, age and weight associated with each subject produced an R-squared value of 0.78, equivalent to a linear correlation coefficient of 0.88, which represents a significant improvement over present ultrasound bone densitometers, but not nearly as good as the simulation results. Reasons for this have been identified (*viz.*, errors in distance measurement and lack of coincidence between the *DEXA* and ultrasound regions of interest) and a new device (*QRT™ 3500*) and experimental protocol to deal with these sources of error are being developed that should improve the accuracy of the ultrasound device over existing technology even more. In addition, an examination of the *MTD* parameter - which appears to be sensitive to both mass *and* architecture - is being carried out in conjunction with *NTD* measurements to determine if both parameters together may be used to more accurately estimate fracture risk than bone mass alone. Finally, the *QRT™* devices were designed to be manufactured at very low cost, and therefore should enable the significant expansion of quantitative ultrasound measurements to, for example, primary care physicians in this country and abroad, including for use in the developing world as well as in spaceflight.

Quantitative Prediction of Bone Density and Strength in Human Calcanei Using a Scanning Confocal Acoustic Diagnostic System. Y. Qin[1], Y. Xia[1], W. Lin*[1], B. Gruber[2], S. Judex[1], C. Rubin[1]. [1]Biomedical Engineering, SUNY Stony Brook, Stony Brook, NY, USA, [2]Medicine, SUNY Stony Brook, Stony Brook, NY, USA.

Microgravity and aging induced osteopenia is a critical skeletal complication occurred particularly in the weight-supporting skeleton, which leads to osteoporosis and risk of fracture. Bone integrity is dependant not only on the mineral density, but also on the quality of bone which includes the strength and structural parameters. Advents in quantitative ultrasound (QUS) provide a potential method for evaluating both strength and density of bone. The object of this study was to integrate automatic region of interest (ROI) algorithm and using a Scanning Confocal Acoustic Diagnostic (SCAD or SCAN) system to non-invasively assess bone quality in human calcaneus trabecular region. An imaging pattern recognition algorithm is developed and integrated in a newly developed SCAD system. The method was designed for the selection of an irregular ROI in the ultrasound attenuation (ATT) images from calcaneus bone. When the ROI is automatically determined, broadband ultrasound attenuation (BUA), and ultrasound velocity (UV) for bone quality in the real body region were evaluated. Total of 36 human cadaver calcanei, age from 60 to 97 years old, were tested by SCAD, micro-CT and DEXA, as well as mechanical failure tests. The SCAD properties were then correlated to the bone mineral density (BMD), structural and strength parameters. Correlations between BMD and ultrasound parameters were significantly improved by using SCAD with the automatic ROI algorithm, yielding correlations between BMD (DEXA) and SCAD parameters as R2=0.83 (BUA), and R2=0.65 (UV). Correlations were significant between bone volume fraction and BUA, R2=0.75, and between volume fraction and UV, R2=0.54. SCAD parameters predicted the trabecular bone strength, in which correlation between BUA and elastic modulus was R2=0.54, and correlation between ultimate strength and BUA was R2=0.60. These data have suggested that scanning confocal ultrasound may provide potentials for in vivo bone quality prediction. It may be used for monitoring instant changes of both bone strength and density alteration, e.g., progressive bone loss and evaluation of treatment of osteopenia. High resolution bone acoustic images can be generated at particular sites, e.g., calcaneus, with automatic region of interest algorithm. Prediction of bone quality by imaging based ultrasound in density and strength assessment may ultimately provide a non-invasive modality for bone quality evaluation in space and on Earth.

Trait Loci Determining the Degree of Disuse Osteopenia. S. Judex[1], H. Chung*[1], S. Xu*[1], V. Guido*[2], A. Torab-Parhiz*[1], A. Li[1], C. Rubin[1], L. Donahue[2]. [1]Stony Brook University, Stony Brook, NY, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

The extent of disuse-related trabecular bone loss during space flight or bedrest is high, approaching declines in vBMD of up to 2.7% per month. In contrast to the uniformity of the newly imposed environment across individuals, including similarity in diet and length of daily exercise regimes, the degree of bone loss between individual astronauts is highly variable, indicating the influence of genetic factors. In an effort towards elucidating the genetic basis of bone's sensitivity to the loss of appropriate mechanical signals, here we subjected a genetically heterogeneous mouse population to simulated weightlessness and report preliminary data from the genetic and phenotypic analyses. Five hundred second generation (BALBxC3H) female mice (4mo), were subjected to 3wk of disuse (hindlimb suspension). The progenitor strains were selected based on their greatly different skeletal mechano-sensitivity. In each mouse, in-vivo microCT scanning quantified longitudinal changes in trabecular bone morphology and architecture of the distal femur over the 3wk of unloading. Upon sacrifice, DNA was extracted and regions with single nucleotide polymorphisms (SNP) were identified via allele typing. Map Manager QTX was used to regress variations in genotype to variations in the morphological response to disuse. Over 3-wk of disuse, trabecular bone volume fraction diminished on average by 52%±16% ($p<0.0001$) with losses ranging from 17%-83%. Trabecular bone architecture also deteriorated with unloading; connectivity density decreased on average by 54% ($p<0.0001$), and trabecular thickness by 17% ($p<0.0001$). The values for each trait were normally distributed, indicating that multiple loci are involved in defining the changes in bone quantity and micro-architecture to mechanical unloading. Because of the small number of mice used for this preliminary analysis (100), no QTL could be determined with statistical significance ($p=0.0001$). Nevertheless, a large number of QTL was suggested by the regression analyses when using a higher significance value. These preliminary data confirm the strong genetic influence on bone's susceptibility to unloading and suggest that this particular F2 double-cross is well suited to define the chromosomal regions that modulate the degree of bone loss induced by a catabolic mechanical stimulus. Identification of the QTL (and the responsible genes) may ultimately be used as a critical predictive sensor for disuse osteopenia, as a discovery tool for novel drug targets, and for the selection of individual countermeasures of bone loss.

Genome Wide Linkage of Hip Geometry: Framingham Study. S. Demissie*[1], D. Karasik[2], S. Menn*[2], Y. L. Tsai*[1], L. A. Cupples*[1], T. J. Beck[3], D. P. Kiel[2]. [1]School Pub Health, Boston University, Boston, MA, USA, [2]Research & Training, Hebrew SeniorLife, Boston, MA, USA, [3]Radiology, Johns Hopkins University, Baltimore, MD, USA.

Femoral geometry contributes to bone strength and predicts hip fracture risk. The technique of hip structural analysis (HSA) expresses the bone mass data in a mechanically interpretable form so that genetic influences on mechanical properties might be directly evaluated. There has been only one previous genome-wide linkage analysis of femoral geometry in women only using plain radiographs. The purpose of this study was to evaluate heritability (h^2) and to perform a whole-genome genetic linkage analysis of geometric indices of the proximal hip in men and women from extended pedigrees. Proximal femur scans from 1351 members of 326 pedigrees (mean age 67.8 (SD 12.8), range 31- 96 yrs) from the population-based Framingham Osteoporosis Study were analyzed. A set of 401 microsatellite markers were genotyped. Femur cross-sectional geometry was measured at 3 sites: the narrowest neck (NN), intertrochanteric (IT), and femoral shaft (S) regions. HSA provided measures of endosteal diameter (END, cm), subperiosteal width (WID, cm), cross-sectional area of bone (CSA, cm^2) - a measure of axial strength, and section modulus (Z, cm^3) - measure of bending strength. Bone geometric measures were adjusted for age, age^2, body mass index, height, and physical activity, in each sex and generation. Multipoint quantitative linkage analyses were performed for 4 indices at each of the 3 femoral regions using the maximum likelihood variance components method. A moderate to strong genetic influence was found for all indices, with h^2 values between 0.321 [NN_Z] and 0.567 [IT_END]. Multipoint linkage analysis revealed loci of suggestive linkage (LOD scores >=1.9) on chromosomes 3p, 4q, 12p, 13q, and 16p. The maximum LOD score was 3.1 for IT_END at 3p26.1. The same region provided LOD score 2.7 with IT_WID. Also, IT_END was also linked to 12p13 and IT_WID to 13q21 (both LOD=2.7). In general, both endosteal and subperiosteal diameters were linked to the same chromosomal regions: NN_END and NN_WID were linked to 16p12, with LODs>2.0. IT_CSA and SS_CSA were linked to a long region of 4q. In conclusion, these results suggest that measures of femoral bone geometry are heritable and linked to several autosomes. This represents an important step toward identifying genes contributing to geometric aspects of strength. Despite the limitation of HSA method is that it is based upon two-dimensional projections of complex three-dimensional anatomy, use of hip geometric traits may help clarify the genetic contributions to bone strength and osteoporotic fragility in the general population.

Admixture Mapping of Genes Underlying Peak Bone Mineral Density Variation in Humans. D. L. Koller*[1], M. Peacock[2], T. Foroud[1], M. J. Econs[2]. [1]Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Medicine, Indiana University School of Medicine, Indianapolis, IN, USA.

Identification of genes underlying variability in peak bone mineral density (BMD) is an important goal in osteoporosis research. However, while progress has been made, the major fraction of the genetic variation in BMD remains unexplained. The study designs employed so far to identify these genes (polymorphisms within candidate genetic loci and linkage screens in humans and animals) have notable strengths as well as weaknesses. To overcome some of these weaknesses, we have applied a recently developed method, admixture mapping (McKeigue, 2005; Hoggart, 2004), to human peak BMD and genetic marker data. This method complements the three established study designs by providing much finer genetic resolution of linkage regions, directly testing large human chromosomal regions, and substantially narrowing critical genetic intervals before the identification of positional candidate loci is undertaken. Admixture mapping is applicable when a trait such as BMD is significantly different between ancestral populations, and when recent admixture between these populations (20 generations ago or less) results in individuals having varying degrees of genetic material from each of the ancestral groups. These conditions are met in the African-American population. Sizable chromosomal regions (2-3 cM) of African or European ancestry remain intact in African-Americans. The ancestry of these specific regions can be determined using genetic markers whose allele frequencies differ between the ancestral populations. Importantly, BMD and fracture risk also differ significantly between the European and West African populations. Given ancestrally informative markers, admixture mapping tests whether variability in BMD is predicted by variation in ancestry at the chromosomal position of interest. We have applied admixture mapping using the software package ADMIXMAP (O'Donnell, 2004) to a sample of 230 unrelated premenopausal African-American women, selected from a sibpair cohort. A 9 cM genome screen and spine BMD was obtained in each individual. A significant relationship between BMD and ancestry ($p<0.02$) on chromosome 10p was found, and the genome screen markers on 10p provided adequate ancestry information. This is the same region where some evidence of linkage was found in our American white and African-American sample (LOD=1.8 at D10S1432). We anticipate that using additional informative markers, and increasing marker density from 9 cM to 2-3 cM, will enable the use of admixture mapping to effectively narrow linkage regions to a more manageable size for identification of genes.

Genotype-by-Parity Effects on Bone Mineral Density in Pedigreed Baboons. L. M. Havill, J. Rogers*, D. E. Newman*, M. C. Mahaney. Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX, USA.

The dramatic sex difference in osteoporosis (OP) prevalence requires explanation and may provide avenues for deciphering OP pathogenesis. The obvious sex-specificity of pregnancy and lactation have focused attention on possible effects of reproductive history on bone maintenance and turnover in women. While these events can result in transient changes in bone mineral density (BMD), studies of their long-term effects on BMD and fracture risk show inconsistent results. While these apparent inconsistencies may be due in part to differences in study design, the effects of genes on a woman's bone metabolism during pregnancy and lactation may also contribute to variation in the long-term effects of reproductive history on bone fragility. We tested the hypothesis that genotype interacts with reproductive history effects on BMD in a non-human primate model by analyzing genotype-by-parity (G×P) interaction effects on lumbar spine and forearm BMD in pedigreed adult baboons (N=676). We previously reported that BMD in these baboons is heritable and that increasing parity has a significant negative effect on BMD at all sites ($p<0.0001$ to $p=0.01$; 0.5% to 0.8% per pregnancy). Using maximum likelihood-based variance components methods developed to test for genotype-by-environment interactions, we modeled the additive genetic covariance for BMD in the baboon pedigrees as a function of parity. More specifically, we defined the additive genetic variance as an exponential decay function of parity. We modeled the genetic correlation between relative pairs similarly. Significant parity-dependent changes in the genetic variance and/or departures from complete pleiotropy (genetic correlation=1) between relatives as a function of parity were interpreted as evidence of G×P interaction. We simultaneously estimated the phenotype, BMD, as a linear function of these two G×P interaction terms and the mean effects of sex, age, weight, and parity. At no skeletal site in these baboons does the genetic correlation between BMD in relatives change significantly in a parity dependent manner; therefore, we conclude that the genes affecting BMD do not differ as a function of parity. However, because the estimated genetic variances in BMD at all skeletal sites do change significantly in a parity-dependent manner ($p<0.00001$ to $p=0.01$), we conclude that the magnitude of the effect of those genes is influenced by parity. This first formal test for genotype-by-parity interaction shows that at trabecular bone sites (spine and ultradistal radius) the effect of genes on BMD decreases with increasing parity. At cortical bone sites (diaphyseal radius and ulna) the effect of genes increases with increasing parity.

Quantitative Trait Loci for Bone Mineral Density Identified by Genome-Wide Linkage Scan to Chromosomes 7q and 21q in Men from the Amish Family Osteoporosis Study. E. A. Streeten, J. R. O'Connell*, D. J. McBride*, T. I. Pollin*, A. R. Shuldiner*, B. D. Mitchell. Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore,, MD, USA.

Bone mineral density (BMD) is highly heritable, with genetic factors accounting for 50-70% of variation in adult BMD and up to 85% of variation in peak bone mass. The purpose of this study was to identify genes contributing to variation in BMD. We carried out a genome-wide scan among participants of the Amish Family Osteoporosis Study (AFOS), a study designed to identify genes that influence bone health. The Amish are a genetically closed population who descended from a relatively small number of founders. Importantly, most Amish follow a homogeneous lifestyle, rarely smoke or drink alcohol and prefer to avoid prescription medications. Our genome scan was carried out in 988 participants (mean age $\pm$ SD = 50.2$\pm$ 16.3 yrs, range 18-99 yrs) recruited from 50 large multigenerational families, including 4 having more than 100 members. BMD was measured at the spine, hip and radius using dual x-ray absorptiometry (DXA). Mean T scores in the participants were: spine (L1-4) -1.3 $\pm$ 1.4, total hip -0.4 $\pm$ 1.2, total wrist -0.2 $\pm$ 1.3. Multipoint linkage analysis was carried out using 731 highly polymorphic microsatellite markers with average spacing of 5.4 cM. Sub-analyses were conducted in men (n = 386) and women (n=602). No significant QTLs related to BMD were identified in the study population as a whole (highest LOD = 2.11 for radius BMD at 3q26). On subgroup analysis of all men, we found significant evidence for QTLs influencing variation in both total hip (LOD = 3.83) and femoral neck (LOD = 3.09) BMD at 7q31 and for spine BMD at 21q22 (LOD = 3.19). For the women only subgroup, no significant QTLs related to BMD were identified (highest LOD = 2.11 for spine BMD at 1q21). Previous studies in mice have found a QTL for femur BMD at a mouse site syntenic to human 7q32 and in humans a QTL for trochanter BMD at 21q22. In conclusion, these results provide evidence for QTLs in men that influence hip BMD on chromosome 7q and spine BMD on 21q, replicating previous findings in mice and humans.

Genomic Regions Identified for BMD in an Exceptionally Large Sample by Considering Epistasis. P. Xiao, Y. F. Guo*, R. R. Recker, H. W. Deng. Osteoporosis Research Center, Creighton University, Omaha, NE, USA.

Low bone mineral density (BMD) is an important risk factor for osteoporosis and under strong genetic control. Several whole genome scan (WGS) studies have been conducted for BMD in humans, resulting in largely inconsistent results so far. It is now recognized that small samples and thus lack of statistical power are an undisputable reason behind the inconsistent and none-robust results. No previous WGS for BMD considered epistatic effects, which usually underlie complex traits. In this study, an exceptionally large and powerful sample of 471 Caucasian families with 4,251 subjects was phenotyped and genotyped for 410 microsatellite markers throughout the human genome. WGS was conducted. In WGS analyses, a LOD score of 3.01 was achieved on 5q23 for wrist BMD. For spine and hip BMD, the highest LOD scores were obtained on 3p25 (LOD = 2.27) and 3q27 (LOD = 2.62), respectively. Another interesting suggestive linkage region on 2q32 was detected for spine BMD (LOD = 1.91), hip BMD (LOD = 2.17), and wrist BMD (LOD = 1.98). However, in further analyses that incorporated epistasis into the original WGS, quite interesting results emerged. When epistasis was considered with 3p25 for spine BMD, we identified highly significant results in two genomic regions that showed only suggestive linkage evidence or small LOD score in the original WGS. Specifically, the LOD score increased from 1.91 to 3.75 at 2q32, and increased from 1.35 to 3.29 at 11q23. This study highlights large sample and incorporation of epistasis in WGS in identifying QTLs for complex diseases.

Is There Evidence of Heritability of Hyperkyphosis in Older Women? D. M. Kado[1], L. Palermo*[2]. [1]Medicine, University of California, Los Angeles, Los Angeles, CA, USA, [2]Epidemiology and Biostatistics, University of California, San Francisco, San Francisco, CA, USA.

Hyperkyphosis, or an increased thoracic curvature, is often considered one of the undesirable consequences of osteoporosis. However, up to one half of those with the worst hyperkyphosis do not have vertebral fractures. Therefore, hyperkyphosis is likely a result of other important and possibly reversible causes. We hypothesized that compared to unaffected women, older women with hyperkyphosis would be more likely to have a family history of hyperkyphosis. Study participants were from the Study of Osteoporotic Fractures and included 611 women, aged 67 or older, who had their thoracic spinal curvature assessed using an architect's flexicurve during the second clinic visit. In addition to assessing morphometric vertebral fractures, spine and hip bone mineral density, and a family history of fractures, these women answered questions that inquired whether their natural mother and/or natural father had a history of a dowager's hump, or a spine that was stooped or bent forward. Of the original 611 women, 557 (91%) answered the question regarding family history. Of those, 17% reported that their mother had a dowager's hump and 5% reported that their father had a dowager's hump. Modeled continuously, there was a significant age-adjusted association between either having a mother or father's history of dowager's hump and worse degrees of kyphosis ($p = 0.001$). In multivariable models adjusted for age, spine or hip bone mineral density, and prevalent vertebral fracture, the

association between a positive family history of dowager's hump and worse degrees of kyphosis remained significant (p = 0.009). In similarly adjusted logistic models examining the odds of being in the highest quartile of kyphosis, reporting a father's history of dowager's hump was the strongest predictor (Odds ratio = 3.0; 95% CI: 1.2-7.3, p = 0.015). A positive family history of fracture was not associated with degree of kyphosis. While we cannot exclude the possibility of recall bias as a potential explanation for our study findings, these results present preliminary evidence that hyperkyphosis is a heritable condition that is not simply reflective of underlying osteoporosis.

QTL for Bone and Body Composition Phenotypes Are Sex Specific in a Mouse Model of GH/IGF-I Deficiency. L. Donahue, W. Beamer, K. Shultz*, J. Hurd*, V. Guido*, C. Rosen. The Jackson Laboratory, Bar Harbor, ME, USA.

QTL analysis is a powerful tool for the discovery of regulatory genes for complex traits such as body composition and skeletal phenotypes. Crosses between inbred strains of mice provide QTL data and are contributing to new genetic insights regarding body morphology. Our QTL analysis has 2 goals: to identify genes that are independent of GH/IGF-I regulation, and to determine if these genes are sex specific. We are utilizing a spontaneous mouse mutation, *little,* with a non-functional GHRHR. A congenic strain was made by transferring the *little* mutation from the low BMD C57BL/6J (B6) to the high BMD C3H/HeJ (C3) strain. In both B6-*lit/lit* and C3.B6-*lit/lit* mice, circulating GH is undetectable, serum IGF-I is low, and femoral vBMD (pQCT), aBMD (PIXImus), femur length, and body mass are reduced compared to *lit/+* mice. Although C3.B6-*lit/lit* mice are of the same body weight and femur length as B6-*lit/lit* mice, C3.B6-*lit/lit* mice have higher aBMD and vBMD. Crosses between B6-*lit/lit* and C3.B6-*lit/lit* produced 1037 male and 1095 female F2 GH/IGF-I deficient mice, but segregating alleles from B6 and C3. Analyses of genome-wide data from 120 polymorphic markers (nearly 192,000 genotypes) revealed gender-specific and gender-independent regulatory loci for all phenotypes. Data show: 1) The best QTL for all phenotypes differs between sexes, per ex the best QTL for vBMD is on Chr 11 in females (F) and on Chr 1 in males (M); 2)The best QTL for one sex often has a significant (not necessarily the best) QTL for the other sex, per ex the QTL for vBMD on Chr 1 has a LOD score of 11.2 for males and 9.2 for females, but the best QTL for vBMD in females is on Chr 11 (LOD 12.6); 3) Some QTL have significant (but not the highest) LOD scores for sexes combined and for each individually, per ex all of the QTL for vBMD are significant for all 3 groups. We conclude that it is important to separate sexes when performing QTL analyses. Moreover, it is misleading to infer significance for a QTL in both sexes when it is found to be important in one or the other, or in sexes combined. In addition, the QTL for vBMD on Chrs 1,4, and 11 are in approximately the same location as those found in B6C3H +/+ F2 mice; however the QTL on Chr 8 is unique to the GH/IGF-I deficient mice.

A Major QTL on Mouse Chromosome 12 That Regulates Bone Nanoindentation Property. Y. Jiao*[1], Z. Fan*[2], H. Chiu*[3], F. Jiao*[1], E. C. Eckstein*[3], J. Rho*[3], W. G. Beamer[4], W. Gu[1]. [1]University of Tennessee Health Science Center, Memphis, TN, USA, [2]Marquette Univ, Marquette, WI, USA, [3]Univ. of Memphis, Memphis, TN, USA, [4]The Jackson Laboratory, Bar Harbor, ME, USA.

It has speculated that regulate bone quality measured by nanoindentation technology represents a novel approach in our understanding of molecular mechanisms that control bone matrix properties. In this study, we measured bone quality of mouse tibiae by nanoindentation and three-point bending. We then mapped and compared quantitative trait loci (QTLs) detected by these two methods. 1) Mouse tibiae for age testing were from C3H/HeJ and for QTL mapping were from a F2 population derived from C57BL/6J and C3H/HeJ. Those tibiae were from the same population used for the analysis of QTLs of bone mineral density at The Jackson Laboratory. 2) For nanoindentation measurement, a Triboindenter (Hysitron, Inc. Minneapolis, MN) was used to conduct all indentation tests. The Oliver-Pharr method was used to determine the elastic modulus. 3) The bone strength of the same set of bones was tested for three-point bending using ISO 4049, with the support width adjustable to accommodate specimen sizes outside the scope of ISO 4049. 4) Genome scan was performed in The Jackson Laboratory using microasatellite markers. 5) QTL mapping was conducted using Map Manager QTX software. Analysis of data of nanoindentation obtained 683 F2 mice detected five QTLs on hardness and four on stiffness of the nanoindnetaion properties. 2). Analysis of data of three-point bending detected four QTLs of Elastic Modulus and 11 QTLs of Maximum Loading (hardness). 3) Most of the QTLs from three-point bending have been mapped on to the same locations of bone mineral density. QTL on Chr. 4 (60% influence) has the most impact on the bone strength measured by three-point bending. 4) The QTL on Chr. 12 (12% influence) has the most influence on nanoindentation property. While previously there is no bone related QTL reported on mouse Chr. 12, homologous region of this QTL on human Chr. 14q has been linked to peak bone mineral density at the hip. Our study suggests that nanoindentation has a great potential as a novel approach to improve our understanding of molecular mechanisms that control the matrix properties of bone.

The Relationship between Interleukin-1 System Gene Polymorphism and Change in Bone Mineral Density after Hormone Replacement Therapy in Postmenopausal Korean Women. J. KIM, D. Lee*, S. Ku*, B. Jee*, C. Suh*, S. Kim*, Y. Choi*, S. Moon*. Dept. of Obsterics & Gynecology, Seoul National University Hospital, Seoul, Republic of Korea.

The purposes of this study were to investigate the relationship between interleukin-1 (IL-1) system gene polymorphisms, and change in production of IL-1 by whole blood cells (WBCs), and bone mineral density (BMD) after hormone replacement therapy (HRT) in postmenopausal Korean women. The IL-1α C-889T polymorphism, IL-1β C-511T polymorphism and 86-base pair variable number tandem repeat (VNTR) polymorphism in the IL-1 receptor antagonist (IL-1ra) gene was analyzed by restriction fragment length polymorphsim (REFLP), polymerase chain reaction-Genescan, and DNA sequencing in 206 postmenopausal Korean women receiving sequential HRT for 1 year. IL-1α, IL-1β, and IL-1ra produced by WBCs cultured with lipopolysaccharide for 2 days, and serum CrossLaps (CTX), and osteocalcin were measured using enzyme-linked immunosorbent assay (ELISA) and immunoassay respectively. BMD at the lumbar spine and proximal femur was determined by dual energy X-ray absorptiometry. The IL-1 system genotypes were not distributed differently between HRT-responders and HRT-nonresponders (women who lose more than 3 % of bone mass per year), and no differences in the annual percent change of BMD after HRT were noted among IL-1 system genotypes. After HRT, the production of IL-1α by WBCs decreased but no changes in the production of other components of IL-1 system were noted. There were no differences in the 6 month changes of bone turnover markers and the production of IL-1 system components by WBCs and IL-1β/IL-1ra ratio after HRT across IL-1 system genotypes. Except a negative correlation between IL-1α with annual change of BMD at trochanter after HRT, the production of other components of IL-1 system by WBCs and their changes after HRT of 6 month did not correlated with annual change of BMD after HRT. In conclusion, the IL-1 system gene polymorphisms do not affect change in BMD, and change in the production of ILs by WBCs after HRT in postmenopausal Korean women.

Influence of Genetic Factors Related to Estrogen Synthesis and Activity on Peak Bone Mass. J. A. Riancho[1], C. Valero*[1], A. L. Zarrabeitia*[1], M. T. Zarrabeitia*[2], J. Gonzalez-Macias[1]. [1]Internal Medicine, Hospital U.M. Valdecilla, University Cantabria, Santander, Spain, [2]Legal Medicine, University Cantabria, Santander, Spain.

Osteoporosis may result from an accelerated loss of bone mass with advancing age, or from an impaired accretion of bone during the growth period, which leads to an inadequate peak bone mass in early adulthood. Although the factors that actually determine peak bone mass are not well known, there is evidence that both heredity and estrogen activity are important in females as well as in males. Therefore we studied healthy individuals between 22 and 45 years of age (147 men, 194 women) and analysed the relationship between bone mineral density (BMD) and a number of frequent polymorphisms in genes related to estrogen metabolism and activity. They included a T/C SNP in the 5' region of the 17-hydroxylase gene; an A/G SNP in the 3' UTR of aromatase; a CA microsatellite in intron 6 of the estrogen receptor beta; and four polymorphisms of the estrogen receptor alfa (TA repeat in promoter; C/T and G/A SNPs in intron 1, and A/G SNP in exon 8). Areal BMD was higher in men than in women (spine: 1.048±0.120 vs. 1.034±0.112; hip: 0.907±0.131 vs. 0.822±0.104 g/cm^2, p<0.001). Body weight was the single most influential factor on BMD in both sexes, explaining 8-9% of BMD variance. Among the genetic factors studied, a common CA repeat polymorphism in estrogen receptor beta showed a significant association to BMD in women (p=0.03 at the spine, and 0.008 at the hip). The effect of estrogen receptor genotype persisted after adjustment by body weight, explaining a further 2-3% of BMD variance. Other polymorphisms did not show an independent association with BMD. These results suggest that body weight and some common allelic polymorphisms in estrogen receptor beta contribute to determining peak bone mass. However, they only explain a small proportion of the overall BMD variance. Therefore, other unidentified factors exerting a significant influence must exist.

Farnesyl Diphosphate Synthase (FDPS), a New SNP that Is Associated with BMD in Elderly Women. M. Levy[1], R. E. Ferrell*[2], R. A. Parker*[3], S. L. Greenspan[1]. [1]Medicine, University of Pittsburgh, Pittsburgh, PA, USA, [2]Genetics and Pharmaceutical Sciences, University of Pittsburgh, Pittsburgh, PA, USA, [3]Center for Biostatistics in AIDS Research, Harvard School of Public Health, Boston, MA, USA.

Previous studies have demonstrated single nucleotide polymorphisms (SNPs) in several candidate genes, including the estrogen receptor alpha gene and the vitamin D receptor gene, have a minimal impact on bone mass in postmenopausal women. Farnesyl diphosphate synthase (FDPS) is an enzyme involved in the mevalonate pathway in osteoclasts and is inhibited by nitrogen-containing bisphosphonates. We postulated that an FDPS SNP (rs2297480) may be associated with bone mineral density (BMD) and response to antiresorptive therapy. To test this hypothesis, we examined FDPS in addition to polymorphisms associated with the estrogen receptor alpha gene (ESR1: *PvuII* and *XbaI*), the vitamin D receptor gene (VDR: *BsmI* and *FokI*), and a lipoprotein-related protein 5 (LRP5: *A1330V*) polymorphism in elderly women who had completed a 3-year, double-

blind, placebo-controlled clinical trial of alendronate, hormone replacement, or combination antiresorptive therapy. As previously reported, bone mass increased significantly at all skeletal sites in women on active treatment. Our study found FDPS was associated with baseline BMD. Patients with AA genotypes had significantly higher BMD than those with either the CA or CC genotype (combined) at the spine ($P = 0.009$), hip ($P = 0.018$) and trochanter ($P = 0.010$). Each C allele decreased BMD by 0.036 g/cm^2 at the spine ($P = 0.029$), 0.021 g/cm^2 at the hip ($P = 0.064$), and 0.022 g/cm^2 at the trochanter ($P = 0.027$), after adjustment for age and body mass index. VDR, ESR1 and LRP5 SNPs were not associated with baseline BMD. None of the polymorphisms were related to change in BMD during treatment. We conclude that FDPS is related to baseline bone mass, but does not influence response to therapy. Further studies are needed to examine whether this polymorphism is related to fracture risk in addition to BMD.

	Baseline BMD (g/cm2, mean +/- SD)		
FDPA Alleles (n)	Spine*	Total Hip	Trochanter*
AA (145)	0.906±0.166	0.802±0.118	0.614±0.101
CA (120)	0.858±0.160	0.772±0.123	0.588±0.102
CC (14)	0.850±0.146	0.754±0.144	0.563±0.118

*$P < 0.05$ difference across FDPS alleles

Estrogen Receptor Beta Polymorphisms Predict Risks of Osteoporosis in Men and Women: A Linkage and Association Study. A. W. C. Kung[1], B. M. H. Lai*[1], M. Y. M. Ng*[1], W. M. W. Cheung*[1], V. Chan*[1], P. C. Sham*[2]. [1]Department of Medicine, The University of Hong Kong, Hong Kong, China, [2]Genome Research Centre, The University of Hong Kong, Hong Kong, China.

Estrogen receptor beta is expressed in both osteoblast and osteoclast and estrogen receptor beta gene (ESR2) is likely to play a role in bone mass determination. We previously reported a weak association between a dinucleotide CA repeat polymorphism (D14S1046) in the intronic region of ESR2 with bone mineral density (BMD) in women. To evaluate the role of ESR2 in BMD determination and osteoporosis risk prediction in men and women, linkage and association approach were utilized by evaluating 1484 subjects from 306 extended southern Chinese pedigrees and 770 pairs of population-based case-control subjects. The cases were subjects with BMD Z score <-1.3 at either the spine or total hip region (equivalent to the lowest 10th percentile of the population) and the controls were subjects with BMD Z score > +1. Out of 11 SNPs, a SNP in the promoter region (nt -1068T→C) was in significant linkage diseqilibrium with 21 CA repeats of D14S1046. Using Merlin program, 6 tagged SNPs were in linkage with spine BMD (LOD 1.50 to 1.67, p=0.003) and femoral neck BMD (LOD 1.21, p=0.009). Using quantitative trait disequilibrium test (QTDT), nt -1068T→C was found to be associated with hip BMD in women (p=0.005) but not in men in both total family association and within-family association testing. In the population-based study, nt -1068T→C was associated with 10% reduction in spine and hip BMD in men, 4% reduction in spine BMD in premenopausal women and 4-6% reduction in spine and hip BMD in postmenopausal women. Furthermore, this SNP was associated with higher risk of osteoporosis at the lumbar spine (male: odds ratio 3.4, female: odds ratio 2.8) and at the hip (male: odds ratio 1.9, female: odds ratio 2.9). SNP haplotype analysis provided similar results as individual SNP analysis. In conclusion, nt -1068T→C polymorphism of the ESR2 gene is associated with lower BMD and higher risk of osteoporosis in both males and females. This SNP may serve as a potential marker for assessing the risk of osteoporosis and identification of at risk subjects.

A Deletion Polymorphism in the Gene for the Estrogen Receptor Alpha Coactivator RIZ1 Is Associated with BMD in Elderly Men - MrOS, Sweden. E. Grundberg*[1], O. Johnell[2], Ö. Ljunggren[1], D. Mellström[3], E. Orwoll[4], C. Ohlsson[3], H. Mallmin*[5], A. Kindmark[1], H. Brändström[1]. [1]Department of Medical Sciences, Uppsala University, Uppsala, Sweden, [2]Department of Orthopaedics, Malmö University hospital, Malmö, Sweden, [3]Center for Bone Research, Department of Internal Medicine, The Sahlgrenska Academy at Goteborg University, Göteborg, Sweden, [4]Department of Medicine, Oregon Health Sciences University, Portland, OR, USA, [5]Department of Surgical Sciences, Uppsala University, Uppsala, Sweden.

Predisposition to osteoporosis is largely genetically determined. It is likely that the genetic risk consists of several common polymorphisms of genes that have weak effects individually, but major effects in concert. A novel candidate gene for BMD is the estrogen receptor-alpha (ERalpha) coactivator RIZ1 that strongly enhances ERalpha function. The gene contains a natural occurring deletion encoding a proline in exon 8. Previously, we have demonstrated that the deleted form of RIZ1 shows an impaired response in coactivating ERalpha in a ligand- and dose-dependent manner compared with the non-deleted form of RIZ1. In this study we examined the relationship between the deletion in the RIZ1 gene and BMD in 3000 Swedish elderly men, included in the Swedish part of the MrOs study. The study is population based and the participants were between 70 and 80 years old at inclusion. BMD was measured by dual x-ray absorbtiometry (DXA). Serum levels of testosterone, estradiol and SHBG were measured using radio immuno assay and free estradiol levels were derived from the mass action equations. The genotypes for the RIZ1 polymorphism were named homozygous presence P704+, absence P704-, heterozygosity P704+/- of a proline at position 704. The genotype frequencies in the study population were P704+ 18%, P704 +/- 49% and P704- 33% which is in agreement with Hardy-Weinberg equilibrium. A significant association was observed between spine BMD and RIZ1 genotype (ANOVA p=0.024). Multiple regression analysis was used to adjust the data for differences in weight, height, age, smoking, physical activity, total calcium intake and free estradiol levels, to define the relative contributions of independent variables to the variation of spine BMD. After adjustment, the RIZ1 genotype was an independent predictor of spine BMD in elderly men (p=0.004, β=-0.06).

Dinucleotide CA Repeat Polymorphisms in ESR1 Gene Are Associated with Increased Risk of Low BMD and Osteoporotic Fractures. B. M. H. Lai*, A. W. C. Kung. Medicine, The University of Hong Kong, Queen Mary Hospital, Hong Kong, China.

Studies of PvuII and XbaI polymorphisms of the estrogen receptor alpha (ESR1) gene have shown that these intronic polymorphisms may be associated with fracture risk, but their relation with bone mineral density (BMD) is controversial. We postulated that other polymorphic sites of ESR1 may be of importance in determining osteoporosis and fracture risk, such as the dinucleotide CA repeats polymorphism (D6S440) in intron 5 of the gene. To assess the role of D6S440 as a marker for predicting risk of low BMD and osteoporotic fractures, we studied 770 Southern Chinese case-control pairs (93 male, 677 female pairs). Cases were subjects with BMD Z scores <-1.28 at either the spine or hip (equivalent to lowest 10th percentile of the population), and controls were subjects with BMD T scores >+1. Among them, 88 perimenopausal women (aged 45-55years) were studied at 18 months to determine the association between the CA repeat and rate of bone loss. All subjects were followed prospectively for incidence of osteoporotic fractures. The results showed that allele size shorter than 18 CA repeats (CA<18) were associated with 6% reduction in hip BMD (p<0.01) and 3% reduction in lumbar spine BMD (p<0.05) in female but not male subjects. During the 18 month study period, peri-menopausal women carrying CA<18 demonstrated greater bone loss at the hip than those with CA>18. (2.65% vs 0.468%, p=0.01). Postmenopausal women with CA<18 had a 5-fold increase in osteoporosis risk and a 2-fold increase in fracture risk at both the spine and hip (p<0.01) These results indicate that ESR1 CA repeats may be a useful diagnostic marker for osteoporosis and fracture risk assessment in peri- and postmenopausal women.

A Polymorphism in the Gene Coding for Low-Density Lipoprotein Receptor-Related Protein-5 (LRP5) Is Associated with Peak Bone Mass in Men - Results from the Odense Androgen Study. K. Brixen[1], T. L. Nielsen*[1], K. Wraae*[1], L. Batum*[2], M. Andersen*[1], B. Abrahamsen[3]. [1]Endocrinology, Odense University Hospital, Odense, Denmark, [2]Clinical Biochemistry, Odense University Hospital, Odense, Denmark, [3]Internal medicine, Roskilde County Hospital Koege, Odense, Denmark.

Twin studies have demonstrated that genetic factors account for 50-80% of the inter-individual variation in bone mineral density (BMD). The transmembrane protein LRP5 has been implicated in the adaptive response of bone to mechanical load and mutations in this gene are responsible for the rare conditions of “high bone mass phenotype” and the “osteoporosis pseudoglioma syndrome”. Moreover, a number of common polymorphisms in this gene have also been reported to affect bone accretion in childhood, to increase the risk of osteoporosis, and susceptibility to osteoporotic fractures. We hypothesized that the 3989C>T polymorphism in exon 18 of the LRP5 gene is associated with peak bone mass in men. The Odense Androgen Study is a population-based, prospective, observational study on the inter-relationship between endocrine status, body composition, muscle function, and bone metabolism in young men. In brief, 3000 males aged 20-30 years were randomly selected from the civil registration database in Funen County, Denmark, and invited by mail to participate in the study. A total of 2042 men returned the questionnaire, 783 gave written informed consent to participate in the study, and data from 779 are presented here. Participants were genotyped using real-time PCR. BMD of the spine and hip was measured using a Hologic-4500a densitometer. A total of 589 of the participants had the CC, 170 the CT, and 20 the TT genotype, compatible with Hardy-Weinberg equilibrium (χ^2=0.13, p=0.93). No association between genotypes and BMD was observed in the overall group. In physically active young men (n=589), however, BMD of the spine was significantly higher in CC genotype (p=0.02) than in the combined CT and TT genotypes. In sedentary young men (n=190) there was no significant effect of genotype on BMD (p=0.26). Using multiple regression analysis and adjusting for body mass index, smoking, chronic medication, and serum 25-hydroxy-vitamin-D, a significant relationship between the number of T alleles and BMD of the spine was found in the physically active men (R=-0.21, p<0.05). No such relationship could be demonstrated regarding BMD of the proximal femur or in the sedentary young men. We conclude that the CC polymorphism of the LRP5-gene is significantly associated with lumbar spine peak bone mass in physically active men. This gene-environment interaction provides support for LRP5 as a mediator of load-induced bone formation.

Q89R Polymorphism in the LDL Receptor-Related Protein 5 Gene Is Associated with Spine Osteoarthritis in Postmenopausal Japanese Women. T. Urano[1], M. Shiraki[2], K. Narusawa[3], T. Usui*[1], T. Hosoi[4], Y. Ouchi*[1], T. Nakamura[3], S. Inoue[1]. [1]Department of Geriatric Medicine, University of Tokyo, Tokyo, Japan, [2]Research Institute and Practice for Involutional Diseases, Nagano, Japan, [3]Department of Orthopedic Surgery, University of Occupational and Environmental Health, School of Medicine, Kitakyushu, Japan, [4]Tokyo Metropolitan Geriatric Medical Center, Tokyo, Japan.

Recent studies indicate that the appearance of osteoarthritis is influenced by genetic factors, physical loading, and other factors not yet identified. Association studies using various definitions of osteoarthritis have been performed, mainly investigating genes encoding structural proteins of the extracellular matrix of cartilage or genes that participate in the regulation of the bone and cartilage metabolism. Wnt-β-catenin signaling pathway regulates bone density through the low-density lipoprotein receptor-related protein 5 (LRP5), a receptor of this signaling. This pathway is also involved in cartilage development and homeostasis in vivo, suggesting that genetic variation in Wnt-β-catenin signaling genes may affect the pathogenesis of cartilage diseases, such as osteoarthritis. Therefore, we analyzed the association between a single nucleotide polymorphism causing amino-acid change (Q89R) in the LRP5 coding region and the severity of radiographically observable osteoarthritis of the spine. Ethical approval for the study was obtained from appropriate ethics committees, and informed consent was obtained from all subjects. For this purpose, we evaluated the presence of osteophytes, endplate sclerosis, and narrowing of disk spaces in 357 healthy postmenopausal Japanese women. Because only one of these subjects carried the RR genotype of the Q89R polymorphism, we compared those who carried the R allele (QR or RR) with those who did not (QQ). We found that subjects without the R allele (QQ; n = 321) had a significantly lower osteophyte formation score than did subjects bearing at least one R allele (QR + RR; n = 36) (7.80 vs 10.89, $p = 0.0019$ by analysis of covariance). On the other hand, the occurrence of disk narrowing and endplate sclerosis did not significantly differ in those with and without at least one R allele. Thus, we suggest that a genetic variation at the LRP5 gene locus is associated with spine osteoarthritis, in line with the involvement of the LRP5 gene in the bone and cartilage metabolism.

Association of a Single Nucleotide Polymorphism in Low-Density Lipoprotein Receptor-Related Protein 5 (LRP5) Gene Promoter Region with Peak Bone Mineral Density: A Case-Control Study. C. L. Cheung, W. W. Ng*, B. M. H. Lai*, V. Chan*, A. W. C. Kung. Department of Medicine, The University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China.

Low-density lipoprotein receptor-related protein 5 (LRP5) is important for osteoblast differentiation and mutations of the gene are associated with both low and high bone mass syndromes. To determine the importance of LRP5 in determining peak bone mass acquisition in the general population, we performed a population-based case control study. 187 pairs of sex and age matched case-control pairs (mean 36.4, range 20-44 years) of southern Chinese in ethnicity were evaluated. Cases were subjects having a BMD Z score at either the hip or spine ≤-1.28, which is equivalent to the lowest 10th percentile of the population, and controls were subjects having a BMD Z score Z ≥+1. Mutations and single nucleotide polymorphisms (SNPs) were determined in 30 case-control pairs of subjects by sequencing 3000 bp in the promoter region, all the coding exons and 100bp upstream and downstream of the adjacent intronic regions. Using this gene-based approach, 8 SNPs with a minor allele frequency >5% were studied. BMD were adjusted for age, sex and body weight and height. The results showed that subjects bearing a variant T allele (TT and TC) at the C-864T polymorphism (rs682429) in the promoter region was significantly associated with lower BMD at the lumbar spine (p= 0.006), trochanter (p= 0.016) and total hip (p= 0.014). When the two sex were analyzed separately, this polymorphic site was associated with a reduction in BMD in men at all sites measured (lumbar spine -15.6%, p= 0.01, femoral neck -15.9 %, p=0.04; trochanter -15.9%, p=0.04 and total hip -15.1%, p=0.03), and in women at the lumbar spine (-3.7%, p=0.03). Haplotype TATGCCAC was associated with lower BMD in female at the lumbar spine (p=0.01), femoral neck (p=0.003), trochanter (p=0.002) and total hip (p=0.001). The C allele was associated with a 2.9 folds low risk of low BMD (Z score<-1.28) in whole population, and 2.6 folds low risk of low BMD in female. The C-864T polymorphic site is 2 bases adjacent to a consensus recognition site for the Elk-1 binding element. In conclusion, C-864T polymorphism of LRP5 is associated with low BMD in both young men and women, and may be a useful marker for predicting low peak bone mass.

Association of Vitamin D Receptor Start Codon and CDX-2 Polymorphism with the Effect of Calcium Supplementation on Bone Mineral Density in Postmenopausal Women. Z. Zhang, Y. Qin*, J. He*. Center for Osteoporosis, Shanghai Sixth Hospital, Shanghai Jiaotong University, Shanghai, China.

AIM To investigate the association of vitamin D receptor (VDR) gene start codon and CDX-2 polymorphism with the effect of calcium supplementation on bone mineral density (BMD) in postmenopausal women. **Methods** 200 Shanghai postmenopausal women of Han nationality were randomly divided into 2 groups of 100 women: high calcium group (1000 mg element calcium and 400 units of vitamin D were given daily for 12 months) and low calcium group (300 mg element calcium and 300 units of vitamin D were given daily for 12 months). BMD and bone metabolism markers were measured before and after calcium supplementation. VDR gene start codon (Fok I) and CDX-2 polymorphisms were analyzed using polymerase chain reaction-restriction fragment length polymorphism (PCR-RFLP) and allele-specific multiplex PCR, respectively. **Results** 171 women completed 12-month study period. By the end of study, the lumbar spine BMD was increased by 0.90 % ± 2.90 %($P < 0.05$)and 1.31% ± 3.40%($P < 0.01$)in the high calcium group and low calcium group, respectively. The trochanter BMD was increased by 1.29 % ± 3.62 %($P < 0.05$) and 1.06 % ± 3.65 % ($P < 0.01$)in the high calcium group and low calcium group, respectively. But the percent increase of BMD between groups was not significant difference. The serum ALP and PTH decreased by 14.0 % and 27.8 % respectively in the high calcium group, both significantly more than those in the low calcium group ($P< 0.01$ and $P< 0.05$, respectively). The frequencies distribution of *Fok* I and CDX-2 alleles were not deviation with Hardy-Weinberg equilibrium in study population. No significant difference in BMD between *Fok* I genotypes or CDX-2 genotypes was observed in two study groups. Moreover, after 12 moths of calcium supplementation, there was no effect of an interaction between *Fok* I or CDX-2 polymorphism and calcium supplementation on BMD or bone metabolism markers either in high calcium group or low calcium group. **Conclusion** The calcium and vitamin D supplementation on postmenopausal women could reduce the loss of bone mass. No significant association was found between VDR gene *Fok* I or CDX-2 polymorphism and the effect of calcium supplementation on BMD and bone metabolism markers in postmenopausal Chinese women of Han nationality.

Bone Architecture, Biomechanical Properties and their Relationships in Two Mice Strains. N. Bonnet*[1], A. Basillais*[1], H. Beaupied*[1], S. Pothion*[2], J. Bizot*[2], F. Trovero*[2], Y. Herault*[3], E. Lespesailles[1], D. Courteix*[1], L. Benhamou[1]. [1]U658Inserm & ATOSEP, Université d'Orléans, Orléans, France, [2]Key-obs, Orléans, France, [3]CNRS FRE 2815, Orléans, France.

There is a growing interest in bone characterization of mice strains. The relationship between architecture and bone strength deserves to be detailed in each genetic mice. The aim of this study was to evaluate the relation between bone architecture and biomechanical properties in C3H/Hej and CBA/H mice. Ten C3H and 10 CBA male mice were studied at an age of 14 weeks. The femur geometry was measured with a digital calliper. Trabecular bone microarchitecture was characterized by X-ray microcomputed tomography : on the distal femur metaphysis. The 2D slices obtained by µCT were used to measure the cortical parameter at the mid diaphysis. Mechanical properties were obtained using three-point bending tests. C3H mice weighed 23.66 ± 2.23 g, and CBA mice 26.11 ± 2.54 g. Mid-diaphysis diameter was lower in C3H than in CBA (1.65 vs 1.74mm) whereas bone length was higher in C3H (14.47 vs 14.08mm). Compared to CBA, C3H mice had a significantly higher BV/TV (51%, p<0.001); Tb.Th (13%, p<0.001) and Tb.N (50%, p<0.006). Structural model index indicated a significantly lower proportion of rod shape in C3H (SMI = 2.32) than in CBA (2.52; p<0.01). C3H had a higher ultimate force (+38%, p<0.001), stiffness (+22%, p<0.04) and lower ultimate displacement (-29%, p<0.001) than CBA. Multiple regression coefficient of ultimate displacement of the total mice indicated that Tb.N (r=0.77), mid-diaphysis diameter (r=0.835) and cortical/bone marrow ratio (r=0.84) were the explicative factors (p<0.01). The table gives the multiple regression coefficient of ultimate force for the total group and for each mice model. When studied in a global group of 20 mice the analysis indicate cortical width as the most explicative factor. But when considering each genetic mice model, the ultimate force is not explained by the same bone characteristics. C3H ultimate force was more dependent upon cortical width whereas CBA ultimate force was more dependent upon Tb.Th. Different studies have previously suggested that the genes which regulate BMD or architecture are different in genetic mice models. In addition to these genes differences, our data suggest that the link between the different bone properties are not the same in genetic mice models.

Multiple regression coefficient for ultimate force ($p < 0.01$)		
CBA and C3H mice (n=20)	CBA mice (n=10)	C3H mice (n=10)
C.width r = 0.86	Tb.Th r = 0.99	C.width r = 0.55
C./ B.marrow r = 0.91	Mid-diaphysis Φ r = 0.999	Tb.Th r = 0.81
Tb.Th, length, SMI, Tb.N r = 0.95

Polymorphisms in the PPARγ Gene Influence Bone Density in Humans. D. P. Kiel[1], S. Ferrari[2], L. A. Cupples*[3], D. Karasik[1], J. Dupuis*[3], C. J. Rosen[4], A. Imamovic*[5], S. Demissie*[6]. [1]Hebrew SeniorLife, Boston, MA, USA, [2]Div Bone Dis, Geneva Univ Hosp, Geneva, Switzerland, [3]BU Sch Pub Health, Boston, MA, USA, [4]Maine Ctr Osteo, Bangor, ME, USA, [5]BU Dept Neuro, Boston, MA, USA, [6]BU Sch Pub Health & Prog Genom Applic, Boston, MA, USA.

PPARγ is a key transcription factor for differentiation of mesenchymal progenitors into adipocytes, In turn PPARγ gene haploinsufficiency promotes osteogenesis in mice. Allelic differences in the PPARγ gene produce a senescent skeletal phenotype in the 6T congenic mouse. Since PPARγ effects on bone in humans remains unknown, we studied the association between polymorphisms in this gene and BMD and BUA. Seven intronic/3'-transcr region, and 1 missense, exonic SNPs in the PPARγ gene were genotyped in the Framingham Offspring Study (740 males, 776 females). Three sets of markers in high LD were identified (1) *rs1805192 missense* (exon 1) *[C>G], rs4684848[G>A]*; (2)

rs1151999[A>C], rs709150[C>G], rs1175544[C>T]; (3) *rs1152004[T>C], rs1175381[T>C], rs1186464[A>G]*). Femoral neck (FN), troch (FT) and spine (LS) BMD was measured using a Lunar DPX-L and calcaneal BUA using a Hologic Sahara. Genotype and haplotype (for markers in LD) sex-specific associations with bone measures were analyzed using ANCOVA first adjusting for age and estrogen (women), then for BMI and height, and finally, diabetes (DM), as PPARγ is associated with obesity and DM. Mean age (±SD) was 61.3 ± 9.1 yrs. Women with the CC genotype of rs1805192 (minor allele (G) freq 12%) had higher FN, LS BMD, and BUA (p=0.01-0.045, age, estrogen adjusted) and the effect size remained unchanged across all models (p=0.009-0.093). Men with the CC genotype had lower FN and FT BMD (p=0.011-0.028, age adjusted) even with additional adjustments (p=0.008-0.028). Women with the C allele of rs1175381 in LD region 3 (allele freq 4%) had lower age- and estrogen-adjusted FN, FT, and LS BMD (p=0.045-0.077) and remained with additional adjustment (p=0.011-0.035). Haplotype analyses in LD regions 1 and 3 were similar. In contrast, whereas single SNPs in LD region 2 were not associated with BMD or BUA, women with the haplotype *rs1151999[A]- rs709150[C]-rs1175544[C]* (frequency 21%) had lower age- and estrogen-adjusted BMD at the FN (p=0.013). The effect size was slightly less after adjustment for all covariates (p=0.062). Similar findings in women were observed for the ACC haplotype at the FT (p=0.004-0.014), LS (p=0.01-0.05), and BUA (p<0.0001). On average, BMD decreased by 0.10-0.15 SD per copy of the ACC haplotype, equivalent to the effect of 3 yrs of age at FN and 8 yrs at LS. Polymorphisms in the PPARγ gene are associated with BMD and BUA, particularly in women, independent of BMI and DM, supporting a direct role of PPARγ on bone mass in humans.

Modest Association of Fibroblast Growth Factor Binding Protein 1 (FGFBP1) with Bone Mineral Density in Mexican Americans. N. Hoppman*[1], D. J. McBride[1], J. Bruder[2], R. L. Bauer[2], J. R. O'Connell*[1], C. M. Kammerer*[3], B. D. Mitchell[1]. [1]Division of Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD, USA, [2]University of Texas Health Science Center, San Antonio, TX, USA, [3]University of Pittsburgh Graduate School of Public Health, Pittsburgh, PA, USA.

The San Antonio Family Osteoporosis Study (SAFOS) was designed with the goal of identifying genes and environmental factors influencing bone mineral density (BMD) in Mexican Americans. In a set of 29 large Mexican American families, we previously detected strong evidence for linkage of forearm BMD, measured by DXA, to a region on chromosome 4p near D4S2639 (lod = 4.3). This region contains several strong candidate genes for bone metabolism, including fibroblast growth factor binding protein 1 (*FGFBP1*). *FGFBP1* is 234 amino acids in length and can bind fibroblast growth factor-2 (FGF2) and modulate its activities, one of which is to stimulate osteoblast replication. We sequenced both exons, the intron-exon boundaries, and approximately 2 kb of the 5' and 3' UTR regions of this gene in 40 Mexican American subjects who were selected for having high or low forearm BMD. We identified 9 SNPs, as well as a novel deletion mutation in exon 2 that resulted in a nonsense mutation at amino acid position 27. After genotyping these SNPs in 887 Mexican Americans, we tested for associations of BMD of the forearm, spine, and hip, following adjustment for age, sex, BMI, and family structure. Significant, albeit modest, associations ($p < 0.05$) were observed between forearm BMD and SNPs rs12503796 and rs732245 under an additive genetic model. Three additional SNPs showed modest associations ($p < 0.05$) with BMD at either the forearm, hip, or spine under a dominant genetic model. The nonsense mutation was observed in 5 individuals from the same family and was not associated with variation in BMD. These findings suggest that sequence variation in *FGFBP1* may have a modest effect on osteoporosis.

Osteoblastic Bone Forming Capacity Is Stimulated *In Vitro* by Metformin, an Anti-diabetic Drug. C. Sedlinsky*[1], V. Castro*[2], A. D. McCarthy*[2], L. Schurman*[1], A. Blanco*[1], A. M. Cortizo*[2]. [1]Centro de Endocrinologia y Metabolismo, Hospital Frances, Buenos Aires, Argentina, [2]Catedra de Bioquimica Patologica, Facultad de Ciencias Exactas, Universidad Nacional de La Plata, La Plata, Argentina.

Metformin, an oral anti-hyperglycaemic agent, is widely used in the management of type 2 Diabetes mellitus and metabolic syndrome, although its mechanism of action is incompletely known. Recently rosiglitazone, an anti-diabetic PPAR-γ agonist, has been shown to promote commitment of osteoprogenitor cells to the adipocyte lineage while inhibiting osteoblastogenesis. In the present study, we evaluated the effects of metformin on the growth and differentiation of osteoblasts in culture. In addition, we investigated its possible mechanism of action. Two osteoblast cell lines (MC3T3E1 and UMR106) were examined for the ability to progress in the presence of different doses of metformin. 24 hours of culture with 25-500 μM metformin significantly increased the proliferation (crystal violet bioassay) of both cell lines (p<0.05-0.01). Cell differentiation (alkaline phosphatase activity and type-I collagen production) was also stimulated in a dose-dependent manner by 25-500 μM metformin (p<0.05-0.02). Alizarin red staining of mineralised nodules was greatly increased by 200-500 μM metformin (120-290% basal, p<0.05-0.01). We assessed the possible involvement of extracellular-signal regulated kinase (ERK) in metformin action on osteoblastic cells. ERK phosphorylation (western immunoblot) was transiently increased by 1 mM metformin after 5-15 minutes incubation, but decreased to basal levels after 90 minutes. A similar temporal pattern was observed for P-ERK evaluated by immunofluorescence. Additionally, a transient translocation of P-ERK was observed from cytoplasm to nuclei, showing a peak after 15 minutes incubation with metformin. These results show for the first time a direct osteogenic effect of metformin on osteoblasts in culture. These potentially bone-preserving effects of metformin could be particularly relevant in a clinical setting, in view of the deleterious side effects which other anti-diabetic drugs have on bone.

Inhibitory Effect of (-)-Epigallocatechin Gallate on Titanium Particle-Induced TNF-α Release through Inhibition of MAP Kinase and AP-1/NF-κB In RAW264.7 Cells. J. Shan*[1], J. Park*[2], J. Hong*[2], T. Kim*[2], J. Choi[3], E. Park[2], S. Kim[4]. [1]Skeletal Disease Genome Research Center, Kyungpook National University Hospital, Daegu, Republic of Korea, [2]Skeletal Diseases Genome Research Center, Kyungpook National University Hospital, Daegu, Republic of Korea, [3]Department of Biochemistry, Kyungpook National University, School of Medicine, Daegu, Republic of Korea, [4]Department of Orthopedic Surgery, Kyungpook National University Hospital, Daegu, Republic of Korea.

Macrophage activation by particulate debris from orthopaedic implants triggers an inflammatory response that ultimately leads to periprosthetic bone resorption and implant failure. Tumor necrosis factor-α (TNF-α) has been identified as a critical cytokine involved in the response to the debris particles but the mechanisms underlying activation of TNF-α synthesis by titanium (Ti) particle are unclear. Moreover, there is no drug that can effectively treat aseptic loosening in patients. In the present study we demonstrate an inhibitory effect of EGCG, a major component of green tea, on Ti particle-induced TNF-α release in murine macrophage and its underlying mechanism. As previously shown, Ti particles stimulated TNF-α release with a time and dose dependent manner and treatment of EGCG substantially suppressed TNF-α release. Ti particle induced activation of ERK and JNK as well as degradation of IkB and specific inhibitors of JNK (SP600125) and NF-κB (MG132) dramatically inhibited Ti-stimulated TNF-α release, suggesting that JNK and NF-B pathways are primarily involved in Ti particle-induced TNF-α release and that EGCG may suppress Ti particle-induced activation of JNK and degradation of IkB in macrophages. In fact EGCG dramatically inhibited activation of JNK, degradation of IkB and transcriptional activation of AP-1 and NF-κB.Taken together, these results demonstrated that Ti particles induced TNF-α release is at least in part mediated through JNK/AP-1 as well as NF-B pathways and EGCG has an inhibitory effect on Ti particle-induced TNF-α release. Therefore, EGCG may be a potential candidate compound in the prevention and treatment of osteolysis and bone loosening after total joint arthroplasty.

Osteoformin Accelerates Repair of Fresh Fracture in Rats. L. X. Bi, E. G. Mainous*, Y. Zeng*, W. L. Buford*. Depts. of Surgery and Orthopaedics & Rehabilitation, The University of Texas Medical Branch, Galveston, TX, USA.

Our previous studies have shown that Osteoformin (negatively charged polypeptide) increases activity of alkaline phosphatase, expression of type-I collagen and BMP-7 and bone mineralization by human preosteoblast cells (Bi LX et al, JBMR 18: S212 Suppl. 2, 2003) and negatively charged resins increase bone formation and accelerate bone defect healing in vivo. In order to investigate potential effect of osteoformin on experimental femoral fracture healing in young male rats, femurs in anesthetized rats were stabilized with intramedullary pins and subjected to closed midshaft transverse facture by bending to failure. In experimental rats (6 rats/group), fracture (Fx) sites were injected with 100ug of Osteoformin dissolved in 0.1 ml Phosphate buffered saline (PBS) at day 1 and day 7 postop, in controls (6 rats/group), Fx sites received 0.1 ml PBS at the indicated time above. Between 2 and 4 weeks post-Fx, animals were sacrificed and the healing femurs were removed for radiography and histology. Both forms of analysis indicated that Osteoformin treatment advanced Fx repair. In the Osteoformin treated group, histological study showed that the fracture gap was completely filled with newly formed cartilaginous tissue and woven bone two weeks after treatment, and was entirely replaced by woven bone at three weeks. Newly formed bone was partially transited from woven bone to lamellar bone at four weeks. In contrast, the control group showed newly formed bone only at the fracture ends, while the center of the fracture site was filled with fibrous tissue two weeks after the fracture. Cartilaginous tissue was seen at three weeks and woven bone was formed four weeks after the fracture. Radiographic assessment showed that the Osteoformin treated fractures had evidence of mineralized callus and blurring of the fracture gap as early as two weeks after treatment. By three weeks, the fracture ends were bridged with newly formed bone. By four weeks, the fracture line was no longer visible and remodeling callus was observed. In the control group, new bone formed only at the fracture ends, and the fracture gap was visible two weeks after the fracture. Although the fracture gap was blurring, the fracture line was still seen four weeks after the fracture. We conclude that Osteoformin stimulates the differentiation of osteoblast cells in vitro and accelerates femoral fracture healing in vivo.

Canonical Wnt Signaling and Twist1 Represses Chondrogenesis and Chondrocyte Gene Expression. M. C. Naski, M. I. Reinhold*, R. Kapadia*. Pathology, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA.

Wnt signaling is essential for many developmental processes including skeletogenesis. To investigate the effects of Wnt signaling during chondrogenesis we studied the effects of Wnt on cultured chondrocytic cells and differentiating limb bud mesenchyme. Wnt3a strongly repressed chondrogenesis and chondrocyte gene expression. The expression of type II collagen and aggrecan was strongly repressed and the development of cartilage was similarly inhibited. Canonical Wnt signaling was responsible for the repression of differentiation, as evidenced by results showing that inhibition of glycogen synthase kinase 3 or expression of β-catenin caused similar repression of differentiation and cartilage gene expression. Significantly, we showed that the transcription repressor Twist1 was induced by canonical Wnt signaling. We hypothesized that Twist1 was responsible for the inhibition of chondrocyte gene expression. Consistent with this, adenoviral transduction of Twist1 strongly inhibited aggrecan and type II collagen gene expression. Moreover, shRNA knockdown of Twist1 transcript levels increased the expression of aggrecan and type II collagen. We inferred that Twist1 indirectly repressed the chondrocyte gene expression and interestingly Twist1 interfered with BMP2-induced expression of aggrecan and type II collagen expression. Additionally, knockdown of Twist1 augmented BMP2-induced aggrecan and type II collagen expression. These data support the conclusion that Twist1 contributes to the repression of chondrogenesis and chondrocyte gene expression resulting from canonical Wnt signaling. In addition these results support a model whereby Twist1 inhibits chondrogenesis by interfering with BMP-dependent signaling.

Efficacy of CP-533,536 a Selective EP2 Agonist of Prostaglandin E_2 in Oblique Canine Tibial Osteotomy. F. Borovecki*[1], D. D. Thompson[2], S. Vukicevic[1], V. M. Paralkar[2]. [1]Laboratory for Mineralized Tissues, Zagreb Medical School, Zagreb, Croatia, [2]Pfizer Central Research, Pfizer Inc., Groton, CT, USA.

Previously we have shown that CP-533, 536, an EP2 selective PGE_2 agonist, stimulates local bone formation and enhance bone healing in animal models. However, bone quality and mode of healing of newly formed bone were not fully determined. In this study we tested different modes of administration of CP-533,536, in an oblique dog osteotomy model to stringently asses its ability to accelerate bone healing at different bone compartments in 40 dogs. Poly-(D,L-lactide-co-glycolide) (PLGH) matrix alone or CP-533,536 dissolved in PLGH was administered at the defect site, either as a single application in the middle of the defect or the dose was split into two applications at the opposite ends of the osteotomy. The animals were divided into 5 groups, namely: (1) control (0.1 ml PLGH), (2) 1 mg CP-533,536 in 0.1 ml PLGH (single), (3) 1 mg CP-533,536 in 0.1 ml PLGH (split), (4) 0.1 mg CP-533,536 in 0.01 ml PLGH (single), (5) 0.1 mg CP-533,536 in 0.01 ml of PLGH (split). Radiographic analysis of *in vivo* and following termination at 10 weeks revealed accelerated healing of animals treated with CP-533,536. In particular, animals treated with a 1 mg of CP-533,536 exhibited 85% (7/8) rate of healing when compared to control, showing that a single application is sufficient to achieve the maximum efficacy. CT analysis showed that animals treated with 0.1 ml of PLGH exhibited no endosteal ossification, with most of the bone formed periosteally. In animals treated with a single application of CP-533,536 abundant callus formation could be observed, with pronounced osteogenesis in all bone compartments, including periosteum, endosteal surface and the cortical bone of the fractures site. Non-destructive four point bending tests revealed that animals treated with 1 mg of CP-533,536 in a single dose exhibited the highest stiffness index and the area ratio, with mean values 1.3 and 1.9 fold, respectively, higher than in control dogs. Histological assessment confirmed the CT analysis, with CP-533,536 achieving new bone formation in all bone compartments. Normal fracture healing pattern was observed in all dogs treated with CP-533,536. The results collectively demonstrate the ability of CP-533,536 to accelerate bone healing in a canine model of oblique tibial osteotomy achieving superior bone quality in a single dose administration.

Bone Marrow of Multiple Myeloma Patients Provides an Environment Favoring Osteoclastogenesis. A. Huston[1], A. Lokshin*[1], G. Anderson*[1], S. Primeaux*[2], J. Anderson*[1], N. Callander*[3], G. D. Roodman[1], S. Lentzsch*[1]. [1]Hem/Onc, Univ. of Pittsburgh, Pittsburgh, PA, USA, [2]UT-Health Science Ctr., San Antonio, TX, USA, [3]Comprehensive Cancer Ctr., Univ. of Wisconsin, Madison, WI, USA.

The pathogenesis of multiple myeloma (MM) is believed to occur as a multistep transformation process. In addition to genetic alterations in MM cells, the bone marrow (BM) microenvironment contributes to the progression of myeloma through cytokines promoting the growth of myeloma cells and osteoclastogenesis. This study's aim was to investigate which cytokines, in the BM microenvironment, contribute to progression of MM and osteolytic lesions**.** BM plasma samples were evaluated for their cytokine expression profiles from 40 patients with MM and 40 normal controls. Supernatants were analyzed for IL-1α, IL-1β, IL-2, IL-4, IL-5, IL-6, IL-7, IL-8, IL-10, IFNα, IFNγ, GM-CSF, TNFα, IL-12p40, IL-13, IL-15, IL-17, MCP-1, MIP-1α, MIP-1β, EOTAXIN, RANTES, IP-10, MIG, TNF-RI, TNF-RII, DR5, EGF, VEGF, FGFβ, G-CSF, HGF, EGFR, FASL, FAS, and Kallikrein 8 by LabMAP technology (Luminex). Cytokines differing significantly between MM patient and control samples are listed in Table 1. Specific trends included IL-1α and IL-6, which appeared to fall following autologous stem cell transplantation. IL-1α, IFNα and VEGF trended towards lower levels with lower stage disease. A significant up-regulation of cytokines supporting osteoclastogenesis (Table 1, asterisk) and the soluble receptor of TNF-RI and TNF-RII were also observed.

Table 1. Significantly regulated cytokines from MM patients compared to normal controls.

Up-Regulated	P-value	Up-Regulated	P-value	Up-Regulated	P-Value
IL-1α	p<0.01	IL-15	p<0.01	TNF-RI	p<0.01
*IL-6	p=0.02	*IL-17	p<0.01	TNF-RII	p<0.01
*IL-7	p=0.04	*MIP-1β	p=0.04	EGF	p<0.01
*IL-8	p<0.01	RANTES	p<0.01	VEGF	p<0.01
IFNα	p<0.01	IP-10	p<0.01	HGF	p<0.01
IL-12p40	p<0.01	MIG	p<0.01		
Down-Regulated					
IL-5	p<0.01				

Cytokine array analysis represents a powerful method for characterizing the microenvironment of MM. Our data shows that the bone marrow microenvironment in MM supports the growth of myeloma cells, angiogenesis, and osteoclastogenesis, through multiple cytokines simulating these processes. In contrast to prior studies using peripheral blood and individual ELISA kits, our results represent a more accurate reflection of the scope of cytokine dysregulation in the BM of MM patients. To our knowledge, this is the first time a comprehensive analysis of the cytokine regulation of MM patients and disseminated bone disease has been done. Therefore, it provides a framework for future areas of investigation in further defining the role of cytokines in the BM microenvironment of MM.

Disclosures: ***A. Huston****, None.*

***In Vitro* Osteogenic Response of Rat Bone Marrow Cells to bFGF and BMP-2 Treatments.** M. Varkey*[1], C. Kucharski*[1], T. Haque*[1], W. Sebald*[2], H. Uludag[3]. [1]Department of Chemical & Materials Engineering, Faculty of Engineering, University of Alberta, Edmonton, AB, Canada, [2]Theodor-Boveri-Institut für Biowissenschaften, Universität of Würzburg, Würzburg, Germany, [3]Department of Chemical and Mat. Engineering, Dept. of Biomedical Engineering, Faculty of Medicine, University of Alberta, Edmonton, AB, Canada.

To explore the use of bFGF and BMP-2 for systemic therapy in osteoporosis, their *in vitro* effects on bone marrow cells (BMC) which are the primary target of growth factor therapy *in vivo*, were investigated. The osteogenic effects of bFGF and BMP-2 on BMC in culture were directly compared, and the effects of cell source (young and old rats) and duration of growth factor exposure on induced osteogenic parameters were evaluated. The relative potencies of these prototypical growth factors to achieve the desired osteogenic response in BMC were assessed by monitoring the changes in two well established osteogenic markers, alkaline phosphatase (ALP) activity and mineralization. BMC were obtained from young (8 weeks) and adult (34 weeks) female Sprague-Dawley rats by femoral aspiration, expanded *in vitro,* and exposed to osteogenic medium containing known concentrations of growth factors (0-50 ng/mL bFGF and 0-500 ng/mL BMP-2). The cells were treated with BMP-2 and bFGF either continuously for 3 weeks, or for a short duration of 1 week followed by 3 weeks of culture in osteogenic medium with no growth factors, and the osteogenic response was investigated in both cases. Cells were harvested after 1, 2 and 3 weeks of continuous growth factor treatment or after 1, 2 and 3 weeks of the removal of the growth factors, for the short growth factor treatment. Quantitative measures of DNA content, ALP activity and calcification were obtained, and the results statistically analyzed by ANOVA ($p<0.05$). Results suggested that both bFGF and BMP-2 were osteogenic and were capable of stimulating mineralization under select set of culture conditions, but significant differences in their effects were evident. Irrespective of the duration of exposure, a clear dose-response was consistently obtained for BMP-2, with progressively higher levels of mineralization upto 500 ng/mL. Interestingly, although bFGF effects were evident even at ~ 10 ng/mL, on continuous treatment, no significant effects on short-time exposure was observed. The extent of mineralization of BMC varied with the source of the cells, it being significantly lower for old rats than for young rats. Interestingly, a synergistic effect of lower doses of BMP-2 on bFGF responses was observed on BMC from the old rats, but not from the young rats. In conclusion, although bFGF was more potent for stimulating osteogenic parameters, BMP-2 effects were more lasting on the BMC.

ELR^+ CXC Chemokine Secretion during Human Mesenchymal Stem Cell Osteogenic Differentiation Is Dependent on Dexamethasone. D. S. Bischoff*, N. S. Makhijani*, J. H. Zhu*, D. T. Yamaguchi. Research Service, VA Greater Los Angeles Healthcare System, Los Angeles, CA, USA.

The potential role of ELR^+ CXC chemokines in early events in bone repair was studied using human mesenchymal stem cells (hMSCs). Inflammation, which occurs in the initial phase of tissue healing in general, is critical to bone repair. Release of cytokines from infiltrating immune cells and injured bone can lead to recruitment of MSCs to the region of repair. CXC chemokines bearing the glu-leu-arg (ELR) motif are also released by inflammatory cells and serve as angiogenic factors stimulating chemotaxis and proliferation of endothelial cells. hMSCs, induced to differentiate with osteogenic medium (OGM) containing ascorbate, β-glycerophosphate (β-GP), and dexamethasone (DEX), showed an increase in mRNA and protein secretion of the ELR^+ CXC chemokines IL-8

and GROα. At day 7, OGM induces significant increases in both IL-8 mRNA expression (65 ± 11 vs. 0.05 ± 0.01 relative units) and IL-8 secretion (9089 ± 494 vs. 79 ± 10 pg/ml). GROα also had significant increases in mRNA expression (3.8 ± 1.1 vs. 0.18 ± 0.05) and protein secretion (12257 ± 865 vs. 18.5 ± 1.2 pg/ml). This increased expression/secretion is a result of DEX in the OGM. hMSCs cultured in media containing DEX alone had a relative expression level of IL-8 mRNA at 185 ± 0.15 (P<0.001) at Day 10, significantly higher than cultures containing ascorbate alone (0.73 ± 0.25; P>0.05), β-GP alone (2.5 ± 0.9; P>0.05), or in non-OGM media (1.1 ± 0.15). IL-8 secreted into the media also increased from 212 ± 62 (non-OGM media) to 847 ± 78 pg/ml (P<0.001) for DEX, whereas ascorbate (108 ± 31; P>0.05), or β-GP-containing media (195 ± 55; P>0.05) did not significantly alter protein levels. GROα gave similar patterns of mRNA expression and protein secretion in the DEX-containing cultures. Experiments were conducted three times in triplicate. Values are mean ± SD of one representative experiment. RNA interference by transient expression of IL-8 siRNA could inhibit expression of IL-8 as determined by real-time RT-PCR. This effect was short-lived and did not have any effect on alkaline phosphatase mRNA, a marker of osteogenic differentiation. To test the ability of IL-8 inhibition to affect later differentiation events, an adenovirus has been constructed that expresses the IL-8 siRNA providing long-term suppression of IL-8 production by hMSCs. Conclusions: 1) hMSCs are induced to produce CXC chemokines, IL-8 and GROα, when stimulated towards osteogenic differentiation; 2) DEX is the component in OGM responsible for the stimulation of IL-8 and GROα mRNA and protein; 3) short-term suppression of IL-8 production in hMSCs can be accomplished using siRNA technology.

Nell-1 Induced Bone Formation, Fusion, and Regeneration. C. M. Cowan*[1], T. Aghaloo*[2], Y. Chou*[1], X. Zhang*[2], C. Soo*[3], B. Wu*[1], K. Ting[2]. [1]Bioengineering, UCLA, Los Angeles, CA, USA, [2]Dental and Craniofacial Research Institute, UCLA, Los Angeles, CA, USA, [3]Divisions of Plastic and Reconstructive Surgery, USC, Los Angeles, CA, USA.

Researchers in the developing field of regenerative medicine have identified bone tissue engineering as an attractive translational target. The discovery of Nell-1 (a protein strongly expressed in neural tissues and containing EGF-like domains, type 1) in craniosynostosis presents a potential for bone growth in other acquired and congenital craniofacial deformities. The purpose of these studies was to further elucidate the ability of Nell-1 to accelerate bone regeneration within the calvaria. The methods for these experiments were as follows: biodegradable PLGA scaffolds were coated with 200 ng of recombinant rat (rr)Nell-1 or recombinant human bone morphogenetic protein-2 (rhBMP-2) and implanted into 3 mm full-thickness calvarial defects in Sprague-Dawley rats. All animals were handled in accordance with guidelines of the Chancellor's Animal Research Committee of the Office for Protection of Research Subjects at our institution. Rats were sacrificed after 1, 2, or 4 weeks and examined by microCT. Area quantifications were performed using software BioQuant. Ten micron thick paraffin-embedded sections were examined histologically. The data clearly demonstrate that after 4 weeks of healing, Nell-1 (97% ± 3%) and BMP-2 (93%± 8%) implanted defects reached near 100% closure, while control (54% ± 16%) defects were only minimally healed. Additionally, live imaging revealed increasing bone mineralization over a 12 week time period. Trichrome staining demonstrated mature bone within defects, while BSP indicated accelerated osteogenic differentiation. In conclusion, calvarial defect healing can be augmented by growth factors, as their delivery can provide the necessary environmental cues for cellular migration, proliferation, and differentiation; creating a suitable niche for bone regeneration. Nell-1 and BMP-2 are both known to induce bone formation *in vivo*; however, the transition from animal studies into clinical studies has been only mildly successful with BMP-2. The ability of Nell-1 and BMP-2 to accelerate bone formation may relate to their ability to influence cells out of a proliferative phase and into a differentiated phase. Nell-1's ability to accelerate calvarial bone regeneration, equivalent to BMP-2, may provide an alternative non-BMP-based paradigm for the study of calvarial bone healing and future tissue engineering studies. Thus, grafting Nell-1 coated scaffolds into calvarial defects has pharmacological value and reveals alternatives to currently accepted techniques for bone regeneration.

The Role of Adiponectin in Bone Remodeling. J. E. Reseland[1], M. V. Tamburstuen*[1], H. S. Berner*[1], A. K. Stunes*[2], G. Kvalheim*[3], L. Thommesen*[4], S. P. Lyngstadaas*[1], U. Syversen[4]. [1]Oral Research Laboratory, University of Oslo, Oslo, Norway, [2]Department of Cancer Research and Molecular Medicine, University of OsloUniversity of Science and Technology, Trondheim, Norway, [3]Department of Oncology, The Norwegian Radium Hospital, Oslo, Norway, [4]Department of Cancer Research and Molecular Medicine, University of Science and Technology, Trondheim, Norway.

We have previously demonstrated the expression of adiponectin in bone forming cells. Although recombinant adiponectin do stimulated osteoblast proliferation, the role of adiponectin in bone metabolism and maintenance remains largely unknown. We aim at describing the relationship between adiponectin and mechanical properties of bone, and characterizing possible autocrine and paracrine effects of adiponectin on osteoblasts and osteoclasts. Bone mineral density (BMD) was measured by DXA scanning in intact female Fisher-344 rats. Bone biomechanical data were recorded, and RNA was isolated from femur. The effect of adiponectin was tested on primary human osteoblasts, bone marrow stem cells, and osteoclasts (differentiated from peripheral mononuclear cells) from different donors, and on RAW 264.7 cells. There was no significant relationship between plasma adiponectin levels, BMD and bone biomechanical properties observed in these rats. In contrast, the relative expression of adiponectin mRNA in femur correlated positively to ultimate bending moment, ultimate energy absorption and deflection. However, a negative correlation to bending stiffness was observed. When compared to untreated cells, recombinant adiponectin acutely stimulates adiponectin mRNA expression, as well as leptin mRNA expression and leptin secretion to the medium after 6 hours incubation. Recombinant adiponectin enhanced the differentiation of human peripheral monocytes into osteoclasts ($p < 0.004$) and activates ($p < 0.001$) the promoter of NF- B in transfected RAW 264.7 cells. Adiponectin stimulates proliferation, but only minor effects were observed on osteoblast differentiation and the expression of markers involved in osseoid mineralization. Based on our observations adiponectin may play a role in regulating elasticity and flexibility of the bones, by regulating recruitment and differentiated endpoint of cells involved in bone remodelling.

Early Response of Circulating Osteoprotegerin in Patients Treated with Zoledronic Acid. R. A. Hannon[1], D. Santini*[2], B. Vincenzi*[2], G. Tonini*[2], I. Holen*[3]. [1]Academic Unit of Bone Metabolism, University of Sheffield, Sheffield, United Kingdom, [2]Clinical Oncology, University Campus Bio-Medico, Rome, Italy, [3]Clinical Oncology, University of Sheffield, Sheffield, United Kingdom.

Bisphosphonates, including zoledronic acid, have been shown to stimulate osteoprotegerin (OPG) expression in primary human osteoblasts[1]. Early response of circulating OPG to bisphosphonates has not been observed *in vivo*. The aim of this study was to investigate the response, including the very early response, of plasma OPG and the bone resorption marker C terminal crosslinked telopeptides of Type I collagen (βCTX) to zoledronic acid in patients with metastatic bone disease. Twenty four patients (9 males, 15 females), aged 44-76 years (median age, 65), with advanced solid cancer and bone metastases, who had not been previously treated with bisphosphonate, were infused with a single infusion of 4mg zoledronic acid in 100 ml of 0.9% saline over a period of 15 minutes. Exclusion criteria were any steroid therapy, radiotherapy, chemotherapy or haemopoetic growth factors during the study or in the 4 weeks prior to the study. Blood samples were collected before 10.00 after an overnight fast at baseline, prior to infusion, and on days 1,2,7 and 21 after infusion. Plasma was stored at -80 deg C until analysis. Plasma levels of βCTX were measured by electrochemiluminescent assay (Roche Elecsys, Roche Diagnostics GmBH, Penzberg, Germany). Plasma levels of OPG were measured by ELISA (BioVendor Laboratory Medicine Inc, Brno, Czech Republic). All samples from an individual were measured in the same analytical batch. Table shows median change in OPG and βCTX

Day	OPG median % change from baseline (CI)	P*	βCTX median% change from baseline (CI)	P*
1	+12.8 (-8.6, +20.6)	0.057	-67.1 (-76.3, -52.4)	<0.0001
2	+11.6 (-1.5, +38.9)	0.010	-85.7 (-90.2, 78.2)	<0.0001
7	-2.6 (-7,2, +8.5)	0.900	-79.2 (-87.0, -67.4)	<0.0001
21	-2.7 (-13.6, +9.3)	0.807	-76.9 (-83.4, -35.0)	<0.0001

*Signed rank test vs baseline

At day 1, but not at the other timepoints, percentage change in OPG was inversely correlated with percentage change in βCTX ($r = -0.44$, $P<0.05$). We conclude that the early response of plasma OPG to zoledronic acid may indicate a direct action of zoledronic acid on osteoblasts to stimulate OPG production which, in turn may contribute to the suppression of osteoclast activity and bone resorption.

Interleukin-4 and Interleukin-13 Inhibit Osteoclast Formation and Bone Resorption by Increasing OPG and Decreasing RANKL and RANK in a STAT-6 Dependent Pathway. P. Palmqvist*[1], P. Lundberg*[1], E. Persson*[1], A. Johansson*[2], I. Lundgren*[1], A. Lie*[1], H. H. Conaway[3], U. H. Lerner[1]. [1]Department of Oral Cell Biology, Umeå University, Umeå, Sweden, [2]Department of Periodontics, Umeå University, Umeå, Sweden, [3]Department of Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Interleukin-4 (IL-4) and interleukin-13 (IL-13) are cytokines which inhibit bone resorption. In the present study we studied molecular mechanisms in osteoclasts and osteoblasts by which IL-4 and IL-13 inhibit bone resorption. We found that release of ^{45}Ca from cultured mouse calvarial bones stimulated by different cytokines, peptides and steroid hormones was inhibited by both IL-4 and IL-13. The effect could not be attributed to inhibition of prostaglandin formation since stimulation by several agonists, the effect of which was not inhibited by indomethacin, was inhibited by IL-4 and IL-13. IL-4 and IL-13 decreased receptor activator of nuclear factor-κB ligand (RANKL) and RANK mRNA expression and increased osteoprotegerin (OPG) mRNA expression in mouse calvariae. In agreement with the mRNA data, IL-4 and IL-13 decreased RANKL protein and increased OPG protein in calvarial bones. In osteoblasts isolated from calvariae, both an increase in RANKL mRNA and a decrease in OPG mRNA and protein elicited by D3 were reversed by IL-4 and IL-13. IL-4 and IL-13 decreased the number of tartrate resistant acid phosphatase (TRAP) positive multinucleated cells and the mRNA expression of calcitonin receptor, TRAP and cathepsin K in mouse spleen cells and bone marrow macrophages (BMM) treated with M-CSF/RANKL. Inhibition of mRNA for RANK and the transcription factor NFAT2 was also noted in spleen cell cultures following treatment with

IL-4 and IL-13. In addition, RANK mRNA and formation of RANK protein were decreased by IL-4 and IL-13 in RAW 264.7 cells. Mouse calvarial osteoblasts and spleen cells expressed mRNA for the four proteins making up the IL-4 and IL-13 receptors and the expression levels were regulated by D3 and M-CSF/RANKL. The data indicate that IL-4 and IL-13 can inhibit osteoclast differentiation and bone resorption by affecting the RANKL/RANK/OPG system. In addition to activating receptors in osteoclasts and decreasing RANK formation, IL-4 and IL-13 activate receptors in osteoblasts, causing decreased RANKL formation and increased OPG formation. The effects of IL-4 and IL-13 on mRNA expression of RANKL and bone resorption in mouse calvarial bones as well as osteoclast formation in mouse spleen cell cultures were dependent on STAT6, since no effects were seen in cells from STAT6$^{-/-}$mice.

Activation of the Oncostatin M Receptor Results in Substantially More Effective Stimulation of Bone Resorption, RANKL and IL-6 mRNA Expression, and STAT3 Activation, Compared to the Leukemia Inhibitory Factor Receptor. E. Persson*, U. H. Lerner. Oral Cell Biology, Umea University, UMEA, Sweden.

The members of the interleukin-6 (IL-6) family are pleiotropic cytokines, often inducing overlapping actions. In mouse tissues, murine and human leukemia inhibitory factor (mLIF and hLIF, respectively), and human oncostatin M (hOSM), all exert their effects through the LIF receptor (LIFR), whereas murine OSM (mOSM) signals through the OSM receptor (OSMR). In the present study, the effects of LIF and OSM on bone resorption, mRNA expression of IL-6, RANKL and OPG, as well as IL-6 promoter induction have been investigated. Both mLIF and mOSM concentration-dependently stimulated ^{45}Ca release in mouse calvarial bones, OSM being about 3-4 times more effective than LIF. Furthermore, treatment with mLIF or mOSM for 48 h resulted in increased IL-6 and RANKL mRNA expression in mouse calvarial osteoblasts, as assessed by PCR. The effects were concentration-dependent, with OSM being a substantially more effective stimulator of both IL-6 and RANKL mRNA expression. In contrast, neither mLIF nor mOSM caused any regulation of OPG mRNA expression in calvarial osteoblasts. In cells from the osteoblastic cell line MC3T3-E1 transfected with a fragment (-225 to +13) of the human IL-6 promoter coupled to a luciferase reporter, human and murine LIF and OSM all stimulated IL-6 promoter induction as assessed by luciferase activity. Treatment with mOSM resulted in about 10-fold higher luciferase activity compared to mLIF, hLIF, and hOSM. To investigate possible explanations for the differences between mOSM and mLIF, we studied the mRNA expression of LIFR and OSMR, and the activation of the transcription factor STAT3 that mediates the effects of both receptors. Murine OSM clearly increased the OSMR mRNA level in calvarial osteoblasts, and the effect was present from 1 h up to at least 72 h of incubation compared to control cells. Furthermore, the stimulatory effect was specific for OSM since incubation with IL-11, IL-6 + soluble IL-6R, PTH or vitamin D3 did not result in any regulation of OSMR mRNA levels. Treatment with LIF did not result in any regulation of neither OSMR nor LIFR mRNA levels. Incubation of calvarial osteoblasts with mLIF or mOSM resulted in activation of STAT3, OSM treatment resulting in a more prominent activation as assessed by Western blot for the phosphorylated form of STAT3. These data show that both LIF and OSM stimulate bone resorption in mouse calvariae, and that stimulation of IL-6 and RANKL expression are downstream effects of the LIF and OSM receptors. Signaling through the OSM receptor is substantially more effective, with specific autostimulation of the receptor by mOSM being one possible explanation.

Regulation of SOST Expression by Osteotropic Factors in Calvaria Organ Culture. H. Keller, H. Jeker*, A. Studer*, J. Wirsching*, M. Kneissel. Bone & Cartilage Unit, Novartis Institutes for BioMedical Research, Basel, Switzerland.

SOST is an osteocyte-expressed potent negative regulator of bone formation and a putative bone morphogenetic protein (BMP) antagonist. Recently, we have shown that SOST expression is regulated by parathyroid hormone (PTH) in bone. SOST was down-regulated during PTH-induced bone formation *in vivo*. Consistent with this finding, PTH suppressed SOST expression in calvaria organ culture *in vitro*. Now, we have further analyzed SOST regulation by various factors impacting on bone metabolism using quantitative real-time RT-PCR (qPCR) in calvaria culture, since this well established bone organ culture system offers a relevant model to study an osteocyte-expressed factor *in vitro*. Similarly to PTH, transforming growth factor β1 (TGFβ1), basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF) and vitamin D3 (VitD3) strongly reduced SOST expression in cultured calvaria of newborn mice after 24h treatment. In contrast and in line with published data, BMP-2, -5, -6, and -7 stimulated SOST expression several-fold. Steroid hormones and prostaglandin E2 (PGE2) did only weakly or not regulate SOST expression: dexamethasone and 17β-estradiol weakly induced, while progesterone, dihydro-testosterone and PGE2 only marginally regulated SOST expression. The relatively minor impact of sex hormones on SOST expression in calvaria organ culture is in line with our observation that estrogen status has no impact on *in vivo* SOST expression in rats as opposed to regulation by PTH. We proceeded to analyze SOST expression during TGFβ1 or BMP-2 induced *in vitro* bone formation. Stimulation of bone formation was assessed by histology. In addition, expression of the bone formation marker genes alkaline phosphatase (ALP) and osteocalcin (OSC) was determined. Compared to freshly dissected calvaria, SOST expression decreased about 80% during the 24h pre-incubation period, but regained initial levels after three day culturing. TGFβ1 increasingly repressed SOST expression over the three day monitoring period. BMP-2 induced SOST expression at day one, but the induction was lost at day three compared to control levels. ALP was not regulated by any treatment, but OSC was strongly decreased during pre-incubation by about 90% and in contrast to SOST expression continued to decrease in control cultures reaching about 100-fold down-regulation. TGFβ1 treatment led to almost complete extinction of OSC expression, while BMP-2 had no impact. In summary, calvaria organ culture experiments demonstrate differential regulation of SOST by TGFβ1, BMPs and other osteotropic factors providing further evidence for an important role of this osteocyte-expressed factor in bone metabolism.

Leptin Inhibits Bone Formation and Controls Bone Mass not only in Rodents, but also in Sheep. P. Pogoda*[1], J. C. Schnell*[1], M. Egermann*[2], M. Priemel[1], A. F. Schilling[1], M. Alini*[2], J. M. Rueger*[1], S. Thorsten[1], E. Schneider*[2], I. Clarke*[3], M. Amling[1]. [1]Trauma Surgery, Hamburg University School of Medicine, Hamburg, Germany, [2]AO Research Institute, Davos, Switzerland, [3]Department of Physiology, Monash University, Melbourne, Australia.

Genetic studies in mice have identified leptin as a potent inhibitor of bone formation acting through the central nervous system and unravelled the central nature of bone mass control and its disorders. Although these studies have radically enhanced our understanding of skeletal physiology as they have established a hypothalamic regulation of bone remodeling via the sympathetic nervous system, controversy remains about the physiological relevance of these observations as leptin's effect on bone after intracerebroventricular application have only been demonstrated in mice. In addition, the conflicting reports on bone mass in leptin-deficient ob/ob mice and leptin-deficient fa/fa rats have further questioned whether leptin has a role in regulating bone mass beyond rodents. To address this question we have treated ewe by long term intracerebroventricular application (icv) of leptin and analyzed the bone phenotype after a period of 3 month of treatment. Three groups of corriedale sheep (n=16) were compared (i) control entire (entire), (ii) ovx and icv application of cerebrospinal fluid (csf), and (iii) ovx and icv application of leptin (leptin). Analysis included histomorphometric characterization of iliac crest, spine and femur by histology and microcomputed tomography as well as measurement of bone turnover parameters in serum and urine. Indeed, central application of leptin decreased both bone formation by 70% and mineralizing surface (MS/BS 39.4±3.3% vs. 16.1.±2.1%) significantly ($p<0.01$). While ovariectomy increased osteoclast indices and urinary crosslap excretion by 2- and 3-time respectively, serum parameters (bone alkaline phosphatase and osteocalcin) of osteoblast activity were significantly reduced by icv application of leptin ($p<0.01$). Consequently ewe treated with leptin were highly osteopenic (iliac crest BV/TV entire 22.7±1.3% vs. csf 18.9±2.4% vs. leptin 12.4±2.6%) after 3 month of treatment ($p<0.01$). Taken together, these data suggest that leptin controls bone formation via a hypothalamic relay leading to osteopenia in sheep. Most importantly however, they demonstrate that the central regulation of bone formation is not limited to rodents, but also found in large animals confirming that bone remodeling in vertebrates is centrally controlled.

Relationships of Serum Leptin and Adiponectin Concentration with Bone Mineral Density in Korean Postmenopausal Women. D. Byun, J. Mok*, K. Lee*, Y. Kim*, H. Park*, C. Kim*, S. Kim*, K. Suh*, M. Yoo*. Endocrinology, Soonchunhyang University Hospital, Bucheon-si, Republic of Korea.

Overweight is associated with both higher fat mass and higher bone mineral density(BMD). Leptin is synthesized and secreted by adipocytes and serum concentrations are highly correlated with fat mass. It has been suggested that leptin levels may play a mediating role in maintaining bone mass. Unlike other adipokines such as leptin, adiponectin levels decrease in obesity. The porpose of this study was to investigate associations of serum leptin and adiponectin with BMD. We measured the bone markers, serum leptin, adiponectin level and bone mineral density(BMD) in 33 Korean postmenopausal women. Serum leptin level was significantly increasing associated with weight and body mass index(BMI)($r=0.69$, $p=0.0001$ and $r=0.78$, $p=0.0001$ respectively), while serum adiponectin level was not changing. Serum leptin and adiponectin levels were not correlated with alkaline phosphatase level, urine N-telopeptide, lumbar BMD and femoral BMD. Only femoral BMD was decreased following by serum adiponectin levels but it was not significant($r=-0.31$, $p=0.08$). These results suggested that serum leptin and adiponectin concentrations did not appear to affect directly BMD in Korean postmenopausal women.

Bone Loss in the Femur but not the Spine Is Attenuated in Lactating Interleukin-1 Receptor 1 Deficient Mice. J. N. VanHouten*[1], J. Kalinowski*[2], J. J. Wysolmerski[1], J. A. Lorenzo[2]. [1]Endocrinology, Yale University, New Haven, CT, USA, [2]Medicine, University of Connecticut Health Center, Farmington, CT, USA.

Lactation is associated with the transient loss of significant amounts of bone from the maternal skeleton. Previous studies have shown that estrogen-deficiency is an important component of lactational bone loss in mice. Interleukin-1 (IL-1) is an inflammatory cytokine with osteoclastogenic properties. In addition, IL-1R1-/- mice, which lack the bioactive receptor for IL-1, are protected from the bone loss that occurs after ovariectomy. This finding suggests that IL-1 is an important mediator of the bone loss that occurs with estrogen deficiency. In order to examine if IL-1 might similarly contribute to bone loss during lactation, we first examined circulating levels of IL-1alpha, IL-1beta, and IL-1ra in nulliparous and lactating wild-type mice. None of these cytokines was elevated during lactation, suggesting that any actions of IL-1 in this model would be autocrine or paracrine within the skeleton. To examine this possibility, we studied lactating IL-1R1-/- mice and wild-type (WT) littermate controls. Total body bone mineral density (BMD), spinal BMD and vertebral BMD were measured by DEXA. Mice were examined 3 and 10 days postpartum. Dams were of equivalent age and litter sizes were adjusted to be similar between groups. We found that lactation decreased total body and spine BMD at similar rates in IL-1R1-/- and WT mice. However, bone loss at the femur was attenuated in IL-1R1-/- mice as compared to controls. Femoral BMD in WT controls declined by 13.7 +/- 0.7 % between day 3 and 10 of lactation, while BMD declined by only 9.6 +/- 1.3 % (30% less) in the IL-1R1-/- dams ($p<0.02$). Circulating concentrations of biochemical markers of bone formation (osteocalcin) and bone resorption (urine CTX) were similar in WT and IL-1R1-/- mice, suggesting that rates of bone turnover were similar despite the loss of IL-1 signaling. Finally, levels of serum calcium, PTH, urine calcium and milk calcium were not significantly different in lactating IL-1R1-/- mice as compared to controls. These data demonstrate that IL-1 signaling has only minor, site-specific effects on bone loss induced by lactation in mice. Furthermore, these results suggest that the downstream mediators of bone loss due to lactation are fundamentally different than those that mediate the effects of estrogen withdrawal in ovariectomized mice.

Long-Term Serotonin Administration Affects Cortical Bone Architecture and Increases Bone Mineral Density in Rats. B. I. Gustafsson*[1], I. Westbroek*[1], E. Waarsing*[2], L. Thommesen*[1], K. Stunes*[1], H. Waldum*[1], H. van Leeuwen*[2], H. Weinans*[2], U. Syversen[1]. [1]Cancer Research and Molecular Medicine, NTNU, Trondheim, Norway, [2]Internal Medicine and Orthopaedics, Erasmus MC, Rotterdam, The Netherlands.

Recently, more and more evidence is found for a control of bone mass by the central nervous system. Many studies indicate a role for the nervous system in embryonal skeletal development, during fracture healing, and during remodelling after insertion of implants. We have previously shown functional serotonin receptors in bone cells and a stimulatory effect of serotonin on proliferation of osteoblast precursor cells. In this study we investigated the effects of serotonin on bone metabolism *in vitro* and *in vivo*. Murine preosteoblasts (MC3T3-E1) were treated with serotonin and OPG and RANKL release were measured. We also investigated if osteoblasts and osteoclasts express tryptophane hydroxylase (Tph) mRNA. Two months old female Sprague-Dawley rats were treated with daily subcutaneous serotonin injections (5mg/kg) for 3 months. DXA scans were made after two and three months of treatment. We further investigated bone architecture and mechanical properties by µCT and mechanical testing. Serotonin induced OPG and inhibited RANKL release from murine preosteoblasts. Murine osteoblasts as well as murine (RAW 264.7) and human osteoclasts expressed Tph, the rate-limiting enzyme in serotonin synthesis. Despite a significant decrease in body weight, total body BMD was significantly increased in the treated animals after two and three months. µCT analysis of femurs after 3 months of treatment showed significantly increased cortical thickness, while trabecular bone volume was significantly decreased. Interestingly, the perimeter and cross-sectional moment of inertia (MOI), a proxy for geometrical bone strength, were the same in both groups. These data suggest a reduced endosteal bone resorption in serotonin treated animals. The mechanical testing showed that bone stiffness was increased in serotonin treated animals whereas the strength remained unchanged. In conclusion, serotonin treatment seems to decrease endosteal bone resorption, leading to an increase in BMD and cortical bone thickness, and a decrease in trabecular bone volume. These effects may be mediated through a serotonin induced increase in OPG/RANKL ratio. We also find that bone cells express Tph, indicating that they are capable to produce serotonin. Our study shows that serotonin has important effects on bone metabolism.

AC-100, a Fragment of MEPE, Promotes New Bone Formation via Enhanced PGE2 Production and Cell Binding to Matrix Proteins. C. A. Middleton-Hardie[1], S. Aswani*[1], D. M. Rosen[1], M. S. Shih*[2], R. Leininger*[2], M. Lazarov[1]. [1]Acologix, Hayward, CA, USA, [2]Skeletech, Bothell, WA, USA.

MEPE, a protein originally cloned from tumours associated with hypophosphatemic osteomalacia, increases renal phosphate excretion and is expressed in normal human bone and odontoblast cells. AC-100 (Dentonin), a central 23-amino acid fragment of MEPE, contains motifs important in regulating cell activities in the bone and dentin microenvironment and has demonstrated potent anabolic activity on osteoblast and odontoblast precursor cells *in vitro*. *In vivo* studies in rodents indicate AC-100 is able to stimulate new dentin formation in teeth, and bone formation at fracture healing sites. Previous studies have implicated COX2 involvement in AC-100 induced proliferation of hMSC cells (1). Here we report the activity of AC-100 is associated with induction of the bone anabolic factor PGE2, increased production of matrix proteins and upregulation of integrin binding. **Methods** Hemi-calvariae from neonatal mice were incubated in the presence of AC-100, BMP2 or media alone. AC-100 was added to the media daily for seven days. Samples of the conditioned media were collected on days 2 - 8 for analysis of anabolic factors. At day 8 the hemicalvariae were embedded in paraffin and sectioned. The sections were analysed using a qualitative scoring system for osteoblast surface, cell density and new bone growth (0-4). **Results** AC-100 significantly increased new bone formation, bone cell density and osteoblast surface with levels comparable to the BMP2 treated group. The optimum AC-100 dose was 10µg/mL. Analysis of the conditioned media samples showed that AC-100 potently induces PGE2 production in a dose dependent manner. The optimal AC-100 dose for new bone formation induced a 5-fold increase in PGE2 production. AC-100 also induced modest increases in TGFβ-1 and fibronectin production but does not stimulate BMP2 production. Analysis of hMSC with the CytoMatrix Screen Kit (Chemicon) demonstrated that AC-100 not only induced the production of fibronectin but also increased the binding of hMSC to different matrices (laminin, fibronectin, vitronectin and collagen). This increased binding was accompanied by upregulation of β1, β2, β3 and β4 integrin binding but not β6 or αVβ5 integrin binding as assayed by the Beta-integrin-mediated cell adhesion array (Chemicon). **Conclusion** This study indicates the bone anabolic activity of AC-100 is strongly connected to the induction of PGE2 production and the stimulation of cell binding to matrix proteins. These results reinforce the findings of previous studies where AC-100 has been shown to increase proliferation of hMSC cells via induction of COX2 (1).

Intracellular Fate of Plasmid DNA and Non-Viral (Polymeric) Carriers in Bone Marrow Stromal Cells. H. Uludag, L. Farell*, B. Acan*, W. Hu*, C. Kucharski*. University of Alberta, Edmonton, AB, Canada.

Non-viral methods to transform Bone Marrow Stromal Cells (BMSC) are advantageous over the viral vectors, since non-viral carriers do not integrate into cellular genome, and they cannot transform the target cells. Polymeric non-viral vectors function by binding to a desired DNA sequence, condensing it into compact structures, and facilitating the uptake into the cells through the anionic cell-surface membrane. Little information is available about the intracellular fate of the delivered DNA and the polymeric carriers in BMSC. This study was conducted to investigate the fate of a plasmid DNA and polymeric carriers in rat BMSC. Towards this end, two cationic polymeric, poly-L-Lysine (PLL) and polyethyleneimine (PEI), were labelled with fluorescein isothiocyanite (FITC) and Alexafluor-350TM. A commercially-available plasmid DNA (pEGFP-N2) was also labelled with the same fluorescent markers and the cellular uptake of DNA in conjunction with unlabeled polymers were followed. BMSC were derived from Sprague-Dawley rats and used between passage 2 and 4 for growth on glass cover slips. Atomic force microscopy indicated plasmid/polymer complex formation with 50-200 nm size at the optimal plasmid:polymer ratios. The PEI and PLL polymers were both readily taken up by the cells, irrespective of the fluorescent label used on polymers. Flow-cytometry also confirmed the abundant uptake of the polymers. Close to 100% of the cells exhibited polymer uptake with 70-80% of the cells exhibiting polymer uptake in the nucleus for both PEI and PLL. DNA was also taken up by the cells (90-100% of BMSC), but nuclear localization of the DNA was significantly less (5-10%). These results indicated a strong ability of the cationic polymers to target to cellular nucleus, but the DNA payload appeared to be dissociated form the polymers intracellularly, and not targeted to nucleus. Understanding the mechanism(s) by which DNA transport to nucleus is impeded might provide superior carriers for genetic modification of bone marrow stromal cells.

Mechanical Strain Regulates Effectors of both Formation and Resorption in an Immortalized Osteoblast Cell Line. X. Fan[1], J. A. Rahnert*[1], T. C. Murphy*[1], M. S. Nanes[1], E. M. Greenfield[2], J. Rubin[1]. [1]Dept. of Medicine, Emory University/VA Medical Center, Decatur, GA, USA, [2]Dept. of Orthopaedics, Case Western Reserve University, Cleveland, OH, USA.

Mechanical strain inhibits osteoclastogenesis by regulating osteoblast functions: we have shown that strain inhibits RANKL expression and increases eNOS and nitric oxide levels through ERK1/2 signaling in primary bone stromal cells. The primary stromal culture system, while contributing greatly to understanding of how the microenvironment regulates bone remodeling is limited in use for biochemical assays and studies of other

osteoprogenitor cell responses to mechanical strain: stromal cells proliferate poorly and loose aspects of the strain response after a relatively short time in culture. In this study, we used the established mouse osteoblast cell line, CIMC-4 cell, which was harvested from mouse calvaria conditionally immortalized by insertion of the gene coding for a temperature-sensitive mutant of SV40 large T antigen. The CIMC-4 line is known to support osteoclastogenesis. We characterized these cells showing that vitamin D induced RANKL expression and nitric oxide decreased the RANKL/OPG mRNA ratio. Osteoblast characteristics consistent with differentiation were studied: mineralizing medium as well as Wnt-3a conditioned medium enhanced alkaline phosphatase activity and osteocalcin secretion. This panel of responses was next studied to see if the cells were able to sense mechanical strain. We applied mechanical strain (0.5-2%, 10 cpm, equibiaxial) to the CIMC-4 cultures. Strain caused magnitude-dependent decreases in RANKL expression to less than 50% those of unstrained cultures. Overnight strains of 2% also increased osterix (OSX) and RUNX2 expression by nearly 2-fold as measured by RT-PCR. Importantly, the ERK1/2 inhibitor, PD98059, completely abrogated the strain effects bringing RANKL, OSX and RUNX2 gene expression completely back to control levels. This data indicates that the strain effects on CIMC-4 cells require activation of ERK1/2 pathway. Therefore, the CIMC-4 cell line is a useful alternative *in vitro* model which effectively recapitulates aspects of the primary stromal cells and adds an extended capacity to study osteoblast control of bone remodeling in a mechanically active environment.

ATP Release Mediates Fluid Flow-Induced Proliferation of Human Mesenchymal Stem Cells. R. C. Riddle, A. F. Taylor*, H. J. Donahue. Orthopaedics, Pennsylvania State University College of Medicine, Hershey, PA, USA.

Accumulating evidence points to a role for ATP and purinergic signaling in bone cell mechanotransduction. Both osteocytes and osteoblasts have previously been shown to release ATP in response to mechanical stimulation and *in vivo* models illustrate that the expression of purinergic receptors is necessary for skeletal homeostatis. In these studies, we examined the effect of oscillatory fluid flow on the release of ATP and the effect of this signaling molecule on human mesenchymal stem cell proliferation. Exposing mesenchymal stem cells to fluid flow inducing a shear stress of 20dynes/cm^2 at 1Hz triggered a robust increase in ATP release compared to static controls (6.3±0.9nM to 0.3±0.1nM) without disrupting plasma membrane integrity. Concentrations of released ATP peaked within one minute of the initiation of fluid flow but remained elevated through 15 minutes of flow. As we and others have shown fluid flow to induce a proliferative response in human mesenchymal stem cells, we hypothesized that the release of ATP may be an important step in the mechanism by which biophysical signals regulate mesenchymal stem cell behavior. Two different approaches were utilized to test this hypothesis. Initially, cells were treated directly with physiologic concentrations of ATP ranging from 0 to 250μM to determine whether mesenchymal stem cells respond to ATP treatment with an increase in proliferation. We observed a dose-dependent increase in mesenchymal stem cell proliferation following ATP treatment, with 25μM ATP stimulating the greatest increase in proliferation (147.3±17.4% increase over untreated controls). Subsequently, cells were exposed to fluid flow in the presence of apyrase (10U/mL), an enzyme that degrades extracellular nucleotides, to determine whether ATP release is necessary for fluid flow-induced proliferation. Fluid flow inducing a shear stress of 20dynes/cm^2 stimulated a 109.9±18.8% increase in human mesenchymal stem cell proliferation over static controls. Treatment with apyrase completely abolished this response to fluid flow. These data provide strong evidence of a role for ATP in the biophysical regulation of mesenchymal stem cell behavior. Current efforts are focused on identifying the purinergic receptor responsible for this response as both P2Y2 and P2X7 isoforms have previously been implicated in bone cell mechanotransduction.

Enhanced Real-Time Ca^{2+} Oscillations Induced by Rest-Inserted Loading Predicts Sustained Osteoblastic Activity. B. J. Ausk*, T. S. Gross, S. Srinivasan. Orthopaedics, University of Washington, Seattle, WA, USA.

Inserting 10 s rest between each load cycle transforms low-magnitude loading events into potent osteogenic stimuli primarily via more sustained osteoblast function. To begin to explore mechanisms underlying the effectiveness of rest-inserted loading, we implemented a complimentary approach utilizing an agent based model of real-time Ca^{2+} signaling in osteocyte networks to generate hypotheses testable *in vivo*. In model simulations, we found that real-time Ca^{2+} oscillations induced by cyclic loading display a high-magnitude transient followed by low-level fluctuations while rest-inserted loading induced a series of secondary spikes following the initial transient. This phenomenon has also been observed when osteocytes were subject to oscillating fluid flow *in vitro*. We then employed a data mining approach to partition real-time Ca^{2+} oscillations induced in the model into two distinct components: initial activation and sustained activation. Initial activation was slightly but consistently increased by rest-inserted versus cyclic stimuli (19 ± 4%, range: 10 to 47%, n = 10; p =0.02). In contrast, sustained activation was much more dramatically increased by rest-inserted versus cyclic stimuli (310 ± 150%, range: 60 to 1600%, n = 10; p = 0.04). Based on these emergent data and assuming that Ca^{2+} signaling in osteocytes scales to subsequent osteoblast function, we hypothesized that a single bout of rest-inserted loading would induce a more sustained osteoblast response than a single bout of cyclic loading. We examined this hypothesis by subjecting the right tibiae of 16-wk C57BL/6J mice to a single bout of cyclic or 10 s rest-inserted loading (1600 me, 50 cycles, n = 4 per group). The relative periosteal percent labeled surface (r.LS) was quantified in loaded vs intact contralateral tibia at 5 d (alizarin) and 9 d (calcein) post-loading. In response to cyclic loading, r.LS was increased by 5 d, but declined to near background levels by 9 d (13.6 ± 9 to 3.7 ± 6%, p=0.05). In contrast, r.LS induced by rest-inserted loading was sustained through 9 d (d 5: 15.1 ± 13.9% vs d 9: 17.7 ± 9.9%). At 9 d, r.LS was significantly enhanced by rest-inserted loading compared to cyclic loading (by 380%; p=0.03). These data, albeit preliminary, demonstrate that real-time cellular events initiated during a single bout of loading (order of seconds) potentially control distinct down-stream adaptations (over a week later). Importantly, the nonlinear analysis enabled by agent based modeling coupled with predictive validation via *in vivo* models should provide a unique framework to identify novel pathways underlying mechanotransduction function within bone.

The Canonical Wnt Pathway Is Downstream to the BMP Signaling Pathway in Mediating Fluid Shear Stress-Induced Osteoblast Proliferation. S. Kapur, D. J. Baylink, K. H. W. Lau. Musculoskeletal Disease Center, J. L. Pettis Memorial VAMC, Loma Linda, CA, USA.

C57BL/6J (B6) inbred mice, but not C3H/HeJ (C3H) mice, responded to loading with an increase in bone formation. Our previous microarray study showed that genes of the Wnt, BMP/TGFβ, IGF-I, and Estrogen receptor (ER) pathways were upregulated in B6, but not in C3H, osteoblasts (Obs) 4 hrs after the 30-min steady shear strain of 20 dynes/cm^2, suggesting that the Ob mitogenic response to shear stress may involve these 4 pathways. Since there is abundant evidence for the involvement of IGF-I and ER pathways in shear stress-induced Ob mitogenic response, the present study focused on the potential role of and crosstalk between the Wnt and BMP pathways. Obs isolated from B6 mice were subjected to a 30-min steady shear stress at 20 dyne/cm^2. Cell proliferation was assessed by [^{3}H]thymidine incorporation. Expression of genes of the Wnt and BMP pathways (normalized against β-actin) was measured with real-time PCR 4 hr after the stress. The stress significantly increased cell proliferation (by 2-fold, $p<0.005$) in B6 Obs but not in C3H Obs. It also significantly ($p<0.05$ for each) upregulated the expression of genes of the canonical Wnt pathway: Wnt1 (2.3-fold), Wnt3a (3.3-fold), β-catenin (3.4-fold), LEF-1 (2.8-fold), and Axin (3.5-fold) and that of the BMP pathway: BMPR (2.6-fold), BMP4 (1.7-fold), Necdin (1.4-fold), and DLX1 (1.6-fold), in B6 Obs. The upregulation of many of these genes was confirmed by immunoblots. This shear stress-induced Ob proliferation and BMPR expression was each completely abolished by the BMP pathway inhibitor, noggin (300 ng/ml), while it was only partially (~60%, $p<0.002$) blocked by endostatin (10 μg/ml), an inhibitor of the canonical Wnt pathway. The lack of a complete inhibition was not due to an incomplete blockage of the shear stress-induced upregulation of canonical Wnt pathway, since this dose of endostatin abolished the shear stress-mediated upregulation of β-catenin expression completely. To evaluate potential crosstalk between the canonical Wnt and BMP pathways, we examined the effect of the noggin pretreatment on shear stress-induced upregulation of genes of the canonical Wnt pathway. The shear stress-induced Wnt1, Wnt3a, and β-catenin expressions were completely blocked by the noggin pretreatment. The shear stress also upregulated Wnt5a expression (non-canonical Wnt pathway) by 1.7-fold ($p<0.01$), but noggin had no significant effect on the shear stress-induced Wnt5a expression. In conclusion, the canonical Wnt pathway is downstream to the BMP pathway in the shear stress-mediated Ob proliferation and the BMP pathway mediated the shear stress-induced Ob proliferation partially through the canonical Wnt pathway.

MAPK and GSK Signaling Pathways Are Involved in the Mechanical Responses of Cementoblasts to Fluid Shear Stress. D. Liu, R. L. Duncan. Orthopaedic Surgery, Indiana University, Indianapolis, IN, USA.

External apical root resorption (EARR) occurs in 75-80% of patients undergoing orthodontic treatment and can be caused by multiple factors. However, the cellular and molecular mechanism of this process is unclear. Cementum, the shielding layer covering the dental root, bears a dynamic mechanical load during orthodontic tooth movement. Cementoblasts secrete the mineral matrix and ultimately become embedded in cementum. We hypothesize that cementoblasts actively respond to mechanical loading and play a pivotal role in the control of cementogenesis and remodeling of cementum. To determine whether cementoblasts respond to mechanical loading, OCCM.30 cells, an immortalized murine cementoblastic cell line (a gift from Somerman MJ, U. Washington, Seattle), were seeded onto glass slides coated with type I collagen (10μg/cm^2) and grown in DMEM supplemented with 10% FBS and 2mM L-glutamine. Upon confluency, OCCM.30 cells were subjected to 12 dyn/cm^2 laminar fluid shear stress (FSS) for 30 minutes or 1 hour. Static controls were kept in the identical environment without flow. During flow, media samples were taken at 5 and 15 minutes to determine the release of ATP and PGE_2, respectively. Following application of FSS, OCCM.30 cells were post incubated for either 30 minutes or 6 hours to determine Cox-2 or osteopontin (OPN) production. FSS induced a rapid release of ATP in OCCM.30 cells, followed by increased PGE_2 release at 15 min. FSS also increased both Cox-2 and OPN production compared to static controls. We, and others, have shown that MAP kinases are rapidly phosphorylated by shear in osteoblasts. As in cementoblasts, both ERK1/2 and P38, but not JNK, were phosphorylated within 30 min by FSS. Glycogen Synthase Kinase (GSK)3β was also phosphorylated in cementoblasts in response to FSS within 1 hour. These data indicate that, like osteoblasts, cementoblasts are mechanosensitive, activating many of the same signaling pathways involved in the cellular responses to mechanical loading. Further, these results imply a potential role of cementoblasts in the adaptation of cementum to a mechanical environment.

Reloading after Skeletal Unloading Restores Osteoblast Proliferation and IGF-I Responsiveness. S. Nishida[1], Y. Wang[1], R. K. Long*[1], E. C. Buxton*[1], A. Burghardt*[2], B. Boudignon[1], P. Kurimoto*[1], H. ElAlieh*[1], S. Majumdar[2], B. P. Halloran[1], D. D. Bikle[1]. [1]Endocrine Research unit, Univ of Calfornia, Veterans Affairs Medical Center, San Francisco, San Francisco, CA, USA, [2]Musculoskeletal and Quantitative Imaging Research Group, Univ of Calfornia San Francisco, San Francisco, CA, USA.

Skeletal unloading leads to decreased bone formation and decreased bone mass. These results can be explained in part by a failure of IGF-I to activate its signaling pathways in unloaded bone. To determine whether reloading restores IGF-I responsiveness we examined the response of unloaded (4 weeks hindlimb elevation), normally loaded, and reloaded (2 weeks normally loaded after 2 weeks unloaded) tibia and spine to IGF-I administration. The rats were given IGF-I (2.5 mg/kg/day) or vehicle by continuous infusion during the final 2 weeks of unloading, reloading, or normal loading. IGF-I treatment significantly increased the serum level of IGF-I in all animals to the same extent. Unloading and reloading did not affect the serum level of IGF-I in the vehicle-treated rats. We used micro CT to analyze bone mass and structure and BrdU incorporation to assess osteoprogenitor cell proliferation. Unloading decreased BV/TV by 25% in lumber spine and 50% in proximal tibia compared to the control group with partial but not complete recovery in the reloaded group. This decrease in BV/TV was accompanied by a change in the Structure Model Index (SMI) of trabecular bone from a plate to a rod structure. IGF-I treatment did not alter these structural changes caused by unloading. Continued unloading resulted in a reduction in BrdU labeled osteoblasts and blocked the ability of IGF-I to stimulate osteoblast proliferation. However, the reloaded group, vehicle and IGF-I treated, demonstrated an increased number of BrdU labeled osteoblasts, and the reloading enhanced this response to IGF-I. These results indicate that reloading reverses the negative impact of skeletal unloading on osteoblast proliferation and IGF-I responsiveness.

Modeled Microgravity Inhibits Osteoblastogenesis through Downregulation of RhoA Activity and Subsequent Actin Cytoskeletal Disruption. E. C. Seales*, V. E. Meyers*, M. Zayzafoon, J. M. McDonald. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

Low gravity spaceflight-induced bone loss results in part from decreased osteoblastic bone formation; however, the causative mechanisms directing reduced osteoblastogenesis during microgravity conditions remain unclear. Previously, utilizing a modeled microgravity (MMG) system developed by NASA, we demonstrated that culture for 7 days in MMG conditions causes an irreversible switch from an osteoblastic to an adipogenic phenotype in human mesenchymal stem cells (hMSCs). Intriguingly, reduced osteoblastogenesis during microgravity was associated with loss of actin stress fiber formation and dramatically reduced activation of RhoA, a small G protein which is required for integrin-mediated signaling, actin cytoskeletal organization, and lineage commitment in many different cell types. Given that downregulation of RhoA is also linked to adipogenesis, these findings suggested that MMG-induced downregulation of RhoA activity, and subsequent actin cytoskeletal disorganization, is a causative mechanism for failed osteoblastogenesis and subsequent bone loss during spaceflight. The aim of the present study is to determine if blockade of MMG-induced RhoA downregulation can restore osteoblastogenesis under microgravity conditions. Here we show that overexpression of constitutively-active RhoA (RhoA-V14) in hMSCs prevents MMG-induced loss of actin stress fiber formation and completely restores phosphorylation (and, hence, activation levels) of both the actin-severing protein cofilin and focal adhesion kinase. Furthermore, RhoA-V14 expression partially restored expression of osteoblastic markers including runt-related transcription factor 2, Type I collagen, and alkaline phosphatase, while simultaneously reducing expression of the adipocytic markers leptin and GLUT-4. Collectively, our findings suggest that microgravity-induced RhoA inactivation and subsequent actin cytoskeletal dysregulation shift the lineage commitment of hMSCs away from an osteoblastic to an adipogenic phenotype, resulting in bone loss during spaceflight. Ultimately, RhoA downregulation might play a causal role in both age and disuse-related bone loss as well since an osteoblastic-to-adipogenic lineage shift also occurs in these disorders.

Mechanical Stimulation of Rat Bone: Micro-Array. C. M. A. Reijnders*[1], N. Bravenboer[1], H. Beek van*[2], M. A. Blankenstein*[3], P. Lips[1]. [1]Endocrinology, VU University Medical Center, Amsterdam, The Netherlands, [2]Molecular Cell Physiology, Free University, Amsterdam, The Netherlands, [3]Clinical Chemistry, VU University Medical Center, Amsterdam, The Netherlands.

Mechanical loading plays an essential role in maintaining skeletal integrity. Bone modifies its structure throughout life in order to serve as a structural support [1]. Little is known about the molecular mechanisms, which are involved in the translation of mechanical stimuli into bone formation described as osteogenic response. Various animal experiments have been designed to test the effect of mechanical stress on bone formation. The four-point bending apparatus produces controlled mechanical strains in the tibia of living rats. The aim of our study is to investigate which genes are involved in the osteogenic response after mechanical loading. DNA microarray provides a tool for identification of differentially expressed genes. Female 12-week-old Wistar rats (weight 225.2g ± 11.1g) were randomly assigned to two weight-matched groups: load (n=8) and sham (n=8). The right tibia underwent "mediolateral" bending or sham-loading using the 4-point bending system [2,3]. The left tibia served as contra-lateral controls. The rats were subjected to a single episode of loading comprising 300 cycles (2Hz) using a peak magnitude of 60N. After total RNA isolation, cDNA probes were generated and indirectly labelled with Fluorolink Cy3 or Cy5 dyes. Hybridization of 5K oligo rat arrays was performed. Quantification of the Cy3 and Cy5 intensities was processed with Bluefuse. Statistical analysis, micro-array-ANOVA, was performed with the statistical program R. Preliminary results show that 37 genes are differentially expressed as tested in a fixed model with lowess correction. We will perform gene set enrichment analysis to elucidate the role of these candidate genes.

Nuclear Factor of Activated T Cells (NFAT) Is a Mechanical Signal Transducer in MC3T3-E1 Osteoblast-Like Cells. D. KIM, S. Lee*, J. A. Karmin*, H. Minematsu*, H. Lee, F. Y. Lee. Center for Orthopaedic Research, Columbia University, New York, NY, USA.

Bone adapts to mechanical environments, however, the underlying molecular mechanism by which osteoblast responds to physical forces are not fully understood. Although several studies have focused on the key roles of NFAT (nuclear factor of activated T cells) in T cells, cancer cells, kidney cells, cardiac muscle cells, the significance of NFAT in osteoblast in response to mechanical loading has never been studied. Here, we therefore hypothesized that mechanical loading activates calcineurin/NFAT which were known to regulate the transcriptions of various bone active cytokines and/or COX-2 (cyclooxygenase-2), one of proven final products of mechanical loading in osteoblasts. In order to verify our hypothesis, 5 dynes/cm^2 at 1 Hz of fluid shear stress for 15 min was directly applied to MC3T3-E1 pre-osteoblasts which were grown in a monolayer on the cover slide using a STREAMER^{TM} system. After application of 3 hours of shear stress, cells were harvested and divided into cytoplasmic and nuclear fractions to identify the response of NFATc1 to fluid shear stress using immunoblotting. In addition, NFAT nuclear translocation in response to fluid shear stress was visualized under fluorescent microscopy with an ectopically expressed NFATc1-EGFP cDNA construct. We found that nuclear translocation of both endogenous and ectopically expressed NFATc1 were facilitated by fluid shear stress. We also found that calcineurin activity increased 1.8 times upon the application of fluid shear stress. Fluid shear stress caused 50% increase in COX-2 protein expression, and its increase was suppressed with VIVIT, a cell permeable NFAT activation inhibitor, judging from densitometry. NFATc1 overexpression also increased COX-2 protein expression compared to controls. Taken together, our data suggested that NFATc1 regulates COX-2 expression in response to fluid shear stress in MC3T3-E1 osteoblasts. Further studies will shed light on the role of NFATc1 in response to mechanical loading in the regulation of bone active cytokines and enhancement of bone health.

Shear Intensity-Dependent Regulation of Runx2 in MC3T3 Mouse Osteoblasts. Y. Huang*, M. Su*, H. Yokota. Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, IN, USA.

A family of Runx transcription factors (also known as Cbfa and AML) is a lineage-specific regulator of gene expression in developmental pathways. Runx2 (Cbfa1) is known as a key transcription factor in the differentiation of osteoblasts and mesenchymal stem cells. The long-term objective of our research project is to elucidate the role of Runx2 in load-driven bone remodeling, and a specific aim of the current study was to investigate the transcriptional regulation of Runx2 in response to fluid shear. In our *in vitro* experiments, mouse osteoblasts (MC3T3 E1 cell line) were cultured in a three-dimensional porous type I collagen matrix (CollaCote, Sulzer Dental, Inc.) with and without fluid flow. The matrix dimension is 7 mm x 21 mm x 2 mm, and is composed of tubular collagen of 50 to 100 μm in diameter. A custom-made flow chamber, connected to a variable flow mini-pump, was used to induce flow at 0 to 10 ml/min through a 21 mm x 2 mm cross-section, and the flow treatment was applied for 3 min in the αMEM medium with 10% fetal bovine serum. Cells were harvested 1 hr and 3 hrs after the shear treatment, and total mRNA was isolated for RT-PCR. GAPDH was used as control. The mRNA expression data exhibited a unique transcriptional response of Runx2 isoforms. Three major Runx2 isoforms (types I, II, and III) are regulated either by P1 or P2 promoters. Our RT-PCR results show that the transcription driven by the distal P1 promoter was sensitive to fluid shear. However, the proximal P2 promoter was insensitive to fluid shear used in the current study. Interestingly, P1 promoter acted as a multi-stage toggle switch and the expression level altered depending on flow speed. The fluid flow at 5 ml/min upregulated Runx2 expression, while the flow at 1 and 10 ml/min downregulated its expression. Note that the expression of c-fos was upregulated at all flow speeds, and cox-2 mRNA level was elevated under shear at 5 and 10 ml/min. The observed multi-leveled regulation of Runx2 is somehow similar to the response of MMP-1 in other tissues such as chondrocytes, whose expression level was shear intensity dependent. Our results demonstrate for the first time that Runx2 mRNA expression is responsive to fluid shear, and indicate that a minimum shear threshold may exist to trigger load-driven osteogenesis. Consistent to our results, it is reported that the P1-derived type II isoform is bone specific, and the predominantly expressed isoform in non-osteoblastic cells is type I. A further analysis is required to elucidate the molecular mechanism underlying the observed multi-level expression pattern in osteoblast cells.

Homocysteine Enhances Apoptosis via ROS-Mediated Mitochondrial Pathway in Human Bone Marrow Stromal Cells: A Possible Mechanism for Homocysteine-Mediated Bone Loss. D. J. Kim*[1], O. S. Lee*[2], J. M. Koh[1], E. K. Park*[3], J. Y. Choi*[3], S. Y. Kim*[3], G. S. Kim[1]. [1]Division of Endocrinology and Metabolism, Asan Medical Center, Seoul, Republic of Korea, [2]Asan Institute for Life Sciences, Seoul, Republic of Korea, [3]Skeletal Diseases Genome Research Center, Kyungpook National University Hospital, Daegu, Republic of Korea.

Several lines of evidence strongly suggest that high plasma homocysteine (Hcy) concentrations may weaken bone. However, the exact mechanism underlying this effect has not been elucidated. Previously, it has been shown that Hcy significantly reduced cell viability in many types of cells including vascular endothelial cells, and the rate of apoptosis of osteoblast-lineage cells is a critical determinant of bone formation. Therefore, we examined the possible effects of Hcy on apoptosis of osteoblast-lineage cells using primary human bone marrow stromal cell (hBMSC) and HS-5 cell line Hcy significantly reduced cell viability and increased apoptosis by Cell Counting Kit-8 and analysis of cytoplasmic histone-associated DNA fragments. This cytotoxic effect was inhibited by z-VAD-fmk (z-Val-Ala-Asp-fluoromethylketone), a pan-caspase inhibitor, implicating that Hcy-induced apoptosis was caspase-dependent. Further investigation demonstrated that Hcy increased cytochrome C release into cytosol, and activated caspase-9 and caspase-3, but not caspase-8, indicating that Hcy induced apoptosis via mitochondrial pathway. In addition, immunoblotting showed that Hcy enhanced the phosphorylation of IkB, but not of p38, ERK, and JNK. As expected IkB inhibitor, PDTC (pyrrolidine dithiocarbamate), blocked Hcy-induced caspase-3 activation. Hcy also increased intracellular ROS and reduced total glutathione levels. And Pretreatment with N-acetylcysteine prevented Hcy-induced changes such as increased ROS, increased cytochrome C release, IkB activation, and cell death. In summary, Hcy induced apoptosis via ROS mediated mitochondrial pathway in primary hBMSC and HS-5 cell line. To our knowledge, this is the first study demonstrating the direct detrimental effect of Hcy on bone cells.

Heat Shock Protein 60 Induces Apoptosis via ROS-Mediated Mitochondrial Pathway and p38 Activation in Osteoblast-Lineage Cells; a Possible Mechanism of Estrogen Deficiency-Induced Bone Loss. J. M. Koh[1], O. S. Lee*[2], D. J. Kim*[1], E. K. Park*[3], J. Y. Choi*[3], S. Y. Kim*[3], G. S. Kim[1]. [1]Division of Endocrinology and Metabolism, Asan Medical Center, Seoul, Republic of Korea, [2]Asan Institute for Life Sciences, Seoul, Republic of Korea, [3]Skeletal Diseases Genomic Research Center, Kyungpook National University Hospital, Daegu, Republic of Korea.

Postmenopausal osteoporosis is a heterogenous disorder characterized by an accelerated bone loss after natural or surgical menopause, resulting in increased risk of fractures. In spite of several decades of investigation, the mechanisms by which estrogen-deficiency induces bone loss remain complex and elusive. To identify proteins potentially involved in estrogen deficiency-induced osteoporosis, we conducted a proteomics-based analysis using ovariectomy and sham-op rat bones, and found that heat shock protein 60 (HSP60) was up regulated in bones of ovariecomized rats. ELISA assay also revealed that plasma HSP60 concentration was significantly higher in ovariectomized rats than in sham-operated rats, and in postmenopausal women (n=10) than in premenopausal women (n=10). To investigate whether HSP60 affect proliferation of osteoblast-lineage cells that is a critical determinant of bone formation, we examined its effects on cell viability and apoptosis in primary human bone marrow stromal cells (hBMSC), HS-5 hBMSC cell line, mouse calvarial osteoblasts and MC3T3 preosteoblast cell line. HSP60 significantly reduced cell viability, and increased caspase-dependent apoptosis, which were blocked by pretreatment with blocking antibodies for toll-like receptor 2 (TLR2) and TLR4. HSP60 activated caspase-3 and caspase-9, but not caspase-8, and increased the cytochrome c release into cytosol. In addition, immunoblotting showed that HSP60 activated p38, but not ERK, JNK and NFκB, and that a p38 inhibitor, SB203580, abolished the HSP60-induced cell apoptosis. Further investigation demonstrated that HSP60 increased intracellular reactive oxygen species (ROS) levels and reduced total glutathione levels. Antioxidants, such as α-lipoic acid and N-acetylcysteine, completely prevented these HSP60-induced changes, such as reduced cell viability, increased apoptosis, activation of caspase-3, increased cytochrome c release and activation of p38. In summary, endogenous HSP60 was up regulated in estrogen deficient state and HSP60 induced apoptosis via ROS-mediated mitochondrial pathway and p38 activation in osteoblast-lineage cells. The up-regulation of HSP60 may have a critical role for the bone loss in estrogen deficient state.

Control of Runx2 Activity in Proliferating Osteoblasts by Mitotic Phosphorylation and Postmitotic Dephosphorylation. A. Rajgopal*, D. W. Young, A. Javed, J. L. Stein*, J. B. Lian, A. J. van Wijnen, G. S. Stein. Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA.

Skeletal development and osteoblast maturation require the osteogenic activity of the transcription factor Runx2, which controls both cell growth and differentiation in osteoblasts. One function of Runx2 we recently discovered is its ability to control the expression of specific target genes as cells enter and exit mitosis during active proliferation**.** Western blot analysis of proteins from osteoblastic cells released from mitotic inhibition into early G1 show a phosphatase-sensitive shift in the mobility of Runx2 in SDS gels. Therefore, we addressed the hypothesis that post-translational modifications of Runx2 control its activity at mitosis. The slowly migrating form of Runx2 appears to be hyper-phosphorylated and is clearly immunoreactive with a CDK related phospho-epitope (detected by the MPM2 antibody) in mitotic cells but is below detection limits in asynchronous cells. The hyper-phosphorylated form of Runx2 is converted into a faster migrating putative hypo-phosphorylated form of Runx2 when cells complete mitosis. This conversion is inhibited by okadaic acid, an inhibitor of protein phosphatases PP1 and PP2A, but not by deltamethrin which affects PP2B. Thus, Runx2 is rapidly dephosphorylated after mitosis by a PP1 and/or PP2A dependent mechanism. Furthermore, mitotic phosphorylation of Runx2 protein is sensitive to the CDK inhibitors roscovitine and olomoucine, and is phosphorylated in vitro by the CDK1/cyclin B complex. These data together indicate that Runx2 is hyper-phosphorylated during mitosis, and suggest that post-mitotic regulation of Runx2 target genes involves the dynamic PP1/PP2A dependent dephosphorylation of S/T residues in Runx2 that are targeted by the CDK1/cyclin B kinase.

High Osteoblastic Activity in C3H/HeJ (C3H) Mice Compared to C57BL/6J (B6) Mice May Be Related to a Reduced Population Apoptosis in C3H Osteoblasts. M. H. C. Sheng, K. H. W. Lau, D. J. Baylink, J. E. Wergedal. Musculoskeletal Disease Center, J. L. Pettis Memorial VAMC, Loma Linda, CA, USA.

We have previously reported that the higher peak bone density in C3H mice compared to B6 mice was attributed to a greater bone formation (BF) rate that was due to an intrinsic, higher differentiation status and BF ability in C3H osteoblasts (Obs) compared to B6 Obs. In addition to an intrinisic, higher differentiation status and BF activity, C3H Obs also exhibited a significantly lower cell population apoptosis. Because recent studies indicate that cell population apoptosis may have a regulatory effect on Ob differentiation and/or BF activity, this study sought to test whether the higher differentiation status and BF ability in C3H Obs were inversely associated with their lower population apoptosis in vitro. Accordingly, we first measured the basal differentiation status [by measuring alkaline phosphatase (ALP) specific activity, and cbfa1, bmp2, bsp, type-1 collagen, osteoponin, and osteocalcin gene expression (by real-time PCR)] and population apoptosis (measured by FACS) in Obs isolated from new-born and 6-week C3H and B6 mice (n = 6 each). C3H Obs at either age showed significantly greater ALP activity and Ob gene expression ($p<0.05$ for each) and a significantly lower cell population apoptosis ($p<0.001$). C3H Obs also showed a significantly higher bcl2 expression and a lower Caspase activity (with the Roche Caspase assay kit) ($p<0.001$ for each) than B6 Obs. These findings confirm our previous conclusion that C3H Obs had a higher basal differentiation status and a lower cell population apoptosis. To support a potential association between the differentiation status and the cell population apoptosis, we found a highly significant negative correlation between the log of the basal ALP activity and apoptosis ($r=-0.574$, $p=0.012$). We next perturbed cell population apoptosis of C3H and B6 Obs by treating these cells with a number of apoptosis enhancers (TNF, DEX, LPS, Etoposide) and inhibitors (PTH, IGF-I, TGF1, E_2) and then determined their ALP specific activity and insoluble collagen synthesis (an index of bone-forming activity). We again found significant negative correlations between ALP and apoptosis ($r=-0.62$, $p<0.05$) and between insoluble collagen synthesis and apoptosis ($r=-0.46$, $p<0.05$). In summary, these findings suggest a potential inverse relationship between cell population apoptosis and BF activity. Because the differentiation status depends on the cell life span, which is inversely proportional to apoptosis, these findings led us to conclude that the higher differentiation and/or BF activity of C3H Obs than B6 Obs may in part be due to a lower cell population apoptosis in C3H Obs.

Lactoferrin's Potent Anti-Apoptotic Effect in Osteoblasts Is not Mediated by LRP1. A. B. Grey, A. Zhu*, K. E. Callon*, M. Watson*, I. R. Reid, J. Cornish. Medicine, University of Auckland, Auckland, New Zealand.

Previously we have demonstrated that lactoferrin is anabolic to bone. Lactoferrin, in vitro, stimulates osteoblastic cell proliferation and differentiation, stimulates primary chondrocyte proliferation as well as increasing bone formation in vivo. In addition, lactoferrin decreases osteoclastogenesis in mouse bone marrow cultures. We have also reported that the low density lipoprotein receptor-related protein (LRP) 1, mediates the mitogenic effects of lactoferrin in osteoblastic cells. In the present study, we have investigated lactoferrin's effects on osteoblastic cell apoptosis, using TUNEL, DNA fragmentation and colormetric methodology (Biocolor™). Lactoferrin inhibits osteoblast apoptosis induced by serum withdrawal by 70%. This effect is not sensitive to receptor associated protein (RAP), a specific LRP1 and LRP2 inhibitor, suggesting the cell survival signaling activated by lactoferrin is not mediated by LRP1. Furthermore, lactoferrin inhibition of cell apoptosis is demonstrated to a similar degree in LRP1 knockout fibroblast cell line (PEA13 cells) and the wild type fibroblast cell line (MEF-1 cells). Western blot analysis demonstrated that lactoferrin activates PI3K-dependent Akt phosphorylation in osteoblastic cells. This activation is also not RAP-sensitive. We then questioned whether lactoferrin's ability to promote osteoblast survival was acting through the PI3 kinase pathway, however, inhibition of apoptosis in osteoblasts by lactoferrin was not blocked by a PI3 kinase inhibitor, LY294002. We have earlier reported that lactoferrin's mitogenic activity on osteoblasts is involving the ERK pathway. However, the anti-apoptotic effect of lactoferrin in osteoblasts did not appear to be working via the ERK pathway as the MAP

kinase inhibitor U0216 did not block this effect. In conclusion, interestingly, these results indicate that lactoferrin acts through a diversity of pathways to effect multiple functions within the osteoblast. The mitogenic effect of lactoferrin is mediated by LRP1 and signals through the ERK pathway. However, the anti-apoptotic effects of lactoferrin in osteoblasts are not mediated by LRP1 and neither does it involve the PI3 kinase or ERK pathways.

Requirement of Protein Palmitoylation in Osteoblast Differentiation. W. Leong*, T. Zhou*, B. Li. Institute of Molecular and Cell Biology, Singapore, Singapore.

Protein modification plays a critical role in regulating protein function. Palmitoylation, a reversible lipid modification, has been demonstrated to control protein localization, protein-protein interaction, and protein trafficking. Ablation of an enzyme that catalyzes palmitoylation led to defects in mouse development and survival. Moreover, palmitoylation of hedgehog was found essential for bone development. In an attempt to understand the possible roles for protein palmitoylation in osteoblast differentiation, we used an inhibitor for palmitoyl transferase (PAT) and primary osteoblasts isolated from mice deficient for a palmitoyl transferase. Inhibition of PAT with an inhibitor was found to impede osteoblast differentiation, manifested by reduced expression of ALP and osteocalcin, and reduced bone mineralization in *in vitro* cultures. Yet osteoblast proliferation was not significantly affected by the inhibitor. Several proteins were found to be modified by palmitoylation during osteoblast differentiation. Data obtained with the PAT deficient osteoblasts and data on identification of the palmitoylated proteins will be presented.

Decreased Bone Mineral Density in Adult Mice Heterozygous for the PTH-Regulated Transcription Factor Sox4 Is Associated with Suppressed Osteoblast Activity. L. S. H. Nissen-Meyer*[1], R. Paro*[2], M. E. Pedersen*[1], D. Fortunati*[1], S. Reppe*[1], V. T. Gautvik*[1], S. H. Brorson*[3], A. Teti[2], F. P. Reinholt[3], R. Jemtland*[4], K. M. Gautvik[5]. [1]Dept. of Biochemistry, Institute of Basic Medical Sciences, University of Oslo, Oslo, Norway, [2]Department of Experimental Medicine, University of L'Aquila, L'Aquila, Italy, [3]Institute of Pathology, National University Hospital, Oslo, Norway, [4]Endocrine Section, Dept. of Medicine, National University Hospital, Oslo, Norway, [5]Dept. of Biochemistry, Institute for Basic Medical Sciences, University of Oslo, Ullevål University Hospital and Lovisenberg Hospital, Oslo, Norway.

Sox4 is a transcription factor crucial for normal development of the cardiovascular system. We have previously demonstrated expression of Sox4 mRNA in the embryonic cartilage growth plate, and its regulation via the PTH/PTH-rP receptor in osteoblast-like cells. Complete gene knockout induces intrauterine death, while *Sox4*$^{+/-}$ animals have an apparently normal phenotype. We here present data suggesting a potential role for Sox4 in osteoblast regulation. We have examined longitudinal changes in bone mass indices in *Sox4*$^{+/-}$ and wildtype (wt) mice, and characterized primary calvarial osteoblasts from *Sox4*$^{+/-}$ and wt mice and their response to PTH stimulation *in vitro*. Male and female *Sox4*$^{+/-}$ and wt mice were analysed by DEXA every 6-8 weeks (2-12 months). Epoxy-embedded tibiae were analyzed by light and electron microscopy. Osteoblast primary cultures were derived from 8-10 day-old mice. We evaluated cell differentiation, proliferation and mineralization, and the response to PTH-stimulation by intracellular cAMP measurements and c-fos expression. mRNAs typically expressed by osteoblasts were analysed by real-time PCR in unstimulated and PTH-stimulated cells. DEXA measurements of *Sox4*$^{+/-}$ mice compared to sex- and age-matched controls revealed decreased peak bone mass in 6 months old males (-5.1%, $p<0.05$). This difference was later reduced (-2% and -0.8 % at 10 and 12 months). In female *Sox4*$^{+/-}$ mice, BMD was decreased by 3.1% at 6 months (n.s.) and by 5.3 ($p<0.01$) and 4.1 % (n.s) at 10 and 12 months, respectively. In osteoblast cultures, *Sox4*$^{+/-}$ cells incorporated only ~30% [^{3}H]-thymidine ($p<0.001$) compared to wt, and the number of alkaline phosphatase-expressing cells and mineralized bone nodules appeared considerably decreased. Preliminary real-time PCR data indicated a lower expression of c-fos following PTH-stimulation of *Sox4*$^{+/-}$ osteoblasts compared to wt. *Sox4*$^{+/-}$ mice display reduced and delayed peak bone mass compared to wt. Our data show impaired proliferation and function of osteoblasts from *Sox4*$^{+/-}$ mice, providing a possible explanation to these observations.

Pueraria Thunbergiana **Promotes Differentiation and Mineralization in Human Osteoblast-Like SaOS-2 Cells.** D. Y. Kim*[1], J. E. Huh*[2], H. R. Yang*[2], Y. H. Baek*[2], J. D. Lee*[2], D. S. Park*[2], M. C. Yoo*[3]. [1]Internal Medicine, Kyung Hee University Hospital, SEOUL, Republic of Korea, [2]Oriental Medicine Research Center for Bone & Joint Disease, Kyung Hee University, SEOUL, Republic of Korea, [3]Orthopedic Surgery, Kyung Hee University Hospital, SEOUL, Republic of Korea.

The differentiation of osteoblastsis controlled by various growth factors and matrix proteins expressed in bone. *Pueraria thunbergiana (Pueraria T.)* , the root of *Pueraria lobata Ohwi*, a wild creeper leguminous plants, is one of the earliest and most important crude herbs used in oriental medicine. It has been reported that *Pueraria T.* prevents bone loss by growth hormone release in ovariectomized rats. The aim of this study was to identify the *Pueraria T.* that may induce the osteogenic activity in human osteoblast-like SaOS-2 cells. The osteogenic activity of *Pueraria T.* were evaluated by WST-8 assay, alkaline phosphatase (ALP) activity, RT-PCR analysis of vascular endothelial growth factor (VEGF), osteocalcin(OCN), osteopontin(OPN), type I collagen(Col I) mRNA, and ELISA or colorimetric analysis, and mineralization by Alizarin red staining in SaOS-2 cells. *Pueraria T.* had no effect on viability of osteoblastic cells, and dose dependently increased ALP activity. Treatment of the cells with *Pueraria T.* at 1 μg/ml increased VEGF mRNA synthesis at 3, 7, and 14 days of culture in a dose-dependent manner. Extracellular accumulation of proteins such as VEGF, and Col I was increased in a dose-dependent manner. Following treatment of the cells with 1 μg/ml *Pueraria T.* for 14 days of culture, the expression of OCN, OPN, and Col I mRNA was not affected by treatment with *Pueraria T.* at 3 and 7 days, but was markedly enhanced at 14 days of culture. OCN, OPN, and Col I mRNA expression showed a dose-dependent increase at 14 days of culture following *Pueraria T.* treatment compared to vehicle-treated cells. Also, *Pueraria T.* significantly induced mineralization in the culture of SaOS-2 cells. Calcified tissue formation was clearly observed after 14 days of culture with *Pueraria T.*, and the amount of mineralization increased in a dose-dependent manner. This study showed that *Pueraria T.* not affect on viability, but it enhanced ALP activity, VEGF, bone matrix proteins such as OCN, OPN and Col I, and mineralization in SaOS-2 cells. These results propose that *Pueraria T.* plays an important role in osteoblastic bone formation.

Effect of Statins on the *In Vitro* Differentiation of Human Bone Marrow Stromal Cells. K. László*, T. R. Meury*, M. Alini*. AO Research Institute, Davos, Switzerland.

Statins are inhibitors of 3-Hydroxy-3-Methylglutaryl Coenzyme A Reductase. They are known to decrease the amount of isoprenoids in the cell through the inhibition of mevalonate synthesis. Because of this statins are widely used in clinics to reduce the cholesterol level in blood. In addition, recent results suggest a possible role for statins in bone formation. The aim of this study was to evaluate the effect of three statins (lovastatin, simvastatin and pravastatin) on human bone marrow stromal cells (BMSC) differentiation into osteoblasts. The different statins were added to BMSCs and the differentiation process was followed by measuring different osteogenic markers (ALP, BMP-2, osterix and MMP-13). We also determined the DNA, ALP activity and Ca-45 incorporation into the mineralized matrix. Vital staining and apoptotic assays were also performed. In addition, BMSCs were cultured in osteogenic (containing dexamethasone as a positive control of the differentiation process) and non-osteogenic (without dexamethasone as a negative control) media. Our results show that at high concentrations (3 and 5 uM), lovastatin and simvastatin had a significant toxic effect on BMSCs, indicated by a drop in the DNA content and by a reduced number of adherent cells over time in culture. ALP gene expression was as well suppressed and no ALP activity could be measured. However, non-specific calcification was observed, indicating possible cells death. Interestingly, pravastatin showed no toxic effect at these concentrations, probably due to the lack of LST-1 anion transporter protein, which has been shown to be necessary for its internalization into hepatocytes. (D. Nakai et al., 2001) At lower concentrations (50 nM to 1 uM), statins did not show any adverse effect on BMSCs over three weeks of culture period, but at the same time, they also did not induce any osteogenic cell phenotype markers. Overall, these findings suggest that statins (lovastatin, simvastatin and pravastatin) do not play an essential role on human BMSCs differentiation into osteoblasts in vitro.

Functional Interaction between PKA and BMP Signaling during Osteogenic Differentiation of Human Mesenchymal Stem Cells. R. Siddappa*[1], C. Gaspar*[2], R. Fodde*[2], C. van Blitterswijk*[1], J. de Boer[1]. [1]Institute for Biomedical Technology,University of Twente, Prof Bronkhorstlaan10D, 3723MB, Bilthoven, The Netherlands, [2]Dept Of Pathalogy, Erasmus Medical Center, Rotterdam, The Netherlands.

We approach cell based bone tissue engineering by *in vitro* expansion and osteogenic differentiation of pluripotent human mesenchymal stem cells (hMSCs) isolated from bone marrow and subsequent seeding onto calcium phosphate ceramics. To optimise the osteogenic differentiation process we want to understand the molecular signalling pathways underlying differentiation of hMSCs into active osteoblast *in vitro* and *in vivo*. G protein coupled receptors (GPCR) are involved in bone formation. Therefore we investigated the role of GPCR signalling in hMSC osteogenesis. Short term PKA activation using cAMP or cholera toxin induced expression of the osteogenic markers alkaline phosphatase, osteocalcin, collagen type1 and it enhanced *in vitro* mineralization. Inhibition of PKA signalling with H89 reversed the cAMP and cholera toxin induced effects. Micro array studies on 6 hours cAMP treated hMSCs showed an up regulation of BMP target genes Id1, Id2, Id4 and Smad6, which was further confirmed by quantitative PCR. The PKA induced expression of BMP target genes was not inhibited by cycloheximide treatment indicating direct activation of BMP target genes via cyclic AMP response element binding protein (CREB). Micro array studies further show that hMSCs treated with cAMP for 7 days displayed a strong expression of a number of growth factors and cytokines with known osteogenic activity, including BMP2. Since we observed induction of BMP2 upon PKA activation, we tested autocrine induction of BMP target genes using noggin (an inhibitor of BMP signalling). Noggin partially inhibited PKA induced expression of BMP target genes, but reduced the BMP2 induced expression to the basal level confirming the autocrine effect. A similar effect was observed in MG63, a

human osteosarcoma cell line. We conclude that PKA activation in hMSCs not only directs the cells into the osteogenic lineage by direct induction of BMP target genes but also induces the expression of BMPs and other bone inducing cytokines. We currently investigate whether PKA activated hMSCs can stimulate uncommitted progenitor cells into the osteogenic lineage using *in vitro* and *in vivo* models. The functional interaction between PKA and BMP signalling pathways can be further explored to augment current bone tissue engineering protocols.

Identification and Functional Characterization of Fidgetin-Like 1 in MC3T3-E1 Cell. S. Kim*[1], S. Park*[2], S. Park*[1], J. An*[1], J. Byun*[1], D. Kim*[2], S. Lee*[2], Y. Rhee[2], S. Lim[2]. [1]Brain Korea 21 Project for Medical Sciences, College of Medicine, Yonsei Univ., Seoul, Republic of Korea, [2]Internal Medicine, College of Medicine, Yonsei Univ., Seoul, Republic of Korea.

The protein encoded by the fidgetin gene is a new member of the ATPases associated with diverse cellular activities (AAA proteins). The mouse fidget mutation is known to be associated with various skeletal abnormalities in affected mice. The purpose of this study was to determine the function of fidgetin-like 1, one of two closely related proteins, in osteoblast proliferation. We examined the effect of fidgetin-like 1 gene on proliferation, differentiation and apoptosis in MC3T3-E1 cells using flow cytometry, RT-PCR, cell proliferation assays (WST1 assay and FACS) and cell death assays (LDH assay and FACS).Microarray analysis revealed many genes up-regulated or down-regulated greater than twofold in MC3T3-E1 cells after cotreatment of bFGF and PTH compared to the genes regulated by bFGF alone (bFGF vs. bFGF + PTH). Fidgetin-like 1 is one of the genes up-regulated greater than twofold by cotreatment of bFGF and PTH. Fidgetin-like 1 encoding a polypeptide of 2,100 amino acids was obtained from a mouse muscle cell cDNA library. Expression of fidgetin-like 1 using RT-PCR analysis was increased by parathyroid hormone and bFGF, but decreased by bFGF only. Proliferation and apoptosis assay indicated that fidgetin-like 1 increased in osteoblast proliferation by promotion of S-phase, but osteoblast death was not affected by fidgetin-like 1($p<0.01$). In addition, RT-PCR analysis revealed that fidgetin-like 1 was equally expressed at all developmental stages from embryo day(E) 8.5 to embryo day(E)17.5 in mouse embryonic cell. We propose that fidgetin-like 1, a member of the AAA family protein, may play a regulatory role in cell proliferation during embryonic development. Further analyses of fidgetin-like 1 will be required to identify additional mechanism concerned in cell proliferation.

Altered Expression of Extracellular Matrix Genes in Demineralized Bone-Mediated Osteogenic Differentiation. S. Honsawek[1], L. Wolfinbarger[2]. [1]Biochemistry, Faculty of Medicine, Chulalongkorn University, Bangkok, Thailand, [2]LifeNet, Virginia Beach, VA, USA.

The osteoinductivity of bone-derived materials has been shown to play a crucial role in their ability to stimulate de novo bone formation. Demineralized bone matrices (DBM) have been used extensively for clinical repair of bone injuries and abnormalities, including nonunion fractures, bone cysts, and cranio-maxillofacial reconstructions. The objectives of this study were to determine whether DBM promote *in vitro* osteogenic differentiation of human periosteal cells and to identify genes whose expression was altered during osteogenesis. We illustrated that human periosteal cells cultured with DBM acquire the osteoblast phenotype and express alkaline phosphatase activity after 7 days. Macroarray analysis demonstrated altered expression of extracellular matrix genes during osteoinduction of human periosteal cells. DBM-treated periosteal cells revealed that biglycan was upregulated but collagen 14A1 was downregulated. Interestingly, TGF-β1 involved in the enhancement of the formation of extracellular matrix and inhibition of matrix degradation was also upregulated, including its receptor, TGF-βR1 following DBM treatment. In addition, reverse transcriptase-polymerase chain reaction (RT-PCR) analysis of selected genes at 0, 4, 7, 10, and 14 days showed different expression patterns for those extracellular matrix genes during osteogenesis. We found that biglycan was consistently upregulated whereas collagen 14A1 was downregulated and persisted for 14 days in DBM-induced osteogenic differentiation. Biglycan coding for extracellular matrix protein is a prominent osteoblastic marker that has previously been associated with the development and function of osteoblasts and has been shown to play an important role in the bone formation. In contrast, downregulation of the gene encoding for collagen14A1 might have implications during the process of bone development because collagen14A1 occurs in virtually every collagen I-containing tissue. Thus, the results of the present study suggest an induced osteoblast stage with a unique extracellular matrix gene expression that may contribute to a matrix supportive of osteogenesis by periosteal cells.

Canonical Wnt Signaling Is Inhibited by Tumor Necrosis Factor-α. X. Lu, L. C. Gilbert, J. Rubin, M. S. Nanes. Department of Medicine, Division of Endocrinology, Emory University and VA Medical Center, Atlanta, GA, USA.

Wnt signaling is required for differentiation of osteoblasts (OB), skeletal development, and fracture repair. Evidence supporting a role for Wnts derives from inherited mutations of the Wnt co-receptor LRP5 in humans and transgenic modification of components of the wnt canonical signal pathway (LRP5, APC, βcatenin). We have shown that the inflammatory cytokine tumor necrosis factor-α (TNF) inhibits OB differentiation by a mechanism that includes inhibition of expression of the transcription factors Runx2 and Osx. These transcription factors are critical for commitment of precursor cells to the OB phenotype. We hypothesized that the mechanism of TNF action could include inhibition of wnt signaling. To test this, we studied the effect of TNF on wnt-stimulated expression of Osx mRNA, activity of the Osx and RUNX2 promoters, and on wnt activation of the βcatenin-responsive reporter TOPFLASH. Transfection of C3H10T1/2 and MC3T3-E1 cells with a wnt-1 expression plasmid or treatment with conditioned medium from Lwnt3a cells increased Osx, Runx2, and TOPFLASH promoter activity 2, 19, and 9 fold, respectively. Simultaneous treatment with TNF inhibited the wnt-stimulated responses by 50%. Wnt-stimulated Osx mRNA, was also blocked by TNF. TNF inhibition of TOPFLASH suggested interference with the canonical wnt signaling pathway. Since Wnt stimulation promotes βcatenin nuclear entry, we measured the effect of TNF on accumulation of βcatenin in the nucleus of MC3T3-E1 cells by western analysis. TNF treatment inhibited βcatenin nuclear content while simultaneously increasing the entry of free NFκB. The level of RNA polymerase II, a control, was unchanged. Real Time RT-PCR did not reveal an effect of TNF on βcatenin mRNA suggesting that TNF affected βcatenin post-translationally, its transport into the nucleus, or its nuclear stability. To determine the signal pathway mediating TNF effects, specific inhibitors of MAPK were added prior to TNF treatment. TNF inhibition of wnt signaling and Osx promoter was abrogated by PD98059, a MEK1 inhibitor, but not by inhibitors of p38 or JNK. These results suggest that cytokine signal pathways may interact with the canonical Wnt pathway. Such an interaction could contribute to TNF inhibition of OB differentiation.

High Concentration of Serum Low-Density-Lipoprotein Inhibits Maturation of Osteoblast, Decreases Trabecular and End-Cortical Bone Formation, and Results in Osteopenia in Apolipoprotein E Knock-Out Mice Fed with High-Fat Diet. H. Hirasawa*[1], S. Tanaka*[1], A. Sakai[1], M. Tsutsui*[2], H. MIyata*[3], M. Ito[4], T. Nakamura[1]. [1]Dept. of Orthopaedic Surgery, University of Occupational and Environmental Health, Kitakyushu, Japan, [2]Dept. of Pharmacology, University of Occupational and Environmental Health,, Kitakyushu, Japan, [3]Laboratory Animal Reserch Center, University of Occupational and Environmental Health,, Kitakyushu, Japan, [4]Dept. of Radiology, Nagasaki University, Nagasaki, Japan.

Objective; To clarify whether high concentration of serum low-density-lipoprotein (LDL) regulates osteoblast differentiation and bone metabolism. Materials and Methods; 4-week-old male apolipoprotein E (apo-E) knock-out mice and littermates were given high-fat (groups ApoEHf and WildHf) or standard chaw (groups ApoES and WildS) for 12 weeks. At the age of 17 weeks, bilateral femurs, tibias, and lumbar vertebras were harvested, and serum and urine for 24 hours before sacrifice were collected. Assessments; Concentration of serum LDL and urinary deoxypiridinorine (D-pyr) were measured. Micro-CT at lumbar vertebra was analyzed. Bone histomorphometry at diaphysis and distal metaphysis of femur, and proximal tibia was perfomed. mRNA expressions in cortical bone and bone marrow adherent cells of femur were examined using quantitative RT-PCR. Results; Serum LDL levels in ApoEHf were the highest among the four groups, and followed by ApoES, WildHf, and WildS. The values of urinary D-pyr were increased in WildHf and ApoEHf. Trabecular bone volume in lumbar vertebra and cortical bone area of femoral mid-shaft were significantly decreased in ApoEHf compared with those in the other three groups. Bone formation rate in trabecular bone in femoral metaphysis and endosteum of femoral mid-shaft were decreased in ApoEHf. The values of bone formation rate in these areas revealed significant negative-correlation with serum LDL levels (R= -0.819, -0.834). Osteocalcin mRNA expressions in cortical bone in ApoEHf were the lowest, and followed by ApoES, WildHf, and WildS, and also negatively correlated with serum LDL levels (R=-0.761). Type 1a collagen (Col1a1) mRNA in bone marrow adherent cells was increased in ApoEHf, but osteocalcin was not increased. The ratio of Col1a1 to osteocalcin mRNA in adherent cells had significant positive-correlation with p53 mRNA expression (R= 0.849). Osteoclast surface in trabecular bone and eroded surface in endosteum were significantly increased in ApoEHf and WildHf. Conclusion; Serum LDL was related to inhibition of osteoblast maturation. High-fat diet resulted in osteopenia in association with the increase of bone absorption in Apo-E knock-out mice fed with high-fat diet.

Effects of Bisphosphonates on UMR-106 Cells Depend upon their Cultural Milieu. R. W. Katz[1], Q. Sun[2], J. P. Bilezikian[2]. [1]Oral Medicine, College of Dentistry, New York University, New York, NY, USA, [2]Division of Endocrinology, College of Physicians and Surgeons, Columbia University, New York, NY, USA.

Bisphosphonates (BPs) have had a major impact on the management of osteoporosis and other metabolic bone diseases. Previously, we have shown that BPs affect signaling pathways utilized by parathyroid hormone and that osteoblast cultures exposed to BPs in solution exhibit a reduced accumulation of total DNA. In this study, we determined the effects of BPs on cell growth and whether their physical adherence to calcium phosphate coated discs (CPdiscs) would change their actions to influence osteoblast characteristics. The amount of cellular DNA obtained from UMR-106 cultures was decreased significantly, compared to control values, when the cells were exposed to BPs in solution at concentrations greater than 1 uM. BPs were rendered adherent to CPdiscs by soaking them thoroughly before using them as a culture substrate for UMR-106 cells. Under these

conditions, BPs had a different effect, namely increasing total DNA at 1 uM. At this concentration in solution, BPs are associated with a reduction in total UMR-106 DNA. At higher concentrations, BPs on CPdiscs showed the same inhibitory effect on total DNA in UMR-106 cells as is seen with BPs in solution. To determine whether the inhibition of culture growth by BPs in solution was due to increased cell death, cell viability was examined by flow cytometry of propidium iodide exposed suspensions. Treatment with 100 uM BPs led to a 2-3 fold increase in the proportion of non-viable cells as compared to control cultures. Assessing cell proliferation through BrdU incorporation revealed no significant difference in DNA replication between control cultures and those exposed to 100 uM BPs. In summary, our results indicate that BPs affect osteoblast survival and cell accumulation in vitro; that there is a rather uniform inhibitory effect when UMR-106 cells are exposed to BPs in solution; but that when BPs are present on CP-discs, a direct stimulation can be observed at low concentrations. The effect of BPs appear to be directed towards cell viability, not cell proliferation. These results provide further evidence for a direct effect of BPs on osteoblasts, a heretofore unappreciated target cell for these compounds. Further studies are needed to understand by what mechanisms BPs affect osteoblast survival but the results reported here suggest that BPs adsorbed onto mineralized surfaces may affect osteoblast survival in a clinically significant manner.

Inhibition of Osteoblast Differentiation by TNF Requires Mitogen Activated Protein Kinase. L. C. Gilbert, X. Lu, J. Rubin, M. S. Nanes. Department of Medicine, Division of Endocrinology, Emory University, Atlanta, GA, USA.

Commitment of pluripotent precursor cells to the osteoblast (OB) lineage requires expression of the essential transcription factors Runx2 and Osx. We have shown that the inflammatory cytokine tumor necrosis factor-α (TNF) inhibits OB differentiation at an early stage in lineage commitment. Low doses of TNF (0.5 ng/ml) inhibit expression of Runx2 and Osx without decreasing cell viability. Here we investigate the role of TNF-stimulated mitogen activated protein kinase (MAPK) in the inhibition of differentiation using specific inhibitors of MEK1 (PD98059), JNK (SP600125), or p38 kinase (SB203580). Experiments were done using MC3T3-E1 cells cultured in the presence of ascorbate and βglycerophosphate. MAPK inhibitors were added on day 3 of culture prior to TNF (10 ng/ml) and the inhibitors and TNF were removed on day 6. Differentiation was assessed by measuring the phenotypic markers alkaline phosphatase, osteocalcin, and mineralization by alizarin red staining. In addition, Osx mRNA and basal promoter activity were measured by Real Time RT-PCR and transient transfection of an Osx-luciferase promoter construct. TNF inhibited alkaline phosphatase activity, osteocalcin secretion, and mineralization of cells. RUNX2 and Osx mRNA and promoter activity were potently inhibited by TNF. The MEK1 inhibitor abrogated TNF inhibition of alkaline phosphatase, osteocalcin, and mineralization in a dose dependent manner. These results were not observed using inhibitors of JNK or p38. The MEK1 inhibitor partially prevented TNF inhibition of Osx mRNA and Osx promoter activity but did not reverse TNF inhibition of RUNX2 mRNA or promoter activity. The dose of MEK1 inhibitor that restored the phenotypic markers of differentiation also blocked the rapid (5 and 10 minutes) TNF stimulated phosphorylation of ERK1/2 as seen on western analysis. Surprisingly, NFκB expression stimulated Osx mRNA and promoter activity, excluding NFκB as the mediator of TNF inhibition of Osx. These results show that TNF inhibition of OB differentiation requires activation of MAPK. The decrease in OB differentiation in the TNF excess states of inflammatory arthritis or estrogen deficiency could contribute to a blunted bone formation response.

PPAR-γ2 Nuclear Receptor Controls Multiple Regulatory Pathways of Osteoblast and Adipocyte Differentiation Including IGF-1 and TGF-β/ BMP Signaling. K. Shockley*[1], O. Lazarenko*[2], G. Churchill*[1], C. Ackert-Bicknell[1], C. Rosen[1], B. Lecka-Czernik[2]. [1]The Jackson Laboratories, Bar Harbor, ME, USA, [2]Geriatrics, UAMS, Little Rock, AR, USA.

PPAR-γ2 adipocyte-specific transcription factor controls marrow mesenchymal stem cell (mMSC) differentiation toward adipocytes and osteoblasts. *In vitro*, in a model of mMSC differentiation of U-33/γ2 cells, PPAR-γ2 activated with a specific agonist and anti-diabetic drug rosiglitazone (R) acts as a positive regulator of adipocyte and a dominant negative regulator of osteoblast development. In animal models, PPAR-γ2 activation with R leads to a significant bone loss. In order to determine the mechanisms by which PPAR-γ2 exerts anti-osteoblastic effects in mMSC we have performed a high throughput analysis of gene expression using microarray containing 40,000 murine transcripts. An experiment factorial design 2x3x2 corresponded to two cell lines (U-33/γ2 - with, and U-33/c - without PPAR-γ2), three time points of R treatment (2, 24, and 72 hr), and two independently performed experiments. The number of genes which expression was significantly affected in U-33/γ2 cells increased exponentially with a time of exposure to R resulting in 41 genes after 2 hr, 2,349 after 24 hr, and 6,501 after 72 hr ($q<0.01$). None of the analyzed genes was affected by R in U-33/c cells indicating that effects seen in U-33/γ2 are specific for PPAR-γ2. A pathway-specific correlation analysis identified several gene clusters, which function is essential for osteoblasts and adipocyte differentiation, and bone homeostasis. Significant changes in expression of cell proliferation and fatty acid metabolism regulators were among the earliest observed. These changes were followed by a suppression of osteoblast-specific gene markers essential for their development and function, among them transcriptional regulators such as Dlx5, Runx2, and Osterix. Most importantly, PPAR-γ2 had a pleiotropic effect on the expression of members of several signaling pathways controlling bone growth and remodeling, including IGF-1 and TGF-/βBMP. *Ex vivo* analysis of mMSC supported these findings and provided evidence that R-induced changes in the expression of cytokines, their receptors and cellular mediators of their activity corresponded to decreased functional activities of these pathways. In conclusion, our results clearly indicate that PPAR-γ2 is a major regulator of mMSC differentiation. They also provide information about hierarchical interactions between different regulatory pathways and may ultimately lead to the identification of a "master" regulatory mechanism by which PPAR-γ2 controls osteoblast differentiation.

Metabolic Regulation of Osteoblast Gene Expression and Differentiation. G. D. Gibson*, B. Bieber*, R. Irwin*, R. W. Wiseman*, L. R. McCabe. Departments of Physiology and Radiology, Michigan State University, East Lansing, MI, USA.

Osteoporosis can result from conditions that contribute to altered cellular metabolism such as age-related hormone deficiencies, limb disuse, and disease. This is particularly evident in diabetes type I where cells must adapt to conditions of hyperglycemia, hypertriglyceridemia and hypoinsulinemia. Moreover, differentiating osteoblasts undergo phenotypic changes in metabolism (Komarova, et al, 2000). Pre-osteoblasts display higher glycolytic activity, while mature osteoblasts exhibit increased mitochondrial oxidative phosphorylation. Based on these findings, we hypothesize that modulation of osteoblast metabolism alters osteoblast differentiation and gene expression. To test this hypothesis we treated MC3T3-E1 osteoblasts for 24 hours with inhibitors of glycolysis and in parallel experiments we also treated osteoblasts with inhibitors of oxidative phosphorylation. Glucose consumption, lactose production, cell viability, ATP and metabolite levels, and gene expression were measured. All treatments lead to significant changes in osteoblast gene expression. Irrespective of metabolic pathway manipulation, runx2 expression was suppressed in proliferating (day 3) and differentiating (day 14) osteoblasts. In contrast, alkaline phosphatase expression, a marker of osteoblast differentiation, was suppressed only by inhibition of oxidative phosphorylation and not by inhibition of glycolysis. These findings suggest that the metabolic fate of glucose may contribute to the regulation of osteoblast phenotype. The use of additional inhibitors and further monitoring of cellular metabolic status will help us to distinguish between specific effects of cellular ATP depletion and/or metabolic control of bone formation.

Analysis of Functional Knockdown of Rho Kinase Expression in Primary Osteoblasts by siRNA. A. Danikas*[1], A. Coudert*[1], E. Gurzov*[2], M. Izquierdo*[2], A. E. Grigoriadis[1]. [1]Dept Craniofacial Development, King's College London, London, United Kingdom, [2]Universidad Autonoma de Madrid, Madrid, Spain.

Rho family GTPases (Rho, Rac, cdc42) are molecular switches acting at the cell membrane which cycle between inactive, GDP-bound states, and active GTP-bound states. We have recently studied the role of the Rho GTPase in osteoblast differentiation using the unique bacterial protein toxin, Pasteurella Multocida Toxin (PMT). Addition of PMT to primary mouse calvarial osteoblasts results in cytoskeletal rearrangements and stress fibres due to activation of Rho and its downstream effector Rho kinase (ROCK). In primary calvarial cultures, PMT potently inhibited bone nodule formation as well as osteoblast marker gene expression and this inhibitory effect was reversed by addition of Rho and ROCK inhibitors. More importantly, addition of Rho/ROCK inhibitors alone to primary calvarial cultures stimulated bone nodule formation. These results suggested that the Rho/ ROCK pathway is a critical determinant of osteoblast differentiation and bone formation. To investigate further the role of ROCK in osteoblast differentiation, we are using a retroviral strategy to generate functional siRNA produced intracellularly using the pSUPERretro vector. We first determined which ROCK isoform was expressed, and Western blot analysis determined that both ROCK1 and ROCK2 were expressed in primary osteoblasts. Sequences specific for both ROCK1 and ROCK2 were identified and cloned into pSUPERretro, and the resulting vectors, pRETROCK1 and pRETROCK2 were transfected into Phoenix packaging cells. High titre viral supernatant was subsequently used to infect primary osteoblasts and Western blot analysis demonstrated that ROCK1 or ROCK2 protein levels were selectively reduced. To investigate whether the silencing of ROCK was functional, we analyzed cytoskeletal rearrangements. Preliminary results showed that inhibition of ROCK activity abolished stress fibre formation in osteoblasts. These specific siRNAs are currently being used in differentiation studies and ex vivo bone cultures to determine the effects of reduced ROCK levels on bone formation and expression of osteoblast marker genes. This effect, achieved by alteration of endogenous ROCK levels, will provide further evidence of the key role of the Rho-ROCK pathway in osteoblast differentiation.

Comparative Study of Human Fetal Osteoblast Long-Term Growth Dynamics in a Compartmentalized Bioreactor. X. Liu*[1], A. Tabakovic*[2], D. Ravi*[2], E. A. Vogler*[3]. [1]Bioengineering, Pennsylvania State University, University Park, PA, USA, [2]Materials Science and Engineering, Pennsylvania State University, University Park, PA, USA, [3]Bioengineering, Materials Science and Engineering, Pennsylvania State University, University Park, PA, USA.

Long-term (~30d) *in vitro* culturing of human fetal osteoblastic (hFOB 1.19, ATCC, CRL-11372) cells is studied in a compartmentalized bioreactor that employs the simultaneous cell-growth-and-dialysis principle[1] to confer extraordinarily stable culture environment that simulates the *in vivo* condition. hFOB growth dynamics, morphology, differentiation, and extracellular matrix (ECM) mineralization in the bioreactor are compared to that in conventional culture (tissue-culture grade polystyrene: TCPS) for 15 and 30 days. Results show that short-term cell adhesion and proliferation (assayed by hemacytometry) were relatively "slow (time-to-half-maximal adhesion)" and "low (percentage of inoculum)" in the bioreactor compared to relatively "fast" and "high" in TCPS. However, long-term cell densities (assayed by fluorescent staining) were approximately the same in the bioreactor and TCPS. Cells formed confluent, interconnecting multilayer at tissue-like density with distinct cytoplasmic processes and membranes in the bioreactor (relative to TCPS) as observed by SEM and TEM. Apoptosis (assayed by Terminal deoxynucleotidyl Transferase dUTP Nick End Labeling) for hFOB was 2~3x higher in TCPS compared to the bioreactor, possibly correlates with reduced production of insoluble ECM. Alkaline phosphatase (ALP) activity and Ca deposition were quantified with chromogenic assays, respectively. Significantly higher ALP level (6.6-fold) at day 15 and Ca content (1.7-fold) at day 30 in the bioreactor (relative to TCPS) indicate enhanced matrix mineralization due to increased osteoblast activity. Preliminary studies show that hFOB can sustain long-term *in vitro* culture in a compartmentalized bioreactor with superior cell performance relative to conventional culture. Thus, the bioreactor provides an ideal tool for assessing osteoblast-mediated mineralization *in vitro*, which is necessary toward both fuller understanding of bone pathology and development of advanced orthopedic biomaterials.

Polyphenol Extract from Dried Plum Dose-Dependently Increases Nodule Formation in MC3T3-E1 Osteoblast-Like Cells. L. L. Kamkar*[1], S. Hooshmand*[1], A. Soliman*[1], D. Y. Soung[1], J. K. Collins*[2], E. A. Lucas[1], S. V. Madihally*[3], B. H. Arjmandi[1]. [1]Nutritional Sciences, Oklahoma State University, Stillwater, OK, USA, [2]USDA ARS, South Central Agric. Lab, Lane, OK, USA, [3]Chemical Engineering, Oklahoma State University, Stillwater, OK, USA.

Our earlier findings indicate that dried plum is highly effective in preventing and/or reversing ovarian hormone deficiency-associated bone loss in a rat model of osteoporosis. Additionally, our short-term clinical trial results showed that dried plum supplementation significantly increased indices of bone formation in postmenopausal women. However, the question remains as to what component(s) of dried plum modulate bone metabolism. The present study investigated the role of polyphenol extract from dried plum in increasing bone mineralization using MC3T3-E1 osteoblast-like cells. Cells were treated with various doses of polyphenols (0, 0.5, 1, 10, 100, 1000 µg/ml). Medium were collected every three days and analyzed for alkaline phosphatase (ALP) activity, a marker of bone formation. After 14 days, the mineralized nodules were characterized by Alizarin red staining. ALP activity was higher at days six and nine but not thereafter. The reduced ALP activity towards the end may signal the completion of mineralization. Figure shows that dried plum polyphenols dose-dependently increased mineralization without affecting cell viability. In summary, the present preliminary findings suggest that polyphenol extract from dried plum is efficacious in increasing bone formation.

Regulation of Osteoblast Differentiation by the Retinoid Signaling Pathway. A. V. Sampaio*[1], R. A. Chandraratna*[2], T. M. Underhill[1]. [1]Cellular and Physiological Sciences, University of British Columbia, Vancouver, BC, Canada, [2]Vitae Pharmaceuticals, Inc., Irvine, CA, USA.

The active metabolite of vitamin A, retinoic acid (RA), has profound effects on skeletal development and remodeling. RA operates in a stage-dependent manner during skeletogenesis and hyper- and hypovitaminosis-A both result in skeletal abnormalities. RA exerts its pleiotropic effects by modulating the activity of the nuclear receptors for RA (RARs), which are ligand-inducible transcription factors. The negative effects of supra or super physiological levels of RA on the skeleton have been know for more than 70 years; however, the precise mechanisms underlying these actions remains unresolved. Herein, using pharmacological and molecular approaches, we demonstrate that antagonism of the RAR signaling pathway potently induces bone formation in primary osteoblastic cultures derived from rat calvaria (RC). Further, antagonism of RAR-mediated signaling rescues bone formation in "osteogenic-challenged" cultures (cells that have been maintained for 2 weeks at sub-confluence prior to plating under differentiation conditions). Inhibition of RAR-mediated signaling in these cultures increases alkaline phosphatase activity and restores bone nodule formation as determined by von Kossa staining. In unchallenged cultures, quantitative PCR demonstrated that RAR antagonism leads to increased expression of *integrin binding sialoprotein* (*Ibsp*) and *bone gamma-carboxyglutamate protein (Bglap2)* by ~ 47-fold and ~ 8-fold, respectively, in comparison to 20-day vehicle-treated cultures. Further, under these conditions, *Runx2* expression exhibits a modest increase of ~ 1.5 fold, whereas *Sp7* expression is elevated ~ 11-fold. In contrast, treatment of unchallenged RC cultures with RA leads to a dose-dependent decrease in osteogenic activity and decreased expression of the aforementioned genes. In this regard, even physiological concentrations of RA (10 nM) were found to cause an appreciable decrease in bone nodule formation. To further address the role of endogenous RA in osteogenesis, we measured the expression and manipulated the activity of the genes involved in RA synthesis (*Aldh1a2*) and degradation (*Cyp26a1*). Both *Aldh1a2* and *Cyp26a1* were expressed throughout the culture period and inhibition of their activity with diethylaminobenzaldehyde or ketoconazole, stimulated and inhibited bone nodule formation, respectively. Together, these findings reveal novel and unexpected roles for retinoid signaling in regulating osteoblast differentiation--abrogation of retinoid signaling is required for expression of the osteoblast phenotype.

Cell Cycle Regulation of Runx2 Activity Supports the Proliferative Stage of Osteoblast Growth and Differentiation in Osteoblasts. N. Teplyuk[1], M. Galindo*[1], X. Yang*[1], D. W. Young[1], H. Hovhannisyan*[1], M. Q. Hassan*[1], J. Pratap[1], J. Choi[2], M. Montecino[3], J. B. Lian[1], J. L. Stein*[1], G. S. Stein[1], A. J. van Wijnen[1]. [1]Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA, [2]Department of Biochemistry, Kyungpook National University School of Medicine, Daegu, Republic of Korea, [3]Departamento de Biologia Molecular, Universidad de Concepcion, Concepcion, Chile.

Genetic defects that cause human bone abnormalities may be due to alterations in osteogenic lineage commitment, regulatory mechanisms that control osteoblast cell number and/or the subsequent development of cells into mature osteocytes. While the bone-related transcription factor Runx2 is well known to control bone cell differentiation and osteoblast function, we recently discovered a novel regulatory function for Runx2 as a suppressor of osteoblast proliferation. Here we analyzed how cells control the growth inhibitory function of Runx2 during progression of the mitotic cell division cycle. MC3T3 osteoblastic cells were synchronized at different cell cycle stages and analyzed in parallel for multiple parameters of gene expression including western blot analysis, quantitative PCR, run-on analysis, genomic footprinting, chromatin immunoprecipitations and reporter gene assays. When quiescent osteoblasts are stimulated to proliferate by serum growth factors, we find that the levels of Runx2 gene transcription, mRNA and protein are each downregulated as cells initially enter the cell cycle and progress toward the G1/S phase transition. Transcriptional modulation involves increased occupancy of an AP1 (c-Fos/c-Jun) element within a distal suppressor segment of the Runx2 P1 promoter. Transcription may account for decreased accumulation of Runx2 mRNA at the G1/S phase transition. However, our data also indicate that Runx2 protein is actively destabilized in late G1 by a proteasome dependent (i.e., MG132 sensitive) mechanism. As cells progress towards mitosis, Runx2 transcription resumes and mRNA accumulates during the G2/M phases of the cell cycle. However, Runx2 protein levels in G2/M remain low independent of MG132, suggesting translational rather than stability control of Runx2 protein. Following mitosis Runx2 protein levels are acutely upregulated in G1 concomitant with modulations in the expression of cell cycle related Runx2 target genes that may support the Runx2 dependent attenuation of cell growth in G1. We propose that Runx2 levels and function are controlled during the cell cycle by multiple gene regulatory mechanisms (e.g., transcription/ promoter occupancy, protein stability and mRNA translation) to modulate the proliferative potential of osteoblasts.

Optimizing Bone Marrow-Derived Osteogenic Progenitor Cell Expansion Using the RepliCell™ Bioreactor System. J. E. Dennis[1], K. Renshaw*[2], A. Awadallah*[1], K. Goltry*[2]. [1]Biology, Case Western Reserve University, Cleveland, OH, USA, [2]Aastrom Biosciences, Inc., Ann Arbor, MI, USA.

The purpose of this study is to simplify and optimize the bioreactor process to produce osteogenic cells from human-derived bone marrow mononuclear cells (BMMNC). Human BMMNC aliquots were inoculated into AastromRepliCell® System (ARS) bioreactors and cultured for 12 days under different culture conditions, harvested, and combined with porous ceramics, implanted into SCID-17 mice, harvested 6 weeks later and evaluated for *in vivo* bone formation. Control Mesenchymal Stem Cells (MSCs) were obtained from the same donor, when possible, or were prepared from marrow obtained from University Hospitals of Cleveland (All procedures had Institutional Review Board approval) and were cultured under standard conditions. All RepliCell®-derived cells were evaluated for cells expressing Thy-1+, CD-166+, and CD-105+ cell surface markers by flow cytometry prior to *in vivo* osteogenesis assessment. The Total Cell Population (TCP) obtained by a standard trypsinization, and an Adherent Cell Population (ACP) obtained by trypsinization after non-adherent cell depletion were compared. TCPs and ACPs were tested at ceramic loading concentrations of 5, 10, 25, and 50 million cells per ml. Empty ceramics and MSC-loaded ceramics served as controls. A total of 12 mice were used in each experiment (N=6 for each TCP and ACP sample; N = 12 for negative and positive controls); implantation sites were randomized. Serial sections of implants were scored for bone on a scale of 0-5, under blinded conditions. The bone scores for ACP cells consistently showed higher bone scores than TCP cells (Figure 1). Next, TRC-1 medium (IMDM + 10% FBS, 10% horse serum, hydrocortisone, PIXY321 [an IL-3/GM-CSF fusion protein], erythropoietin, and flt3-ligand), and TRC-3 medium (TRC-1 without exogenous growth factors) were compared. The bone scores for the TRC-3 group (N=11, two donors) were consistently higher than those of the TRC-1 group. Based on these results, BMMNCs were cultured in TRC-3 and MSC conditions and compared side-by-side with the *in vivo* bone assay. The TRC-3 bone scores were indistinguishable from that of MSCs. In addition, flow cytometry data indicate that the *in vivo* bone scores correlate closely ($r^2 > 0.92$) with the cell surface markers Thy1, CD-166 and CD-105.

Bone Anabolic Effects of Inhibin A Are Not Mediated by Direct Effects of FSH and LH on Bone Marrow Cells. N. S. Akel, D. S. Perrien, K. M. Nicks*, D. Gaddy. Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Inhibin A (InhA) overexpression protects mice from hypogonadal bone loss via a mechanism that stimulates osteoblast activity and possibly differentiation, without effects on bone resorption. InhA is a known suppressor of pituitary follicle stimulating hormone (FSH) secretion, which occurs in this InhA overexpression model, and changes in serum FSH have previously been correlated with increases in bone turnover in peri-menopausal women. Therefore, the goal of the current study was to determine if osteoblast progenitors are directly responsive to FSH, which might play a role in mediating the anabolic effects of InhA *in vivo*. Our bigenic *Glvp/InhA* mouse model of mifepristone (MFP)-induced InhA overexpression was used. Placebo or MFP pellets were inserted in 6-month old intact mice to induce InhA overexpression, and bone marrow cells harvested after 1, 2, 3, and 4 weeks of control or InhA overexpression, as confirmed by ELISA. *Ex vivo* bone marrow cultures were initiated and cells cultured in osteogenic medium with or without 10 ng/ml of the pituitary hormones FSH, or luteinizing hormone (LH). At 10 and 28 days of culture, cells were harvested and stained and alkaline phosphatase positive (AP+) and Alizarin Red positive (CFU-OB) colonies determined, respectively. Following an initial suppression of AP+ colony development (45%) after 1 wk of *in vivo* InhA overexpression ($p<0.05$), AP+ colonies were significantly increased in response to *in vivo* InhA overexpression for 2, 3, or 4 weeks ($p<0.05$). AP+ colony formation in bone marrow cultures established from either placebo control animals or InhA overexprssing animals was unaffected by *in vitro* treatment with either FSH or LH. Similarly, InhA overexpression significantly increased *ex vivo* development of Alizarin Red + CFU-OB whereas FSH or LH treatment *in vitro* had no effect on CFU-OB development. To exclude the possibility that lack of FSH and LH responsiveness was unique to our InhA overexpression model, similar osteogenic bone marrow cultures were established from untreated adult Swiss-Webster mice. AP+ colony development was unaffected by treatment with either FSH or LH, compared with control osteogenic medium. Together, these data indicate that osteoblast progenitors are not direct targets of FSH or LH action, and suggest that the demonstrated anabolic effects of InhA are not mediated by direct action of pituitary FSH or LH on bone marrow progenitors. Instead, InhA anabolism may occur through increases in the commitment and/or proliferation of osteoblast progenitors.

Expression and Localization of Osteoactivin in Alveolar Bone Regeneration in Post-Extraction Healing Sockets in Normal and Diabetic Rat Model. R. A. Aswad*[1], M. C. Rico[1], H. Devlin*[2], S. N. Popoff[1], F. F. Safadi[1]. [1]Anatomy and Cell Biology, Temple University, Philadelphia, PA, USA, [2]Restorative Dentistry, Temple University , School of Dentistry, Philadelphia, PA, USA.

Delayed healing and impaired alveolar bone regeneration in post-extraction sockets is one of the complications in patients with type I diabetes. In our laboratory we previously showed using a fracture repair model that OA was highly expressed at sites of active osteogenesis. Furthermore, osteoactivin (OA) is known to play a critical role in osteoblast differentiation and function. In this study we investigated the expression and localization of OA during healing of extracted teeth sockets in normal and streptozotocin-induced diabetic rat. One week after the induction of diabetes, animals underwent the extraction of first and second right maxillary molars. Animals were then sacrificed at three, five, seven and ten days post-extraction and sockets were harvested for qPCR and immunohistochemical (IHC) analyses. RNA expression of OA and bone-related genes including alkaline phosphatase, type I collagen, osteocalcin and osteopontin determined by qPCR was significantly decreased in the diabetic sockets compared to control. IHC analysis showed OA expression was localized in osteoprogenitor cells and differentiating osteoblasts within the socket and the expression level was decreased in diabetic compared to normal rats. To further examine the effect of glucose treatment on OA expression in osteoblasts, an *in vitro* study was undertaken to support our *in vivo* results. Primary osteoblast cultures were established and treated with and without different concentrations of D-glucose. Glucose-treated cultures showed an increase in alkaline phosphates staining, nodule formation and calcium deposition compared to control cultures. Glucose treatment also decreased OA mRNA and protein expression determined by qPCR and Western blot analyses and this reduction was associated with a decrease in osteoblast-related genes. In addition cultures treated with OA recombinant protein seemed to rescue the effect of glucose treatment on osteoblast differentiation markers. Future studies will examine the mechanism of action of glucose treatment regulation on OA expression and its relation to osteoblast differentiation and function.

In Vitro **Proliferation and Differentiation Assays of Secreted Frizzled-Related Protein 3 (SFRP3) Transgenic Mice.** Y. Chung[1], H. Song*[1], E. Yu*[1], Y. Shen*[1], S. Ahn*[1], D. Kim*[1], K. Lee*[1], Y. Rhee*[2], S. Lim[2]. [1]Endocrinology, Ajou University School of Medicine, Suwon, Republic of Korea, [2]Endocrinology, Yonsei University College of Medicine, Seoul, Republic of Korea.

The authors reported previously that exogenous SFRP3 decreased proliferation and increased differentiation in osteoblast cell culture (J Bone Miner Res 19:1395-1402, 2004). Further studies with SFRP3 transgenic mice were conducted. Osteoblast-like cells were cultured from 12-week and 40-week-old transgenic mice. MTT assay was performed after 48 hrs of explant cell culture. Alkaline phosphatase activity was measured after 3 and 6 days of bone marrow stromal cell culture. Mineral nodules were counted after alizarin red-S stain with 30 days of bone marrow stromal cell culture with mineralization media including ascorbic acid and beta-glycerophosphate. There were no significant differences in cell numbers between 40-week-old wild and transgenic mice (0.110 vs. 0.098). Alkaline phosphatase activities were not significantly different between wild and transgenic mice of 12-week-old (50 vs. 54 mU/mg protein) and 40-week-old (448 vs. 541 mU/mg protein). Mineral nodule numbers were not different between 40-week-old wild and transgenic mice (45 vs. 43). In vitro cell proliferation and differentiation experiments of SFRP3 transgenic mice were not significantly different with wild mice of 12-week and 40-week-old age.

P2X7 Receptors Act through a Cell-autonomous and Cyclooxygenase-Dependent Mechanism to Stimulate Bone Formation. N. Panupinthu*[1], H. Z. Ke[2], S. M. Sims*[1], S. J. Dixon[1]. [1]CIHR Group in Skeletal Development and Remodeling, University of Western Ontario, London, ON, Canada, [2]Pfizer Global Research and Development, Groton, CT, USA.

Nucleotides are released in response to mechanical stimuli and can activate P2X7 receptors, ATP-gated ion channels present on osteoblasts, macrophages and osteoclasts. P2X7 receptor knockout (KO) mice display a skeletal phenotype involving decreased periosteal bone formation and increased trabecular bone resorption, but no change in longitudinal bone growth (Mol. Endocrinol. 17: 1356-67, 2003). Our purpose was to investigate the mechanism through which P2X7 receptors influence bone formation. Cells were isolated from the calvariae of newborn rats and mice by sequential collagenase digestion. Approximately 40% of cells in these osteoblast-enriched cultures were found to express functional P2X7 receptors using a pore formation assay. After reaching confluence, cultures were supplemented with ascorbic acid (50 μg/ml) and β-glycerophosphate (2 mM) to induce nodule formation. Cells expressing P2X7 receptors were found to be associated with bone nodules. Alkaline phosphatase (AP) activity and mineral deposition were quantified by digital image analysis. Mineralization in cultures of cells isolated from P2X7 KO mice was markedly reduced compared to wild-type (WT). At day 21, mineralized area in KO cells was approximately half that in WT, with no difference in AP-positive area. Furthermore, benzoylbenzoyl-ATP (BzATP, a relatively potent P2X7 receptor agonist, 100 μM) promoted mineralization in rat calvarial cell cultures (BzATP induced an 80% increase in mineralized area at day 21). Since BzATP activates several P2 receptors in addition to P2X7, we examined the effect of UTP, which activates a number of P2Y receptors but not P2X7. In contrast to BzATP, neither UTP (100 μM) nor inorganic phosphate (300 μM) affected mineralization at day 21. These data indicate that nucleotides act specifically via P2X7 receptors on osteoblastic cells to promote bone formation. Next we investigated underlying signaling pathways. We have shown previously that P2X7 receptors couple to activation of phospholipase A2, leading to dynamic membrane blebbing of undifferentiated calvarial cells. In rat calvarial cell cultures, inhibition of cyclooxygenases by ibuprofen (10 μM) abolished the stimulatory effect of BzATP on bone formation without affecting mineralization in control cultures. Taken together, these data establish that P2X7 receptors act through a cell-autonomous, cyclooxygenase-dependent mechanism to enhance bone formation. Thus, nucleotides released in response to mechanical stimuli may act through P2X7 receptors to stimulate osteogenesis.

Necessity of Immune Recognition and Control of a Human Organ Stem Cell Circulating in Blood as a Monocyte, in Order to Avoir Proliferating Diseases. Consequences in Term of Transplantation. M. Labat[1], G. Mouthon*[2], F. Escaig*[2], P. Boireau*[3]. [1]Life Sciences, CNRS, Maisons-Alfort, France, [2]Chimie Physique, ENVA, Maisons-Alfort, France, [3]UMR 956, INRA/AFSSA/ENVA, Maisons-Alfort, France.

The aim is the study of the control circulating organ stem cells that are normally almost quiescent but may proliferate, migrate and differentiate in order to participate in tissue repair. Such powerful cells have to be tightly controlled in order to avoid fibrosis and/or malignancies. Organ stem cells are characterized by immunofluorescence and their destruction by phagic T lymphocytes (PTLs) is studied by time-lapse microcinematography. Organ stem cells circulate under the appearance of monocyte that constitutively express HLA-DR molecules.Spontaneous expression of neuronal markers favors a neural crest origin. Once they started to differentiate after the adhere to the support in vitro, the became both the activators and the targets of PTLs that penetrate and circulate inside these stem cells, under complete destruction of the latter. It is a beneficial exception to the principle of self-tolerance that avoids their accumulation out of a precise repair purpose. Contrarily, in disorders suche as fibrosis and malignancies (chondrosarcoma), clones of organ stem cells proliferate indifinitely, escape destruction by PTLs and as a consequence, accumulate, giving rise to a 'tissue' that evokes the disorder of the patient. In vivo, this control probably takes place at the capillary-tissue.interface. Failure in the control of circulating stem cells is involved in the early steps leading to fibrosis and malignancy. Therefore, in term of transplantation, to avoid such disorders, the host has to be able to control the grafted organ stem cells. Transplantation rules for stem cells differ from those for specialized cells: although they are not rejected when transplanted into a mismatching host, transplanted organ stem cells have to be of the same tissue type as the recipient, in order to allow their control.

This work was supported by a grant from Foundation Jerôme Lejeune.

Effects of Wnts on Colony Formation and Proliferation in Human Connective Tissue Progenitor Cells. R. Rakos*[1], C. Boehm*[2], J. Tao*[2], K. Powell*[2], G. F. Muschler[3], S. Villarruel*[2]. [1]Department of Biomedical Engineering, Cleveland Clinic Foundation and Hathaway Brown School, Cleveland, OH, USA, [2]Biomedical Engineering, Cleveland Clinic Foundation, Cleveland, OH, USA, [3]Orthopaedics and Biomedical Engineering, Cleveland Clinic Foundation, Cleveland, OH, USA.

Connective Tissue Progenitor cells (CTPs) are capable of developing into a variety of tissues including bone, cartilage, fat, and muscle. Optimal assay and use of CTPs in therapeutic applications requires improved characterization CTPs from human tissues and their response to mediators of proliferation and differentiation. Wnt signaling is an important regulator of these events. Wnt proteins bind to transmembrane Frizzled receptors, preventing GSK-3β driven phosphorylation of β-catenin and its subsequent degradation. Wnts: 6,7a, 8b, and 10a are present in SW480 conditioned media. This study assessed the response of CTPs to these exogenous Wnts using a new quantitative colony-forming unit assay strategy. Human marrow-derived CTPs were cultured for 9-days, under increasing doses of SW480 conditioned media (CM) (0% to 100%). Colony formation as a cell level was assessed using quantitative image analysis of DAPI stained colonies. Large field of view (FOV) images (2x2cm^2) were created using a digital camera/motorized microscope controlled by Metamorph. Image analysis algorithms were developed using C/C++ in a Motif X-Windows TM environment. In eleven patient donors, a total of 3,564 colonies containing 1,279,826 total cells were assayed. Colony formation and proliferation were both Wnts signaling dependent, but affected at different dose ranges. Maximum colony formation occurred at 40%CM, and was dramatically reduced at CM ≥ 80%. In contrast, proliferation (cells per colony) decreased progressively with increasing CM. CM ≥80% s produced a majority of small colonies (16-128 cells), where as, 0%CM-20%CM primarily produced large (512-2048) cell colonies. Colony area also decreased 10-fold between 0%CM and 100%CM. These data demonstrate the robust potential for large FOV colony level quantitative image analysis in identifying independent effects of Wnt and other exogenous factors on CTP activation, proliferation, migration and differentiation.

The Effect of Secreted Frizzled-Related Protein 3 (sFRP3) Over-Expression on Bone Metabolism. Y. Rhee[1], S. Park*[1], J. Lee*[1], J. Byun*[2], Y. Chung[3], S. Lim[1]. [1]Internal Medicine, College of Medicine, Yonsei Univ., Seoul, Republic of Korea, [2]Brain Korea 21 Project for Medical Sciences, College of Medicine, Yonsei Univ., Seoul, Republic of Korea, [3]Internal Medicine, Ajou University School of Medicine, Suwon, Republic of Korea.

sFRP3 is known to have a strong influence on limb skeletogenesis. *In vitro* treatment of sFRP3 inhibited the proliferation of the primary cultured osteoblasts and surprisingly accelerated the differentiation of these cells. Therefore, to see the *in vivo* effect of sFRP3 over-expression, we generated sFRP3 transgenic mice. After testing the sFRP3 gene construct in vitro as to secreting the sFRP3 protein, the gene was integrated into C57BL6 mice. The COL1A1 promoter(2.3kB) was used for the gene to be specifically expressed in the osteoblasts. The 3 generation with sFRP3 over-expression confirmed by PCR & Southern blot generation was breeded. The mice with various ages from the most successfully breeded generation were tested. The whole body densitometry by PIXIMUS(Lunar, USA) was compared(Figure 1). There were tendency of Tg mice to be in the lower level of BMD throughout the ages with no statistically significant differences between the wildtype and the Tg mice. Some of these mice were assessed by the microcomputed tomography (Skyscan) of L2 vertebrae without any differences between two groups. However, 20 male mice and 10 female mice which were grew for another 4 months showed an interesting change. There was significantly more increase in the BMD of the Tg female mice(11%) compared with Wt mice(6%) with no differences in the male mice group. Additional result of the response to the anabolic agent is being tested and will

be addressed. In conclusion, it seemed that sole over-expression of sFRP3 was not enough to see the effect of modifying the wnt pathway to find specific phenotype. However, according to an accelerated differentiation *in vitro* might well be adapted to interpret the higher increase in the gain of BMD during the normal growth period in the female sFRP3 Tg mice.

Nitrogen-Containing Bisphosphonates Activate Purinergic Receptor Signalling and Induce the Expression of Hsp90/Hsp47 in Osteoblast Cell Lines. G. Tell*[1], M. Romanello*[2], N. Bivi*[1], A. Pines*[2], D. de Feo[3], L. Moro*[1]. [1]Biomedical Science and Technology, Udine University, Udine, Italy, [2]Biochemistry, Center for the Study of Metabolic Bone Diseases, Trieste University, Trieste, Italy, [3]Procter & Gamble, Rome, Italy.

The reduction in fracture risk with bisphosphonate (BP) treatment cannot be explained by the increase in BMD alone, and beneficial effects on other aspects of bone quality need to be considered. BPs prevent osteoblast apoptosis by a mechanism involving extracellular signal-regulated kinase (ERK) activation, but whether this has a role in BP effects on bone formation and bone quality in vivo is unclear. We investigated the hypothesis that this effect on osteoblasts is mediated through cellular membrane purinergic receptors, which based on recent data might provide a link to control of collagen structure and thus to bone quality. The existence of possible cross-talk between BPs and purinergic receptor signalling might be expected since both nucleotide triphosphates and BPs have a high negative charge. In previous work we demonstrated that in response to mechanical stress, osteoblasts release ATP via a non-lytic mechanism. In addition, extracellular nucleotides exert stimulatory effects on osteoblasts via the P2 family of membrane-bound receptors that comprise P2Y (G-protein-coupled) and P2X (ligand-gated ion channel) receptors, by acting on Egr-1 and Runx2 transcription factors (Pines et al. Biochem. J. 2003 373: 815-824; Costessi et al., Bone 2005 36 418-432). In this study in co-stimulatory experiments on different osteoblast-like cells (HOBIT, MG-63, ROS17/2.8, Saos-2), we found that purinergic signaling was activated by direct and indirect BP (10^{-7}M) induction of ERKs phosphorylation. Both risedronate and alendronate significantly promoted non-lytic ATP extrusion. The BP-induced ERK-1/2 phosphorylation was partially blocked by pretreatment of the cells with the ATP/ADPase apyrase. In addition, BP-induced ERK phosphorylation was not seen in the ROS17/2.8 cell line not expressing P2Y1 and P2Y2 receptors, and was blocked by suramin. These data support a primary role for P2Y receptors in mediating the BP activation of ERK and ERK phosphorylation. The relevance of these observations is significant in light of recent data showing that the expression of chaperonin is a target of purinergic signalling. In fact, both Hsp90beta protein, which has a protective and mitogenic roles, and Hsp47 protein, which is strongly involved in the control of collagen folding and therefore on the quality of collagen fibril, are stimulated by BPs. Thus these data provide a new explanation for a molecular mechanism of BP action which may ultimately result in effects on bone quality.

Activation of p38 MAP Kinase Mediates Induction of Prostaglandin Synthesis and Bone Resorption by Metabolic Acidosis. N. S. Krieger, K. LaPlante*, J. Sullivan*, D. A. Bushinsky. Medicine, University of Rochester, Rochester, NY, USA.

Chronic metabolic acidosis stimulates net calcium (Ca) efflux from bone by modulation of osteoblastic activity leading to stimulation of osteoclastic bone resorption. This acid-induced bone resorption is mediated, in large part, by stimulation of osteoblastic cyclooxygenase 2 (COX2) mRNA and subsequent prostaglandin E2 (PGE2) synthesis; however, the initial signaling pathway(s) activated by acidosis in the osteoblast are not known. Activation of p38 MAP kinase (p38) has been shown to regulate COX2 and subsequent PGE2 production. We utilized a specific inhibitor of p38, SB203580 (SB), to determine the role of p38 in acid-induced stimulation of PGE2 synthesis and bone resorption. We incubated neonatal mouse calvariae for 48 h in neutral pH (pH=7.45, [HCO3-] =24 mM, Ntl) or physiologically acid pH (pH=7.19, [HCO3-]=12 mM, Acid) medium in the absence or presence of 10 M SB. SB significantly inhibited the acid-induced increase in PGE2 production and net Ca efflux at both 24 and 48h (Table, below). P38 is activated by phosphorylation. To determine if there is also an increase in phosphorylated p38 (phos-p38) in response to acid, we measured changes in phos-p38 compared to total p38 levels in primary cells isolated from calvariae, which are almost exclusively osteoblasts. Cells were made quiescent by overnight incubation in Ntl medium in the absence of serum and then incubated in Ntl or Acid medium each containing 1% serum. Cells were lysed in the presence of phosphatase inhibitors followed by Western analysis using a specific antibody to phos-p38; blots were reprobed with an antibody to total p38 to normalize data. Compared to incubation in Ntl medium, incubation in Acid led to a significant increase in the ratio of phos-p38 to total p38 within 1 min (Ntl= 100%+3; Acid = 139%+9, $p<0.05$). Thus acid-induced activation of p38 appears to be an integral signaling step leading to induction of COX2 mRNA and subsequent PGE2 production in the osteoblast, ultimately resulting in increased osteoclastic bone resorption.

@ 48h	Ntl	Acid	Ntl + SB	Acid + SB

Differentiation Switch of Mesenchymal Stem Cells through Suppression of PPARgamma Function by NLK. I. Takada*, M. Suzawa*, S. Takezawa*, Y. Yogiashi*, Y. Mezaki*, M. Igarashi*, S. Kato. Nuclear signalling, Institute of Molecular and Cellular Bioscience, University of Tokyo, Tokyo, Japan.

Pluripotent mesenchymal stem cells in bone marrow differentiate into osteoblasts, adipocytes and the other cells. Balanced cytodifferentiation of stem cells is essential for the formation and maintenance of bone formation, however the mechanism of these differentiation switch is largely unknown. Recently, several factors controling these cytodifferentiation have been identified. Among them, PPARgamma is known as a major inducer of adipogenesis. PPARgamma is a ligand-dependent nuclear receptor and activated by fatty acid derivatives and synthetic compounds such as the TZDs. In addition, several cytokine signals are known to modulate the transactivation function of PPARgamma in a ligand-independent manner. We previously found that TAK1-NIK/NFkappaB signaling activated by IL-1 or TNFalpha, strongly suppressed the ligand-dependent transactivation function of PPARgamma and inhibited adipogenesis of bone marrow mesenchyamal stem cells (Suzawa, et al., Nat. Cell Biol. 2003, 224-230). Interestingly, PPARgamma ligand togather with IL-1 or TNFalpha potentiate differentiation of ST2 cells into osteoblasts. These results raised the possibility that the transactivation function of PPARgamma might be suppressed by other signlaing molecules. To identify such factors, we examined the transcriptional activity of PPARgamma in ST2 cells using a reporter assay and found that NLK(Nemo Like Kinase), which is a MAP kinase like protein, suppressed the transactivation function of PPARgamma. NLK is activated by Wnt or TGFbeta through CaMKII-TAK1/TAB2 cascade and we confirmed that these signaling cascade also suppressed the PPARgamma function. We then elucidated molecular mechanism of this repression and found that the C-terminal region of NLK is required for repression activity. We have established the HeLa cells stably expressing Flag-NLK and purified a number of NLK interacting proteins from these cells. As a result, we identified NLK interacting proteins and found that histone modification played a significant role in the repression of PPARgamma function by NLK. Thus, we found that suppressive PPARgamma function by activated NLK is involved in differentiation switch of mesenchymal stem cells into osteoblastgenesis.

Adenosine Receptor Expression by MC3T3-E1 Osteoblasts. J. M. Russell*, H. P. Benton*. VM:Anatomy, Physiology and Cell Biology, University of California, Davis, CA, USA.

Extracellular purine and pyramidine nucleotides and nucleosides signal through two classes of purine receptors: P1 which primarily recognize adenosine and P2 which primarily recognize ATP and related molecules. Interest is growing in the role of ATP in bone metabolism via P2 receptors but the P1 receptor class has not yet been explored in bone cells. The purpose of this study was to determine whether osteoblast cells express members of the P1 purine receptor class (A1, A2a, A2b, A3) that bind adenosine. MC3T3-E1 (clone 14) cells were grown in alpha minimal essential medium with 10% FCS and antimicrobial agents. Total RNA was isolated (RNeasy mini kit, Qiagen, Inc) and P1 adenosine receptor transcripts were reverse transcribed and then amplified (ONEstep RT-PCR, Qiagen). Receptor protein expression was investigated using receptor sub-type specific polyclonal antibodies (Abcam, Inc) for immunostaining of cells cultured on glass coverslips. Using gene specific primers for the A1, A2a and A2b receptor gene transcripts, RT-PCR produced a single band, as resolved by gel electrophoresis. Identity of each band was confirmed by sequencing. Using gene specific primers for the A3 receptor gene transcript, multiple bands were observed along with the expected product, suggesting the presence of multiple isoforms. By immunofluorescence, all four known adenosine receptor sub-types were identified on the osteoblast cell surface. The P2 receptors that recognize ATP are G protein-linked calcium mobilizing receptors whereas the P1 adenosine receptors are all linked to adenylate cyclase with the A2a and A2b receptors stimulating cAMP via Gs and the A1 and A3 receptors inhibiting cAMP via Gi, resulting in protein kinase A (PKA) activation or inhibition. It is well accepted that the cAMP-linked pathways, through which adenosine receptors are known to act, are essential for regulating bone metabolism. For example, PTH is a major player in the regulation of osteoblast function and many of the actions of this hormone are known to be PKA-dependent. Our results identifying adenosine receptors on osteoblasts indicate that manipulation of this class of receptors, using receptor specific agonists and antagonists, may represent a novel mechanism through which PKA-dependent osteoblast responses can be manipulated.

Endothelin-1 Stimulates Bone Formation by Regulating Osteoblast Secretion of the Paracrine Regulators IL-6, Cyr61, CTGF and Dkk1. G. A. Clines, K. S. Mohammad, L. L. Wessner*, J. M. Chirgwin, T. A. Guise. Internal Medicine, University of Virginia, Charlottesville, VA, USA.

Endothelin-1 (ET-1) secreted by breast and prostate cancers activates the endothelin A receptor (ETAR) on osteoblasts, leading to cellular proliferation and new bone formation. ETAR blockade inhibits osteoblastic responses and prevents the development of bone metastases in an animal model. This treatment also reduces progression of bone metastases in men with advanced prostate cancer. Targets of ET-1 action in osteoblasts were identified by gene microarray analysis of murine calvarial organ cultures and confirmed by real-time RT PCR of primary osteoblast cultures. We focused on secreted factors with potential

effects on bone. Transcripts for interleukin-6 (IL-6) and two related proteins, cysteine-rich protein 61 (Cyr61) and connective tissue growth factor (CTGF) were increased within one hour of ET-1 treatment. Messenger RNA for the Wnt inhibitor dickkopf homolog 1 (Dkk1) was decreased by 24 hours. These effects of ET-1 on osteoblast transcription were blocked by an antagonist selective for the ETAR receptor, but not by one selective for the endothelin B receptor. IL-6 has complex effects on bone, while CTGF is an established stimulator of osteoblast proliferation and bone formation. We concentrated on the less-understood roles of Dkk1 and Cyr61. Recombinant Dkk1 blocked ET-1-mediated increases in osteoblast numbers and new bone formation in calvarial organ cultures but did not suppress basal levels of new bone formation. Dkk1 also blocked the actions of two other osteoblast stimuli, insulin and BMP2. Conversely, Dkk1 neutralizing antibodies markedly increased osteoblast numbers and new bone formation. These data suggest that ET-1 acts on osteoblasts via a common Dkk1 inhibitory pathway through which multiple factors regulate new bone formation. Cyr61 and CTGF are expressed in the developing skeleton, but an action of Cyr61 on osteoblasts has not been reported. Human Cyr61 protein expressed under control of the CMV promoter was delivered to calvarial organ cultures by transduction with a lentiviral vector for 48 hours. Cyr61 lentivirus resulted in significant new bone formation (10,700 μm^2) equivalent to positive control, compared to control beta-galactosidase lentivirus or untreated control calvariae (5,200 μm^2) ($p<0.01$). Our results suggest that ET-1 stimulates new bone formation by inducing osteoblast expression of paracrine factors. The negative regulator Dkk1 may be a common mediator of many bone anabolic agents, while Cyr61 and CTGF may be positive paracrine stimulators of bone in response to tumor-secreted ET-1.

IGF-1 Stimulated beta3 Integrin Recruitment Is Associated with Potentiation of the IGF-1 Receptor. R. K. Long*, S. Nishida, D. D. Bikle. Endocrine Unit, University of California, Veterans Affairs Medical Center, San Francisco, CA, USA.

Recent studies have demonstrated an interaction between the IGF-1 and integrin signaling pathways in osteoblasts. Skeletal unloading by hind limb suspension of rats causes IGF-1 resistance by blunting IGF-1 receptor phosphorylation following IGF-1 binding. Bone marrow stromal cells (BMSC) from these unloaded limbs demonstrate a decreased expression of the beta3 integrin subunit. Echistatin, an alphaVbeta3 integrin blocker, when added to BMSC, recapitulates the IGF-1 resistant state of unloading suggesting a role for alphaVbeta3 integrin in IGF-1 signaling in rats. The role of the beta3 integrin subunit in IGF-1 signaling of human osteoblasts was evaluated. Human fetal osteoblasts (ATCC hFOB 1.19) were grown to confluence. Cells were transitioned to a non-proliferative environment, serum free at 37 degree C, for various periods of time and treated with IGF-1 (100 ng/mL) or vehicle for 10 minutes. Binding of beta3 integrin subunit to the IGF-1 receptor and its activation by IGF-1 were evaluated by immunoprecipation and immunobloting. Activation of the hFOB IGF-1 receptor in response to IGF-1 treatment as assessed by its tyrosine phosphorylation increases as a function of time in culture in a non-proliferative environment. This increased activation of the IGF-1 receptor is accompanied by a coincidental increase in the amount of beta3 integrin subunit bound to the IGF-1 receptor. In addition, IGF-1 treatment further increased the amount of beta3 integrin subunit bound to the IGF-1 receptor. The correlation between increased intensity of IGF-1 receptor phosphorylation and increased amount of IGF-1 receptor bound beta3 integrin subunit suggests a regulatory role for the integrin subunit in IGF-1 signaling pathway in human osteoblasts. The increase in beta3 integrin binding to the IGF-1 receptor in response to IGF-1 illustrates an "inside-out" activation of integrin signaling. The binding of the beta3 integrin subunit in turn may potentiate the "outside-in" activation of the IGF-1 receptor by IGF-1.

Bone and Cartilage Stimulating Peptides (BCSP) "Superactivate" Osteoblast-Like Cell Lines to Increase Adhesion on Collagen Substrates. J. W. Terryberry*, J. Auluck*, D. R. Sindrey. Millenium Biologix Corp., Mississauga, ON, Canada.

Several collagen-derived fragments and peptides have been shown to exert various effects on cell migration, proliferation and differentiation. Some cryptic and exposed sequences in collagen I provide ligand binding sites for a spectrum of integrins, including $\alpha1\beta1$, $\alpha2\beta1$, $\alpha9\beta1$, $\alpha11\beta1$ and $\alpha IIb\beta3$. Bone and Cartilage Stimulating Peptides (BCSP™) are matricryptic peptides found in collagen I (procollagen 1A1 1156-1174). We compared their effects in a standardized cell adhesion assay to other non-overlapping sequences reported in the literature to exert effects on integrin binding and/or osteoblast-like cell adhesion. Peptides were tested for inhibitory or activating activity using collagen substrates coated onto microtiter plates, in conjunction with two human osteoblast cell lines: MG-63 ($\alpha2\beta1$ integrin-dominant) and SAOS-2 ($\alpha1\beta1$ integrin-dominant). Cumulative results indicated that BCSP-1, -12, and -21 caused significant ($p<0.05$) increases in the adhesion of SAOS-2 cells to collagen at doses of 0.2-2.0 μM. Superactivation, defined as the ability of a ligand to promote receptor binding, was greatest for BCSP-1 and -12 ligands facilitating the binding of SAOS-2 cells to rat tail collagen I substrate. Less dramatic activating effects were seen with MG-63 suggesting that the BCSP sequence exhibits preferential partial agonist activation of $\alpha1\beta1$ integrin. Control peptides "P-15" (PepGen, procollagen 1A1 947-961) and KTTKS (procollagen 1A1 1430-1435) were without any activating or inhibitory effects on cell adhesion; whereas the $\alpha2\beta1$ integrin-binding sequence DGEA (procollagen 1A1 232-235) demonstrated significant inhibitory antagonistic effects at high doses (>100 μM). A Newman-Keuls multiple comparisons test revealed that dose responses to all 3 BCSPs were significantly ($p<0.001$) different than that obtained for DGEA. Moreover, the RGD peptide GRGDSPK inhibited adhesion at doses > 1 μM, indicating that it too was a functional antagonist as opposed to BCSP's agonistic effect. These findings demonstrate that BCSP ligands have significant osteoinductive potential at physiological doses, whereby they activate osteoblast like cells to adhere to the extracellular matrix in what is likely to be an integrin-mediated allosteric mechanism. This is in contrast to the effects of DGEA and RGD peptides which act as integrin-binding competitive substrates rather than ligands that conformationally activate the receptor from a low affinity to a high affinity state. Further studies are in progress to determine the binding parameters of BCSPs to purified integrins and recombinant ligand-binding (inserted) domains.

Wnts Suppress Osteoclast Survival and Formation and Prevent Apoptosis of Uncommitted Osteoblast Progenitors and Osteoblasts by β-Catenin-Dependent as well as Independent Signaling Cascades Involving Src/ERK and PI3K/Akt. M. Almeida, L. Han, A. Warren*, T. Bellido, S. C. Manolagas, S. Kousteni. Div. Endocrinol., Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. Arkansas Med. Sci., Little Rock, AR, USA.

Murine models with mutations in LRP5 and secreted Frizzled-related protein-1 have revealed an involvement of Wnt signaling in the control of osteoblast apoptosis. Based on this, we examined the ability of canonical and non-canonical Wnts to affect the survival and/or formation of bone cells. We have found that in cultures of the uncommitted cell line C2C12, the pre-osteoblastic cell line MC3T3-E1, or the MLO-Y4 osteocytic cell line serum withdrawal from the culture medium or etoposide induced apoptosis within 6 hours, which could be reversed by the addition of purified Wnt3a protein or transfection of a Wnt1 expression plasmid. Importantly, MC3T3-E1 cells transfected with an expression plasmid for the non-canonical Wnt5a were also protected from apoptosis. In MC3T3-E1 cells, Wnt3a induced a rapid (within 2 min) and transient phosphorylation/nuclear accumulation of ERKs as well as phosphorylation of Akt. However, Dkk1, an inhibitor of Wnt signaling, did not affect Wnt3a-induced phosphorylation of ERKs or Akt indicating that the kinase-activating actions of Wnt3a do not involve LRP5 and canonical Wnt signaling. Further, the anti-apoptotic effects of both Wnt3a or Wnt5a was abrogated by dominant negative mutants of MEK, Src, PI3K, or Akt. On the other hand, transfection of MC3T3-E1 cells with Dkk1, axin or a dominant negative TCF, abrogated the anti-apoptotic effect of Wnt3a, but did not interfere with the effect of Wnt5a. Nonetheless, activation of canonical Wnt signaling by itself was not sufficient to promote survival as constitutive active β-catenin did not rescue cells from apoptosis. Further, Wnt3a induced phosphorylation of the GSK-3, and increased the expression of the anti-apoptotic protein Bcl-2 in MC3T3-E1 cells; both of these effects were inhibited by the MEK kinase-specific inhibitor PD98059. In contrast to its protective actions on osteoblast precursors and osteoblastic cells, Wnt3a promoted apoptosis of mature bone marrow-derived osteoclasts and suppressed osteoclastogenesis in the presence of 30 ng/ml RANKL and M-CSF. These results demonstrate that irrespective of their ability to activate the canonical pathway, Wnts prolong the survival of osteoblasts, osteocytes, and uncommitted osteoblast progenitors via activation of the Src/ERK and PI3K/Akt signaling cascades. Conversely, Wnt signaling promotes apoptosis of osteoclasts and suppresses osteoclast formation.

Modulation of Connexin43 Alters the Osteoblast Response to Serum, FGF2 and IGF1. F. Lima*[1], C. Niger*[1], R. Civitelli[2], J. P. Stains[1]. [1]Orthopaedics, University of Maryland School of Medicine, Baltimore, MD, USA, [2]Bone and Mineral Diseases, Washington University, St Louis, MO, USA.

Gap junctions composed of connexin43 (Cx43) are abundantly expressed in osteoblasts. Previously, we have shown that activation of extracellular signal regulated kinases (ERK) signaling is required for optimal elaboration of osteocalcin transcription, and that disruption of Cx43 function attenuates both ERK activation and osteocalcin gene transcription. Using highly Cx43-coupled ROS17/2.8 cells and moderately Cx43-coupled MC3T3 cells, we are investigating the molecular details of the influence of Cx43 on osteoblast transcription. In both cell lines, disruption of Cx43 function with chemical inhibitors or connexin45 (Cx45) overexpression followed by serum stimulation results in a ~50% attenuation of extracellular signal regulated kinase (ERK) activation and an attendant >2 fold decrease in osteocalcin transcription. In contrast, transient overexpression of Cx43 in moderately coupled MC3T3 cells potentiates cellular response to serum stimulation both at the level of ERK activation (66%) and osteocalcin transcription (1.7 fold greater than mock transfected cells). To elucidate growth factors that may transmit signals via Cx43, we have begun to analyze signal transduction and gene transcription in response to treatment of osteoblasts with fibroblast growth factor 2 (FGF2) and insulin-like growth factor 1 (IGF1). Both FGF2 and IGF1 play a critical role in bone formation by regulating osteoblast gene expression. Treatment of MC3T3 cells with 5ng/ml FGF2 and 50ng/ml IGF1 increases phosphorylation of ERK as determined by western blotting, an effect that is attenuated by blocking Cx43 function. In addition, treatment of MC3T3 cells with FGF2 stimulates osteocalcin promoter activity 1.8-fold, as determined by luciferase activity. When Cx43 is overexpressed, the osteocalcin response to FGF2 is potentiated; resulting in a 2.7-fold stimulation, suggesting that Cx43 gap junctions amplify FGF2 activated signaling to affect cellular function. Disruption of Cx43 function by expression of Cx45 attenuates the action of FGF2 on osteocalcin transcription. However, the molecular details of the gap junction-influenced effects of FGF2 on osteocalcin

transcription are still under investigation. Similar to FGF2, overexpression of Cx43 enhances the IGF1-mediated increase in bone sialoprotein expression by >50%, an effect that is not observed when cells are transfected with Cx45. In total, our data reveal that Cx43 regulates signal transduction affecting the responsiveness of osteoblastic cells to growth factors, and gain or loss of function of Cx43 can potentiate and attenuate these responses, respectively.

Ascorbic Acid Protects Osteoblast from ER Stress. Z. Zhao[1], G. Xiao[1], C. Ge*[1], D. Jiang*[1], R. J. Kaufman*[2], R. T. Franceschi[3]. [1]Department of Periodontics, Prevention, and Geriatrics, School of Dentistry, University of Michigan, Ann Arbor, MI, USA, [2]Department of Biochemistry, School of Medicine, University of Michigan, Ann Arbor, MI, USA, [3]Department of Periodontics, Prevention, and Geriatrics; Department of Biochemistry, University of Michigan, Ann Arbor, MI, USA.

The osteoblast is a major secretory cell responsible for production of collagen and other extracellular matrix (ECM) proteins of bone. The synthesis and secretion of this ECM is highly regulated in response to the dynamic changes occuring during skeletal development and remodeling. Ascorbic acid (AA) promotes collagen matrix production by stimulating procollagen hydroxylation and folding, which is necessary for proper ECM assembly. We previously showed that AA-dependent accumulation of a type I collagen matrix stimulates osteoblast differentiation in part by interacting with cells via a2b1 integrins that subsequently stimulate MAP kinase activity and osteblast-specific gene expression. However. AA may have other functions in osteoblasts related to regulation of the protein folding response. AA may alter matrix production by increasing rates of translation and processing of ECM proteins. The underlying mechanism coupling the synthesis and secretion of these proteins is still unclear. The endoplasmic reticulum (ER) serves as the site where all secretory proteins are folded and assembled. An imbalance between ER protein folding load and the ability to secrete the protein causes ER stress. Eukaryotic initiation factor 2 (eIF2) is involved in the early events of ER stress. ER stress leads to phosphorylation of the a-subunit of eIF2, thereby inhibiting the translation initiation. Here we demonstrated that AA promotes collagen synthesis by inhibition of ER stress. AA induced the dephosphorylation of eIF2a as early as three hours after treatment. 3,4-dehydroproline, a specific collagen matrix synthesis inhibitor which inhibits collagen hydroxylation, blocks AA-induced dephosphorylation of eIF2a. AA induced eIF2a dephosphorylation is mediated by PERK, an eIF2a kinase, in that AA treatment induced the dephosphorylation of PERK.

Both Phosphatidylethanolamine and Phosphatidylcholine Are Hydrolyzed by Phospholipase D following Parathyroid Hormone Treatment of UMR-106 Cells. A. T. K. Singh[1], M. A. Frohman*[2], P. H. Stern[1]. [1]Dept of Molecular Pharmacology & Biological Chemistry, Northwestern University Feinberg School of Medicine, Chicago, IL, USA, [2]Pharmacology, Center for Developmental Genetics, Stony Brook, NY, USA.

Parathyroid hormone (PTH) activation of phospholipase D (PLD) has been identified as a signaling pathway for the hormone in normal osteoblasts and osteoblastic UMR-106 cells. PTH also stimulates phosphatidylcholine (PC) hydrolysis in the cells, although the effects on PLD were several fold greater than effects on PC hydrolysis. In other tissues phosphatidylethanolamine (PE) is also hydrolyzed by PLD. Differential sensitivities of PC and PE hydrolysis to stimulators have been reported. Studies were carried out (a) to determine if hydrolysis of PE is also activated by PTH, (b) to compare the time- and dose-dependence of the effects of PTH on the hydrolysis of the two phospholipids, and (c) to determine if PTH-stimulated PC and PE hydrolysis is mediated through PLD, since phospholipase C can also mediate hydrolysis of these phospholipids. UMR-106 cells were co-labeled with ^{3}H-choline and ^{14}C-ethanolamine and treated with PTH. ^{3}H and ^{14}C radioactivity released into the medium was determined by dual channel scintillation counting. The selectivity of radioactive labeling in the products (no significant ^{3}H in ethanolamine and no significant ^{14}C in choline fractions) was established by thin layer chromatography. PTH (10nM) stimulated PC and PE hydrolysis within 5 min, and the responses were sustained for at least 60 min. PTH (1-100nM) showed biphasic effects on PC hydrolysis, while its effects on PE hydrolysis plateaued at 10nM. The calcium ionophore ionomycin (1μM) and the PKC activator phorbol-12,13-dibutyrate (PDBu, 5-500nM) had similar effects to PTH to increase both PC and PE hydrolysis, although PTH effects on PC hydrolysis are not dependent on PKC. To test whether the PTH effects on PC and PE hydrolysis were mediated by PLD, UMR-106 cells were transfected (Lipofectamine Plus^{R}) with dominant negative constructs of PLD1 and PLD2, using pcDNA3 as a control vector (48h transfection, 0.5μg DNA). The dominant negative constructs inhibited PTH-stimulated increases in PC or PE hydrolysis, suggesting the involvement of PLD in these effects of PTH. The findings indicate that PE is a phospholipid substrate for PTH actions in osteoblasts. The possibility of PE hydrolysis by PLD provides another PTH-stimulated signal that could provide differential regulation of osteoblast responses.

Activation of PKCdelta Is Required in Wnt-Induced Osteogenesis. X. Tu*, F. Long. Internal Medicine, Washington University in St. Louis, St. Louis, MO, USA.

Wnt signaling has been implicated in osteoblast development, however the underlying mechanism is not understood. By employing a proteomics approach in the mouse stromal cell line ST-2 cells, we identified that a specific substrate for protein kinase C, Myristoylated-Ala-Rich Kinase C Substrate (MARCKS), was markedly phosphorylated in the cytosol of cells stimulated with either Wnt3a conditioned medium or recombinant Wnt3a protein. Moreover, MARCKS phosphorylation induced by Wnt3a was dramatically inhibited by a PKCδ-specific drug, Rottlerin. Remarkably, Rottlerin completely inhibited Wnt3a-induced osteogenesis in ST-2 cells, as assayed by the expression of Alkaline Phosphatase (AP), Collagen I and Bone Sialoprotein (Bsp). Importantly, Rottlerin did not inhibit activation of the canonical pathway by Wnt3a, as neither the induction of a *lef-1_luc* reporter nor the stabilization of β-catenin was affected. Finally, immunostaining experiments demonstrated that recombinant Wnt3a recruited PKCδ to the cell membrane within 30 minutes, and in preliminary experiments siRNA know-down of PKCδ markedly repressed osteoblast differentiation in ST-2 cells. In summary, these results demonstrate an essential role for PKCδ activation in Wnt-induced osteogenesis.

BCA3 (Breast Cancer-Associated Gene-3) Is a Novel Rac-Interacting Protein in Osteoclasts. K. Yu, T. Itokawa, K. Insogna. Endocrinology, Yale University, New Haven, CT, USA.

Rac-1 is a member of the family of small GTPases with prominent effects on the actin cytoskeleton. In osteoclasts, Rac-1 is required for CSF-1-induced cytoskeletal remodeling. To explore other metabolic pathways in osteoclasts where Rac-1 plays a role, we undertook a yeast two-hybrid screen using the Clontec Matchmaker-3 system with wild-type Rac-1 as bait and a cDNA library prepared from osteoclast-like cells (OCLs) as prey. OCLs were prepared by co-culturing murine bone marrow and calvarial osteoblasts. RNA isolated from these cells was highly enriched for c-src, cathepsin K and calcitonin receptor transcripts. Five clones were identified in an initial mating assay screen of the OCL library, which contained $8.6X10^{5}$ transformants. A repeat Y2H screen confirmed three of the five clones as Rac-interacting proteins. One of these proved to be BCA3 (Breast Cancer-Associated Gene-3) (GenBank accession number AF512007), a protein previously identified as a primarily nuclear protein that contains SH2 and PDZ domain binding motifs as well as putative phosphorylation sites for PKC and PKA. The transcript for BCA3 was found to be highly expressed in OCLs. To determine if the Rac/BCA3 interaction was direct, the cDNA for BCA3 was translated and radiolabeled using rabbit reticulocyte lysates and ^{35}S-methionine. The radiolabeled protein was used in an *in vitro* pull down with GST-coupled Rac in the presence of ATP. GST-coupled Rac was able to efficiently pull down BCA3 under these conditions, confirming a direct interaction of BCA3 and Rac-1. Deletional analysis of BCA3 revealed that amino acids 76-125 were required for optimal binding of BCA3 to Rac-1. Confocal microscopy demonstrated co-localization of Rac-1 with BCA3 in mature murine osteoclasts using an antibody specific for murine BCA3. Despite the reported nuclear localization of BCA3, Rac-1 and BCA3 co-localized in cytoplasmic and perinuclear areas of osteoclasts. These are the first data demonstrating an interaction of BCA3 with another cellular protein and suggest a possible role for BCA3 in cytoskeletal remodeling. The osteoclast will provide an interesting and physiologically relevant model system in which to test this hypothesis.

AAE581, a Potent and Highly Specific Cathepsin K Inhibitor, Prevents Bone Resorption after Oral Treatment in Rat and Monkey. M. Missbach[1], E. Altmann*[1], C. Betschart*[2], T. Buhl*[1], R. Gamse[1], J. A. Gasser[1], J. R. Green*[1], H. Ishihara*[3], C. Jerome[4], M. Kometani*[3], M. Susa*[1], N. Teno*[3], K. Toriyama*[3], R. Lattmann*[1]. [1]Musculoskeletal Diseases, Novartis Pharma AG, Basel, Switzerland, [2]Novartis Pharma AG, Basel, Switzerland, [3]Novartis Pharma KK, Tsukuba, Japan, [4]SkeleTech, Bothell, WA, USA.

Cathepsin K has been shown to be highly expressed in osteoclasts and to play an essential role in bone matrix degradation. The effects of AAE581, a reversible inhibitor of cathepsin K on *in vitro* and *in vivo* assays of bone resorption have been examined. AAE581 inhibits cathepsin K with Ki values of 0.7 nM, 4.2 nM and 57 nM, in human, rabbit and rat, respectively. It is highly specific for the human enzyme with an IC50 of 2.5 nM for cathepsin K versus 7700 nM for cathepsin B, 9700 nM for cathepsin L and >10'000 nM for cathepsin S. However, for the rat enzymes a reduced specificity profile was detected. Cellular activity *in vitro* was demonstrated by the reduction of the total pit volume produced by rabbit osteoclasts on ivory slices with an IC50 of 16±0.9 nM (n=3). Bone matrix degradation by human osteoclasts was inhibited with an IC50 of 8.2±2.1 nM (n=3). *In vivo* activity on bone resorption was tested in ovariectomized rats treated orally with 50 mg/kg bid. AAE581 reduced urinary deoxypyridinoline excretion by 83% after 2 weeks of treatment. In a separate experiment with 100 mg/kg bid over 12 weeks, the ovariectomy-induced loss of cross-sectional BMD at the proximal tibia was prevented by 78% as measured by pQCT. To confirm the ~80-fold higher potency of AAE581 on the human/monkey over the rat enzyme, the compound was evaluated in cynomolgus monkeys rendered estrogen deficient by a depot GnRH agonist. After oral administration of 10 mg/kg bid two serum markers of bone resorption, CTx and NTx, were already at levels far

below those of the non-GnRH treated group at day 1. They remained suppressed throughout treatment over 4 weeks and returned to normal within less than 5 days after the end of dosing with AAE581. Even in intact cynomolgus monkeys, a significant, dose-dependent reduction of serum CTx and NTx compared to vehicle treated animals occurred starting as early as day 1 with an ED50 after 4 day treatment of about 1 mg/kg bid. In conclusion, AAE581 is a highly potent and specific cathepsin K inhibitor that effectively reduces bone resorption markers in rats and monkeys after oral dosing and protects from ovariectomy-induced BMD loss in rats. AAE581 is currently in clinical development for osteoporosis and related diseases with increased bone loss.

Histochemical Examination on the Osteoclastic Function on the Microenvironment of Extracellular Matrices in Osteolytic Metastasis. M. Li*[1], N. Amizuka[1], K. Takeuchi*[2], T. Maeda*[1]. [1]Division of Oral Anatomy, Niigata University Graduate School of Medical and Dental Sciences, Center for Transdisciplinary Research, Niigata University, Niigata, Japan, [2]Division of Oral Anatomy, Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan.

We have examined the osteoclastic function on the microenvironment of extracellular matrices in osteolytic metastasis, by employing well-standardized lung cancer metastasis model of nude mice. Lung cancer cells (SBC-5) were injected into the left cardiac ventricle of 6-week-old nude mice under anesthesia. After confirming an obvious bone metastasis in femur and/or tibia by soft X-ray, the mice were perfused with 4% paraformaldehyde in 0.1 M phosphate buffer (PH 7.4). The metastasized femora and tibiae were processed for paraffin and epoxy-resin embedding. We performed histochemistry of alkaline phosphatase (ALP), osteopontin, CD44, cathepsin K and matrix metalloproteinase 9 (MMP-9) and tartrate resistant acid phosphates (TRAP), as well as transmission electron microscope (TEM) observation on paraffin and ultrathin epoxy-resin sections, respectively. Metastasized tumor nests were formed in the subcartilaginous region of the growth plate. TRAP-positive osteoclasts were found mainly in the ALP-positive osteoblastic layer covering bone surface, but were also localized in the ALP-negative stromal cell layer of the tumor nests. TRAP-positive osteoclasts showed immunoreactivity for CD44 that can bind to osteopontin. Meanwhile, osteopontin was distributed in the stromal tissue of tumor nests widely. Therefore, osteoclasts appeared to easily migrate into the stromal tissue of tumor nests, by attaching to osteopontin. Next, we examined the localization of cathepsin K and MMP-9 in osteoclasts. Osteoclasts adjacent to the bone surfaces were positive for both cathepsin K and MMP-9, whereas the osteoclasts in the stromal tissue of the tumor nests showed only MMP-9 immunoreactivity. Immunoelectron microscopy localized MMP-9 in the Golgi apparatus and vesicular structures in the baso-lateral cytoplasmic region of the osteoclasts in stromal tissue. In addition, vesicular structures positive for MMP-9 included fragmented extracellular fibrils. Therefore, it is likely that osteoclasts in stromal tissue of tumor nests synthesize MMP-9 and have an ability of digesting internalized extracellular fibrils. Thus, osteoclasts appeared to be involved in the alteration of extracellular matrices in the microenvironment of osteolytic metastasis.

A Possible Role for Cathepsin K as a Regulator of Tartrate-Resistant Acid Phosphatase in Osteoclasts. H. Ylipahkala*[1], J. Vääräniemi*[1], K. M. Fagerlund*[1], J. Rissanen[2], S. L. Alatalo*[3], H. K. Väänänen*[1], J. M. Halleen[2]. [1]Anatomy, University of Turku, Institute of Biomedicine, Turku, Finland, [2]Pharmatest Services Ltd, Turku, Finland, [3]Finnish Red Cross, Blood Service, Helsinki, Finland.

Osteoclasts secrete tartrate-resistant acid phosphatase (TRACP) into the circulation as a highly active two-subunit form known as TRACP 5b. TRACP 5b is formed by cleaving the polypeptide chain of TRACP at a protease sensitive loop peptide. TRACP is capable of generating reactive oxygen species (ROS) that can destroy bone collagen. We have studied the possible role of cathepsin K in cleaving TRACP in osteoclasts. Confocal microscopy with specific antibodies revealed co-localization of TRACP and cathepsin K in transcytotic vesicles of resorbing osteoclasts. Using recombinant enzymes we were able to show that cleavage of TRACP by cathepsin K *in vitro* increased both the phosphatase activity and the ROS generating activity of TRACP. Addition of the cysteine protease inhibitor E64 into cultures of resorbing human osteoclasts dose-dependently decreased medium TRACP 5b activity levels, whereas total TRACP protein amount did not change, suggesting that the specific activity of secreted TRACP enzyme was decreased because of inhibition of cysteine proteases such as cathepsin K. C-terminal cross-linked telopeptides of type I collagen (CTX) is formed as a result of degradation of bone collagen by cathepsin K. Medium CTX was dose-dependently decreased by addition of E64, and medium CTX and TRACP 5b levels correlated significantly in the human osteoclast cultures. Because total TRACP protein amount did not change by addition of E64, it suggests that TRACP is secreted at a constant rate from osteoclasts despite of their resorption activity. This supports recent evidence suggesting that TRACP 5b would be a marker of osteoclast number rather than osteoclast activity. These results suggest that cathepsin K cleaves TRACP into the two-subunit TRACP 5b isoform with high specific activity in transcytotic vesicles of resorbing osteoclasts and that this TRACP 5b generates ROS that finalize degradation of bone matrix components in the transcytotic vesicles. TRACP 5b is released from the osteoclasts into the blood circulation at a constant rate, being a marker of osteoclast number in situations where cathepsin K activity is not modified.

Trypsin-Cleavage Enhances the ROS Generating Activity of Human Recombinant Tartrate-Resistant Acid Phosphatase. K. M. Fagerlund*[1], H. Ylipahkala*[1], S. L. Alatalo*[2], A. J. Janckila[3], H. K. Väänänen*[1], J. M. Halleen[4]. [1]Institute of Biomedicine, Department of Anatomy, University of Turku, Turku, Finland, [2]Finnish Red Cross Blood Service, Helsinki, Finland, [3]Veterans Affairs Medical Center, Louisville, KY, USA, [4]Pharmatest Service Ltd, Turku, Finland.

Osteoclasts and macrophages express high amounts of tartrate-resistant acid phosphatase (TRACP). TRACP contains a redox-active iron that can catalyze generation of reactive oxygen species (ROS) and a loop-peptide that can be cleaved by proteases. We have studied the effects of proteolytic cleavage and reduction on the phosphatase and ROS generating activity of human recombinant TRACP produced in insect cells. The 35 kD monomeric native TRACP was cleaved by trypsin into two subunits of 23 and 16 kD that were linked together by a disulfide bridge. Ascorbate and β-mercaptoethanol were used as reducing agents. β-mercaptoethanol had no effect on the pH-optimum of the phosphatase activity measured using pNPP as substrate, but either trypsin-cleavage or reduction by ascorbate alone changed the pH-optimum from 5.4 to 6.2. Cleavage alone had no effect on k_{cat}/K_m but reduction of the cleaved form with β-mercaptoethanol increased k_{cat}/K_m approximately 5-fold. Ascorbate increased k_{cat}/K_m of both native and cleaved form approximately 5-fold. The cleaved high activity form was similar to osteoclast-derived serum TRACP 5b, and the monomeric low activity form was similar to macrophage-derived serum TRACP 5a. ROS generating activity was measured in the presence of ascorbate using hydrogen peroxide as substrate. Formation of ROS was monitored in the presence of coumarin-3-carboxylic acid, a non-fluorescent compound that is converted to a fluorescent product in the presence of ROS. Trypsin-cleavage increased the k_{cat}/K_m-value of the ROS generating activity by 2.5-fold, and the pH-optimum of both the cleaved and non-cleaved forms was 7.0. These results suggest that the osteoclast-derived TRACP 5b circulates in blood in an active cleaved form, and the macrophage-derived TRACP 5a in a less active non-cleaved form. The different effects of ascorbate and β-mercaptoethanol on the phosphatase activity suggest that these two reducing agents act differently. Cleavage of the polypeptide chain of TRACP may be an important regulator of both the phosphatase and the ROS generating activity of TRACP. The neutral pH-optimum of the ROS generating activity together with the acidic pH optimum of the phosphatase activity suggests that pH of the environment may be an important regulator for these two separate TRACP activities.

Disclosures: ***K.M. Fagerlund****, None.*

Changes in Serum Cathepsin k Levels in the Evaluation of Postmenopausal Women Treated with Alendronate. R. Reyes-García*[1], D. Fernández-García*[1], G. Alonso*[1], P. Mezquita-Raya*[2], M. Ruiz-Requena*[3], M. Muñoz-Torres[1]. [1]Bone Metabolism Unit. Endocrinology Division, San Cecilio Hospital, Granada, Spain, [2]Endocrinology Division, Torrecárdenas Hospital, Almería, Spain, [3]Biochemistry Division, San Cecilio Hospital, Granada, Spain.

Cathepsin k is a member of the cysteine protease family that plays a critical role in osteoclast function and the degradation of protein components of the bone matrix. This protease cleaves both helicoidal and telopeptide regions of collagen type I, the major type of collagen in bone. Postmenopausal osteoporosis is caracterized by an increase of bone resorption, resulting in a high turnover state that may be indentified by measurements of biochemical markers. Alendronate therapy induce sharply reductions in bone remodelling but there is no data on serum Cathepsin K changes after this treatment. Our aim was to evaluate the performance of serum cathepsin K as a biochemical marker of bone resorption in women with postmenopausal osteoporosis before and after 3 months of treatment with alendronate and a control group of healthy premenopausal women. We selected 30 patients (64±7 years) with densitometric criteria of osteoporosis (T-score < 2.5 SD) that started alendronate treatment (70 mg/weekly).). Serum samples were obtained at baseline and after 3 months for measurements of biochemical markers of bone remodelling. Serum cathepsin K levels were measured by ELISA (Biomedica Medizinprodukte GhbH & Co KG Wien,Austria). The reference range was 0-300 pmol/l.The detection limit was 1.1 pmol/l,and the intra and inter-assay coefficients of variation (CV) were 4% and 6% respectively. The control group consisted of 12 nonselected healthy premenopausal women (26± 3 years). We found increased levels of cathepsin K compared with the premenopausal control control group ($p<001$). After 3 months of alendronate treatment cathepsin K decreased significatly ($p<0.001$). Baseline and 3 months levels were significantly correalted (r: 0.69; $p<0.0001$). We not found correlation between cathepsin levels, age or years since menopause. Baseline concentrations of cathepsin K and tartrate resistant acid phosphatase (TRAC) were significantly correlated (r: 0.35; $p<0.045$). Our data suggest that serum cathepsin K measurements seem to be a valuable parameter in the evaluation of women with osteoporosis treated with antiresorptives.

Tartrate-Resistant Acid Phosphatase Plays an Essential Role in Antigen Presentation by Dendritic Cells. E. Esfandiari*[1], C. R. Stokes*[1], M. Bailey*[1], T. M. Cox*[2], M. J. Evans*[3], A. R. Hayman[1]. [1]School of Clinical Veterinary Science, University of Bristol, Langford, BS40 5DU, United Kingdom, [2]Department of Medicine, University of Cambridge, Cambridge, CB2 2QQ, United Kingdom, [3]School of Biosciences, University of Cardiff, Cardiff CF10 3US, United Kingdom.

Tartrate-resistant acid phosphatase (TRAP) is highly expressed by osteoclasts, activated macrophages and dendritic cells (DCs). DCs are the most potent antigen-presenting cell of the immune system, critically involved in the initiation of primary immune responses, graft rejection, T cell dependent humoral immune responses and autoimmune diseases such as rheumatoid arthritis (RA). RA is associated with Th 1 hyperactivation. Blood-derived human DCs matured by induction with LPS displayed a five-fold increase in TRAP activity compared with immature DCs suggesting a role for TRAP in the immune response. Osteopontin (OPN) has been shown to be a substrate for TRAP *in vivo*. OPN, also known as early T cell activating factor-1 (Eta-1) is a phosphorylated glycoprotein secreted by activated T lymphocytes and has been implicated in the pathogenesis of inflammatory arthritis. Our aim in this study was to investigate the significance of TRAP in dendritic cells. DCs were cultured from the bone marrow of TRAP deficient (KO) and wild-type (WT) mice and matured with LPS. The expression of MHCII and CD80 was significantly up-regulated in DCs from WT mice compared with DCs from KO mice. DCs from KO mice produced significantly higher amounts of IL10, but showed no significant differences in the production of IL12. The number of mature DCs in KO DC cultures were significantly less than in WT DC cultures. TRAP KO mice exhibited a defect in the expression of delayed hypersensitivity responses. Mice from both genotypes were sensitised and challenged with the contact sensitising agent picryl chloride. The response in KO mice was significantly reduced compared with WT. The ability of TRAP deficient mice to generate antigen-specific immune responses *in vivo* was investigated. Mice were immunised with ovalbumin. Ten days later T cells isolated from spleens of TRAP KO mice showed less proliferation than T cells isolated from the spleens of WT mice in response to OVA, suggesting that the antigen-specific priming of T cells was deficient in mice lacking TRAP. T cells from TRAP deficient mice produced less IFN-γ in response to OVA, however there was no difference in IL-4 production. KO mice produced reduced amounts of OVA-specific IgG2a after immunization with OVA. Differences in IgG1 OVA-specific levels were not significant. In conclusion TRAP has an essential role in the maturation of DCs. It is the Th1 pathway and not the Th 2 pathway that is affected in TRAP deficient mice.

A Potent and Orally Active Inhibitor of Cathepsin K Selectively Suppresses Bone Resorption without Affecting Bone Formation in Cynomolgus Monkeys. H. Yamada*, Y. Ochi*, N. Kawada*, Y. Nakanishi*, H. Mori*, R. Kayasuga*, A. Hatayama*, K. Ohmoto*, M. Tanaka*, K. Kishikawa*. Discovery Research Laboratories II, Ono Pharmaceutical Co., Ltd., Osaka, Japan.

Cathepsin K, a cysteine protease highly expressed in osteoclasts, is capable of degrading bone type I collagen. Recently, cathepsin K inhibitors have drawn much attention as novel therapeutic agents for treatment of elevated bone turnover including osteoporosis. We investigated anti-bone resorptive activities of cathepsin K inhibitor, compound A, in ovariectomized cynomolgus monkeys. *In vitro* studies showed that this compound potently inhibited human cathepsin K with a Ki value of 0.10 nM. In addition, this compound concentration-dependently inhibited the release of C-terminal telopeptide of type I collagen (CTX) from bovine bone slices incubated with rabbit bone cells. In ovariectomized cynomolgus monkeys (>9 years old), this inhibitor was given orally once daily from next day of operation for 8 months at 3 dose levels (0.3, 3 and 30 mg/kg). As the bone resorption marker, serum CTX, urinary CTX, serum N-telopeptide of type I collagen (NTX), urinary NTX, urinary free deoxypyridinoline, and as the bone formation marker, serum Osteocalcin and serum bone alkaline phosphatase were measured to monitor bone turnover. The compound A strongly and immediately suppressed bone resorption markers dose-dependently without affecting bone formation markers.These results suggest that an orally active compound A specifically suppressed bone resorption in ovariectomized monkeys. We conclude that cathepsin K inhibitors have the therapeutic potential in primates, and that would be new ideal drugs for the osteoporosis therapy.

Cathepsin K-Deficient Mice Exhibit Pycnodysostosis Geatures due to Loss of Cathepsin K-Mediated Osteoclast Senescence for Bone Homeostasis. Y. P. Li[1], Y. Abe*[1], R. Isoda*[1], R. Moroi*[1], S. Yang*[1], J. Z. Shao*[1], E. Li*[2], W. Chen*[1]. [1]The Forsyth Institute & Harvard School of Dental Medicine, Boston, MA, USA, [2]Department of Medicine, Cardiovascular Research Center, Massachusetts General Hospital, Harvard Medical Medicine, Charlestown, MA, USA.

Osteoclast is a bone resorption cell and its numbers need to be precisely controlled to keep bone homeostasis. How osteoclast life is regulated is unclear. Pycnodysostosis resulted from *Cathepsin K* mutation that exhibited a unique phenotype characterized by short stature, wide cranial sutures, osteolysis and osteoscleosis due to bone homeostasis defect. To understand the role of *Cathepsin K* in pathogenesis of pycnodysostosis, we generated a novel *Cathepsin K* knockout mouse strain. Surprisingly, osteoclast numbers in the *Cathepsin* $K^{-/-}$ mice largely increased up to 15-fold high compared to that in wild-type, whereas extracellular acidification function was unaffected in *Cathepsin* $K^{-/-}$ osteoclasts. This suggests that the large amounts of *Cathepsin* $K^{-/-}$ osteoclasts with normal acidification ability and impaired bone matrix degradation function may be the cause of pycnodysostosis. We hypothesized that *Cathepsin K* may be involved in the regulation of osteoclast life. *Cathepsin* $K^{-/-}$ OCLs grew 10-fold faster than wild-type osteoclasts and can continue for more than forty passages. Apoptosis was not detected in both *Cathepsin* $K^{-/-}$ osteoclasts and wild-type osteoclasts *in vivo* or *in vitro* with conditional medium, indicating apoptosis may not be the major anti-osteoclast survival pathway in bone homeostasis. Notably, senescence was observed in 95% of wild-type osteoclasts, but was not detected in C*athepsin* $K^{-/-}$ osteoclasts. Our data showed that *Cathepsin K* regulates osteoclastic senescence by acting as a modulator of the p19, p53 and p21 senescence pathway. Forced expression of *Cathepsin K* in pre-osteoclast cell line, MOCP-5, induces premature senescence. This is the first report that *Cathepsin K*-deficient mice exhibit unique pycnodysostosis features due to loss of C*athepsin K*-mediated osteoclast senescence, and *Cathepsin K*-mediated p53 and p21 senescence pathway may be the major anti-osteoclast survival mechanism to control osteoclast life and bone homeostasis.

Aquaporin 9 Plays a Role in Osteoclast Differentiation. R. Aharon*, Z. Bar-Shavit. Experimental Medicine and Cancer Research, Hebrew University Faculty of Medicine, Jerusalem, Israel.

Aquaporins are water channels that selectively enhance the water permeability of the membrane. The distribution of mammalian aquaporins suggests their participation in a wide range of physiological events. Empirical evidence of a physiological role for aquaporins is emerging from studies in both mice and humans, and suggests that aquaporins are likely to play significant roles in human pathophysiology. Since osteoclast differentiation includes a dramatic increase in volume of the cell we hypothesize that aquaporin(s) is/are critical for the formation of the multinucleated osteoclast from its mononuclear precursor. For our studies we used two cell models, bone marrow macrophages (BMMs) and the murine macrophage-like cell line, RAW264.7, as osteoclast precursors. RANKL+M-CSF and RANKL were used to induce osteoclast differentiation in BMMs and RAW264.7 cells, respectively. We first used qualitative RT-PCR to examine which of the aquaporins are expressed in osteoclasts and in their precursor cells. Out of the ten aquaporins examined, only aquaporin 9 (AQP9) was expressed in the osteoclast lineage cells. Characterization of AQP9 revealed that it has a unique aqueous pore mediating in addition to water the passage of a wide variety of non-charged solutes. Quantitative real-time PCR analyses demonstrated higher AQP9 mRNA levels in RANKL-treated cells.Western analyses using specific antibodies revealed also a higher AQP9 level in RANKL-treated cells. Finally, we examined the effect of phloretin, an AQP9 inhibitor, on RANKL-induced osteoclast differentiation. Cells were incubated with RANKL for 5 days, and phloretin was added for the last two days, when most fusion occurs. A dramatic reduction in osteoclast number was observed in cultures containing phloretin. The inhibitor did not exhibit a significant effect on the number of mononuclear phagocytes in cultures not treated with RANKL. Our results suggest a role for AQP9 in osteoclast differentiation, and specifically in the fusion process.

Osteoclasts Produce Interferon Ggamma: A Novel Autoregulation Mechanism of Osteoclastogenesis. S. Yang, Y. Z. Zhang*, S. V. Reddy, W. Ries, L. L. Key. Pediatrics, Children's Research Institute, Medical Univ. of SC, Charleston, SC, USA.

Osteoclasts are multinucleated cells formed from hemopoietic cells, and their formation is tightly controlled by a network of cytokines produced in the bone microenvironment. While there are intensive efforts in recent years to understand the mechanisms of osteoclastogenesis by positive stimulators, very little attention has been given to negative regulatory mechanisms. Interferon gamma (IFN-γ), a systemic immune factor produced primarily by T and NK cells, inhibits osteoclastogenesis and bone resorption. In this study, we demonstrated that osteoclasts express IFN-γ by immunostaining and RT-PCR analysis. ELISA analysis showed that IFN-γ produced by osteoclasts reached 0.37 ng/ml, which is above the minimum dose (0.2 ng/ml) required to inhibit osteoclastogenesis. IFN-γ mediates its biological effects through the receptor. The presence of IFN-γ receptors in osteoclasts is demonstrated by their binding activity to ^{125}I-labeled IFN-γ. Scatchard plot analysis revealed that osteoclast progenitors have an average of 5300 IFN-γ receptor sites/cell. We have also identified that IFN-γ inhibits osteoclast precursor proliferation significantly. These data suggest that a negative feedback loop exists by which osteoclasts negatively control their own differentiation and formation by producing IFN-γ. Evidence that supports our study is obtained from the IFN-γ receptor null mice, which have a more rapid onset of arthritis and bone resorption, as more osteoclasts appeared in the IFN-γ receptor (-/-) mice than in wild type mice. IFN-γ failed to suppress osteoclastogenesis in bone marrow cell cultures derived from the IFN-γ receptor (-/-) mice. These data suggest that osteoclast formation in the IFN-γ receptor (-/-) mice lacks negative regulation when the IFN-γ signaling is interrupted. Without such negative control, more osteoclasts are formed and lead to excess bone resorption in the IFN-γ receptor (-/-) mice. Osteoclast-derived IFN-γ may be one of the major negative regulators of osteoclastogenesis in the bone microenvironment. This regulation may function more efficiently than the systemic source of IFN-γ, through paracrine and autocrine mechanisms. This negative regulation limits the number of osteoclasts during bone remodeling by a feed-back mechanism. Our study provides the novel concept that osteoclasts negatively control their own differentiation and formation by producing IFN-γ in the bone microenvironment.

Menatetrenone (MK-4) Directly Inhibits Osteoclast Formation and Enhances the Inhibitory Effect of Aminobisphosphonates on Osteoclast Precursor Cell Differentiation. D. C. Ireland*, S. Bord, J. E. Compston. Department of Medcine, University of Cambridge, Cambridge, United Kingdom.

The aim of this study was to determine the direct effects of MK-4, alone and in combination with the aminobisphosphonate pamidronate (PAM), on human osteoclast formation and activity. MK-4 affects the γ-carboxylation of certain bone proteins and has effects on bone cells that appear to depend on its geranylgeranyl side chain. In a model of osteoclastogenesis and bone resorption, osteoclasts were generated on dentine slices and calcium phosphate films from human CD14+ blood cells cultured with macrophage colony stimulating factor and receptor activator of NFκB ligand. Osteoclasts were identified by morphology, TRAP-staining and dentine resorption. Calcium phosphate films allowed the addition of compounds to mature, resorbing osteoclasts and quantification of resorption. MK-4, geranylgeraniol (GGOH) and PAM were added, alone and in combination, to cells, both at the outset to detect changes in osteoclast formation and to mature osteoclasts to detect changes in activity. Total cell proliferation was estimated by MTS assay and substrate resorption was quantified by image analysis of von Kossa stained calcium phosphate films. TUNEL staining was used to detect apoptosis. Four replicates were used for each group and results compared to carrier controls using Student's t-test. Compared to carrier alone, resorption, but not total cell proliferation, was significantly inhibited by 10^{-5}M MK-4 (39% cf control), GGOH (33%) and PAM (14%) ($p<0.05$) when these compounds were added at the outset. Examination of the stained cells showed that decreased resorption was due to inhibition of osteoclast formation not inhibition of activity. Combinations of PAM with MK-4 or GGOH further decreased osteoclast formation. None of the cultures showed increased TUNEL staining compared to the controls. When compounds were added to cultures with mature osteoclasts, 10^{-5}M MK-4, GGOH and PAM did not alter cell proliferation or substrate resorption but 10^{-4}M PAM (32% cf control) and 10^{-4}M PAM plus 10^{-5}M MK-4 (no resorption) significantly decreased resorption ($p<0.05$) whereas 10^{-4}M PAM plus 10^{-5}M GGOH did not. In summary, MK-4 directly inhibited osteoclast formation from CD14+ precursors and enhanced the inhibitory effect of PAM without inducing apoptosis. Unlike GGOH, MK-4 was unable to reverse the antiresorptive effect of PAM on mature osteoclasts.The data suggest that MK-4 directly inhibits osteoclastogenesis and enhances the effects of pamidronate on osteoclast formation and activity.

Use of Acumen Explorer to Quantitate Calcitonin Receptor-Positive Mononucleated and Multinucleated Cells in Differentiating Cultures of Osteoclasts. R. J. S. Galvin, L. L. Burris*, T. Fuson*, A. Kriauciunas*. Musculoskeletal Team, Lilly Research Labs, Indianapolis, IN, USA.

The traditional method for quantifying the number of osteoclasts (OCs) is labor intensive, time consuming and highly subjective. *In vitro*, OCs differentiate unevenly across a well making it imperative to analyze the entire well. OCs are typically identified as multinucleated cells that stain positive for tartrate-resistant acid phosphatase or calcitonin receptor. Counting the number of mononuclear cells present in a differentiation culture is usually not practical and therefore is rarely done. The purpose of this study was to develop a novel assay using high content analysis to simultaneously quantify both multinucleated and mononucleated calcitonin-receptor positive cells in differentiating cultures of bone marrow cells. Murine bone marrow cells were isolated from male balb/c mice and cultured in the presence of rmM-CSF (25 ng/ml) and rh-RANKL (0.31-80 nM) in the presence or absence of TGF-β1 (0.01- 10 ng/ml). On day 6, the cultures were fixed and stained with calcitonin receptor antiserum using a secondary Alexa Fluor 488 antibody for detection. The nuclei were counterstained with propidium iodide. The number of calcitonin-receptor positive mononucleated and multinucleated cells (OCs, two or more nuclei) per well were quantified using the Acumen Explorer. An argon laser was used to excite the sample and the emitted light was captured by one of four photomultiplier tubes. Multi-parametric analysis was used to exclude fluorescent artifacts. The Acumen Explorer allows for discrimination between the cell populations and also for more rapid data collection with acquisition and analysis taking approximately 15 minutes for a 96-well plate. RANKL induced a concentration-dependent increase in OC differentiation with an EC_{50} of appropriately 5 nM and increased OC numbers approximately 350% at 10 nM RANKL. The mononucleated cell numbers were decreased by RANKL in a concentration-dependent manner with an approximately 25% decrease at 10 nM RANKL. TGF-β1 enhanced OC differentiation in a concentration-dependent manner with a 430% increase at 10 ng/ml of TGF-β1 and 1.5 nM RANKL. Under these conditions monucleated cell numbers were decreased by about 50%. Manual counting of OCs correlated ($r^2=0.98$) with the counts generated with the Acumen Explorer. These results demonstrate that high content analysis using the Acumen Explorer can be used to monitor OC differentiation providing quantitative information on both osteoclast and mononucleated cell number.

Osteoclast Fusion Is Mediated by DC-STAMP, a Seven Transmembrane Receptor via its C-Terminus Domain. T. Miyamoto[1], M. Yagi*[1], N. Fujita*[1], K. Morita*[1], Y. Toyama*[2], T. Suda*[1]. [1]Cell Differentiation, Keio University School of Medicine, Shinjuku, Japan, [2]Orthopaedics, Keio University School of Medicine, Shinjuku, Japan.

Osteoclasts are bone resorbing cells, which play a pivotal role in bone remodeling. Osteoclasts form large multinuclear giant cells by cell fusion of mononuclear osteoclasts. While some osteoclast fusion mediating factors were reported, essential molecules remain unclear. Here we identify the dendritic cell-specific transmembrane protein (DC-STAMP), a putative seven transmembrane protein by DNA subtraction screen between multinuclear osteoclasts and mononuclear macrophages. DC-STAMP is highly expressed in osteoclasts, and thus the function in osteoclast formation was analyzed in DC-STAMP deficient mice. The targeting vector was constructed to insert an EGFP sequence into exon 2 such that EGFP was in-frame with amino acid Leu55 of DC-STAMP. Osteoclasts were identified as GFP-positive cells in vivo and in vitro in DC-STAMP-heterozygous mice. DC-STAMP-null mice were generated at Mendelian ratios, and osteoclastogenesis was analyzed in DC-SATMP homozygous mice. The transcription factors required for osteoclast differentiation such as c-Fos and NFATc1, or osteoclast maturation marker including TRAP, cathepsin K and bone resorbing activity were induced in osteoclast derived from DC-STAMP deficient mice as wild type osteoclast. However, the cell fusion of osteoclasts was completely abrogated in DC-STAMP deficient mice in vivo. The in vitro osteoclast multinucleation was not detected in the culture of bone marrow cells from DC-STAMP-deficient mouse in the presence of M-CSF and RANKL and was not rescued by a high-dose M-CSF or co-cultivation with osteoblasts. As osteoclast multinucleation was restored by retroviral expression of DC-STAMP, the loss of cell fusion is directly attributed to the lack of DC-STAMP. Interestingly, DC-SATMP-delta lacking a C-terminus putative cytoplasmic domain failed to rescue the cell fusion of DC-STAMP deficient osteoclast indicating that DC-SATMP is an essential protein for osteoclast cell fusion, and its C-terminus domain is required for cell fusion signaling of osteoclasts. We will discuss about the mechanism of cell fusion mediated by DC-STAMP.

Proteomic Study of Osteoblast Differentiation Using Isotope-Coded Affinity Tags And Maldi-Tof Analysis. Y. Zhang*, A. F. Taylor*, D. C. Genetos*, Z. Zhou*, B. A. Stanley*, H. J. Donahue. The Pennsylvania State University, Hershey, PA, USA.

The aim of this study was to identify the protein expression profile or "fingerprint" of differentiating human mesenchymal stem cells (hMSC) using the ICAT-MALDI-TOF-TOF approach, which permits the quantitation and identification of proteins, including lower-abundance proteins, membrane proteins, and highly charged proteins. hMSC and murine MC3T3-E1 were cultured in growth medium. Upon reaching 70-80% confluence cells were switched to differentiation medium for an additional 14 days. Proteins isolated from undifferentiated and differentiated hMSC/MC3T3-E1 were labeled on cysteine residues with either a "light" or a "heavy" ICAT reagent (mass difference of 9.03 atomic units), and then pooled together. The pooled ICAT-labeled proteins were separated on a 10% SDS-PAGE gel. Following electrophoresis, individual gel lanes were divided into 10 pieces and soaked in a trypsin solution. Peptides eluted from the gel pieces were then affinity purified and separated into 100 or more fractions using a nanoflow LC reverse-phase column which mixes the fractions with matrix and spots them onto MALDI plates. Peptide / matrix spots were analyzed by MALDI-TOF, and peak clusters differing by multiples of 9.03 Daltons, indicative of light-heavy ICAT labeled peptide pairs, were selected for further analysis. The relative levels of matched peptides from undifferentiated and differentiated cells were indicated by the relative areas of the light vs. heavy peaks in these pairs. The identity of peptides showing 30% or greater differences in peak areas was then determined by fragmenting the parent peaks and comparing the tandem ms/ms spectra generated to the theoretical ms/ms spectra of all known peptides having the parent peak mass. Alkaline phosphatase activity was increased dramatically in hMSC cells cultured for 14 days in osteogenic media, confirming that they had differentiated to osteoblastic cells. In total, we saw 607 and 2237 ICAT labeled peptides pairs in hMSC and MC3T3-E1 samples, respectively, at a signal/noise ratio of 25 or better (Table). The median values for pairs were 0.9857 and 0.9967, suggesting that there was no bias in the Light vs. Heavy ICAT label sampling. Our results demonstrate that an ICAT-based proteomic approach can be used as a method to generate protein "fingerprints" of osteoblast differentiation.

Cell	hMSC	MC3T3
Peptides pairs identified (S/N=25)	607	2237
Peptides pairs with difference more than 30%	442	1270
Protein matched (expression level difference>30% and C.I.>90%)	45	64
Up regulated proteins (>30%)	21	7
Down regulated proteins (>30%)	24	57

CaMKII gamma Is the Sole Osteoclastic CaM Kinase Responsible for the Regulation of Osteoclastogenesis via Modulating RANK Signaling. C. Yao*[1], P. H. Stern[2], J. J. Mao[3], L. Zhang[1]. [1]Biomedical Sciences, University of Illinois at Chicago, Rockford, IL, USA, [2]Molecular Pharmacology and Biological Chemistry, Northwestern University, Chicago, IL, USA, [3]Orthodontics, University of Illinois at Chicago, Chicago, IL, USA.

Recently, Ca^{2+}/ calmodulin signaling has been recognized as a major regulator in osteoclastogenesis. Efforts have ensued to identify the downstream targets of this signaling pathway in the context of regulating osteoclastogenesis. Calcineurin-NFAT pathway has thus been identified as such a target. In this presentation, we describe the discovery of another novel downstream target, CaMKIIγ, as the sole known CaMK expressed with significant amounts in bone marrow derived osteoclasts and their precursors. Other known CaMKs such as CaMKIV and CaMKIIα, β, δ, are not detectable, while CaMKI is expressed at a negligible level. Furthermore, the expression of CaMKIIγ is tightly correlated with the osteoclastogenic process, with a peak level on Day 3 of cell culturing. Osteoclastogenesis is halted by treatment with the CaMKIIγ inhibitor, KN93, independently from apoptosis, with the IC_{50} for osteoclastogenesis matching that for blocking CaMKIIγ function. In addition, KN93 blocked RANK-NFκB and RANK-Akt pathways in the osteoclast precursor cells. Collectively, these data indicate that CaMKIIγ is a novel regulator of osteoclastogenesis via modulating RANK signals.

TIEG Expression in Osteoclast Precursors Suppresses Osteoclast Differentiation. L. Pederson*[1], M. Subramaniam[2], J. R. Hawse[2], T. C. Spelsberg[2], M. Oursler[3]. [1]Endocrinology/Metabolism & Internal Medicine, Mayo Clinic, Rochester, MN, USA, [2]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA, [3]Endocrinology, Mayo Clinic, Rochester, MN, USA.

We have shown that TGF-b Inducible Early Gene 1 (TIEG) plays an important role in osteoblast (OB) differentiation and OBs isolated from TIEG knockout mice are less efficient in supporting OC differentiation. Tibial bone histomorphometry of TIEG knockout mice exhibited increased OB numbers with no change in OC numbers. This study examines the effect of loss of TIEG on osteoclast (OC) differentiation. We have examined differentiation of M-CSF dependent nonadherent OC precursors from marrow and spleen in co-cultures with ST2 cells and following treatment with RANKL and M-CSF. In both models, loss of TIEG enhanced OC differentiation. The combination of increased numbers of OBs present in bones and increased ability of OC precursors to differentiate into mature OCs may result in a net effect of normal OC numbers in the bones of mice lacking TIEG. This is supported by increased OC differentiation when we increase the density of calvarial OBs in TIEG knockout co-cultures. The increased OC differentiation in the TIEG knockout models may be due to (a) the presence of more precursors or (b) an increased capacity of a similar number of precursors to differentiate. This was examined by identifying OC precursors using flow cytometry analysis of CD11b, c-fms, and/or RANK expression. We found no significant differences in the number of OC precursors between wild type and TIEG knockout spleen or marrow cells. Moreover, equal numbers of CD11b+ OC precursors were differentiated in the presence of M-CSF and RANKL. Compared to wild type, there was enhanced differentiation of TIEG knockout OC precursors, verifying that loss of TIEG increased the capacity of OC precursors to differentiate. Transfection with siRNA to block TIEG expression in wild type OC precursors resulted in enhanced differentiation, similar to TIEG knockout OC precursors. Conversely, using adenovirus delivery, restoration of TIEG expression in TIEG knockout OC precursors resulted in reduced OC differentiation. Thus, TIEG expression in OC precursors directly impacts OC differentiation. We examined known pathways important in OC differentiation. We found increased activation of the NFkappaB pathway in knockout compared to wild type OC precursors, whereas activation levels of other pathways critical to OC were unchanged. In summary, TIEG expression in OC precursors directly affects OC differentiation, and loss of TIEG expression in OC precursors enhances OC differentiation through sustained activation of the NFkappaB pathway.

Role of Sphingosine Kinase in RANKL-Induced Osteoclastogenesis. J. Ryu*, H. Kim*, K. Han*, S. Lee*, H. Kim. Dept of Cell and Developmental Biology Seoul National University Dental School, Seoul, Republic of Korea.

Oseoclasts are highly specialized multinucleated cells that differentiate from monocyte/ macrophage lineage hematopoietic precursors. Two hematopoietic factors are both necessary for ostoclastogenesis, the TNF-related cytokine RANKL and the polypeptide growth facor M-CSF1. The mature, multinucleated osteoclast is activated by signals, which lead to initiation of bone remodeling. The differentiation and activation of osteoclast stimulate bone resorption, therby contributing to the pathogenesis of rheumatoid arthritis, periodontitis, and bone metastases. Sphingosine kinase (SPHK) is an enzyme that catalyzes the phosphorylation of sphingosine to sphingosin-1-phosphate (S1P). Diverse external stimuli, particularly growth and survival factors and chemoattractants stimulate the sphingosine kinase to generate intracellular S1P. Sphingosine-1-phosphate is a bioactive lipid that regulates cell proliferation, differentiation, motility and survival. The discovery that S1P can bind to specific cell surface G protein-coupled receptors has led to the concept that S1P can function as an extracellular first messenger. The activation of the small GTPase Rac and Rho has been linked to cytoskeletal rearrangements and motility. Other related signaling pathways include the activation of ERK and p38 MAP kinases, intracellular calcium mobilization, and activation of AKT. In this study, we evaluate the role of SPHK and its product, sphingosine-1-phosphate in RANKL-induced osteoclastogenesis. Knock-down of SPHK gene with siRNA increased phospho-p38 activation as well as RANKL-induced osteoclastogenesis. The overexpression of SPHK to bone marrow-derived macrophage cells and Raw cells reduced the formation of multinucleated osteoclasts. In addition, treatment of S1P into BMC-derived macrophage inhibited the formation of TRAP positive multinucleatd osteoclastogenesis. These data demonstrate the important role of SPHK and its product S1P in RANKL-induced osteoclastogenesis.

EphrinB2 Is a Transcriptional Target Gene of NFATc1 during Osteoclast Formation. N. Irie*[1], C. Zhao*[1], T. Miyamoto[2], T. Suda*[2], K. Matsuo[1]. [1]Department of Microbiology and Immunology, Keio University School of Medicine, Tokyo, Japan, [2]Department of Cell Differentiation, Keio University School of Medicine, Tokyo, Japan.

Bone remodeling is delicately regulated at the level of differentiation and activation of osteoclasts and osteoblasts. Eph receptor tyrosine kinases and ephrin ligands have key roles in regulating migration and adhesion of cells in neuronal and vascular development. Both Ephs and ephrins are membrane-bound proteins which evoke bidirectional signaling upon interacting with each other. Last year, we reported that ephrinB2 (encoded by *Efnb2*) and EphB4 are expressed on osteoclasts and osteoblasts, respectively. Reverse signaling through ephrinB2 into osteoclast precursors suppresses osteoclast differentiation, while forward signaling through EphB4 enhances osteoblast differentiation. Expression of *Efnb2* in osteoclasts was initially identified by microarray analysis using osteoclast precursors isolated from mice lacking c-Fos (*Fos*$^{-/-}$ mice). Although *Fos*$^{-/-}$ precursors do not differentiate into osteoclasts, overexpression of a major c-Fos target gene, *Nfatc1*, rescued osteoclast differentiation and restored expression of *Efnb2*. We examined whether *Efnb2* could be a direct target gene of the transcription factor NFATc1. First, we transiently transfected *Efnb2* promoter-luciferase constructs into the osteoclast precursor cell line RAW264.7. The DNA fragment containing the 3.1-kb *Efnb2* sequence upstream of the translaton initiation site responded to both RANKL treatment and overexpression of a constitutively-active form of NFAT. Next, we examined the seven putative NFAT sites in the mouse *EfnB2* promoter within the 3.1-kb upstream region. Electrophoresis mobility shift assays (EMSA) revealed one strong NFAT binding site (-2863 relative to ATG codon) and two adjacent weak sites. Furthermore, NFATc1 supershift was observed only with nuclear extracts from wild-type but not *Fos*$^{-/-}$ osteoclastogenic cultures, which lack NFATc1. This demonstrates that NFATc1 binds to the -2863 site. These data suggest that the RANK-c-Fos-NFAT cascade activates not only osteoclastogenic genes, but also *Efnb2*, which encodes anti-osteoclastogenic molecule during osteoclast formation.

Effects of Calcitonin on Osteoclast Formation and Gene Expression. S. Granholm*, P. Lundberg*, U. H. Lerner. Department of Oral Cell Biology, Umeå University, Umeå, Sweden.

Calcitonin (CT) was discovered in 1962 as an acute hypocalcemic hormone and this hypocalcemic effect has later been shown to be due to inhibition of bone resorption, caused by activation of calcitonin receptors (CTR) in mature osteoclasts. Studies on effects by CT on osteoclast differentiation are however limited. Here, the effects of CT on osteoclast formation and gene expression have been studied in cultured mouse spleen cells and mouse bone marrow macrophages (BMM). CT inhibited formation of tartrate resistant acid phosphatase positive multinucleated osteoclasts ($TRAP^+$ MuOCL) in spleen cells and BMM, cultured in the presence of macrophage colony-stimulating factor (M-CSF) and receptor activator of NF-κB ligand (RANKL), with half maximal effect at 10^{-12} M of salmon CT. The effect was obtained also by adding CT during the last 24 h of the 96 h cultures. CT did not affect the mRNA expressions of RANK and c-fms, nor the mRNA expressions of c-Fos, c-Jun, NFAT2 or IκBα. The increased mRNA expression of CT receptor (CTR) caused by M-CSF/RANKL was abolished by CT. In contrast, CT did not affect M-CSF/RANKL induced increase of the mRNA expressions of TRAP, cathepsin K, MMP-9, proton pump subunit Atp6i, chloride channel ClC-7, or the integrins α_v and β_3. CT induced inhibition of $TRAP^+$ MuOCL formation was not associated with any decrease of total TRAP activity resulting in large number of $TRAP^+$ mononucleated cells in CT treated cultures. Fusion of mononucleated osteoclast progenitor cells has been suggested to be controlled by the two ITAM harboring adaptor proteins DAP12 and FcRγ, forming complexes with several cell surface receptor proteins in the immunoglobulin-like superfamily. The critical role of these co-stimulatory signals has been demonstrated by the finding that *FcRγ*$^{-/-}$*/DAP12*$^{-/-}$ mice are osteopetrotic and lack osteoclasts. CT did not affect the mRNA expression of DAP12 or FcRγ, nor were the mRNA expression of the receptors affected. It is concluded that CT is a potent inhibitor of osteoclast formation, caused by a direct effect on the osteoclast progenitor cells, and that this effect is not associated with decreased transcription of a variety of genes known to be important for osteoclast progenitor cell differentiation, fusion or function.

Comparison of Human and Bovine Bone Substrates in Human Osteoclast Cultures. J. P. Rissanen, S. Suutari*, S. Ylönen*, J. M. Halleen. Pharmatest Services Ltd, Turku, Finland.

Bovine bone and dentine slices are widely used substrates for *in vitro* osteoclast (OC) cultures. In order to perform effective and reliable antiresorptive drug screening assays, it would be advantageous to use human bone as substrate for human osteoclasts. We have compared the performance of human and bovine bone substrates in two different human OC assays, a 7-day OC differentiation assay and a 10-day OC activity assay. We cultured commercially available CD34-positive osteoclast precursor-cells (Cambrex, East Rutherford, NJ, USA) on bovine bone slices (obtained from Nordic Bioscience, Herlev, Denmark) or on human bone plates (OsteoAssay™, Cambrex, East Rutherford, NJ, USA) in the presence of M-CSF and RANKL. Osteoprotegerin (OPG) was used as a reference inhibitor in the OC differentiation assay and the cysteine protease inhibitor E64 was used as a reference inhibitor in the OC activity assay. In the OC differentiation assay, OPG was added at day 0 and the cultures were stopped at day 7. Tartrate-resistant acid phosphatase isoform 5b (TRACP 5b) was measured from the culture medium collected at day 7 as an index of OC number using a commercially available immunoassay (BoneTRAP®, SBA-Sciences, Oulu, Finland). In the OC activity assay, culture medium was replaced with fresh medium at day 7 and the formed OCs were allowed to resorb bone for an additional 3 days. At day 10, C-terminal cross-linked telopeptides of type I collagen (CTX) were measured from the culture medium as an index of osteoclast activity using a commercially available immunoassay (CrossLaps® for culture, Nordic Bioscience). Baseline cultures without added compounds were included in both OC assays. In the OC differentiation assay, OPG decreased dose-dependently OC number in both substrates. TRACP 5b values were substantially higher in the baseline cultures in bovine bone than in human bone, and the decrease caused by OPG was significantly larger in bovine bone than in human bone. However, there was also considerably more variability in the TRACP 5b values in bovine bone than in human bone. In the OC activity assay, E64 decreased significantly medium CTX values in both substrates and the values of baseline cultures were substantially higher in bovine bone than in human bone. We conclude that both the bovine bone slices and human bone plates are convenient and reliable substrates when studying the effects of antiresorptive agents on OC differentiation and activity.

The Ratio of Osteoclast Activity/Osteoclast Number (CTX/TRACP 5b) Improves the Interpretation of the Effects of Anti-Resorptive Treatment in Human Osteoclast Cultures. J. P. Rissanen[1], S. Suutari*[1], S. Ylönen*[1], M. Baugh*[2], C. Long[2], J. M. Halleen[1]. [1]Pharmatest Services Ltd, Turku, Finland, [2]Organon Laboratories, Newhouse, United Kingdom.

C-terminal cross-linked telopeptides of type I collagen (CTX) are released from bone collagen during bone resorption, and serum CTX is a useful marker of osteoclast activity. It has been shown recently that serum tartrate-resistant acid phosphatase isoform 5b (TRACP 5b) reflects osteoclast number. We have studied the use of CTX and TRACP 5b as endpoint measurements in human osteoclast cultures. We cultured commercially available CD34-positive osteoclast precursor-cells (Cambrex, East Rutherford, NJ, USA) on bovine bone slices (obtained from Nordic Bioscience, Herlev, Denmark) for 7 days in the presence of M-CSF and RANKL, allowing their differentiation into bone-resorbing osteoclasts. At day 7, the culture medium was changed and test compounds were added. A baseline group without added compounds, a control group with the reference inhibitor E64 and groups with 7 different concentrations of two potential resorption inhibitors named as resorption inhibitors A and B were included in the study. The formed osteoclasts were cultured for an additional 3 days, allowing them to resorb bone in the presence of the test compounds. TRACP 5b was measured from the culture medium collected at day 7 as an index of osteoclast number using a commercially available immunoassay (BoneTRAP®, SBA-Sciences, Oulu, Finland). At day 10, CTX was measured from the culture medium as an index of osteoclast activity during days 7-10 using a commercially available immunoassay (CrossLaps® for culture, Nordic Bioscience). The reference inhibitor E64 significantly decreased CTX in the medium. The second lowest test concentration of compound A as well as the two lowest test concentrations of compound B showed decreased CTX in the medium compared with baseline CTX levels. However, TRACP 5b values at day 7 were lower in these three groups, suggesting that the decreased CTX values at day 10 were due to the presence of lower number of osteoclasts in these groups before the addition of the test compounds. CTX values were divided by TRACP 5b values to obtain a resorption index calculated per osteoclast. The resorption index was dose-dependently decreased by both compounds A and B. These results suggest that the resorption index (CTX/TRACP 5b) is a useful endpoint measurement in human osteoclast cultures, preventing variable results caused by the presence of different number of osteoclasts in different test groups when studying the effects of test compounds on osteoclast activity.

Adrenocorticotrophic Hormone Modulates Osteoclastic Cell Differentiation. S. Sridhar[1], Q. Zhong[1], C. M. Isales[2]. [1]Medicine, Medical College of Georgia, Augusta, GA, USA, [2]Medicine and Orthopedic Surgery, Medical College of Georgia and the Augusta VA Hospital, Augusta, GA, USA.

We have previously reported the presence of melanocortin receptors in osteoblastic and osteoclastic cells. Melanocortin receptors are activated by peptides derived from processing of a larger prohormone, pro-opiomelanocortin (POMC) which include hormones such as adrenocorticotrophic hormone (ACTH) and melanocyte stimulating hormone (MSH). We have also shown that POMC derived fragments such as ACTH can be synthesized and released from osteoclasts although what autocrine effect these fragments have on osteoclastic function is unknown. In an effort to define ACTH effects on osteoclast differentiation we utilized an osteoclast cell line RAW264.7. RAW cells were stimulated with 10 nM ACTH (1-24) and gene expression for the osteoclastic markers tartrate resistant acid phosphatase (TRAP), c-Fms and Cathepsin-k were measured sequentially over nine days by RT-PCR and quantitated by comparing to the housekeeping gene GAPDH. ACTH was not found to have any effect on c-fms expression. However, significantly increased expression of TRAP and cathepsin K was observed by the fifth day of exposure to ACTH. In contrast, in the absence of ACTH, expression of these markers was not evident in RAW cells until the seventh day of culture. Taken together these data demonstrate that ACTH facilitates the maturation of the osteoclastic cell line RAW264. into a more mature phenotype and suggests a novel autocrine mechanism for local regulation of bone resorption.

A Central Role for Caspase 3 and Hydrogen Peroxide in RANKL-induced Osteoclast Differentiation. K. H. Szymczyk, T. A. Freeman*, I. M. Shapiro, M. J. Steinbeck. Orthopaedic Surgery, Thomas Jefferson University, Philadelphia, PA, USA.

Recent studies indicate that caspase 3 plays a crucial role in events unrelated to programmed cell death, including cell cycle progression, cell activation, and cellular differentiation. To this end, we used pharmacological inhibitors specific for caspase 3 and created a permanent RNAi procaspase 3 clonal knockdown of RAW264.7 cells (RAWC3KD) to investigate the role of caspase 3 in RANKL-induced differentiation of osteoclasts. In the absence of stimulation, RAW264.7 cells contained measurable amounts of procaspase 3 that co-localized to lipid rafts within the plasma membrane and to the cytosol by immunofluorescent microscopy. Within 5 min of RANKL treatment, immunoreactive caspase 3 levels increased and co-localized to lipid raft regions. Since RANK co-localizes to lipid rafts, our results suggest a potential interaction between these two proteins. The increase in caspase 3 in response to RANKL occurred as early as 5 min, peaked at 15 min, and returned to baseline levels within 30 min. Western blot analysis confirmed early activation, and showed that procaspase 3 levels decreased as caspase 3 levels increased. Based on these spatio-temporal events, we evaluated the involvement of caspase 3 in early RANKL signaling. Our results demonstrate that in the absence of caspase 3, NF-kB activation and nuclear translocation were defective, indicating that this enzyme plays a role in mediating early RANK signaling events. In addition, the increase in caspase 3 in RANKL treated cells was inhibited by pretreatment of cells with a NADPH-oxidase inhibitor. Conversely, caspase 3 levels increased in response to exogenous hydrogen peroxide, a reactive oxygen species shown by others to be important in RANKL-mediated signaling. Most compellingly, cells without active caspase 3 were TRAP negative and remained mononucleate. Our results point to a central role for caspase 3 and hydrogen peroxide in mediating osteoclast differentiation.

Relationship of Osteoclast Mitochondrial Mass and Potential to its Morphology and Function. S. J. Wimalawansa, C. S. Herath, J. Ghosh*. Medicine, Robert Wood Johnson Medical School, New Brunswick, NJ, USA.

The molecular basis of age-related oxidative-stress associated imbalance in bone cell coupling is complex. These include enhanced osteoclast differentiation, life span, and increased bone resorption. We have developed methodologies to quantitate osteoclastic mitochondrial mass and potentials using a dual-color Florescent Activated Cell Sorting (FACS) method based on osteoclast marker RANK receptors (RANK-R) expression and osteoclast nuclear density. Bone marrow cells were cultured on glass cover slips to obtain over 98% pure osteoclast progenitors cells. Cells were harvested at 48, 72, 96 and 192 hrs, and their differentiation rates were analyzed on reference to their expression of RANK-R protein (immuno-labeling of RANK-R using goat-anti-mouse RANK-R Ab, and secondary labeling with Green flurochrome Labeled-rabbit anti-goat IgG). RANK-R labeled cells were stained with Propidium Iodide for simultaneous analysis of nuclear density. Osteoclast formation rates were examined at same time points by counting multi-nucleated vs. mono nucleated cells on randomly selected 16 fields after staining with Hoechet nuclear stain in a fluorescents microscopy. This method accurately separates distinct sub-population of high nuclear density and RANK-R expressing mature osteoclast cells. Linearity of the method and its' simplicity allowed us to accurately measure the osteoclast cell differentiation rates per unit time (i.e., slope of the graph) in many situations. Using this methods we have analyzed osteoclast differentiation rates from bone marrow cells, osteoblast mediated regulation on osteoclasts, and rates of osteoclast differentiations and maturity. An example of differentiation rates of RANK-R expressing and high nuclear

density (multinucleated) osteoclasts by FACS method is shown in figure 1. Mitochondrial mass and potential are highly correlated with the osteoclastic cell maturation, morphology and cellular integrity, and its bone resorbing activity. This simple methodology can be adapted to further understand the role of osteoclasts in different disease status.

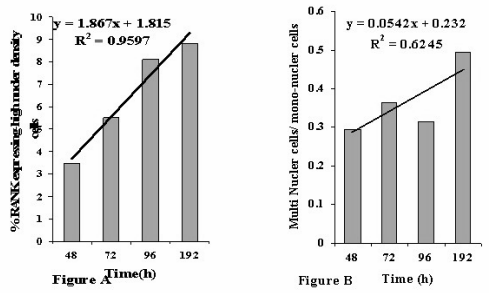

Figure A: Differentiation rates of RANK-R expressing & high nuclear density OCs by FACS method. Figure B: Multi- nuclear OCs formation rate by nuclear counting.

A Specific Requirement for the Microphthalmia Transcription Factor (Mitf) in Osteoclast Differentiation and Bone Development. C. L. Hershey[1], Y. L. Lin[2], M. L. Bouxsein[3], H. R. Widlund*[1], D. E. Fisher[1]. [1]Pediatric Oncology, Dana-Farber Cancer Institute, Boston, MA, USA, [2]Oral Pathology, University of Kentucky, Lexington, KY, USA, [3]Orthopedic Biomechanics, Beth Israel Deaconess Medical Center, Boston, MA, USA.

The Microphthalmia-associated transcription factor (Mitf) is a member of the MiT basic/helix-loop-helix/leucine zipper transcription factor family, which includes Mitf, Tfe3, Tfeb and Tfec. Dominant negative *Mitf* mutations (*Mitf*^{microphthalmia}) demonstrate that the MiT family is required for the differentiation and survival of osteoclasts, melanocytes, retinal pigment epithelium and mast cells. However, the requirement for individual family members is not known. Here we demonstrate a specific requirement for Mitf in osteoclast differentiation and bone development using a previously identified *Mitf*-null mouse, *Mitf*$^{VGA-9}$, (Hodgkinson et al., 1993). It is shown here that the *Mitf*$^{VGA-9}$*/Mitf*$^{VGA-9}$ mice have a mild osteopetrosis. Histological analysis of femurs and tibiae from *Mitf*$^{VGA-9}$*/Mitf*$^{VGA-9}$ mice reveals residual primary and secondary spongiosa compared to control littermates, indicating a defect in bone resorption. The increase in bone was visible in the majority (87%, n=47) of *Mitf*$^{VGA-9}$*/Mitf*$^{VGA-9}$ mice examined but varied in severity and appeared to improve with age. Micro CT measurements indicate increased trabecular bone in the femurs and vertebrae of *Mitf*$^{VGA-9}$*/Mitf*$^{VGA-9}$ mice compared to heterozygous controls, with significant differences in femoral ($p<0.05$) Tb.N, Tb.Sp and BMD and vertebral ($p<0.001$) bone volume fraction (BV/TV%), Tb.N and Tb.Sp. The micro CT, histology and X-ray evaluations of the *Mitf*$^{VGA-9}$*/Mitf*$^{VGA-9}$ mice demonstrate they have a nearly solid block of bone below the growth plate in the femurs and tibia. In *in vitro* osteoclast differentiation assays, the *Mitf*$^{VGA-9}$*/Mitf*$^{VGA-9}$ bone marrow and spleen had an impairment in the generation of multinucleated TRAP+ cells. The *Mitf*$^{VGA-9}$*/Mitf*$^{VGA-9}$ cultures showed a decreased ability to resorb bone *in vitro* when grown on bovine cortical bone slices. We examined *in vitro* osteoclastogenesis in another recessive *Mitf* allele, *Mitf cloudy-eye (Mitf*^{e}*)* and found the ability to generate bone-marrow derived osteoclasts was also diminished in the *Mitf*^{e}*/Mitf*^{e} mice. The results presented here indicate that loss of Mitf produces a bone phenotype that cannot be fully compensated for by other MiT family members, identifying a specific requirement for Mitf in osteoclastogenesis. This places Mitf among the transcription factors, including Pu.1, AP1, NFκB and NFATc1 that are fundamentally required for osteoclast differentiation and proper bone development.

RANKL Inhibition with Osteoprotegerin (OPG) Prevents Bone Loss but Does not Affect Immune Status in Arthritic Rats. M. Stolina[1], S. Adamu*[1], D. Dwyer*[1], S. Middleton*[1], F. Asuncion*[1], M. Ominsky[1], G. Schett*[2], U. Feige*[1], P. Kostenuik[1], D. J. Zack*[1]. [1]Amgen Inc., Thousand Oaks, CA, USA, [2]Div Rheum, Med Univ Vienna, Vienna, Austria.

Rheumatoid arthritis (RA) is an autoimmune disease characterized by inflamed joints, focal bone erosions, and periarticular osteopenia. Overproduction of receptor activator of NF-κB ligand (RANKL) is present at sites of erosion and is implicated in juxta-articular osteopenia. Rat adjuvant arthritis (AdA) is an immune-mediated, rapidly destructive disease characterized by the presence of RANKL-expressing activated T cells in the juxta-articular intramedullary space of bone. OPG, a RANKL inhibitor, prevents bone loss during the course of AdA. The role of RANKL inhibition on the inflammatory aspects of arthritis was evaluated by administering OPG during the course of AdA. AdA was induced in male Lewis rats using heat-killed mycobacteria in paraffin oil. AdA rats were treated subcutaneously every 3 days with placebo (PBS) or recombinant OPG-Fc (3 mg/kg) for 10 days beginning 4 days after disease onset, and sacrificed on day 14 after onset. Concentrations of RANKL and TRAP 5b (a bone resorption marker) were evaluated in terminal serum, as were PGE2 and pro-inflammatory cytokines (IL-1β, TNF-α, , IL-6, KC/GRO, and MCP-1) associated with progression of inflammatory arthritis. Hind paw volume was measured by water plethysmography and BMD by DXA. Serum RANKL concentrations were 138% higher in AdA rats vs non-arthritic controls ($p<0.01$). RANKL concentrations were significantly reduced to levels similar to non-arthritic controls ($p<0.01$) by OPG treatment. OPG also caused significant reduction in bone resorption, as shown by a 90% reduction in serum TRAP-5b ($p<0.001$ vs PBS-AdA rats). AdA rats had significantly lower ankle joint BMD ($p<0.05$ vs. non-arthritic controls), and OPG prevented this bone loss. Despite these potent antiresorptive effects, OPG had no apparent effect on the inflammatory component of arthritis. Hind paw volume in AdA rats was 100% greater than in non-arthritic controls ($p<0.05$); OPG had no effect on paw volume. AdA rats also had significantly greater serum levels of IL-1β, TNF-α, KC/GRO, IL-6, MCP-1 and PGE2 (2, 5, 2.5, 5, 2.5, and 4.5-fold greater than non-arthritic controls, respectively, $p<0.05$). OPG had no effect on serum concentrations of these pro-inflammatory cytokines. RANKL inhibition by OPG effectively prevented bone loss in arthritic rat paws. Despite clear evidence of systemic suppression of bone resorption and the presence of activated T cells expressing RANKL, OPG treatment did not influence any measured indicators of inflammation. These data suggest that RANKL plays an important role in bone resorption, but not in immune function.

Lipid Rafts, Vacuolar H^+-ATPases, and the Formation of the Ruffled Membranes of Osteoclasts. L. S. Holliday, J. Zuo. Orthodontics, University of Florida College of Dentistry, Gainesville, FL, USA.

Osteoclasts form ruffled membranes by transporting cytosolic vesicles to the plasma membrane. Subunit a3-containing vacuolar H^+-ATPases (V-ATPases) are abundant components of ruffled membranes. Osteoclasts contain both the constitutively expressed a1 isoform of subunit a, and a3, which is upregulated during osteoclastogenesis. After extraction of osteoclasts with cold 1% Triton X-100, 92% of a1 remained soluble while 94% of a3 pelleted during centrifugation of extracts at 150 KXg for 60 minutes. Flotillin, a marker for lipid rafts, was also abundant in the detergent-insoluble pellet along with a3. Treatment of osteoclasts with methyl--cyclodextrin altered the distribution of a3 in subcellular fractions, and triggered disruption of the ruffled membranes of pre-activated osteoclasts. V-ATPases co-segregated with flotillin in lipid raft fractions isolated by density gradient centrifugation. Cholera toxin subunit (CTB), which detects ganglioside GM_1, another marker of lipid rafts, stained the plasma membranes of unactivated, fixed, unpermeabilized, osteoclasts weakly. In contrast, CTB stained internal vesicular structures in these cells intensely, after they were permeabilized. Many of these internal vesicles were also stained with a polyclonal antibody against subunit E of V-ATPase. The ruffled membranes of resorbing osteoclasts were stained intensely by both CTB and the anti-E subunit antibody. These data suggest that integration of V-ATPases into lipid raft-rich vesicles plays a role in their transport to ruffled membranes, and that ruffled membranes, formed as these vesicles fuse with the plasma membrane, are rich in lipid rafts. The need for cholesterol for the formation of V-ATPase-containing lipid rafts may contribute to the profound sensitivity osteoclasts exhibit to inhibitors of farnesyl pyrophosphate synthase and HMG-CoA reductase.

Expression of the Zinc Transporter ZIP1 in Osteoclasts. S. N. Sahu*, M. A. Khadeer*, G. Bai*, A. Gupta. Biomedical Sciences, University of Maryland, Baltimore, Baltimore, MD, USA.

Zinc has been demonstrated to be an essential trace element for normal skeletal growth, and zinc deficiency has been associated with retarded growth. Zinc has been implicated in bone mineralization through regulation of alkaline phosphatase and other metalloenzymes. Zinc is fairly abundant in bone. Zinc has been previously demonstrated to be a potent inhibitor of osteoclastogenesis and osteoclast function. The mechanisms for cellular uptake of zinc into osteoclasts have not been characterized. Intracellular zinc homeostasis is maintained by two distinct families of transporters, *Z*rt-/Irt-like *p*roteins (ZIP) and the cation diffusion facilitator (CDF) family. The ZIP family of transporters mediates uptake of zinc into cells, whereas the CDF family is involved in zinc efflux and intracellular sequestration. We have corroborated previous studies on the reduction of osteoclastogenesis in the presence of extracellular zinc in murine osteoclasts. The optimal concentration of extracellular $ZnCl_2$ supplementation of culture medium for significant inhibition (45-55%) of osteoclastogenesis was determined to be ~5-10 μM $ZnCl_2$. Using reverse transcriptase-polymerase chain reaction, a ZIP1 fragment of 230 bp from murine osteoclasts was amplified. The sequence homology between the human and murine ZIP1 transcripts revealed ~82% nucleotide identity. ZIP1 is a 324 amino acid protein with a predicted molecular mass of ~34 kD, but can be seen as a dimer, presumably because of a leucine zipper motif. In both the human osteoblast and murine osteoclast, the ZIP1 protein can be detected at ~68 kD. The protein levels of ZIP1 were not appreciably changed during the transition from pre-osteoclast precursors (between days 1-4 of culture) to multinucleated osteoclasts (between days 5-6 of culture). ZIP1 was both diffusely distributed throughout the cytoplasm and present at the plasma membrane. Following an adenoviral-mediated overexpression of ZIP1 in murine osteoclasts, ZIP1 was predominantly colocalized with actin at the sealing zone, and significantly inhibited osteoclast function, as assessed by *in vitro* assays for resorptive activity. Finally, overexpression of ZIP1 negatively impacted NF-κB binding activity in osteoclasts, as assessed by electrophoretic mobility shift assays. In conclusion, these data both corroborate previous studies on regulation of osteoclast formation and activity by zinc, and provide the first direct evidence for a zinc transporter negatively impacting osteoclast differentiation and activity.

Characterization of the Actin-Binding Activity of Subunit B of Vacuolar H^+-ATPases. J. Zuo, S. Vergara*, S. Chen*, J. Jiang, M. KAKU*, S. Kohno*, Y. Gong*, I. Hurst, H. Huang*, L. Holliday. Orthodontics, University of Florida, Gainesville, FL, USA.

The B1 "kidney" and B2 "brain" isoforms of subunit B of vacuolar H^+-ATPase (V-ATPase) have actin binding sites that mediate interactions between the intact enzyme and filamentous-actin. Osteoclasts express B2, but not B1. Adeno-associated virus vectors were used to transduce mouse osteoclasts with wild-type B1 or $B1^{mut}$, a full length B subunit that contained minor alterations that disrupted actin-binding activity. Immunoprecipitations suggested that both B1 and $B1^{mut}$ assembled with endogenous V-ATPase subunits to form intact enzyme. Both B1 and $B1^{mut}$ were localized like endogenous V-ATPase subunits in unactivated osteoclasts. Wild-type B1 associated with the actin cytoskeleton and was transported to ruffled membranes, domains of the plasma membrane of resorbing osteoclasts. In contrast, $B1^{mut}$ failed to associate with the actin cytoskeleton and was not transported efficiently to ruffled membranes. Yeast subunit B also bound microfilaments with similar affinity as the mammalian B subunits, and competed with mammalian B subunits in vitro microfilament binding assays. Efforts are underway to disrupt the actin binding site in yeast subunit B to test to what extent the mutant, compared with wild type, rescues V-ATPase function when transduced into a B subunit null strain. These data show that the B1 isoform of B subunit contains the necessary information for targeting to the ruffled membranes of osteoclasts, even though it is not normally expressed in osteoclasts. The actin binding activity of B1 is involved in proper ruffled membrane targeting. Complimentary studies of the actin binding activity of yeast subunit B are ongoing.

***In Vitro* Effects of 5 Bisphosphonates on Apoptosis and Death of Macrophage-Like Cells.** M. Moreau*, P. Massin*, M. F. Basle*, D. Chappard. Faculté de Médecine, INSERM, EMI 0335-LHEA, Angers, France.

Bisphosphonates (BPs) inhibits bone resorption by reducing osteoclastic activity. This implies either a reduction of osteoclast number by cell death (apoptosis) or a reduce activity at the cell level, or by a combination of both effects. Pathophysiology of prostheses loosening is complex and implies an inflammatory reaction secondary to the phagocytosis of wear debris by macrophages with a secondary increased bone resorption by osteoclasts. It has been reported that BPs can inhibit proliferation and cause cell death in macrophages by induction of apoptosis and necrosis. We have used mouse macrophage-like J774.1 cells to evaluate the effects of 5 BPs. These cells can express TRAcP activity in vitro, like osteoclasts. Macrophage-like cells $5x10^4$ were cultured in 6-wells plates for 2 days. BPs (alendronate, pamidronate, etidronate, risedronate, zoledronic acid) were added in the medium at concentration of 10^{-6}, $5x10^{-6}$, 10^{-5}, $5x10^{-5}$ and 10^{-4}M during 3 days. For each concentration, experiment was done in triplicate. Cells were washed and resuspended. The effects of BPs were measured by flow cytofluorometry using annexin V-FITC (apoptosis) and propidium iodide (necrosis) on 2000 cells per technique. Etidronate did not cause apoptosis or cell death at any concentration. Alendronate and pamidronate caused apoptosis and death only at very high concentration [10^{-4}M]. On the contrary, apoptotic and dead cells were evidenced with risedronate or zoledronic acid at lower concentrations. These effects were dose-dependant and occurred when concentration reached [10^{-5}M]. The number of apoptotic cells was higher with zoledronic acid. AminoBPs could be proposed as a countermeasure in aseptic loosening of joint prostheses.

Rapid Osteoclast Apoptosis at the End of Lactation in the Maternal Skeleton. B. M. Bowman, S. C. Miller. Radiobiology, University of Utah, Salt Lake City, UT, USA.

Lactation is a period of high turnover dominated by bone resorption to permit utilization of skeletal mineral for milk production. At weaning, however, there is a rapid transition to an anabolic phase that rebuilds skeletal mineral stores. Within several days after weaning there is a rapid expansion of the osteoblast population, with a substantial portion of the cells being derived from proliferating progenitors. The purpose of this study was to document this rapid reversal period and to correlate these events with changes in the endocrine milieu. Established breeder, Sprague-Dawley rats were assigned to 5 groups; 1) Day 10 of lactation, 2) Day 19 of lactation, 3) 1 day post-weaning, 4) 1 week post-weaning and 5) age-matched, non-mated, estrus cycling females. The litters were normalized and pups weaned on day 20 of lactation. Estrus status was determined by vaginal smears and at necropsy tissues were collected to determine bone cell populations, morphology and apoptosis. Sera were collected for measurements of estrogen (E), prolactin (PRL), PTH and calcitonin (CT). Through lactation the animals were continually in diestrus, consistent with low serum E levels. At Day 10 and 19, TRAP-positive osteoclasts were abundant and spread over much of the cancellous bone surface. There was little, if any, indication of osteoclast apoptosis during this period as determined by morphological criteria and ISOL-BrdU labeling of DNA fragmentation. By one day after weaning most of the osteoclasts had rounded up and were removed from bone surfaces. There were numerous TRAP-stained apoptotic fragments of osteoclasts in the bone marrow and osteoclast nuclei were observed with the ISOL-BrdU label in the marginalized chromatin. Interestingly, on the day after weaning, serum CT levels were over 6 times greater than those observed the day before weaning, 136 ± 40 pg/ml vs. 21 ± 7 pg/ml, respectively. The greatly increased CT levels were transient, and returned to about 15 ± 3 pg/ml within 6 days after weaning. E levels also increase shortly after weaning and by the second day, all animals showed estrus-positive vaginal smears. The physiological change initiated by weaning triggers a mechanism in the maternal skeleton for the rapid reduction in the osteoclast population by apoptosis. These rapid changes are associated with a marked increase in circulating CT as well as the re-initiation of estrus (with increased circulating E). These rapid changes in osteoclast morphology are consistent with known effects of CT. This study further demonstrates the well synchronized events and adaptations that occur in the maternal skeleton during and after the reproductive cycle and provides new insights into endocrine regulation of natural physiological cycles in skeletal tissues.

Suppressions of Phenytoin in the Bone Resorption and Production of PGE_2 Induced by LPS. M. Koide, S. Fujita*, T. Sobue, N. Sato, M. Suzuki*, Y. Ishihara*, N. Yoshinari*, K. Inagaki, T. Noguchi*. Department of Periodontology, School of Dentistry Aichi-Gakuin University, Nagoya, Japan.

Phenytoin (Diphenylhydantoin, DPH) is often used a drug for seizure control. Gingival overgrowth is well known as an adverse effect and is characterized by increased proliferation of gingival fibroblasts and collagen synthesis. However, the effects of DPH on bone metabolism are still unclear. The purpose of this study is to examine the effect of DPH on bone resorption stimulated with lipopolysaccharide (LPS), as a bacterial pathogenic component *in vitro*. The effects of DPH stimulated with or without LPS which examined by mouse calvarial organ culture and osteoclast formation methods. DPH inhibited significant bone resorption and osteoclast formation induced by LPS. Moreover, RANKL mRNA expression examined in primary osteoblast (OB) cell by RT-PCR method. DPH did not affect RANKL mRNA expression in OB cell. We previously reported that the PGE_2 production is an important mediator for bone resorption induced by LPS. Therefore, the amount of PGE_2 measured in mouse calvarial organ and osteoclast formation culture supernatants by EIA method. DPH reduced the PGE_2 production stimulated with or without LPS in both culture supernatants. Furthermore, DPH inhibited bone resorption and osteoclast differentiation induced by LPS. Thus, it is suggested that DPH will have a possibly to protect an alveolar bone resorption induced by bacteria in periodontal disease.

Osteopontin Deficiency Impairs Wear Debris-Induced Osteolysis. S. Shimizu*[1], Y. Asou[2], N. Okuda*[3], N. Kato[4], S. R. Rittling[5], K. Shinomiya*[2], T. Muneta*[3], D. T. Denhardt[5], M. Noda[4]. [1]Tokyo Medical and Dental University, Center of Excellence program for Frontier Research Program on Molecular Destruction and Reconstruction of Tooth and Bone, tokyo, Japan, [2]Tokyo Medical and Dental University, Department of Orthopaedic Surgery, tokyo, Japan, [3]Devision of Bio-Matrix, Graduate School Tokyo Medical and Dental University, Section of Orthopeadic Surgery, tokyo, Japan, [4]Medical Research Institute, Tokyo Medical and Dental University, Department of Molecular Pharmacology, tokyo, Japan, [5]Rutgers University, Department of Cell Biology and Neuroscience, Piscataway, NJ, USA.

Periprosthetic osteolysis is the major complication following total joint replacement. Osteolysis reflects progressive generation of implant-derived wear particles that initiates a macrophage-mediated inflammatory response by resident macrophages, leading to osteoclast activation and bone resorption at the implant interface. To investigate molecular mechanisms underlying this clinically important event, we focused on osteopontin (OPN),

a cytokine and cell attachment protein. OPN is produced at high levels by macrophages in granulomas and is implicated in the mediation of inflammatory process and subsequent bone resorption by osteoclasts. The purpose of this study was to investigate the functions of OPN by previously established in vivo murine model of particle-induced osteolysis. OPN-deficient mice and wild-type littermates (1.5- to 3-month-old female mice), were anesthetized and the scalp incised longitudinally to expose the external cranial periosteum. The periosteum was elevated off the external cortex of the calvarium by sharp dissection. Thirty mg of commercially prepared titan particles were placed directly on the surface of the bone. Sham operation consisted of the entire procedure without particle implantation. Animals were sacrificed at 10 days, and each calvaria was excised, fixed, and decalcified. Frontal histological three sections of parietal bones with 200um intervals were picked up for each animal and evaluated immunohistologically. Whereas an inflammatory reaction was observed regardless of the genotypes, bone resorption area more than 400um away from sagittal suture was 50% decreased in OPN deficient mice compared with littermates. Histomorphological analysis indicated that osteoclast surface/bone surface was significantly reduced in OPN-deficient mice. Bone volume/tissue volume in vertebral body and urinal deoxypiridinoline was not affected by recipient genotypes after the particle implantation, indicated that general bone matabolism was not affected by OPN-deficiency. These results indicate that OPN plays a critical role in wear debris-induced osteolysis.

Tartrate-Resistant Acid Phosphatase 5b Is a Marker of Osteoclast Number in Human Osteoclast Cultures. H. Ylipahkala*[1], J. Rissanen[2], H. K. Väänänen*[1], J. M. Halleen[2]. [1]Anatomy, University of Turku, Institute of Biomedicine, Turku, Finland, [2]Pharmatest Services Ltd, Turku, Finland.

Tartrate-resistant acid phosphatase 5b (TRACP 5b) is released into the blood circulation from osteoclasts, and serum TRACP 5b has proved to be useful marker of bone resorption. Recent evidence has suggested that serum TRACP 5b would be a marker of osteoclast number rather than osteoclast activity. We have studied the effects of osteoprotegerin (OPG), sodium azide, alendronate (ALN) and clodronate (CLN) on secretion of TRACP 5b from human osteoclasts *in vitro*. Human osteoclast precursor cells (Poietics™, Cambrex, East Rutherford, NJ, USA) were cultured on bovine bone slices for 9 days. OPG was added into the culture medium at day 0 and azide at day 7, whereas ALN and CLN were coated into the bone slices before starting the culture period. TRACP-positive multinucleated osteoclasts and apoptotic osteoclasts were counted under a microscope. Medium TRACP 5b activity was determined using an in-house immunoassay and medium C-terminal cross-linked telopeptides of type I collagen (CTX) using a commercial immunoassay (CrossLaps® for culture, Nordic Bioscience, Herlev, Denmark). OPG, azide, CLN and ALN inhibited bone resorption by decreasing the number of osteoclasts. Both medium TRACP 5b activity and medium CTX decreased dose-dependently by all four compounds. Medium TRACP 5b activity correlated with both medium CTX and osteoclast number, and the correlation was in all cases stronger with osteoclast number. Azide, CLN and ALN dose-dependently increased cell death and decreased medium TRACP 5b activity, suggesting that TRACP 5b is not released from dying osteoclasts as an active enzyme. We conclude that medium TRACP 5b activity reflects the number of osteoclasts in this human osteoclast culture system, and TRACP 5b is not released from dying cells as an active enzyme.

RANKL Inhibition with AMG 162, a Fully Human MAb, Causes Sustained Suppression of Bone Resorption and Increased BMD in Knockin Mice Expressing Humanized RANKL. P. J. Kostenuik, K. Warmington*, M. Grisanti*, S. Morony*, Z. Geng*, H. L. Tan*, C. Christensen*, J. Sullivan*, H. Nguyen*, S. Adamu*, F. Asuncion, M. Ominsky, X. Li, J. McCabe*. Metabolic Disorders/Functional Genomics, Amgen Inc., Thousand Oaks, CA, USA.

RANKL plays an essential role in osteoclast formation, function, and survival. The RANKL inhibitor OPG-Fc suppresses bone resorption in postmenopausal women and in many animal models of bone disease. AMG 162, a fully human monoclonal antibody, is a RANKL inhibitor that increases BMD in postmenopausal women. AMG 162 does not neutralize rat or murine RANKL, which has hindered the direct comparison of AMG 162 and OPG-Fc in non-primate models. We therefore genetically engineered mice to express a chimeric form of RANKL that is neutralized by AMG 162. Knockin technology was used to replace the 5th exon of the murine RANKL gene with a hybrid exon containing a human coding region and a murine non-coding region. We compared the pharmadynamic response of these mutant homozygous (huRANKL) mice to AMG 162 and huOPG-Fc. Male huRANKL mice (2-3 months old, 8/group) or normal wild type (WT) controls were treated with PBS or with AMG 162 or OPG-Fc (5 mg/kg, twice/week, SC) for 3 weeks. As expected, AMG 162 had no detectable pharmacologic effects in normal WT mice. In contrast, treatment of huRANKL mice with AMG 162 caused a significant increase in lumbar BMD (by DXA) from week 1 through week 3 ($p<0.05$ vs PBS controls). OPG-Fc caused smaller, non-significant increases in BMD in huRANKL mice. The greater BMD response with AMG 162 was associated with more sustained suppression of bone resorption versus OPG-Fc. AMG 162 and OPG-Fc both caused rapid (24 h) and significant (75%) reductions in serum TRAP-5b. However, AMG 162 maintained this antiresorptive effect through day 21, while the antiresorptive effect of OPG-Fc was no longer apparent at day 21. Results in these young mice may have been influenced by their rapid growth, so the efficacy of AMG 162 was tested in aged (10 month old) female huRANKL mice. Mice were treated once/week with PBS or AMG 162 (2 or 10 mg/kg, SC) for 3 weeks. AMG 162 caused significant, dose-dependent reductions in serum TRAP-5b. Histomorphometric analysis of the proximal tibia showed that both doses of AMG 162 caused increased bone volume and decreased osteoclast surface ($p<0.05$ vs PBS controls). MicroCT analysis of lumbar vertebra showed that AMG 162 (10 mg/kg) increased bone volume and trabecular thickness ($p<0.05$ vs PBS controls). In summary, huRANKL mice represent a novel non-primate system for testing the pharmacologic effects of AMG 162, a fully human RANKL monoclonal antibody. AMG 162 caused greater increases in BMD and more sustained suppression of bone resorption compared to OPG-Fc.

Flavopiridol Inhibits Osteoblasts and Osteoclasts. J. Nguemo-Djiometio*[1], W. Jaeger*[2], O. Hoffmann[1]. [1]Pharmacology and Toxicology, University of Vienna, Vienna, Austria, [2]Clinical Pharmacy and Diagnostics, University of Vienna, Vienna, Austria.

Flavopiridol (FP) is a novel cyclin-dependent kinase inhibitor currently undergoing clinical development for the treatment of cancer. The aim of this study was to examine the effects of FP on osteoclast (OC) and osteoblast (OB) survival and function to determine whether this may be a potential treatment for tumour metastasis to bone. FP was evaluated in osteoclastogenesis using OC generated from spleen cells incubated with RANKL (25 ng/ml) and M-CSF (20 ng/ml). We assessed OC isolated from 4 day old New Zealand rabbits to test the effects on bone resorption and attachment**.** Primary cultures of mouse osteoblastic cells obtained by sequential collagenase/dispase digestion from calvaria of 1- to 2-day-old mice were used to investigate the effect of FP on cell viability and attachment. We stained OB and OC cytoskeleton with phalloidin-rhodamine and evaluated the actin content in OB under the fluorescence microscope. OB and the OC precursor cell line RAW 264.7 were evaluated for survival and apoptosis in the presence of FP using nuclear DAPI staining and the Celltiter96 Assay. FP inhibited bone resorption of mature rabbit OC by 100%, 50% and 25% at 10, 1, and 0.1 μM, respectively. FP at doses greater than 0.1 μM significantly decreased OC attachment to bovine bone slices. FP exerts its inhibitory effects at the NF-*k*B level through inhibition of I*k*Bα phosphorylation resulting in inhibition of OC differentiation. Osteoclastogenesis was completely inhibited when FP was added to cultures at early time points (0-4 days), and was only inhibited by approximately 10% when cells were treated after 4-5 days of culture showing that early differentiation was affected. FP reduced OC and OB viability after 12 hours of in vitro FP treatment. FP inhibited OB and RAW 264.7 cell proliferation, it induced apoptosis in OB at high doses (10 μM) and in RAW 264.7 cells at lower doses (1 μM). At low FP doses (0.1 μM), we observed altered cytoskeleton organization and stress fibers, which resulted in spindle-shaped OB. Taken together, these results demonstrate that FP inhibits both OB and OC. It affects differentiation, function and viability of OC and interferes with cytoskeletal organisation and survival of OB. The mechanism of action is not entirely clear, however, FP inhibits the activation of NF-*k*B and therefore reduces the expression of genes that regulate OC differentiation and survival. FP may be a novel treatment approach for bone tumours and metastases.

A Computational Model Delineates Differences in Hydroxyapatite Binding Affinities of Bisphosphonates in Clinical Use. F. H. Ebetino[1], B. L. Barnett*[2], R. G. G. Russell[3]. [1]Procter & Gamble Pharmaceuticals, Mason, OH, USA, [2]Dept.of Chemistry, University of Cincinnati, Cincinnati, OH, USA, [3]Institute for Musculoskeletal Sciences, Oxford University, Oxford, United Kingdom.

Differences in bone mineral binding affinities of clinically utilized bisphosphonates(BPs) have been described with a decreasing rank order of zoledronate>alendronate>ibandronate>risedronate>etidronate, (Nancollas et al, Bone, in press). Although all of these contain the central hydroxyl group, characteristic of high mineral affinity, significant differences in affinity among these drugs exist which may lead to differences in bone uptake and release. Work on early generation BPs demonstrated the importance of a tridentate binding mode to calcium in hydroxyapatite (HAP). In this current analysis, similar modeling on the HAP mineral surface with the nitrogen (N) - containing BPs allowed a computer-aided 3-D analysis of the potential orientation of the N functionality of these agents. Once a low energy conformation of each BP was oriented in this tridentate binding mode on the trigonal prismatic column of calcium atoms in HAP, the N side chain conformations of the BPs were examined for their interaction with the [001] surface. The 4-amino group of alendronate can form a strong N-H---O hydrogen bond (132°, 2.7Å N---O distance) to the labile ¯OH oxygen on HAP, where carbonate and fluoride are known to substitute. The corresponding ring N of zoledronate can only form a weaker electrostatic interaction with this labile ¯OH site. However it can form an additional strong hydrogen bond to a bifurcated network between two P-O oxygen atoms closely oriented within the crystal lattice including a 132° angle and a 2.7 Å N---O distance, explaining its high binding affinity. In the case of risedronate, steric hindrance of the pyridyl ring prevents its N from strong hydrogen bonds in either fashion and it may form only weaker electrostatic interactions, such as at the labile ¯OH (N---O distance 3.0 Å, 102°) This affords weaker binding affinity compared to alendronate and zoledronate, but does lead to higher affinity than that of etidronate (which has no N functional group). Comparative modeling of other BPs further demonstrates this affinity/H-bonding correlation. For example, the higher affinity 2-pyridyl analog of risedronate, NE-58018, can form a strong N-H---O hydrogen bond (127°, 2.9Å N---O distance) to the labile ¯OH and a strong bifurcated interaction at the P-O oxygen atoms. There is increasing evidence that the mechanism of action of each BP combines a differing ratio of biochemical activity vs bone mineral interaction, which can lead to different pharmacology and perhaps different bone quality over extended dosing periods.

Cathepsin K siRNA Transfection Inhibits Bone Resorption in Primary Human Osteoclasts. C. I. Selinger*, C. J. Day*, N. A. Morrison. School of Medical Science, Griffith University, Gold Coast, Australia.

The ability to easily transfect siRNAs into mature human osteoclasts, while they are in the process of resorbing actual bone, would provide an extremely useful tool for the large scale analysis of target genes in osteoclasts. We have undertaken a study which outlines the effectiveness of 'diced' siRNA in primary human osteoclasts using a number of transfection reagents, the potency of diced siRNA and its ability to significantly diminish bone resorption. Highly specific human siRNA for Cathepsin K was generated using recombinant human Dicer RNase III. Six transfection reagents (SiLentFect, Oligofectamine, Lipofectamine, GeneSilencer, JetPEI and Fugene6) were tested for effectiveness of siRNA incorporation using quantitative PCR and their cellular toxicity was monitored. Fugene6 and Lipofectamine were found to be the most effective for siRNA incorporation with the least cytotoxic effects in primary human osteoclast cells. We found 25nM to be the most potent siRNA concentration which achieved a reduction in Cathepsin K expression of >91% using Fugene6 and Lipofectamine. Osteoclasts could be transfected directly on dentine slices. For this method, human osteoclasts were differentiated for 14 days in the presence of RANKL and M-CSF on collagen coated plates and resuspended with dissociation buffer, then purified by low g centrifugation through 20% serum in medium at 200 rpm for 5 minutes. Resulting giant cells were plated directly onto sperm whale dentine slices cultured in normal medium and transfected immediately. Osteoclastic bone resorption was then monitored quantitatively by pit formation. Using this assay osteoclast bone resorption was significantly inhibited by Cathepsin K siRNA. This was demonstrated by a reduction in bone resorption area ($p=0.03$) and pit number ($p=0.03$). We show siRNA generated using Dicer enzyme is a potent inhibitor of the osteoclast gene Cathepsin K, and significantly inhibits the ability of primary human osteoclasts to resorb bone. siRNA provides a ready means of testing novel target genes directly for the bone resorption phenotype using the best possible standard, electron microscopy of bone resorption pits on whale dentine. Further optimizing and scaling up this technique should permit the simultaneous analysis of the involvement in bone resorption of large numbers of gene targets.

Disclosures: ***C.I. Selinger,*** *None.*

Rosuvastatin Inhibits Bone Resorption *In Vitro* by Inhibiting Protein Prenylation, and Prevents Ovariectomy-Induced Bone Loss *In Vivo*. A. Hughes*, J. C. Crockett*, A. I. Idris*, R. J. van't Hof*, M. J. Rogers. Medicine and Therapeutics, University of Aberdeen, Aberdeen, United Kingdom.

Statins are highly effective drugs that inhibit HMG-CoA reductase activity, thereby reducing the biosynthesis of cholesterol via the mevalonate pathway. Inhibition of HMG-CoA reductase also reduces protein prenylation by reducing the synthesis of farnesyl- and geranylgeranyl-diphosphate, which account for many of the pleiotropic effects of statins. For example, we have previously shown that mevastatin is a potent inhibitor of osteoclast function in vitro by causing loss of prenylated small GTPases, although others have suggested that statins may have bone anabolic properties. We investigated the in vitro effects on osteoclasts of the hydrophilic statin rosuvastatin (RSV, Crestor) in comparison to cerivastatin/CER, pravastatin/PRA and simvastatin/SIM. All four statins (0.1 to 10 microM) prevented the prenylation of the small GTPase Rap1A in rabbit osteoclasts in a concentration-dependent manner (order of potency CER>SIM>RSV>PRA). These concentrations also significantly inhibited bone resorption in cultures of rabbit osteoclasts, with the same order of potency. Addition of mevalonic acid (100 microM) or geranylgeraniol (20 microM) at least partially restored protein prenylation and bone resorption from inhibition by all four statins, confirming that these agents inhibit bone resorption by inhibiting the mevalonate pathway. 20mg/kg RSV also inhibited prenylation in osteoclasts in neonatal rabbits in vivo, demonstrated by accumulation of unprenylated Rap1A in osteoclasts purified from long bones 24 hours after injection. The effects of statin treatment on ovariectomy (OVX)-induced bone loss were examined in 8-week old Balb-C mice. Groups of seven sham operated or OVX mice were injected intraperitoneally with RSV for three weeks, then changes in bone parameters were measured by pQCT and microCT in the proximal tibia. OVX caused an 11% decrease in cortical BMD and a 54% decrease in trabecular bone volume. RSV significantly prevented loss of cortical BMD (47% recovery from OVX-induced loss with 2 mg/kg/day RSV, $p<0.002$) and loss of trabecular bone volume (27% recovery from OVX-induced loss with 2 mg/kg/day RSV, $p<0.05$). Mineral apposition rate, assessed by calcein double labelling, was significantly decreased by RSV treatment in sham and OVX mice. In conclusion, RSV, like other statins, inhibits bone resorption in vitro by reducing protein prenylation in osteoclasts. RSV can also inhibit protein prenylation in osteoclasts in vivo and appears to prevent OVX-induced bone loss in mice, primarily by inhibiting bone resorption.

Resorbing Osteoclasts Increase the Availability of Mineral-Bound Bisphosphonates to Non-Resorbing Cells. F. P. Coxon*[1], K. Thompson*[1], F. H. Ebetino[2], M. J. Rogers[1]. [1]Medicine & Therapeutics, University of Aberdeen, Aberdeen, United Kingdom, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

Bisphosphonates (BPs) target to bone due to their high affinity for calcium ions. During resorption, BPs are released from the acidified bone surface and taken up by osteoclasts, where they act by inhibiting the prenylation of small GTPases essential for osteoclast function. We recently investigated whether osteoclasts are the only cells in the bone microenvironment that can internalize BPs from the bone surface, by using a fluorescent alendronate analogue (FL-ALN) and by examining changes in the prenylation of the small GTPase Rap1A following treatment of cells with risedronate (RIS). Non-resorbing osteoblasts, macrophages and tumour cells internalized small amounts of BP from bone surfaces, but it remained unclear whether this was sufficient to affect the function of these cells. In this study, we measured the number of J774 macrophages and MCF-7 breast cancer cells remaining on dentine discs pre-coated with RIS, after 48 or 72 hours of culture, respectively. J774 cells were more susceptible to inhibition of prenylation under these conditions than MCF-7 cells, presumably due to the higher endocytic activity of the macrophages. Whereas 100μM RIS in solution reduced viable cell number by 96% (J774 cells) and 45% (MCF-7 cells), culturing these cells on dentine discs pre-coated with 100μM RIS caused only a small reduction in viable cell number (9% for J774 cells; 12% for MCF-7 cells). When cells cultured on dentine were incubated continuously with RIS, an intermediate effect was found (36% and 24% respectively), presumably because only a proportion of RIS becomes bound to dentine and unavailable for uptake by the cells. However, these cultures were carried out in the absence of osteoclasts, and it is possible that BPs released from the surface of mineralized tissues by the resorptive activity of osteoclasts can then by internalized by other cells in the local microenvironment. To investigate this possibility, we used confocal microscopy to analyse the uptake of FL-ALN by J774 cells co-cultured with rabbit osteoclasts. J774 cells adjacent to resorbing osteoclasts frequently internalized more FL-ALN than J774 cells distant from osteoclasts, although it is unclear whether this FL-ALN had diffused through the sealing zone or passed through the osteoclasts by transcytosis. In addition, J774 cells occupying resorption pits that had been vacated by osteoclasts internalized more FL-ALN than those attached to unresorbed surfaces. These results indicate that BPs may have direct effects on non-resorbing cells such as tumour cells, particularly those that are in the vicinity of resorbing osteoclasts *in vivo*.

Osteoclasts Resorb Human Cortical Bone Anisotropically. C. Janeiro*, R. Bizios*, D. Vashishth*. Biomedical Engineering, Rensselaer Polytechnic Institute, Troy, NY, USA.

When *in vivo* osteoclastic resorption occurs, the cutting cones are led longitudinally by osteoclasts through the long bones. It is unknown how osteoclasts orient themselves to lead the basic multicellular unit [1,2]. The present *in vitro* study investigated the role of bone microstructural elements in directing osteoclastic bone resorption. Longitudinal and transverse slices (4mmx4mmx200-300μm, WxLxH), were obtained from 17 frozen human tibiae (Ages 34 to 89). Human osteoclast precursor cells (Cambrex Poietics™) were prepared per the manufacturer's instructions, and cultured on the human bone slices (10,000 precursor cells/bone slice) for 14 days. The osteoclastic phenotype was confirmed by cell multinuclearity, TRAP-positive staining, and the ability to resorb bone. The bone slices were cleaned of osteoclasts and stained with toluidine blue; the area and the number of resorption pits were measured. For each transverse slice, the resorption pits were categorized based on their interaction with a cement line. These interactions were classified as either Type I (the resorption area contacts a cement line but does not cross it) or Type II (the resorption area crosses a cement line) [4]. The number of resorption pits/ mm^2 and average resorption pit surface area of the longitudinal and transverse slices, as well as the number of Type I and Type II interactions, were compared using parametric tests (MiniTab). The number of resorption pits formed on the longitudinal slices was significantly ($p<0.01$) greater than the number of resorption pits found on the transverse slices. The resorption pits found on the longitudinal slices were also significantly ($p<0.01$) larger than those found on the transverse slices. On the transverse slices, the number of Type I interactions was significantly ($p<0.05$) higher than the observed Type II interactions. Based on these results we conclude that microstructural element of bone, including the cement lines, may be involved in directing osteoclastic bone resorption. More importantly, a large proportion of the resorption pits did not cross the cement line, which is consistent with literature results [3,5] that showed that dephosphorylation of osteopontin (OPN) causes osteoclast detachment. The mechanism of this event may involve OPN, which is known to be present in high amounts in the cement line [4], and the propensity of osteoclasts to bind with OPN [5].

Interferon-γ Regulation of Osteoclast Inhibitory Peptide-1 (OIP-1/hSca) Gene Promoter Activity. S. Srinivasan*, E. Tsuruga*, W. L. Ries, L. L. Key Jr, S. Yang, S. V. Reddy. Children's Research Institute, Medical University of South Carolina, Charleston, SC, USA.

Osteoclast formation and activity are regulated by autocrine/paracrine factors produced in the bone microenvironment. We have previously identified and characterized osteoclast inhibitory peptide-1 (OIP-1/hSca), a member of Ly-6 gene family. Immune cell products such as IFN-γ are potent inhibitors of osteoclast formation. We have previously shown that IFN-γ stimulates OIP-1/hSca expression in osteoclast precursor cells. However, IFN-γ modulates gene expression through complex regulatory mechanisms. To determine the molecular mechanisms that regulate OIP-1 gene expression in osteoclast precursor cells, we isolated and characterized the human OIP-1/hSca gene (2 Kb) promoter. IFN-γ treatment of RAW 264.7 cells transfected with an OIP-1 gene promoter-luciferase reporter plasmid demonstrated a significant (4 fold) enhancement of luciferase activity. Analysis of the OIP-1 gene promoter sequence identified a potential Stat-1 binding motif at -1625 to -1640 bp position relative to the transcription initiation site. We therefore examined Stat-1 regulation of OIP-1 gene promoter activity in response to IFN-γ treatment to osteoclast precursor cells. IFN-γ stimulation of RAW 264.7 cells transfected with OIP-1 gene (-1 to -1988 bp) promoter-luciferase reporter construct in the presence of Stat-1 inhibitor, fludarabine (50μM) abolished IFN-γ stimulated OIP-1 gene promoter activity. Electrophoretic mobility shift assay (EMSA) demonstrated activated Stat-1 binding to the OIP-1 gene promoter sequence. Antiphospho-Stat-1 antibody addition to the EMSA reaction abolished Stat-1 binding to the OIP-1 gene promoter region. Furthermore, nuclear extracts derived from fludarabine treated IFN-γ stimulated RAW 264.7 cells did not demonstrate binding to the Stat-1 consensus sequence present in the OIP-1 gene promoter. However, IFN-γ treatment did not stimulate the activity of a OIP-1 gene promoter deletion construct that lacked the Stat-1 binding region. These data suggest that IFN-γ regulates OIP-1 gene promoter activity in osteoclast precursor cells through a Stat-1 dependent signaling pathway.

Access to BMD Testing Is Weakly Associated with Osteoporosis Management. D. H. Solomon[1], J. Polinski*[1], C. Truppo*[2], C. Egan*[2], S. Jan*[2], M. Patel*[2], Y. Chen[3], T. Weiss[3], M. A. Brookhart*[1]. [1]Division of Pharmacoepidemiology, Brigham and Women's Hospital, Boston, MA, USA, [2]Horizon Blue Cross Blue Shield of New Jersey, Newark, NJ, USA, [3]Merck, Whitehouse Station, NJ, USA.

Introduction: While sub-optimal management of osteoporosis has been well described, the correlates are not well understood. We assessed whether decreased access to BMD testing was related to lower rates of osteoporosis management in a large cohort of at-risk beneficiaries of Horizon Blue Cross Blue Shield of New Jersey (NJ). Methods: We identified 9639 at-risk beneficiaries, including women ≥ 65 years old (n = 8283), and men and women ≥ 45 years old with a fracture (n = 740) or taking chronic oral glucocorticoids (n = 616) during the period 2003-2004. Osteoporosis management measured by a BMD test and/or filled a prescription for a medicine used for osteoporosis was determined through insurance claims data. Two aspects of access were examined -- the number of persons ≥ 65 per DXA machine for each of the 21 counties in NJ and the driving time for each person to the nearest DXA machine. To assess the independent effects of these measures of access on osteoporosis management we constructed regression models that included patient variables such as age, prior fracture, and comorbid conditions. These models were constructed using Generalized Estimating Equations and accounted for the clustering at the county level. Results: Of 9639 at-risk subjects, we found that 3104 (32%) had undergone a BMD test, 2893 (30%) had filled a prescription for an osteoporosis medication, and 4364 (45%) had one or the other. Across the 21 counties of NJ, the percentage of at-risk patients who had a BMD test and/or medication for osteoporosis ranged from 38% to 52%. In a multivariate model adjusting for various patient factors, an increase of 1000 people per DXA machine was associated with a decrease in probability of 1.6% (p=0.01) of a patient being screened or treated for osteoporosis. However, driving times were not associated with screening or treatment. There was a reduced probability of being screened or treated for patients with more comorbidities, -1.6% (p<0.001) per condition. Conclusion: Access to BMD testing as measured by the number of persons ≥ 65 years old per DXA testing center appears to be a significant but relatively weak predictor of receiving BMD and/or medications for osteoporosis. However, driving times to DXA testing centers were not associated with osteoporosis management. These data suggest that increasing the number of BMD testing sites may only have a weak impact on improving the management rates for osteoporosis in a state like NJ.

Diagnosed Osteoporosis: The Tip of the Iceberg. M. S. Anthony*, B. D. Bradbury*, J. A. Satia*. Epidemiology, Amgen Inc., Thousand Oaks, CA, USA.

Osteoporosis is a silent disease that is often undiagnosed until there is a bone fracture. This study was done to determine the prevalence of physician-diagnosed osteoporosis in U.S. men and women and relate this to osteoporosis prevalence determined by bone mineral density (BMD) measurement. Data were from the National Health and Nutrition Examination Surveys (NHANES) III (1988-1994) and IV (1999-2002) which were designed to obtain a representative sample of the non-institutionalized, U.S. civilian population. Demographic data and self-reported physician diagnosis of osteoporosis were collected by questionnaire. Femoral BMD was measured using dual-energy X-ray absorptiometry. Classification of osteoporosis was based on total femur BMD (t-score<-2.5) using data for non-Hispanic white women as the referent. Prevalence of osteoporosis at hip+spine was projected from the NHANES III hip data. Age- and gender-specific hip osteoporosis prevalence estimates from NHANES were multiplied by gender-specific ratios of osteoporosis prevalence at hip+spine/hip from published reports. Weighting variables provided by NHANES were used to project to the U.S. population and prevalence estimates were calculated using "surveymeans" procedure in SAS (Cary, NC). The prevalence of osteoporosis and diagnosed osteoporosis increased with age and was higher in women than men. Prevalence of osteoporosis and diagnosed osteoporosis differed by racial group in women, with highest prevalence among non-Hispanic whites, lowest in non-Hispanic blacks, and intermediate in Hispanics (data not shown). The biggest discrepancy between prevalence of osteoporosis determined by BMD and self-reported, physician-diagnosed osteoporosis was in older men and women. Prevalence of osteoporosis projected to hip and spine may be an underestimate of the true osteoporosis prevalence; therefore, the discrepancy between physician-diagnosed and BMD-determined osteoporosis might be even greater. The recent Surgeon General report cited that about 10 million U.S. individuals over age 50 have osteoporosis at the hip. When projected to hip and spine, to reflect physician practice, osteoporosis prevalence is likely double that. Osteoporosis appears to be under-diagnosed by physicians, suggesting that a sizeable portion of the population may have unrecognized and untreated disease and is therefore at significant fracture risk.

Projected osteoporosis prevalence determined by BMD and physician-diagnosed osteoporosis prevalence

	Females		Males	
Age group	Hip+spine osteo prevalence	Diagnosed 1999-2002	Hip+spine osteo prevalence	Diagnosed 1999-2002
50-59	6.0%	7.8%	3.9%	1.2%
60-69	24.4%	15.5%	4.3%	2.2%
70-79	35.7%	23.3%	6.7%	2.7%
80+	62.3%	28.6%	11.6%	3.6%

A Meta-Analysis of Relationships among Leptin, Fat Mass, Lean Mass, and Bone Mineral Density. C. Pongchaiyakul[1], N. D. Nguyen[2], V. Pisprasert*[3], T. V. Nguyen[2]. [1]Division of Endocrinology and Metabolism, Department of Medicine, Khon Kaen University, Khon Kaen, Thailand, [2]Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia, [3]Division of Nutrition, Department of Medicine, Khon Kaen University, Khon Kaen, Thailand.

While the association between leptin and fat mass is well established, the association between leptin and bone mineral density (BMD) is not clear due to conflicting finding from observational studies. The present study was aimed at examining the inter-relationships among leptin, fat mass (FM), lean mass (LM) and BMD by a meta-analysis. A systematic search of literature (via PubMed and Medline search engines) was conducted to identify all published studies on the association among the variables. The publication was limited to English language. Only studies on post-menopausal women were included in the analysis. For each study, the correlation coefficients among the variables were manually extracted and tabulated in the SAS system for analysis. The DerSimon-Laird random-effects meta-analysis model was used to estimate the overall correlation coefficient and its 95% confidence interval. In total, 25 studies were identified from the literature, which involved 5803 post-menopausal women aged between 50 and 90 years. Results of the random-effects meta-analysis indicate that leptin was significantly correlated with FM (r=0.61; 95%CI: 0.55-0.67) and whole body BMD (r=0.13; 0.10-0.16). There was no significant correlation between leptin and femoral neck BMD (r=-0.04) or lumbar spine BMD (r=-0.03). Moreover, the correlation between LM and BMD (rLM) was consistently and significantly higher than that between FM and BMD (rFM): for whole body BMD: rLM=0.30 (95%CI: 0.24-0.36) vs. rFM=0.19 (0.13-0.25); for lumbar spine BMD: rLM=0.34 (0.30-0.39) vs. rFM=0.19 (0.19-0.29); and for femoral neck BMD: rLM=0.37 (0.32-0.43) vs. rFM=0.24 (0.17-0.29) for femoral neck. At the femoral neck, there were 99.4% chances that rLM>0.3, but there were only 0.9% chances for rFM>0.3. In each correlation analysis, there was a significant heterogeneity among studies. These results suggest that although leptin was highly correlated with fat mass, the effect of leptin on BMD was modest, accounting for around 1% of BMD variance. The modest leptin-BMD association was partly due to the fact that BMD was more likely to be correlated with lean mass rather than fat mass.

Bone Loss Associated with Primary Biliary Cirrhosis in Japnese Women. K. Takaguchi*[1], T. Inaba*[1], K. Kita*[1], Y. Onoda*[2], H. Miyatake*[3], Y. Takei*[4], A. Satou*[5], M. Ando*[6], K. Kawamura*[7]. [1]Department of Internal Medicine, Kagawa Prefectural Central Hospital, Takamatsu, Japan, [2]Department of Surgery, Kagawa Prefectural Central Hospital, Takamatsu, Japan, [3]Department of Internal Medicine, Hiroshima Municipal Hospital, Hiroshima, Japan, [4]Department of Orthopaedics, Ritsurin Hospital, Takamatsu, Japan, [5]Department of Internal Medicine, Kagawa Prefectural Saiseikai Hospital, Takamatsu, Japan, [6]Department of Internal Medicine, Mitoyo General Hospital, Toyohama, Japan, [7]Department of Health, Kibi International University, Takahashi, Japan.

Primary biliary cirrhosis (PBC) is a chronic cholestatic liver disease mostly occurred in women and associates increasing rate of bone loss and higher risk of fractures. The objective of this study was to investigate the pathogenesis of bone loss associated with PBC in postmenopausal Japanese women. Forty PBC Japanese female in- or out-patients who are already post-menopause and fifty age-matched post menopausal women without PBC living in Kagawa prefecture were investigated. Both PBC patients and the control group were examined their bone mineral density (BMD) with dual X-ray absorptiometry (QDR2000 or QDR4000, Toyo-Medic Inc.) at the lumber spine. Osteoporosis or osteopenia were diagnosed according to their T-scores. The biological markers for bone metabolism and hepatic were evaluated in PBC group. No significant difference was observed in ages, BMD's and T-Score's between PBC group and control group. Numbers of patients diagnosed as osteopenia and osteoprosis in PBC group were 7 (17.5%) and 13 (32.5%), respectively. Those in control group were 13 (25.5%) and 5 (9.8%), respectively and the frequency of osteoporosis including osteopenia in PBC group was significantly higher than that in the control group ($p<0.005$). Serum levels of i-PTH, osteocalcin and 1,25(OH) $_2D_3$ in all patients were within the control levels. Negative association between BMD and serum osteocalcin was observed ($p<0.05$). PBC patients showed higher urinary NTX levels suggested the stimulated bone resorption in PBC patients with bone loss who were diagnosed as osteopenia or osteoporosis. No apparent relationship was confirmed between BMD and impaired absorption of vitamin D due to cholestasis which were reported in the literatures. No significant correlation between BMD and biological parameters of hepatic function such as γ-GTP, but a negative correlation was observed. This does not suggest that the reduced BMD was attributed to the impaired hepatic function. Further investigation should be required in severe chronic hepatitis patients in order to reveal the pathogenesis of bone loss in patients with lowered hepatic function such as PBC.

Growth- and Age-Related Deficit in Bone Mass in Women with Low Volumetric BMD: Insights from their Daughters. Y. Duan[1], P. Garnero[2], X. Wang*[1], P. Szulc[2], O. Borel*[2], S. Filardi*[1], P. D. Delmas[2], E. Seeman[1]. [1]Endocrinology and Medicine, the University of Melbourne, Heidelberg, VIC, Australia, [2]INSERM Unit 403, Hôpital Edouard Herriot, Lyon, France.

We measured remodelling markers, bone size, and volumetric BMD (vBMD) at the femoral neck (FN) in healthy postmenopausal women, women with spine or hip fractures and their premenopausal daughters to test the following hypotheses: (i) the deficit in vBMD in the mother will be due to low peak vBMD if the daughter has a deficit in vBMD and remodelling markers are normal; (ii) the deficit in vBMD will be due to high remodelling (and excess loss) if the daughter has normal vBMD and markers but mother has high remodelling markers. From our 300 mother-daughter pairs, we selected 70 postmenopausal mothers (mean age 69.3 yrs) with low FN vBMD (T < -1.5SD) with or without fractures and their 62 premenopausal daughters (mean age 40.0 yrs). We further divided mothers with low vBMD into those with higher remodelling markers (26 mothers and their 23 daughters) and mothers with low vBMD with normal and lower remodelling markers (44 mothers and their 39 daughters). We measured FN diameter and vBMD using dual energy x-ray absorptiometry. Serum osteocalcin and β-CTX were measured by Elecsys immunoassay analyser.

Trait Z-Scores (SD unit) in Premenopausal daughters

	FN Diameter	vBMD	Osteocalcin	β-CTX
Mother with low vBMD	0.31±0.10*	-0.66±0.08*	-0.02±0.15	-0.12±0.12
Mother with low vBMD & high marker	0.41±0.20*	-0.73±0.14*	0.42±0.30	-0.11±0.22
Mother with low vBMD & normal marker	0.25±0.11*	-0.63±0.11*	-0.27±0.16	-0.12±0.15

* $p < 0.05$ compared with zero

The daughters of mothers with low vBMD, irrespective of marker status, had high FN diameter, reduced vBMD and normal markers suggesting that the larger FN with low vBMD in mothers (data published and replicated here but not shown) originated during growth. Daughters of mothers with low vBMD and high markers had increased FN diameter, reduced vBMD and higher Z-score for osteocalcin, consistent with the view that the low vBMD in the mothers was also due to higher remodelling. In mothers with low vBMD and normal markers, their daughters also had increased FN diameter and reduced vBMD but the markers were normal. We infer that low vBMD in elderly women has its origins in growth and ageing and rational approaches to therapy may require understanding the heterogenous pathogenesis of bone fragility.

Factors that Affect Decision to Undergo a Bone Mineral Density Scan. A. Baheiraei[1], J. A. Eisman[1], N. A. Pocock[2], T. V. Nguyen[1]. [1]Bone and Mineral Research Program, Garvan Institute of Medical Research, St Vincent's Hospital,University of New South Wales, Sydney, Australia, [2]Nuclear Medicine, St Vincent's Hospital, University of New South Wales, Sydney, Australia.

Because bone mineral density (BMD) is a primary predictor of fracture risk, a BMD measurement to diagnose osteoporosis plays a key role in treatment decisions. However, several recent studies suggest that high-risk individuals are not being diagnosed or treated. The aim of the study was to investigate factors that could influence the decision to undergo a BMD measurement in a non-English speaking group in an English-speaking community. The study was designed as a cross-sectional investigation, in which 131 Iranian- Australian women aged 35 years or older (range: 35-77) participated in a study of osteoporosis knowledge and preventive behaviors. After obtaining informed consent, each woman completed a set of questionnaires from which data on socio-demographic, clinical characteristics and lifestyle factors were obtained. All women were offered a free BMD scan, which was measured at the lumbar spine and femoral neck by using DXA (GE-LUNAR, WI, USA). Only 90 women (or 69%) took up the offer to have a BMD measurement. Among these women, 13.3% were found to have osteoporosis (T-scores ≤-2.5). In multivariate logistic regression analysis, the following factors were found to be independent predictors of accepting a BMD scan: a familial history of osteoporosis (odds ratio [OR] 2.7; 95% CI 1.1-8.0), higher knowledge of osteoporosis scores (OR 1.3; 1.1-1.5), perception of susceptibility to osteoporosis (OR 1.1; 1.0-1.2), and those with lower calcium intake (OR 1.0; 1.0-1.1) were less likely to accept the offer. These findings in a group with limited access to public media suggest that familial history of osteoporosis was the strongest predictor of BMD scan decision. However, other behavioral factors such as knowledge and perception of osteoporosis also influence a woman's decision to undergo a BMD measurement. These findings should help the development of multilinguinal educational programs designed to overcome the underdiagnosis and undertreatment in osteoporosis.

Gender Discrepancies in Bone Size and Bone Mineral Density. Data from the Copenhagen School Child Intervention Study (CoSCIS). H. Hasselstrøm[1], M. K. Karlsson[2], S. E. Hansen*[1], V. Grønfeldt*[1], L. Andersen*[1]. [1]Institute of Exercise and Sport Sciences, Copenhagen, Denmark, [2]Clinical and Molecular Osteoporosis Research Unit, Department of Clinical Sciences, Lund University, Malmö University Hospital, SE-205 02 Malmö, Sweden.

The aim of this study was to provide gender specific normative data of peripheral bone mineral density (BMD) and bone size in children aged 6 to 8 years. A total of 368 boys and 326 girls with a mean age of 6.7 ± 0.4 years had their BMD (g/cm^2) evaluated by a peripheral dual energy X ray absorbtiometry (DXA) device in the distal forearm and os calcanei. Weight, height, skinfolds, the width of distal forearm and the femur condyles were also measured and body composition estimated from skinfolds measurements according to the Weststrate equation. The results show no difference between the boys and girls was found in calcaneus BMD whereas boys had 4.5% higher forearm BMD than girls ($p<0.001$). Boys also had 2.7% larger distal forearm width and 4.7% larger knee width (both $p<0.0001$, respectively). Calcaneus BMD correlated with weight (partial $r = 0.50$), fat free mass (FFM) (partial $r = 0.50$), fat mass (FM) (partial $r = 0.45$), percent body fat (partial $r = 0.29$) and knee width (partial $r= 0.46$), all $p<0.0001$. Adjusted for weight, no significant relationship remained while adjusted for FFM, the relations remained but all at lower level than in the unadjusted correlations. Forearm BMD correlated with weight (partial $r = 0.37$), FFM (partial $r = 0.39$), FM (partial $r = 0.28$), percent body fat (partial $r = 0.14$) and wrist width (partial $r = 0.24$), all $p<0.0001$. Adjusted for body weight and FFM separately, the relationship remained but at a lower level than the unadjusted correlations. Children measured in the spring had 3.5% greater calcaneus BMD than children measured in the winter ($p<0.01$). In conclusion. This study suggests that in children aged 6 to 8, boys have higher peripheral BMD and larger bone size than girls, a seasonal variation in BMD exists and body weight is the best predictor of calcaneus BMD whereas both body weight and FFM are similar good predictors of forearm BMD.

Evaluation of Gender Differences in Long Bone Shape in Childhood. E. M. Clark*[1], J. H. Tobias[2]. [1]Community Based Medicine, University of Bristol, Bristol, United Kingdom, [2]Clinical Science at South Bristol, University of Bristol, Bristol, United Kingdom.

Recent studies indicate that cross sectional area of long bones is greater in boys compared to girls, reflecting more rapid appositional growth in the former. This is thought to contribute to the well-documented gender differences in bone strength and fracture risk. Whether the relative rates of appositional and longitudinal growth in childhood also differs between boys and girls, leading to gender differences in bone shape, is currently unclear due to difficulties in measuring other parameters such as long bone length. To test the hypothesis that overall shape of long bones differs between boys and girls as a result of gender-specific differences in the relative rates of longitudinal and appositional growth, we developed a novel technique for measuring long bone length, width, and aspect ratio (AR; length divided by width) from total body DXA scans. This technique was applied in 142

girls and 132 boys randomly selected from the Avon Longitudinal Study of Parents and Children (ALSPAC), a birth cohort study from the UK. The humerus was defined as a specific region of interest on total body scans obtained using a Lunar Prodigy at age 9.9 years, following which length, mean width and AR was derived (CV for humeral width = 2.0%, 95% CI 1.51 to 2.50). As expected, humeral width and length were positively correlated with age and height (P<0.01). Gender differences in these measures were subsequently examined by linear regression after adjustment for age and pubertal stage as assessed by self-completion Tanner questionnaires. We found that the humerus in boys compared to girls is shorter but wider, leading to a smaller aspect ratio (see Table). Therefore, as well as gender differences in cross-sectional area, boys and girls show significant differences in the relative rates of longitudinal and appositional growth, which translate into differences in overall bone shape. To the extent that AR is negatively correlated with skeletal strength, as predicted by bioengineering first principles, our results raise the possibility that differences in bone shape make a hitherto unrecognised contribution to gender differences in fracture rate. We are keen to explore this further in future studies.

Mean (SD) age and bone geometry of boys and girls, by linear regression adjusted for age and puberty

	Boys N=132 Mean (SD)	Girls N=142 Mean (SD)	P value
Age (years)	9.9 (0.35)	9.9 (0.36)	0.642
Humerus length (cm)	23.8 (1.6)	24.2 (1.6)	0.023
Humerus width (cm)	1.92 (0.17)	1.86 (0.17)	0.004
Humerus area (cm^2)	45.8 (5.7)	45.2 (5.6)	0.380
Aspect Ratio	12.5 (1.1)	13.1 (1.1)	< 0.001

Birthsize, Adult Size and Body Composition Effect on Bone Mass: The PROGRAM Study*. *PROGRAM= Programming Factors of Growth and Metabolism. A. S. Slingerland[1], A. A. Hellingman*[1], E. P. Krenning*[2], A. C. S. Hokken-Koelega*[1]. [1]Dep. of Pediatrics, Erasmus Medical Centre, Rotterdam, The Netherlands, [2]Dep. of Nuclear Medicine, Erasmus Medical Centre, Rotterdam, The Netherlands.

Low birth size, poor adult height gain and low adult body mass have independently shown to decrease BMD and increase osteoporosis and/or fracture risk in 60 year olds. For preventive measures or early intervention it is necessary to know whether in these populations, bone mass is already decreased at an early age-eg if peak bone mass has just been attained-and at which to aim: birth size, adult size or body composition. We assessed the effect of birth size, adult size and body composition on the total body as in Bone Mineral Content (BMC) and Bone Mineral Density (BMD) and on the lumbar spine as in BMD-LS and Bone Mineral Apparent Density (BMAD) in 167 healthy 18-23 year olds. They were divided into four unique groups as part of the PROGRAM-study: 1. Small for Gestational Age (SGA)-Short 2. SGA-Catch up 3. Appropriate for Gestational Age-Short and 4. AGA-Controls. We found BMC and BMD to be decreased in SGA-Short and AGA-Short but this difference disappeared once completely corrected for height as in BMAD. In multiple regression analyses accross the groups, neither of the measures for bone mass related to birth size. Total body BMC and BMD were best predicted by Adult Weight, whereas Lumbar spine BMD and BMAD were best predicted by Lean Body Mass reflecting muscle mass. We conclude that in populations of low birth size or poor adult height gain, bone mass is not decreased once corrected for adult height, at least in young adulthood when peak bone mass has just been attained. Preventive measures or interventions should aim at body composition especially muscle mass to increase bone mass of lumbar spine.

***Better BonesWorkshop*© Improves Knowledge, Confidence and Intention to Change Among Family Medicine Residents.** M. M. Luckey[1], S. Albert*[2], C. Berry*[3]. [1]Saint Barnabas Osteoporosis and Metabolic Bone Disease Center, Mount Sinai Medical Center, Livingston, NJ, USA, [2]New York University, New York, NY, USA, [3]New York University, Oregon Osteoporosis Center, New York, NY, USA.

Despite the availability of evidence-based guidelines, simple diagnostic tests and effective therapy**,** less than one-third of patients with osteoporosis are identified or treated. Intervention by primary care providers(PCPs) will be key to changing these statistics; however, most PCPs receive little formal training in metabolic bone disease and many lack the confidence and knowledge needed to make osteoporosis surveillance and treatment a routine part of primary care practice The *BetterBones Workshop*© was developed in collaboration with the Academy of Family Medicine Residency Directors and is a 1.5 day intensive, interactive, small-group, case-based osteoporosis workshop for family medicine residents. . Pre-and post-workshop demographics and knowledge were assessed by questionnaire and multiple choice tests in all. Participants in 2004 also answered questions regarding their level of confidence. From March 2003-December, 2004, 738 residents from 256 residency programs attended 20 *BetterBones* workshops. The workshop was well received by residents (overall rating 4.9 on a 5 point Likert scale) Knowledge-test scores increased from a baseline of 58 ± 14% pre-workshop to 88± 11% (mean± SD) immediately post-workshop (p<.0001). Compared to before the workshop: 99% felt"more comfortable ordering & using bone density tests"; 100% agreed that they were "more knowledgeable about how & when to treat osteoporosis" and 98% felt "very confident that I can identify & manage most patients with osteoporosis". 98 % indicated that they had learned something that would change their practice with 83% volunteering an intention to increase bone density testing and/or treatment among at least one high-risk group. These results indicate that an interactive, small-group osteoporosis workshop is highly effective in increasing knowledge as well as confidence and the intention to increase diagnosis and treatment among primary care physicians in training. Additional studies to assess the impact of this workshop on objective measures of behavior are needed.

Rib Fracture as a Marker of Osteoporosis and Mortality in Men and in Women. M. Naves*, J. B. Díaz-López*, C. Gómez-Alonso, A. Rodríguez-Rebollar*, J. B. Cannata-Andía. Bone and Mineral Research Unit, Hospital Universitario Central de Asturias, Oviedo, Spain.

It is well known that hip, spine and distal forearm fractures are important predictors for the risk of future fractures, however few studies have involved rib fracture as a marker of osteoporosis. The aim of this study was to find out the predictive value of rib fracture for risk of both osteoporotic fracture and rate of bone loss in a non-selected population. A likely association between prevalent rib fracture and mortality was also investigated. A cohort of 308 men and 316 women aged 50 years and over participated in this study. Subjects were invited to complete an interview-administered questionnaire which included questions about previous fractures including rib fracture. Prevalent and incident vertebral fractures, according to semi quantitative Genant method, were defined by means of two lateral dorsal and lumbar radiographs performed at baseline and again 4 years later. The rate of bone loss was obtained by lumbar and hip bone densitometry study performed at baseline and again 4 years later. The subjects were followed prospectively during 8 years by 4 postal questionnaires to determine the occurrence of non-vertebral osteoporotic fractures caused either spontaneously or after a fall from a maximum height equal to or below the upright position of the patient. The age and number of any previous fracture, excluding rib fractures, were higher in those subjects with previous rib fractures (n=29) compared with those without (71±7 *vs* 65±9 years old and 72 *vs* 41% respectively, p<0.001), 13.6% of subjects with previous rib fractures had incident osteoporotic fracture compared with 3.5% of those without (p<0.001). Logistic regression analysis after adjustment by age, sex and any previous fracture showed that previous rib fractures increased 4 times the risk of having an incident osteoporotic fracture (odds ratio [OR]=4.33; 95% Confidence Intervals [CI] 1.70, 11.01). After adjustment by age, sex and any previous fracture, the rate of bone loss at lumbar spine in patients with previous rib fracture was significantly higher than those without (-3.94±1.97 *vs* 0.05±0.28, p=0.006 in the univariate analysis and p=0.032 in the covariance analysis). Non-significant differences were found in femoral neck or in total hip. Also after adjustment by age, sex and any previous fracture, the presence of previous rib fractures was associated with an increase in mortality (Relative risk [RR] = 2.03; 95%CI 1.03, 4.12). In summary, previous rib fractures were an important risk factor for future osteoporotic fractures, rate of bone loss and mortality in both sexes, indicating that their presence should be always taken into account as independent marker of osteoporosis.

Detection of Vertebral Fractures by Physical Examination: Comparison between Men and Women. K. Siminoski[1], K. Lee*[2], H. Jen*[2], R. Warshawski*[2]. [1]Radiology and Medicine, University of Alberta, Edmonton, AB, Canada, [2]Radiology, University of Alberta, Edmonton, AB, Canada.

Vertebral fractures are the most common fracture in osteoporosis and the lifetime vertebral fracture risk in men may be similar to the risk in women.We have previously described four physical examination maneuvers that can detect prevalent vertebral fractures in women. There has been little published data available on physical changes in men resulting from vertebral fractures, so in this study we have compared the performances of these four methods between the two sexes. Subjects were men (n = 326) and women (n = 824) referred for specialist assessment of osteoporosis (average age 52 +/- 17 years for men, 57 +/- 15 years for women). Vertebral morphometry was performed on all subjects from T4 to L4. Prevalent vertebral fracture was defined as a vertebral height ratio < 0.80. One or more fractures were present in 39.5% of men and 34.9% of women. Among those with fractures, the average number in men was 2.5 +/- 1.8 and the average number in women was 2.3 +/- 1.9. Height was measured using a Harpenden stadiometer, kyphosis angle using a digital inclinometer from T4 to T12. The four parameters that were compared were (i) historical height loss (HHL; tallest recalled height minus measured height) for detection of all thoracic and lumbar fractures; (ii) wall-occiput distance (WOD) for detection of thoracic fractures; (iii) kyphosis angle (KA) for detection of thoracic fractures; (iv) rib-pelvis distance (RPD) for detection of lumbar fractures. The area under the receiver operating characteristics curve for each maneuver wwas evaluated for its ability to detect fractures and 95% confidence intervals were determined. The AUCs ranged from 0.69 to 0.75 for women and 0.68 to 0.73 for men, falling in the range that is considered to represent good performance The confidence intervals overlapped between men and women for all four maneuvers. These data suggest that the four physical exam maneuvers (HHL, WOD, KA, and RPD) will be useful in men for detection of prevalent vertebral fractures. The thresholds to be used for clinical application will require further analysis and may differ from those in women.

Areas Under the ROC Curves for the Presence of Prevalent Vertebral Fractures

	HHL (cm) (95% CI)	WOD (cm) (95% CI)	KA (degrees) (95% CI)	RPD (fingerbreadths) (95% CI)
Men	0.68 (0.61-0.75)	0.71 (0.63-0.79)	0.73 (0.65-0.81)	0.72 (0.63-0.81)
Women	0.69 (0.64-0.74)	0.75 (0.68-0.82)	0.72 (0.65-0.79)	0.76 (0.71-0.81)

ROC = receiver operating characteristics curve, HHL = historical height loss, WOD = wall-occiput distance, KA = kyphosis angle, RPD = rib-pelvis distance

Detection of Osteoporotic Vertebral Fractures: A Comparison of Radiographs and Sagittal CT Reformations. J. S. Bauer[1], D. Mueller*[2], A. Ambekar*[1], M. Dobritz*[2], M. Matsuura*[3], F. Eckstein*[4], E. J. Rummeny*[2], S. Majumdar[1], T. M. Link[1]. [1]Radiology, University of California, San Francisco, CA, USA, [2]Institut für Röntgendiagnostik, Technische Universität, München, Germany, [3]Anatomy, Ludwig-Maximilian-Universität, München, Germany, [4]Anatomy, Paracelsus Private University, Salzburg, Austria.

Purpose Vertebral fracture assessment is a major issue in diagnosing osteoporosis. Lateral radiographs are currently considered to be the standard technique for vertebral fracture assessment. With the advent of Multislice CT (MSCT) thinner axial sections are obtained routinely during standard CT exams and can serve as a basis for high quality sagittal reformations (SR) of the spine. The purpose of this study was to analyze, which slice thickness in axial CT-datasets is required to reliably identify these fractures as well as to compare lateral radiographs and SR in their performance to identify osteoporotic vertebral fractures. **Materials and Methods** Sixty-five vertebrae were harvested from 21 human cadaver spines in segments with three to four vertebrae each and examined with a 64 row MSCT scanner. Axial images of these specimens were acquired with a slice thickness of 0.6, 1, 2, 3 and 5 mm. SR were obtained using these datasets with the same slice thickness as the axial images. In addition the specimens were radiographed in a.p. and lateral orientation. Radiographs and CT reformations were graded by two radiologists separately according to the spinal fracture index (SFI) classification. These results were compared with the fracture status determined in consensus by two different radiologists based on all combined imaging findings and a pathological examination of the vertebrae. **Results** The level of agreement for the fracture grading in the CT reformations decreased with spatial resolution in the z-axis. Average κ for both readers showed good values for the 0.6, 1, 2 and 3 mm CT reformations (κ=0.74, 0.72, 0.70 and 0.61). It was moderate for plain films (κ=0.51) and fair for the 5mm protocol (κ=0.34). Specificity and sensitivity showed equal trends: In the standard radiographs both readers missed 18% of the fractures with a specificity of 90% and 83%, while in the 1mm SR less than 6% of the fractures were missed, with a specificity of 93% and 100% for the two radiologists, respectively. **Conclusion** Sagittal reformations based on thin section MSCT scans were superior compared to standard spine radiographs in grading and detecting osteoporotic vertebral fractures. For a reliable detection of vertebral fractures SR are, however, required that are based on axial images with a slice thickness of 3mm or less. The thinnest available slice thickness of the axial images performed best in fracture grading.

Knowledge Dissemination Strategies Translate into Improved Post-Fracture Osteoporosis Care. D. R. Cohen*, D. A. Haaland*, C. Kennedy, J. D. Adachi, N. Khalidi*, A. Papaioannou. Department of Medicine, McMaster University, Hamilton, ON, Canada.

Osteoporosis is a major public health problem in Canada, and its prevalence is increasing. Osteoporosis greatly increases fracture risk, thus resulting in significant morbidity and mortality. These fractures, however, can be preventable with appropriate therapy. Current guidelines indicate that individuals who sustain a fragility fracture are at high risk for future fractures and require bone mineral densitometry (BMD) and pharmacologic therapy. There is, however, a recognized gap between guidelines and practice with regard to measurement of BMD and treatment of osteoporosis in individuals with fragility fractures. In Hamilton, Ontario, a prior observational study from April 1st, 1995 to March 31st, 1996 indicated very poor recognition of osteoporosis following discharge from an academic teaching hospital after a fragility hip fracture. Osteoporosis was noted in 2% of 141 patient charts, and only 18% had vitamin D or calcium recorded as discharge medications. No patient was discharged on a bisphosphonate. Since that time, osteoporosis educaton has been disseminated to the geriatric/rehabilitation consultation teams in Hamilton, in an effort to improve care. In this study, a retrospective chart review examined 342 charts of patients age 50 years or older, admitted with a fragility hip fracture to the orthopaedic services of two Hamilton, Ontario, teaching hospitals between March 1st, 2003 and April 30th, 2004. Three quarters of patients were women, with a mean age of 81 years. Twenty six percent and 33% had previous diagnoses of osteoporosis and fracture, respectively. On admission, 14%, 9%, and 18% of patients were on calcium, vitamin D and bisphosphonates, respectively. A new diagnosis of osteoporosis was made in 25% of patients. Thus, 49% of patients left hospital without a diagnosis of osteoporosis. BMD was suggested in 11%. On discharge, calcium, vitamin D and bisphosphonates were prescribed for 38%, 36% and 27% of patients, respectively. Thirty three percent of those with no prior diagnosis of osteoporosis were transferred to a geriatric/rehabilitation unit, while 67% were not. Of those that were transferred, 75% received a diagnosis of osteoporosis as compared with only 19% of those who were not transferred (P<0.001). We conclude that targeted dissemination of information is paramount to osteoporosis recognition and treatment in hospitalized patients with fragility fractures. While a care gap still exists, this study suggests that a multidisciplinary approach to osteoporosis, including consultation teams, osteoporosis education and standardized orders may be useful and warrants further study.

Fracture Frequency in Patients over 50 of Age in a Trauma Hospital in Mexico City. F. A. Cisneros, L. M. Muciño*. Spine, HTOLV, Mexico, Mexico.

In the last 20 years, osteoporosis has been focusing on diagnosis and treatment. In the early years the objective was to improve the BMD, in recent years, however, with better knowledge in the pathology; the main objective is to prevent fractures. The objective of this revision is to learn about fracture frequency in a population over 50 and correlate with the diagnosis of osteoporosis, without a densitometry study to establish the diagnosis and trying to determine which fractures are in a compromised mechanical bone, and at the same time knowing that not all the injuries that happened were in an osteoporotic bone. We can also recognize the need of better resources in orthopedic hospitals to improve the diagnosis and treatment of this condition. RESULTS.- Throughout November and December 2004, we collected all the patients over 50, with a fracture of any bone, who came to the hospital emergency room. We found 509 patients with a traumatic injury and 511 fractures, 340 female (67%) and 169 males (33%). The most common lesion was distal radio cubital fracture with 118 patients (23% of the lesions), 98 female and 20 males, the average age for women was 68 years and for men, 62 years. 94% of the cases were treated conservatively. Hip fracture was the second most common lesion with 101 patients (20% of the cases). 68 females and 32 males, the average age for women was 76 years and for men, 74 years. 80% were treated surgically. Ankle, humeral and foot were the next injuries in frequency; all these 5 anatomical segments constituted 70% of the lesions. CONCLUSIONS. The most frequent fractures found were Colles and hip fractures, both constituted 43% of the cases. Women were affected twice than men. Treatment in patients over 50 is mainly conservative, exceptions are hip and ankle, both are frequent fractures in these patients. Because of the age, hip and femur, shoulder and humeral fractures occur in osteoporotic or mechanical incompetent bones. This means that we have to focus our efforts on treating these patients for osteoporosis.

Increased Prevalence of Morphometric Vertebral Compression Deformities in Canadian Aboriginal Women: The First Nations Bone Health Study. W. D. Leslie[1], C. J. Metge[2], H. A. Weiler[3], M. Doupe*[1], E. A. Salamon[1], P. Wood Steiman*[4]. [1]Faculty of Medicine, University of Manitoba, Winnipeg, MB, Canada, [2]Faculty of Pharmacy, University of Manitoba, Winnipeg, MB, Canada, [3]Human Nutritional Sciences, University of Manitoba, Winnipeg, MB, Canada, [4]Assembly of Manitoba Chiefs, Winnipeg, MB, Canada.

Canadian Aboriginal (First Nations) women are at increased fracture risk compared with the general population with over double the rate of clinical vertebral fractures (CMAJ 2004;171:869-73). The First Nations Bone Health Study (FNBHS) reported site-specific reductions in BMD among a random age-stratified (25-39, 40-59 and 60-75) sample of Aboriginal women compared with age-matched White women (JBMR 2004;19 Suppl 1:S288). The prevalence of vertebral morphometric deformities was assessed in the older subgroup (age 60-75) which included 43 Aboriginal and 49 White women with 1,183 analyzable thoraco-lumbar vertebrae (T4-L4) from lateral spine radiographs. Blinded vertebral morphometry was performed at the Canadian Multicentre Osteoporosis Study (CaM*os*) data centre using published methods derived from 9,424 subjects (Osteoporos Int 2000;11:680-7). Spinal morphometry was used to categorize any deformity using 3 standard deviations (SD) as a limit of normality (Grade 1 if 3-4 SD, Grade 2 if 4-5 SD, and Grade 3 if > 5 SD). Vertebral fractures were more common in the Aboriginals (16.3% vs 11.9%, P<0.05 Chi-square) with significantly higher vertebral fracture grades (P<0.05 Mann-Whitney). The odds ratio for morphometric fracture of 1.45 (95% CI 1.11-1.78) was less than the previously reported standardized incidence ratio for clinical fractures of 2.18 (95% CI 1.88-2.51), possibly reflecting differential ascertainment of subclinical vs. clinical fractures. Nonetheless, these data continue to demonstrate an important effect of Aboriginal ethnicity in terms of bone health with an excess burden of osteoporotic fractures.

Prevalence of vertebral morphometric fractures		
	Aboriginal	White
Normal	468 (83.7)	550 (88.1%)
Grade 1	72 (12.9%)	59 (9.5%)
Grade 2	15 (2.7%)	9 (1.4%)

Low Sensitivity for Visual Recognition of Vertebral Compression Deformities: The First Nations Bone Health Study. W. D. Leslie[1], C. J. Metge[2], H. A. Weiler[3], M. Doupe*[1], E. A. Salamon[1], P. Wood Steiman*[4]. [1]Faculty of Medicine, University of Manitoba, Winnipeg, MB, Canada, [2]Faculty of Pharmacy, University of Manitoba, Winnipeg, MB, Canada, [3]Human Nutritional Sciences, University of Manitoba, Winnipeg, MB, Canada, [4]Assembly of Manitoba Chiefs, Winnipeg, MB, Canada.

Under-recognition of vertebral fractures on routine x-rays is a global problem and leads to a missed opportunity for identifying high risk individuals (JBMR 2005;20:557-63). We hypothesized that radiologists reporting spine radiographs as part of an osteoporosis clinical research study would show a much higher level of fracture identification than in

routine clinical practice. The prevalence of vertebral morphometric deformities was assessed in 92 older women (age 60-75) from the First Nations Bone Health Study (FNBHS) which included 43 Aboriginal (First Nations) and 49 White women with 1,183 analyzable thoraco-lumbar vertebrae (T4-L4) from lateral radiographs. An initial clinical interpretation was provided by practicing radiologists aware that this was an osteoporosis clinical research study, with blinded vertebral morphometry performed at the Canadian Multicentre Osteoporosis Study (CaM*os*) data centre using published methods derived from 9,424 subjects (Osteoporos Int 2000;11:680-7). Spinal morphometry was used to categorize any deformity using 3 standard deviations (SD) as a limit of normality (Grade 1 if 3-4 SD, Grade 2 if 4-5 SD, and Grade 3 if > 5 SD). The clinical report was used to designate each vertebral level as definitely or possibly fractured. Overall, less than one in three morphometric fractures (52 of 165) was clinically reported to be definitely or possibly fractured despite the fact that the radiologists knew that this was a clinical research study being done to look for vertebral fractures. Although visual identification improved with more severe fracture grades, one-third of the grade 3 fractures were still missed. Specificity was also poor with one-half of the visual definite fractures showing normal morphometry and almost all of the visual possible fractures being morphometrically normal.

Comparison of vertebral fractures using visual and morphmetric criteria

	Visual definite	Visual possible	Visual combined
Normal (n=1018)	50 (4.9%)	16 (1.6%)	66 (6.5%)
Grade 1 (n=131)	30 (22.9%)1	1 (0.8%)	31 (23.7%)
Grade 2 (n=24)	13 (54.2%)	1 (4.2%)	14 (58.4%)
Grade 3 (n=10)	7 (70.0%)	0 (0.0%)	7 (70.0%)
Any deformity (n=165)	50 (30.3%)	2 (1.2%)	52 (31.4%)

SU329

Medical Risk Factors Contribute to the High Fracture Risk in Canadian Aboriginal Peoples. W. D. Leslie[1], H. J. Prior*[1], S. Derksen*[1], C. J. Metge[2], L. L. Lix*[1]. [1]Faculty of Medicine, University of Manitoba, Winnipeg, MB, Canada, [2]Faculty of Pharmacy, University of Manitoba, Winnipeg, MB, Canada.

Although Canadian Aboriginal (First Nations) peoples are known to be at high fracture risk, the factors contributing to this have not been well described. The role of diabetes mellitus, disease comorbidity, and substance abuse as defined from administrative health data were examined as possible explanatory variables. A retrospective, population-based matched cohort study of fracture rates was performed using Manitoba (Canada) administrative health data (1984-2003). The study cohort consisted of 27,952 registered Aboriginal adults and 83,856 controls (matched three to one for year of birth and gender). Diabetes, comorbidity (number of ambulatory diagnostic groups [ADGs]), substance abuse and post-inception fractures were based upon validated definitions. Poisson regression models of fracture rates, which included covariates of age, sex, income quintile and area of residence, were constructed to look at the statistical significance of candidate variables both in two-way interactions and main effects. Diabetes, multiple ADGs, and substance abuse were more common in the Aboriginal cohort ($p<0.000001$) and were strongly associated with increased fracture rates, but this effect was similar for the Aboriginal cohort and controls (p for interaction > 0.1). Longer duration of diabetes correlated with hip, spine, and wrist fractures but not craniofacial fractures, but this effect was greatly reduced after controlling for number of ADGs. In conclusion, higher rates of diabetes, comorbidity and substance abuse among Aboriginal people contribute to the higher rates of fracture. Ethnicity is still a significant risk factor for fracture after adjustment for these factors, suggesting additional unidentified risk factors in this high risk population.

Odds ratio for fracture at various sites

	Craniofacial	Hip-spine-wrist	Hip only
Aboriginal	3.67 (3.28-4.12)	2.01 (1.86-2.17)	2.09 (1.58-2.78)
Diabetes	0.76 (0.59-0.98)	1.09 (0.96-1.22)	1.44 (1.06-1.95)
Number of ADGs:	.	.	.
None	Reference	Reference	Reference
1-2	1.21 (1.02-1.44)	1.16 (1.02-1.32)	0.95 (0.60-1.50)
3-5	1.60 (1.95-2.91)	1.47 (1.29-1.66)	1.05 (0.67-1.64)
6 or more	2.38 (1.95-2.91)	1.82 (1.58-2.09)	1.55 (0.97-2.46)
Substance abuse	2.04 (1.80-2.31)	1.72 (1.55-1.91)	2.06 (1.39-3.04)

What Is the Prevalence of Post-Menopausal Fragility Fracture? E. Brankin[1], C. Mitchell*[1], R. Munro*[1], A. Gallagher[2]. [1]Lanarkshire Osteoporosis Service, NHS Lanarkshire, Coatbridge, United Kingdom, [2]Medical Unit, Southern General Hospital, Glasgow, United Kingdom.

Literature review would suggest a prevalence of post-menopausal fragility fracture in the region of 15%. Recent reports have suggested this may be an underestimate and 1-2% higher results may be a more true reflection of fracture prevalence. As part of the Coatbridge Disease Management Programme, questionnaires were sent to 4045 ladies in the locality aged 65 or over to identify those who had already suffered a fragility fracture or those at risk of fracture, according to standard criteria. Responses were received from 2386 patients, a response rate of 59%. Of these 852 patients were identified as having already suffered a fragility fracture, and a further 1395 were identified as meriting an open access bone densitometry scan according to risk factor evaluation. The prevalence of fragility fracture in this patient population was therefore 21.1% (852/4045), a figure significantly higher than previously reported. As this particular study excluded those in nursing and residential homes the prevalence is likely to be even higher. Of the 41% who did not respond, surmising a prevalence rate of approximately that for those who did respond, then an overall prevalence of ~30% could potentially be expected in this population. One might argue that those who did not respond may have lower prevalence rates, since if they had suffered a previous fracture they may be more motivated to respond, but by the same token they may not have responded because they had already been assessed and were on appropriate treatment. Even if the prevalence was half that of responders, this would still give an overall prevalence rate of the middle 20's %. We are currently contacting all those who did not initially respond to the programme to ascertain their fracture risk, but feel that this result is likely to reflect an underestimation of the scale of the problem which should be addressed by initiating programmes such as ours to identify and treat those with prevalent fracture who have previously slipped through the system before fracture liaison services were set up.

Think Fracture! A Comparison between Standard Risk Factor Audit and Targeting Fragility Fracture in Identifying Patients with Osteoporosis. E. Brankin[1], C. Mitchell*[1], R. Munro*[1], A. Gallagher[2]. [1]Lanarkshire Osteoporosis Service, NHS Lanarkshire, Coatbridge, United Kingdom, [2]Medical Unit, Southern General Hospital, Glasgow, United Kingdom.

Running from 1998-2000, the Osteohealth Audit, performed within a family medicine setting, was designed to identify patients with osteoporosis, or at high risk of developing osteoporosis, in 125 general practices across the UK. Patients were identified for review and investigation according to identification of standard risk factors. From 2496 individuals who were subsequently scanned, bisphosphonate therapy was instituted in 615 (24.6%), Calcium & Vitamin D in 401 (16.1%) and HRT in 562 (22.5%). Following on from the Osteohealth Audit, as part of the Coatbridge Disease Management Programme, all ladies over 65 within the town (4045) were sent a postal questionnaire asking about prevalent postmenopausal fracture. 852 were identified as having already suffered from fracture (a prevalence of 21% - higher than previously reported in literature) and further 1395 identified as being at high risk. 1054 patients were subsequently scanned, 659 of those with fracture, and 395 patients were chosen from the 'routine' scanning waiting list based on standard risk factors alone. None of those scanned from the audit were under 65, thereby targeting only those at higher absolute risk as identified by age and fracture. Of those 659 with fracture in the age group 65-75, 49.3% were found to be osteoporotic and in the over 75s, 69.2% had osteoporosis. Of those 395 without fracture the prevalence of osteoporosis was substantially lower at 43% and 47.2% respectively for the two age groups as above. 62.7 % of those with previous fracture were subsequently prescribed an evidence based bisphosphonate plus Calcium/vitamin D compared to 48% of those who had never sustained a fracture. Identifying and treating post-menopausal women at highest absolute risk of osteoporosis, ie those with previous fracture, is a much more cost effective way of targeting management strategies in the secondary prevention of fracture.

10 Year Hip Fracture Risk in Ireland 1995-2003. Are Changes in Life Expectancy Blunting the Effect of Intervention? B. R. Whelan*[1], L. Brennan*[2], E. Falvey*[1], M. Daly*[1], F. Drummond*[3], F. Shanahan*[3], A. McGuinness*[2], M. G. Molloy*[1]. [1]Rheumatology, University College Cork, Cork, Ireland, [2]Orthopaedics, Cork University Hospital, Cork, Ireland, [3]Medicine, University College Cork, Cork, Ireland.

Introduction Hip Fracture is a significant public health problem worldwide and is the most serious consequence of Osteoporosis. Over the past 10 years there has been an increase in the screening for and treatment of osteoporosis. In this time there has also been an increase in life expectancy in Ireland. We undertook to examine the net effect of these changes on individual fracture risk using the endpoint of 10 year fracture risk. Methods All persons resident in Cork city and county who admitted to Cork University Hospital with a hip fracture between 1995-97 and 2001-03 were included. This is the only orthopaedic trauma centre for this area. Population statistics for this population were obtained from the Central Statistics Office in Ireland. Using published life tables for the time periods we calculated the 10 year fracture risk for both sexes at ages 50, 60, 70 and 80. Results There were 1101 fractures in 1.248 million person years from 1995-97 and 1168 fractures in 1.343 million person years from 2001-03. Male life expectancy increased by 1.5 years and female life expectancy inceased by 1.3 years.There was a significant increase in the 10 year fracture risk for the over 80 year olds. Only in 70 year old females was fracture risk significantly reduced.(See Table) Discussion Screening for and treatment of osteoporosis in the 70 year old age group has had an impact on individul fracture risk. The strategies adopted have not had a beneficial imapct in any other age group. The reasons for this require further investigation. The increase in life expectancy and decrease in mortality rate blunting the effect of screening and treatment. This is supported by increased fracture risk in the over 80 year olds where the effect of increasing life expectancy is greatest.

10 Year Fracture Risk (** denotes significant change)

	Male		Femle	
Age	**1995-1997**	**2001-2003**	**1995-1997**	**2001-2003**
50	0.38%	0.31%	0.34%	0.4%

Application of the Norwegian Medicines Agency Osteoporosis Treatment Guidelines on Male and Female Patients with Wrist Fractures in Norway. G. Haugeberg*[1], C. G. Gjesdal*[2], H. C. Gulseth*[3]. [1]Dept. of Rheumatology, Sorlandet Hospital, Kristiansand, Norway, [2]Dept. of Rheumatology, Haukeland University Hospital, Bergen, Norway, [3]Dept. of Rheumatology, Betanien Hospital, Skien, Norway.

Background: Norway is a high endemic area for osteoporotic fractures. Treatment guidelines has been given by the Norwegian Medicine Agency (NMA) to reduce fracture risk in patients with a high risk profile of future fractures. According to these guidelines treatment with bisposphonates is considered as first choice and SERM or estrogens as second treatment choice. In the NMA guidelines patients with low energy fracture with reduced bone mass (T-score ≤-2) is defined as a high risk group of future fractures. **Aim**: To explore the number of patients age 50 years or older with a low-energy wrist fracture in need for specific osteoporosis treatment according to the NMA osteoporosis treatment guidelines for fracture risk reduction. **Material and Method**: A total of 639 patients (84 men and 555 women) were recruited from three centres in Norway (Bergen: 272, Skien 239, Kristiansand 128) and data were collected from spring 2003 to December 2004. Bone density at left total hip and lumbar spine (L2-4) was measured using Lunar DXA machines following standardised procedures. Gender specific T-scores were assessed. In patients with left side hip replacement bone density measures of the right total hip was used. Patients with high energy trauma wrist fractures were excluded. **Results**: Mean age (±SD) was 65.3 years (±10.4) among men and 69.3 (±10.5) among women. Mean weight was 78.3 (±14.7) and 66.9 kg (±12.4) and height 176.1 (±8.3) and 162.8 (±6.4) among men and women, respectively. No major differences in age, weight and height, and hip and spine BMD was seen between the three centres. 99% of the females reported to be postmenopausal. The prevalence of patients with a previous fracture prior to the current wrist fracture was 59% in male and 55% in females. In the table below the prevalence of male and female patients recommended specific osteoporosis treatment according to the NMA osteoporosis treatment guidelines for fracture risk reduction are shown. **Conclusion**: Approximately every second male and female patients aged 50 years or older with low energy wrist fracture is in need of specific osteoporosis treatment applying the NMA treatment guidelines for fracture risk reduction.

T-score ≤-2 SD	Men (n=84)	Women (n=555)
Spine L2-4 (n=627)	25 (29.8%)	237 (43.8%)
Total Hip (n=612)	25 (30.5%)	203 (38.4%)
Spine or Hip (n=639)	37 (44.0%)	307 (55.4%)

Disclosures: ***G. Haugeberg****, None.*

SU334

The Accuracy of Self-Report of Fractures in Older People; a Comparison of Questionnaire and Fracture Registry in the AGES Reykjavik Study. K. Siggeirsdottir*[1], T. Aspelund*[1], G. Eiriksdottir*[1], B. Mogensen*[2], M. Chang*[1], L. Launer*[3], T. Harris*[3], G. Sigurdsson[4], B. Y. Jonsson*[5], V. Gudnason*[1]. [1]Icelandic Heart Association, Kopavogur, Iceland, [2]Department of Emergency Medicine, Landspitalinn University Hospital, Reykjavik, Iceland, [3]NIA, Bethesda, MD, USA, [4]Department of Endocrinology, Landspitalinn University Hospital, Reykjavik, Iceland, [5]Department of Orthopeadics, Malmö University Hospital, Malmö, Sweden.

Epidemiological studies often need to rely on participants' self-report of health status to obtain information. It is therefore important to validate the accuracy of participant answers to questions. Participants from the Reykjavik study, a 35-yr prospective population study are being re-examined in the Age, Gene/Environment Susceptibility (AGES)-Reykjavik Study. For all participants in AGES, we developed a fracture registry (FR) based on an examination of all medical and radiographic records located in hospitals in Reykjavik and Akureyri. The accuracy of self-report (SR) of fractures of the wrist (WR), vertebrae (VT) and hip (HP), was evaluated in a subgroup of 2300 individuals (1324 women and 976 men). The mean age for both sexes was 76 years (range 66 - 95 years). All participants were administered the Mini Mental State Examination (MMSE) and Digit Symbol Substitution Test, (DSST); which together represent cognitive impairment defined as MMSE ≤23 and DSST ≤17. Kappa statistics were calculated to determine agreement between SR and FR. Sensitivity (Sn), specificity (Sp), positive predictive value (PV), negative predictive value (NV) were also calculated (table).

	Fractures	FR %	SR %	Sn	Sp	PV	NV	Kappa
Men N = 970	Wrist *	6.7	7.1	0.56	0.96	0.53	0.97	0.51
	Vertebrae	3.8	3.9	0.44	0.98	0.43	0.98	0.41
	Hip*	1.9	1.1	0.17	0.99	0.27	0.98	0.20
Women N =1316	Wrist *	24.9	25.4	0.84	0.94	0.83	0.95	0.78
	Vertebrae	6.9	10.6	0.71	0.94	0.46	0.98	0.52
	Hip*	4.0	2.6	0.44	0.99	0.68	0.98	0.52

**Significant difference in kappa value between men and women, p<0.05*

SR of the fractures was available for 2286 individuals. Those who recall their fracture were fairly correct about the year it occurred as validated by the FR (spearman rank correlation= 0.85 for VT, 0.79 for WR). Those who were false negative (WR/VT/HP) were more likely to be cognitive impaired, p=0.0008, compared to those who were true positive. There was no evidence of cognitive impairment in those who were false positive, p= 0.31. Men answered consistently less reliably than women. SR is relatively accurate when ruling out fractures (good NV) but less accurate regarding PV, supporting the need for ascertainment of fractures based on radiographs and medical records in epidemiology research.

Frailty and Risk of Falls and Fractures in Older Women. K. Ensrud[1], S. Ewing*[2], H. Fink[1], J. K. Tracy*[3], P. Cawthon[2], M. Hochberg[3], J. Cauley[4], P. Bowman*[1], K. Stone[2], S. Cummings[2]. [1]VAMC & U of MN, Minneapolis, MN, USA, [2]UCSF & CPMC, San Francisco, CA, USA, [3]U of MD, Baltimore, MD, USA, [4]U of Pittsburgh, Pittsburgh, PA, USA.

Although many factors are associated with frailty in older adults, weight loss and leg weakness often characterize this condition and are easily assessed in a clinical setting. To test the hypothesis that older women with frailty simply defined by the presence of both weight loss and leg weakness are at increased risk of falls and fractures (fxs), weight change and leg strength (ability to rise from a chair 5 times without using the arms) were measured at the 4th exam in a cohort of 6777 older women (mean age 76.8 yrs) enrolled in the Study of Osteoporotic Fractures who were then followed prospectively for falls and fxs, including hip fx. Weight loss was defined as a 5% or greater loss in body weight between baseline and 4th exams (5.7 yrs between exams) and leg weakness was defined as inability to rise from chair without arms. At the 4th exam, women were categorized as not frail (64%), weight loss only (24%), leg weakness only (7%) or frail (5%). During an average follow-up of 1 yr, 11% reported ≥2 falls (frequent falls). 33% experienced ≥1 non-spine fx (average follow-up 7.4 yrs) and 10% suffered a first hip fx (average follow-up 8.6 yrs). After controlling for multiple potential confounders, frail women were at increased risk of falls and fxs; in particular, frail women had a 2.7-fold increase in the odds of frequent falls and a 1.8-fold increase in the risk of hip fx. The relationship between frailty and non-spine fx was primarily due to an increased risk of hip fx.

	Relative Risk of Outcome*		
	Frequent Falls OR (95% CI)	Non-spine Fx RH (95%CI)	Hip Fx RH (95% CI)
Not frail	1.0 (referent)	1.0 (referent)	1.0 (referent)
Lost weight only	1.3 (1.1-1.6)	1.3 (1.1-1.4)	1.6 (1.4-2.0)
Leg weakness only	2.4(1.8-3.1)	1.2 (1.0-1.5)	1.3 (0.9-1.8)
Frail	2.7 (1.9-3.9)	1.4 (1.1-1.8)	1.8 (1.2-2.6)

*adjusted for age, health status, smoking status, medical conditions, estrogen use, body mass index and femoral neck bone density

Frailty in older women simply defined by the presence of weight loss and leg weakness may be useful in a clinical setting to identify women at elevated risk of falls and hip fx.

Disclosures: ***K. Ensrud****, None.*

What Accounts for Lack of Osteoporosis Care Following Fracture? The Provider Perspective. A. N. A. Tosteson[1], B. Ettinger*[2], N. Gordon*[3], M. R. Grove*[1], L. H. Pearson*[1], G. T. Ray*[3], P. Silver*[3]. [1]Dartmouth Medical School, Hanover, NH, USA, [2]University of California San Francisco, San Francisco, CA, USA, [3]Kaiser Permanente Medical Care Program, Oakland, CA, USA.

A new HEDIS measure for 2005, defined as osteoporosis work-up and/or treatment in the 6 months following fracture, will be used to evaluate the quality of osteoporosis care. Our objective was to identify physician-reported factors that correlate with post-fracture osteoporosis care in a large health maintenance organization. Primary care providers who had an office visit with a patient aged 60 or older in the 6 months following a hip, wrist, vertebral or humerus fracture received a patient-specific questionnaire regarding osteoporosis care. Using administrative data, we defined osteoporosis care as a filled osteoporosis prescription and/or a bone mineral density test in the 6 months post-fracture. Comparisons between patients with and without care were made using t-tests and chi-square tests. Multiple logistic regression analyses estimated the odds of osteoporosis care as a function of physician responses. Questionnaires for 669/922 patients were completed by 434 physicians (73% response). Mean patient age was 74 years and 72% were female. Osteoporosis care differed significantly by fracture type and patient gender (p-values <0.001). Care was most prevalent following vertebral fracture (51%, 116/227) and least prevalent following humerus fracture (17%, 21/124). Care was more common in women (41%, 119/481) than in men (19%, 36/188). Physician-reported post-fracture osteoporosis counseling occurred for 287 patients of whom 60% received care. Absent counseling, care occurred in 16% (59/376) of patients. The most common reasons for lack of counseling were presence of more pressing comorbidities (57%) and physician unaware of fracture (23%). In multiple regression analyses, adjusted for fracture type, the odds of post-fracture care were significantly decreased by the following: male patient gender (OR: 0.30, 95%CI: 0.19, 0.49), physician report of comorbidities (OR: 0.20, 95%CI: 0.12, 0.33), physician unaware of fracture (OR: 0.19, 95%CI: 0.09,0.38), and physician assessment that osteoporosis treatment is not important or only somewhat important for the specific patient's overall health (OR: 0.39, 95%CI: 0.24, 0.62). Post-fracture osteoporosis care was evident in only a minority of patients. While information systems could improve fracture awareness, competing health concerns are likely to remain an important barrier to osteoporosis care in the primary care setting where physicians have limited time to attend to multiple health concerns. Other care pathways, such as a specialty clinic, warrant consideration.

Vitamin D-Deficiency and Post-Fracture Changes in Lower Extremity Function and Falls in Women with Hip Fractures. M. S. LeBoff[1], W. Hawkes*[2], Y. Yahiro*[3], J. Glowacki[1], S. Hurwitz*[1], J. Magaziner[2]. [1]Brigham & Women's Hospital, Boston, MA, USA, [2]University of Maryland, Baltimore, MD, USA, [3]Union Memorial Hospital, Baltimore, MD, USA.

To evaluate the prevalence of vitamin D deficiency in hip fracture patients and the association of vitamin D levels at the time of fracture with functional capacity after a fracture, we measured 25-hydroxyvitamin D levels (25-OHD) immediately post-fracture and lower extremity function, falls, and other parameters in the year following a hip fracture. In 110 community-dwelling women with hip fractures from Boston, MA (n=30) and the Baltimore Hip Studies, Baltimore MD (n= 80) recruited before 1998, the median 25-OHD levels measured by RIA (DiaSorin, Stillwater, Minn.), were 12.96 and 10.2 ng/ml, respectively. Vitamin D deficiency (defined as a 25-OH D level <15 ng/ml) was present in 66% of the women, with 38% having levels ≤ 9 ng/dl; 3.6% had vitamin D sufficiency with a 25-OHD level >32 ng/ml. In a subset of 61/80 women from Baltimore, post-fracture changes in a performance measure of the lower extremities (Lower Extremity Gain Scale:LEGS) a summary score of 9 tasks that focuses on lower extremity functioning were measured at 2, 6, and 12 months. Falls, grip strength, chair rise time, walking speed, balance, BMD, and lean and fat mass were also measured at these times. Compared to women with a 25-OHD level > 9 ng/ml, those with a 25-OHD level ≤ 9 ng/ml at time of fracture had a significantly worse composite LEGS performance (27.5 vs 20.2; p<0.001) at 1 year (Fig) and more falls (30.0% versus 51.5%; p<0.05). There were no differences between the 2 groups in grip strength, chair rise time, walking speed, balance, or body composition. These data show that vitamin D deficiency was present in 66% of women with hip fractures. Moreover, this is one of the first studies to reveal that very low concentrations of vitamin D at the time of fracture are associated with impaired lower extremity function a year following a hip fracture. Women with very low vitamin D levels at the time of a hip fracture also show increased falls possibly related to impaired muscle function. Prevention of vitamin D deficiency in the elderly may have important beneficial effects on lower extremity function without incurring excessive healthcare costs following hip fractures.

SU338

Personal-Fall History Predicts Non-Spine Fracture but not Spine Fracture. S. Fujiwara, N. Masunari*. Clinical Studies, Radiation Effects Research Foundation, Hiroshima, Japan.

Many limb fractures develop as a result of falls among the elderly. Our previous report demonstrated that age, bone mineral density (BMD) and previous fracture are major predictors for hip and spine fracture, but we did not take into account history of personal falls. We examined the association of personal-fall history with risk of spine fracture or non-spine fracture among a cohort of 2,613 men and women (794 men and 1,819 women) aged 47 to 95 years old, who have been followed up by biennial health examinations. Follow-up averaged four years after baseline measurements of BMD using dual x-ray absorptiometry (QDR-2000, Hologic) and included a questionnaire survey on history of personal falls during the previous six months. Vertebral fracture was assessed using semi-quantitative methods, and information on non-spine fracture was obtained through interview by a trained nurse at the biennial health examinations. A total of 141 persons developed new vertebral fractures and 191 persons developed new non-spine fractures during the four-year follow-up period. Cox regression analysis was used. Incidence of personal falls in the previous six months increased with age: about 18% of men and 17% of women in their seventies reported that they had experienced more than one fall in the previous six months. Relative risk (RR) for vertebral fracture per 1SD decrease in spine BMD was 1.7 (95% Confidence Interval (CI) 1.2 - 2.7) for men and 1.6 (95%CI 1.4-2.0) for women, and RR for non-spine fracture per 1SD decrease in BMD was 1.3 (95% CI 0.9 - 1.8) for men and 1.4 (95%CI 1.1-1.7) for women. After adjustment for age, previous fracture, and baseline BMD, personal-fall history in the previous six months predicted non-spine fracture, but did not predict spine fracture. Personal-fall history was predictive for non-spine fracture with a relative risk of 3.6 (95% CI 1.7 - 7.5) after adjustment was made for age, previous fracture and spine BMD for men, and with a relative risk of 2.1 (95% CI 1.4 - 3.2) for women. In conclusion, personal-fall history is a strong predictor for non-spine fracture in the elderly. Strategies to prevent such falls would lead to a reduction of non-spine fracture in the elderly population.

Reduced Volumetric Bone Mineral Density and Geometric Properties in Hip Fracture Patients. A. Heinonen[1], T. Mikkola*[1], E. Portegijs*[1], R. Sakari-Rantala*[1], M. Kallinen*[2], I. Kiviranta*[2], S. Sipilä*[1]. [1]Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland, [2]Jyväskylä Central Hospital, Jyväskylä, Finland.

Existing literature provides ample human data on areal bone mineral density (aBMD), suggesting an injury of a limb leads to a decline in aBMD in the injured extremity resulting in a considerably side-to-side difference between affected and unaffected limb. However, little is known about the changes in bone geometric properties after considerable trauma such as hip fracture. The purpose of this study was to examine the side-to-side differences in volumetric bone mineral density (vBMD) and geometric properties of tibia in hip fracture patients, and to assess the determinants of the possible side-to-side differences in bone. Thirty-one 60-85- year old men and women with previous hip fracture, on average 34 months earlier, participated in this cross-sectional study. The bone scans were obtained from the distal tibia and tibial shaft of both lower limbs by pQCT (Stratec XCT 2000) to determine volumetric bone mineral density (vBMD) and bone geometry parameters. In addition, physical activity, leg extension strength and power, stair-climbing time and 10 m walking time were measured. Paired t-test and regression analysis were used in statistical analysis. Total density (-5.8%, p<0,001), trabecular density (-4.5%, p=0,001) and polar moment of inertia (-6.9%, p<0,001) were significantly lower in the distal tibia of the injured side compared to the uninjured side. In the tibial shaft of the injured side, total area (-3.5%; p=0,004), cortical area (-4.2%; p=0,001), and polar moment of inertia (-4.7%; p=0,001) were significantly lower than on the uninjured side. Time since injury had no association with the side-to-side differences in bone. Stair-climbing time and physical activity were associated with relative total area of tibial shaft (R^2=0.61) whereas stair-climbing time alone had an association with relative cortical area of tibial shaft (R^2=0.27). Hip fracture results in significantly reduced vBMD in distal tibia and deteriorated geometric properties in tibial shaft of the fractured limb. Physical activity and mobility seem to be of great importance for the good quality of bone geometry in older men and women with hip fracture history.

Association of Wrist Fracture with Subsequent Hip, Spine, Rib, and Wrist or Forearm Fractures in Postmenopausal Women: Results from the National Osteoporosis Risk Assessment (NORA). E. Barrett-Connor[1], E. Siris[2], P. Miller[3], S. Sajjan*[4], Y. Chen[4]. [1]Department of Family and Preventive Medicine, University of California, San Diego, La Jolla, CA, USA, [2]Metabolic Bone Disease Program, Columbia University Medical Center, New York, NY, USA, [3]Colorado Center for Bone Research, Lakewood, CO, USA, [4]Outcomes Research and Management, Merck & Co., Inc, West Point, PA, USA.

Prior wrist fracture has been shown to be associated with an increased risk of future hip or vertebral fracture. Less is known about the increased risk of fracture for other fracture sites. We examine the relationship between prior wrist fractures and self-reported incident fractures at hip, spine, rib, and wrist or forearm during follow-up in postmenopausal women using data from NORA. Women were eligible for NORA if they were >= 50 years old, postmenopausal, had no diagnosis of osteoporosis and were not currently taking bone-specific medication (hormone therapy use was allowed). Current analysis included 158,940 women who responded to follow up surveys either 1 or 3 years post baseline and who had self-reported baseline information on prior wrist fractures occurring after age 45. Women who reported non-wrist fractures at baseline were excluded from the analysis. Absolute risks (per 1,000 person-year) for new fracture were calculated by summing fractures divided by person-years of follow-up. Relative risks for incident fracture were computed for women with prior wrist fracture (N=8665) compared to those with no prior fracture (N=150,275) using Cox proportional hazards model. Models were with and without bone mineral density (BMD), adjusted for covariates including age, ethnicity, health status, maternal history of fracture, education, weight, smoking status, use of hormone therapy, cortisone, or thyroid medication, use of alcohol, and exercise, age at menopause. A total of 4316 women reported 4728 incident fractures, including 697 hip, 669 spine, 1147 rib, 1726 wrist, and 469 forearm. Excess of future fracture (absolute and relative risks) is shown in Table. We concluded that prior wrist fracture is an important predictor of future wrist/forearm, hip, and rib fracture. Women presenting with a wrist fracture should be evaluated for appropriate management to prevent future fractures.

	Absolute Risk (95% CI)		Adjusted Relative Risk (95% CI)	
Fracture site	No Prior Fracture	Covariates	Covariates+BMD	Covariates+BMD
Hip	1.7 (1.5, 1.8)	1.9 (1.5, 2.3)	1.6 (1.3, 2.0)	1.6 (1.3, 2.0)
Spine	1.7 (1.6, 1.8)	1.3 (1.0, 1.6)	1.1 (0.9, 1.5)	1.1 (0.9, 1.5)
Rib	2.9 (2.7, 3.1)	1.6 (1.3, 2.0)	1.4 (1.2, 1.8)	1.4 (1.2, 1.8)
Wrist/Forearm	4.8 (4.5, 5.0)	3.5 (3.2, 4.0)	3.0 (2.7, 3.3)	3.0 (2.7, 3.3)

Incidence and Outcomes of Hip Fractures in Quebec, Canada, 1992-2002. S. N. Morin[1], M. Hudson*[2], H. Behlouli*[2], L. Pilote*[3]. [1]Dept of Medicine, McGill University Health Center, Montreal, PQ, Canada, [2]Research Institute, McGill University Health Center, Montreal, PQ, Canada, [3]Dept of Medicine and Research Institute, McGill University Health Center, Montreal, PQ, Canada.

The morbidity and mortality of osteoporotic hip fractures have a substantial impact on health care systems around the world. Increased awareness of osteoporosis and availability of potent therapies in the last decade may have an impact on incidence of hip fractures and their consequences. Our objectives are to describe recent trends in the incidence of hip fractures and post-hip fracture outcomes, and to evaluate the effect of independent co-morbidities on these endpoints. All patients aged 65 years and older admitted to hospital with a primary diagnosis of hip fracture between 1992 and 2002 were identified through the Quebec hospital discharge summary database. Fracture and re-fracture incidence rates (age and sex-adjusted for the Quebec population during the same period), 30-day and 1-year mortality rates were determined by gender and age group. We identified a number of co-morbidities and defined them using the Manitoba-Darthmouth Index. Logistic regression analyses were done to predict mortality after adjustment for co-morbidities. Overall, there were 50,251 incident hip fractures in 46,974 patients between 1992 and 2002. We identified 11,656 incident hip fractures for men (mean age [SD] 79.7 years [7.4]) and 38,595 for women (81.9 years [7.7]). Men had more associated co-morbidities; namely malignancy, cardiovascular (previous myocardial infarction, congestive heart failure and peripheral vascular diseases), renal and pulmonary diseases. Dementia and hypertension were more frequent in women. The overall annual age-adjusted incidence rates of hip fracture were stable over the study period: 667 fractures/ 100,000p-years for women and 289 fractures/ 100,000p-years for men. The age-specific incidence of hip fractures was also stable over time. The mortality rates were constant over time; being significantly higher in men than in women. After adjusting for age, co-morbidities and fiscal year, the 30-day and the 1-year mortality rates for men were twice that of women (OR 1.93, 95% CI 1.81, 2,05 and OR 1.91, 95% CI 1.81, 2.01, respectively). The higher mortality rate post hip fracture in men has previously been attributed to a higher prevalence of co-morbidities; whereas our findings indicate a two-fold increase in mortality rate even after adjusting for co-morbidities.We conclude that, despite widespread availability of diagnostic and therapeutic modalities for osteoporosis during the last decade, the incidence of hip fractures has not decreased and associated mortality rates have remained stable.

Genetics and Remaining Lifetime Risk of Fracture: The Collagen I Alpha 1 Gene. T. V. Nguyen, N. D. Nguyen, J. R. Center, J. A. Eisman. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia.

The association between genetic polymorphisms and fracture risk is commonly examined in a relative risk-based approach. However, given the time-invariant nature of the genetic information and age-related nature of fracture risk, a lifetime risk approach is more meaningful and appropriate. The present study examined the association between polymorphisms of the Collagen type I alpha 1 (COLIA1) and remaining lifetime risk of fracture in elderly men and women. COLIA1 genotypes (*SS, Ss* and *ss*) were determined in 698 women and 378 men aged 60+ years as at 1989 of Caucasian background, who have been followed for up to 15 years (1989-2004). During the follow-up period, low trauma, non-pathological fractures were recorded and confirmed by X-ray and personal interview. Femoral neck bone mineral density (FNBMD) was measured by dual energy X-ray absorptiometry (GE-LUNAR DXA) at baseline. An individual was classified as having "osteoporosis" if the individual's FNBMD T-scores was less than or equal to -2.5. Remaining lifetime risk of fracture (RLRF) from the age of 50 was estimated by the Cox's proportional hazards model, with adjustment for the competing risk of death. The proportion of individuals with *SS, Ss* and *ss* genotypes in the population of 64%, 31% and 5%, respectively, was consistent with Hardy-Weinberg equilibrium. After adjusting for competing death, the RLRF in women with *ss* genotype was 66% (95% CI: 45-92), significantly higher than those with *SS* (51%; 95% CI: 44- 58) or *Ss* genotype (47%; 95% CI: 38-56). The RLRF for women with osteoporosis was 65% (58-74), which was equivalent to those with *ss* genotype. Moreover, the RLRF for osteoporotic women with *ss* genotype was 94% (95% CI: 82-100). In men, there was no significant difference in RLRF between those with *SS* or *Ss* genotype (32%; 95% CI: 22-39) and *ss* (27%; 95% CI, 10-41). These data suggest that women with the COLIA1 *ss* genotype have a greater remaining lifetime risk of fracture. Their absolute risk was equivalent to that associated with osteoporotic BMD and additive to it. Although there appeared to be difference between men and women, the combination of COLIA1 genotypes and BMD measurement can potentially increase the accuracy of identifying high-risk individuals.

Bone Loss and Weight Fluctuation Predict Mortality Risk in Elderly Men and Women. N. D. Nguyen, J. R. Center, J. A. Eisman, T. V. Nguyen. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia.

Low bone mineral density (BMD) has been suggested as a risk factor for mortality in women. The present study examined the contribution of bone loss, weight loss and baseline BMD to the risk of all-cause mortality risk in both elderly men and women. Data from 1059 women and 644 men aged 60+ years as at 1989 of Caucasian background who have participated in the Dubbo Osteoporosis Epidemiology Study were analyzed. All-cause mortality was recorded annually between 1989 and 2004. Information of concomitant diseases, including cardiovascular diseases (CVD), all type cancer and type I/ II diabetes mellitus was also recorded. Baseline femoral neck BMD (GE-LUNAR DXA) was measured between 1989 and 1992, and repeated approximately every two years afterwards. The rate of change in BMD was derived for each individual by the linear regression model. Weight fluctuation was assessed by the coefficient of variation in weight measurements during the 15-year follow-up. The association between each risk factor and mortality was assessed by the hazards ratio (HR) in a Cox's proportional hazards model after adjusting for age and concomitant diseases. During the follow-up period, 254 and 295 women died; a mortality incidence (per 1000 person-years) of 41.2 in men and 20.4 in women. In men, the annual rate of bone loss at the femoral neck was 0.4 ± 1.2% and 0.7 ± 2.0% for the surviving and deceased, respectively. In women, annually bone loss at femoral neck was 0.5 ± 1.2% and 0.9 ± 2.6% for the surviving and deceased, respectively. In both sexes, the weight fluctuation was higher in the deceased subjects than their surviving counterparts (4.2%/yr vs. 3.5%/yr, p=0.0013 in men and 5.3%/yr vs. 4,2%/yr, p <0.0001 in women). In both men and women, the following factors were independently significant predictors of mortality: bone loss (HR: 1.6; 95% CI, 1.0-2.4 in men and HR 1.6; 1.2-2.2 in women) and weight fluctuation (HR: 1.2; 1.0-1.3 in men, and HR: 1.1; 1.0-1.2 in women). Moreover, in women baseline femoral neck BMD (HR: 1.3; 1.1-1.5) and weight loss (HR: 1.2, 1.1-1.4) were additional independent predictors of mortality risk. Omitting the last weight measurement (before death) did not alter the results. These data suggest that in addition to low BMD, BMD loss and weight change were also significant predictors of all-cause mortality in elderly men and women, independent from age and concomitant diseases.

Fall-Related Factors Predict Fracture Risk in Elderly Men and Women without Osteoporosis. T. V. Nguyen, N. D. Nguyen, J. R. Center, J. A. Eisman. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia.

More than 50% of women with fracture do not have osteoporosis (defined as BMD T-scores being ≤-2.5), yet risk factors for fracture in the non-osteoporosis group have not been well-documented. The aim of this study was to examine the contribution of non-BMD factors to low trauma fracture risk in elderly men and women without osteoporosis. Among women aged 60+ years who participated in the Dubbo Osteoporosis Epidemiology Study, 939 women and 719 men were found to have femoral neck BMD T-scores>-2.5 (non-osteoporosis). The women have been followed for up to 15 years (1989-2004), and during this period, the incidence of low trauma, non-pathological fracture was recorded and confirmed by X-ray and personal interview. Femoral neck BMD was also measured by dual energy X-ray absorptiometry (GE-LUNAR DXA) at baseline. Postural sway was measured by a swaymeter at baseline. During the follow-up period, 227 women and 103 men had sustained a fracture. The majority of fractures occurred at the vertebral (30%), hip (11%) and forearm and wrist (20%). The incidence of fracture (per 1000 person-years) was 23.5 for women and 14.3 for men. In the multivariate Cox's proportional hazards model, the following risk factors were significantly related to fracture risk: postural sway (HR: 1.2; 95% CI: 1.1-1.3 in women, and HR 1.3; 1.1-1.4 in men); fall in the previous 12 months (HR: 2.0, 1.1-3.5 in women and HR 2.3; 1.5-3.5 in men), and baseline femoral neck BMD (HR: 1.6, 1.5-2.6 in women and 1.3; 1.1-1.4 in men). Population attributable risk analysis suggested that an exposure to both highest tertile postural sway and fall accounted for 22% and 15% of any fracture in women and men, respectively. Thus, in non-osteoporotic women and men, the combination of low BMD, a history of fall, and postural instability could identify a subgroup of individuals with high-risk of fracture.

Implementation of a Mandatory Osteoporosis Consultation in Patients with Low Intensity Hip Fracture. A. Q. Macasa*, M. Spady*, R. Quinet, J. Zakem*, W. Davis*, L. Serebro*, Y. Menon*. Rheumatology, Ochsner Clinic Foundation, New Orleans, LA, USA.

Osteoporosis remains an underdiagnosed and undertreated major health problem. The current treatment rate for patients who have experienced at least one osteoporotic fracture is 20 - 25%. In an attempt to improve this situation, the Rheumatology and Internal Medicine Departments of Ochsner Clinic Foundation implemented a mandatory osteoporosis consult as part of the admission orders for all patients admitted with a hip fracture. Methods: 65 patients were admitted with a low intensity hip fracture from June 2004 until March 2005. These patients were seen in the hospital after they had undergone hip fracture repair. They were screened for osteoporosis risk factors and were then advised appropriate treatment. 65 age matched controls admitted for low intensity hip fracture in

2003 served as our comparison group. Pearson chi-square test was used for statistical analysis. Results: Mean patient age was 80.9 (range: 54 - 99). Out of the 65 control patients, 16 (24%) were on treatment (calcium, Vitamin D, hormones or antiresorptive agents) before the hip fracture and 17 (28%) were on treatment post fracture repair. Out of the 65 cases, 29 (44%) patients were receiving osteoporosis treatment prior to hip fracture and 62 (94%)patients were receiving treatment post fracture repair. Conclusion: Improvement in osteoporosis management is achievable by several means. In our institution, we were successful in capturing and treating osteoporosis patients by putting an automatic consult for Rheumatology Department to see post hip fracture patients. The implementation of a mandatory osteoporosis consult resulted in a greater than 100% increase in treatment (p= 0.0001) compared to the control group.

Cognitive Resemblance in Patients Suffering from Osteoporosis and their First Degree Relatives. N. Kafri*[1], P. Werner*[1], I. Vered[2]. [1]Gerontology, Faculty of Social Welfare and Health Studies, University of Haifa, Haifa, Israel, [2]Endocrinology, Sheba Medical Center, Tel Hashomer, Ramat Gan, Israel.

The importance of positive family history as a risk factor for osteoporosis has been widely documented. First-degree relatives of osteoporotic patients are regarded as a high-risk group for development of the disease, and engagement in preventive behaviors aimed at reducing the risk of bone loss and fractures is of utmost importance for them. Studies assessing other chronic diseases demonstrated that rates of adherence to preventive and screening behaviors among first-degree relatives are associated to their illness representations, i.e., to their health beliefs and cognitive representations regarding the disease. The aim of the present study was to assess and compare the illness representations among women suffering from osteoporosis and their first degree relatives. Fifty two dyads of osteoporotic women (mean age = 67.8 years; 98% menopausal, 46% have had an osteoporotic fracture), and their daughters (mean age = 40.9 years; 10% menopausal) participated in the study. Illness representations were assessed using an adapted version of the Illness Perception Questionnaire (Weiman, Petrie, Moss -Morris & Horne, 1996). Overall, although the daughters perceived the symptoms of the disease as more severe than the mothers, especially regarding bending of the back, weakness, and loss of height, the mothers perceived the disease as more permanent than the daughters. The mothers also perceived the outcomes of the disease as more serious than the daughters, particularly regarding the influence of the disease on their lives, and the financial outcomes of the disease. Compared to their daughters, the mothers perceived the disease as caused mainly by internal reasons such as inadequate diet, genetic reasons, life habits, and lack of physical activity, while the daughters tended to perceive external or chance causality. Our findings suggest that osteoporotic women and their daughters do not share similar beliefs regarding various aspects of the disease of the mother, such as the causes of the disease, its symptoms, chronicity and outcomes. These data also provide the foundation for future studies aimed at the development of interventions to increase adequate knowledge and awareness of the disease among relatives of individuals with osteoporosis.

Bone Density and Fracture Risk in Women Who Are HIV Positive--Case Population-Based Control Study with Canadian Multicentre Osteoporosis Study. J. C. Prior[1], D. Burdge*[2], E. Mann*[3], R. Milner*[3]. [1]Endocrinology/ Medicine, U of British Columbia, Vancouver, BC, Canada, [2]Infectious diseases / Oak Tree Clinic, Uof British Columbia / Children & Women's Health Centre, Vancouver, BC, Canada, [3]Oak Tree Clinic, Children & Women's Hospital, Vancouver, BC, Canada.

The purpose of this cross-sectional case control study is to determine whether women who are HIV positive (HIV+) are at increased risk for osteoporosis by bone mineral density (BMD) and lifetime fragility fractures. Cases are women participating in the Canadian Women's HIV Study (cases) who are on anti-retroviral therapy (ART+ n = 100) or not (ART- n = 38). Controls are women from the population-based Canadian Multicentre Osteoporosis Study (CaMOS) matched for age and geographic region. Hypotheses: 1) HIV+ women will have lower BMD related to illness, weight cycling, lifestyle differences and oligomenorrhea; 2) HIV+ women will have more fragility fractures. Methods included completion of the CaMOS interviewer-administered questionnaire in English or French. BMD data were adjusted to common spine and hip phantoms and reported as Hologic values. Cases and controls were matched within-region, by age ± 5 years in a ratio of 3 controls: 1 case. Results show that HIV+ women (n = 138) did not differ from CaMOS controls (n = 401) in age (37.7 versus 38), BMI (25.3 vs. 36.1), age at menarche (13.0 vs. 12.7), number of live births (1.5 vs. 1.9) or oral contraceptive use ≥3 mo. (82.4 vs. 81.3%). Cases' cigarette use was greater (4521 vs. 3594 lifetime packs), but alcohol intake, exercise and education were similar. There was no difference in a family history of osteoporosis (13.6 vs. 14.2%). Oligomenorrhea (≥3 skipped cycles) was greater in cases (29.4 vs. 15.4%; 95%CI -22, -6; OR 2.3). Lifetime weight cycling 20-lb occurred in 66% HIV+ vs. 43% controls (OR 2.6). Finally, fewer controls than HIV+ women had used glucocorticoid therapy (2.9% versus 8.1%, OR 2.9). Outcome measures showed L_{1-4} BMD was 1.0 ± 0.12 in HIV+ and 1.0 ± 0.14 g/cm^2 in controls (95% CI -.27, 0.27). Total hip BMD was 0.91 ± 0.15 vs. 0.93 ± 0.12 g/cm^2 (95%CI -0.005,0.045) in HIV+ vs. controls. However, lifetime history of fragility fracture was significantly greater in HIV+ women. Low trauma fractures were reported by 26.1% of HIV+ vs. 17.3% control women (difference = 8.4%; 95%CI 16.6,0.2, OR 1.7). This difference is important and current data do not adequately explain it. Conclusions from this population-based case:control study of HIV positive women are that, although being closely matched and having similar bone density values, women who are HIV+ are at higher risk for fragility fractures. Hip structural analysis of all participants is planned, as is analysis of bone marker and vitamin D data in the HIV+ women.

Disclosures: ***J.C. Prior****, None.*

Inter-Relationships among Dietary Restraint, Subclinical Ovulatory Disturbances and BMD in Healthy Pre-Menopausal Women. E. J. Waugh*, G. A. Hawker, J. Polivy*. University of Toronto, Toronto, ON, Canada.

The aim of this study was to examine whether cognitive dietary restraint in young women was associated with lower BMD and whether this may be due to an association between dietary restraint and subclinical ovulatory disturbances, subsequent to increased cortisol. Participants were healthy Caucasian pre-menopausal women, aged 20-40 years (mean age 32.4 ± 4.6 y), recruited from the community for a two-year prospective cohort study. Women who reported irregular menstrual cycles, a history of an eating disorder, use of oral contraceptives or other medication or illness known to affect bone metabolism or menstrual function, were excluded. An average of 9.7 cycles per participant was monitored over the two-year time period using salivary progesterone measurements and ovulation detection kits. A single morning serum sample for estradiol, free testosterone and cortisol was collected once during days 3-5 of one menstrual cycle. The restraint subscale of the Three-Factor Eating Questionnaire was used to measure dietary restraint and women were categorized as high or low restrained eaters based on upper and lower tertiles of the baseline scores. Exercise was measured by the Baecke scale. Body composition and BMD (measured at the lumbar spine (L2-L4), femoral neck and total body) were determined by DEXA. Baseline values were used in this analysis. Of the 332 participants assessed at baseline, hormonal data was obtained for n=226 and these participants were included in this analysis. The group classified as high restrained eaters had significantly higher BMI's (p=0.005), lower percent lean mass (p=0.008) and exercised more (p=0.01). There was no significant difference in any hormone values between the two restraint groups. The mean luteal length did not differ between groups (13.6 vs 13.5 d for low and high restraint groups, respectively) and the number of women who had at least one anovulatory cycle and/or short luteal phase was similar (29 vs 28 women for low and high restraint groups, respectively). BMD at each of the 3 sites, adjusted for BMI and exercise, was not significantly different between the two restraint groups. Women with a mean luteal length of < 11 days had lower mean luteal progesterone (p =0.003), a trend towards lower estradiol (p = 0.07) and had significantly lower total body BMD by 0.0245 g/cm^2 (p = 0.047) adjusted for BMI. In conclusion, dietary restraint was not associated with subclinical ovulatory disturbances, increased cortisol or lower BMD but a mean luteal phase length of <11 days was associated with lower total body BMD in healthy pre-menopausal women.

Hyperaldosteronism as a Cause of Osteopenia in Cardiac Cachexia. Z. XING*[1], V. S. Chhokar*[2], R. A. Smith*[1], S. K. Bhattacharya*[3], K. A. Hasty*[1], K. T. Weber*[2]. [1]Orthopaedic Surgery, University of Tennessee, Memphis, TN, USA, [2]Department of Medicine, University of Tennessee, Memphis, TN, USA, [3]Department of Surgery, University of Tennessee, Memphis, TN, USA.

Cardiac cachexia, a complication of congestive heart failure (CHF), is characterized by generalized loss of lean tissue, fat tissue, and bone tissue. Cachectic CHF patients have raised plasma levels of aldosterone1. We hypothesize that hyperaldosteronism is the cause of bone loss in CHF patients. To test this hypothesis, we examined changes in bone in rats with hyperaldosteronism and the effect of spironolactone treatment. Male, 8-week-old SD rats were uninephrectomized and continuously received aldosterone (0.75 g/h) via a subdermal minipump together with 1% NaCl/ 0.4% KCl in drinking water and standard laboratory chow containing 1.13 % Calcium and 0.24% Magnesium. Some rats were also treated with spironolactone via gastric gavage (75mg/rat/day). Unoperated, untreated, age/ gender-matched rats served as controls. Rats were euthanized 6 weeks after surgery. A 24-hour urine was collected prior to sacrifice while blood was collected at sacrifice. Concentrations of urine Calcium and plasma ionized Calcium were tested. Bone mineral density (BMD) was determined for femurs using a GE Lunar PIXImus2. A three-point bending test was performed to determine the flexure stress of rat femoral diaphyses. At 6 weeks, urine Calcium excretion was significantly increased in rats with hyepraldosteronism ($p<0.05$) along with marked decrease of plasma ionized Calcium levels ($p<0.05$). BMD of the femur was significantly decreased in these rats ($p<0.05$) along with a fall in bone strength compared with control rats ($p<0.05$). Spironolactone successfully reduced calcium loss and improved BMD and bone strength ($p>0.05$, compared with the control). Expansion of the extracellular volume is considered as the likely reason of increased urinary excretion of Calcium in hyperaldosteronism. Urinary loss of Calcium would stimulate PTH secretion, which then stimulates calcium release from the bone as well as reabsorption of calcium in renal tubules and intestinal absorption of calcium and phosphate via enhancing the synthesis of 1,25(OH)2VitD3. These early compensatory responses may not be sufficient to preserve plasma Calcium during prolonged hyperaldosteronism. This would represent a continuous stimulus to PTH secretion, thus resulting in progressive bone loss. Spironolactone, an aldosterone receptor antagonist, successfully reduced bone loss in our experiment, further demonstrating the role of aldosterone in bone loss and providing a potential treatment for osteopenia in cardiac cachexia patients.

The Association of Bone Mineral Density and Depression in Postmenopausal Korean Women. H. Kwak, S. Kim. Physical Medicine and Rehabilitation, Dong-A University College of Medicine, Busan, Republic of Korea.

Objective: To assess the impact of bone mineral density (BMD) on depressive symptom in postmenopausal women **Method:** We examined 20 ambulatory postmenopausal Korean women (mean age 66.5±8.7 years). The participants underwent BMD measurements using dual-energy X-ray absorptiometry of the lumbar spine and femoral neck and using quantitative ultrasound (QUS) of the left radius and left tibia. Beck's Anxiety Index (BAI) and Beck's Depression Index (BDI) were used as a questionnaire to assess the depressive symptom. Higher the score indicate more depressive. **Results:** Low BMD of lumbar spine was correlated with high score in BDI. **Conclusion:** In postmenopausal Korean women, BMD of lumbar spine has a major impact on depressive symptom.

Osteoporosis and Fall Risk in Patients with Fragility Fractures. P. P. Geusens[1], S. H. van Helden*[2], A. C. Nieuwenhuijzen-Kruseman*[2], G. Dinant*[2], E. Pijpers*[2], R. ten Broeke*[2], P. R. Brink*[2]. [1]University Hospital & Limburg University Center, Belgium, Maastricht, The Netherlands, [2]University Hospital, Maastricht, The Netherlands.

Low BMD and fall risk are well-documented risk factors for fractures. The prevalence of both risk factors has only scarcely been reported in the same population of patients with recent clinical fractures. *Methods* 261 consecutive patients (women and men of 50 years and older) admitted to the hospital with a recent clinical fracture were included and had extensive evaluation of bone mineral density (BMD) and fall risk (135 patients with fracture of the upper limb, 94 of the lower limb, 12 of the spine, 10 other and 10 multiple simultaneous fractures). Fractures after a car accident were excluded. BMD was measured in the spine and hip using DXA and expressed in gender-specific T-scores. Other evaluated risk factors included an ADL-score (the Groningen Activity Restriction Scale (GARS)), the Timed Get up and Go test (TGUGT), chair stand test, the four test balance scale and classic risk factors for fractures (Table). *Results* Osteoporosis in the spine or hip was present in 41% of the patients and osteopenia in 41%. The prevalence of other risk factors for fractures ranged from 2% (use of glucocorticoids) to 34% (osteoarthritis) (Table). Patients with classic osteoporotic fractures (clinical spine, humerus, forearm, femur or multiple fractures) (n=158) were older (70 *vs.* 64 years; p <0.001), had lower Z-score in the hip (-0.4 *vs.* +0.2; p <0.001), higher GARS (14.7 *vs.* 12.5, p <0.01), lower body weight (68 kg *vs.* 74 kg; p <0.01), more disturbed balance (standing on one leg timed: 13 sec *vs.* 20 sec; p <0.001) and lower hand grip strength (52 kg *vs.* 63 kg, p <0.05) than patients with other fractures. *Conclusions*Patients with clinical fractures had a wide spectrum of risks for fractures in terms of BMD and non-BMD related risks, including fall risk. Patients with classic osteoporotic fractures had lower BMD in the hip and more other risk factors for fractures and falls than patients with other fractures, including lower muscle strength. These results indicate that patients with clinical fractures should have attention for both osteoporosis and fall risk in order to target the right population with the right treatment.

Patient characteristics (n=261)	
Women (%)	74
Age (mean, SD)	67 (12)
Osteoporosis in spine or hip (%)	41
GARS (range: 0-4) >2 (%)	24
TGUGT (range: 5-70 seconds) >15 sec (%)	23
History of clinical vertebral fracture (%)	8
History of non-vertebral fracture (%)	16
Family history of hip fracture in mother (%)	22
Body weight <60 kg (%)	19
Severe immobility (%)	7
On glucocorticoids (%)	2
Disturbed balance (%)	25
Other fall during previous year (%)	26
Using >4 medications/day (%)	20
Osteoarthritis (%)	34

Influence of Endurance Training and Low Dose Oral Contraceptives on Parameters of Bone Mass and Geometry in Young Women. A. Kirchbichler*[1], C. Kleinmond*[1], M. Wiseman*[2], E. Preisinger[3], E. R. Weissenbacher*[4], M. Hartard[1]. [1]Faculty of Sport Science Technical University Munich, Working Group MusculoSkeletal Interactions, Munich, Germany, [2]Bavaria Academy of Sciences, Leibniz Data Processing Center, Munich, Germany, [3]Department Physical Medicine and Rehabilitation, Hospital Lainz, Vienna, Austria, [4]Faculty of Medicine, Klinikum Grosshadern, Ludwig Maximilians Universität, Department of Gynecology and Obstetrics, Munich, Germany.

It was the aim of this retrospective analyze to examine the influences of low dosed oral contraceptives (OC) on parameters of bone mass and geometry in 48 young female endurance athletes, compared to 105 non-exercising young women. Women, aged 18 to 28 years, were separated into four groups according to the data on training history and OC use. Impact on bone was expected after 3 years of regular training with a minimum of three hours per week and an intake of OC for more than 3 years in women younger than 22, or in women, aged 22 - 28 years, when OC use was more than 50% of the time after menarche. Due to this classification, subjects were allocated into exercising OC users (EX-OC, n = 22) or exercising controls (EX-C, n = 26), and into non-exercising OC users (NEX-OC, n = 39) and non-exercising controls (NEX-C, n = 66). Cortical BMC and area, total area, and area of bone marrow were assessed by pQCT (XCT-2000, STRATEC) at distal tibia shank level 38% (diaphysis). Mean values of cortical content and area were lower in OC users compared to non-users, obviously more evident between the exercising OC users and the exercising controls. In addition, OC use was associated with a medullary expansion at tibial diaphysis. Data are given as mean values (SD) in the table; superscripted characters indicate significant differences ($p < 0.05$) between groups.

	EX-C	EX-OC	NEX-C	NEX-OC
Cortical BMC (mg/cm)	350.65 [abc] (46.37)	327.14 [bd] (49.93)	309.56 [ad] (33.58)	304.54 [c] (38.78)
Total Area (mm^2)	393.48 [ef] (53.03)	383.68 [gh] (48.35)	359.16 [eg] (40,07)	353.55 [fh] (46.43)
Marrow (%)	21.44 [ij] (4.60)	24.60 [ij] (5.93)	23.87 (4.49)	23.76 [j] (4.78)
Cortical Area (mm^2)	300.19 [klm] (41.12)	279.37 [kn] (43.77)	263.44 [ln] (28.87)	259.39 [m] (33.26)

We conclude that OC use was associated with influences on parameters of bone mass and geometry at tibial diaphysis, obviously more evident in the exercising women under OC use.

SU353

The Relationships between Dietary Intakes, Parental Fracture History, and Birth Status and Bone Mass of the School-Aged Children in Taiwan Assessed by Quantitative Ultrasound. Y. Lin[1], S. Tu*[2], W. Pan*[3]. [1]Institute of Nutritional Science, Chung Shan Medical University, Taichung, Taiwan Republic of China, [2]Center for Survey Research, Academia Sinica, Taipei, Taiwan Republic of China, [3]Institute of Biomedical Sciences, Academia Sinica, Taipei, Taiwan Republic of China.

The Children Nutrition and Health Survey in Taiwan, 2001-2002 was carried out to evaluate the overall nutrition and health status of school children aged between 7 and 13 years. The survey was conducted using a multi-stage complex sampling scheme and was consisted of two phases including physical examination and questionnaire interview. Bone mass measured as broadband ultrasound attenuation (BUA, in dB/MHz) was taken at heel by quantitative ultrasound (CUBA Clinical, McCue), and the corresponding Z-score was calculated. The preliminary results have been previously reported. In the current analysis, 1161 boys and 992 girls who had complete questionnaire information with ultrasound bone scan were included. Statistical analyses were performed using SAS v8.2 and SUDAAN v8.0. All variables were weighted to represent the children population in Taiwan. In terms of dairy products consumption, there was a significant inverse correlation between frequency of cheese intake (0.25-17.5 slices/week) and BUA Z-score in girls (r^2=-0.22, p=0.009) but not in boys. No significant relationships between consumption of other dairy products and BUA Z-score were observed in these boys and girls. A weak but significant positive correlation also existed between the frequency of fresh fruits/juices intake (0.25-24.5 exchanges/week) and girls' BUA Z-score (r^2=0.08, p=0.02). In addition, the frequency of soymilk drinking was negatively correlated to the BUA Z-score in girls (r^2=-0.15, p=0.001) and also in boys with less significance (r^2=-0.08, p=0.06). On the other hand, boys with paternal fracture history had higher BUA Z-score than those whose fathers did not previously fracture (p=0.055). Maternal history of fracture did not result in significant difference in BUA Z-score in both boys and girls. Girls who were born prematurely (before 38 weeks gestation) had significantly lower BUA Z-score than those born full-term (p=0.0013). Based on the data collected in this island-wide survey on the children in Taiwan, it appears that dietary intake of certain foods, including dairy, fruits, and/or soymilk, may be related to bone health status in the children. The gender difference in the relationships between paternal fracture history or birth status and BUA Z-score deserves further attention.

Impact on Quality of Life of Conditions that May Increase the Risk of Fractures in Women with Established Osteoporosis: A Matched Pair Analysis from the Osso Spanish Cohort. R. Pérez Cano*[1], C. Lozano[2], E. Muñoz*[3], D. Toledo*[4], A. Rodríguez-García*[5], J. Vesga*[6], Á. Oteo*[7], R. Ramos*[8], E. Martín Forero*[9], C. Barbazán*[10], E. Martín Mola*[11], C. Garcés*[3]. [1]H V Macarena, Sevilla, Spain, [2]H Clínico, Madrid, Spain, [3]Lilly, Madrid, Spain, [4]H. Puerta del Mar, Cádiz, Spain, [5]H Ramón y Cajal, Madrid, Spain, [6]H Txarrigurritxu, Vitoria, Spain, [7]H Moratalaz, Madrid, Spain, [8]Private, Sevilla, Spain, [9]H V Salud, Toledo, Spain, [10]H Xeral, Pontevedra, Spain, [11]H La Paz, Madrid, Spain.

The Observational Study on Severe Osteoporosis (OSSO) is a 12-month prospective, European study. The baseline analysis in Spain aimed to know the frequency of conditions that may increase the risk of fracture in established osteoporosis (OP) and their effect on quality of life (QoL) A non-probabilistic sampling of consecutive patients with postmenopausal established OP (BMD≤-2.5 and at least one fragility fracture) was performed in 64 OP outpatient clinics. Age, risk factors for OP and falls (BMI, menopause,

exercise, nulliparity, mother hip fracture, smoking, sight problems, steroids use), and disease data (earliest lumbar T score, years since first fracture, and current use of AR) were collected. We defined following criteria as potentially associated with higher risk for fractures: a) history of 2 or more fragility fractures and/or b) inadequate response to antiresorptives (AR). Inadequate response was defined: 1.new fragility fracture despite prescription of any OP drug for at least 12 months before fracture, 2.discontinuation of any OP drug due to compliance problems or side effects. QoL was assessed with QUALEFFO. Two matched groups were obtained from the cohort, one with 1 or more higher fracture risk criteria and a control group without any. Matching criteria were age, years since menopause and years on AR. Osteoporosis risk factors and QoL were compared between groups 846 women; 68.8 (7.7) years, were recruited. 330 did not present any criteria of higher risk for fracture. 370 (44% from total) had 2 or more fractures, 346 (41%) a new fragility fracture after a minimum of 12 months of AR therapy, and 103 (12%) history of AR discontinuation. 257 matched pairs were found. Most OP risk factors were not different between the 2 groups. QUALEFFO total score, and domains of physical function, social function and general health perception, showed significantly lower QoL in the group with any criteria for higher risk for fractures ($p<0.05$)In summary, prevalence of multiple fractures and fracture despite at least one year of continued AR treatment in established OP is very high. Patients with multiple fractures and/or any criterion of inadequate response to AR therapies as defined above, have a worse QoL than those with no one of these criteria.

Risk Factors for Falling and Fracture in Older Women with Type 2 Diabetes. S. Patel[1], K. Tweed*[1], S. Hyer*[2], A. Rodin*[2], S. Kerry*[3], J. Barron*[4]. [1]Dept of Rheumatology, St Helier University Hospital, Carshalton, United Kingdom, [2]Dept of Endocrinology, St Helier University Hospital, Carshalton, United Kingdom, [3]Dept of Community Health Sciences, St George's, University of London, London, United Kingdom, [4]Dept of Clinical Chemistry, St Helier University Hospital, Carshalton, United Kingdom.

Type 2 diabetes mellitus (DM) is associated with increased risk of hip fracture despite patients with type 2 DM having normal to high BMD. This suggests that non-skeletal risk factors, such as increased fall risk, may be important in the aetiology of fractures in type 2 DM. The aim of this cross-sectional study was to determine risk factors for falling and fracture in older women with Type 2 DM. We recruited women 65 years or older from a Type 2 DM community based register. To date we have recruited 130 women with a mean age of 75 yrs (range 66 to 91), mean duration of DM 11 yrs (range 1 to 54), mean BMI 30 (range 20 to 52) and mean HbA1c of 7.6 (range 5.1 to 11.8). BMD was measured by DXA and quantitative ultrasound (heel). Mean BMD values were significantly higher than the manufacturer's reference range for all skeletal sites. Thus mean lumbar spine BMD Z score was + 1.61 ($p<0.001$), mean total hip BMD Z score was + 1.08 ($p <0.001$) and mean heel Stiffness Z score was + 0.48 ($p <0.001$). A history of one or more falls in the previous 12 months was given by 54 /130 41.5 %) of the women. Those women with a history of falling had higher BMI compared to those without a history of falling (mean 31 versus 29 respectively ; $p=0.02$) and higher vibration perception threshold (mean 21.1 volts versus 17.6 volts respectively; $p =0.02$). We found no differences in duration of diabetes, HbA1c, visual acuity, capillary return, balance tests and lying and standing heart rate and blood pressure between women with and without a history of falling. A history of a previous low trauma fracture was given by 49/130 (38%) of the women. The fracture group tended to be older than the non-fracture group (mean age 75.8 years versus 73.6 years; $p=0.05$) but there were no differences in diabetes related factors. No differences were found in BMD measured by DXA between the fracture and non-fracture groups although Stiffness Z scores tended to be lower in the fracture group versus the non-fracture group (mean 0.31 versus 0.59 respectively; $p = 0.15$). These preliminary findings suggest that both high BMI and reduced vibration sense have a role in contributing to increased risk of falling in women with Type 2 DM. No significant differences were found in the measured variables for differing fracture status.

Menstrual Irregularity and Low Bone Mineral Density in Female High School Runners. M. Barrack*[1], J. Nichols[1], M. Rauh*[2], K. Edwards*[1]. [1]Exercise and Nutrition Science, San Diego State University, San Diego, CA, USA, [2]Public Health, San Diego State University, San Diego, CA, USA.

The purpose of this study was to determine the prevalence of and relationship between menstrual irregularity and low bone mineral density in high school cross-country athletes. One hundred forty two female high school cross country runners ages 13-18 (mean age 15.93 ± 1.22 y) were recruited from 12 high schools in southern California. Menstrual function was assessed by an interviewer-assisted self-report questionnaire. Menstrual irregularity was defined as fewer than 10 menses in the past year. Bone mineral density and mineral content (BMD/BMC) of the spine (L1-L4), proximal femur (total hip), and total body were assessed by dual energy x-ray absorbtiometry (DXA; GE/Lunar DPX NT). The International Society for Clinical Densitometry (ISCD) and the World Health Organization (WHO) criteria of ≤ -2 or ≤ -1 SD, respectively, below age-matched reference data were used to classify athletes as having low BMD relative to age. The prevalence of menstrual irregularity was 25.7%, whereas 9.5% of the athletes met ISCD criteria for low BMD. However, using WHO criteria, 40.9% of the athletes had spine BMD values of 1SD or more below reference values. The number of menstrual cycles in the past year was positively associated with BMD at the spine ($r = 0.26$, $p<0.01$), but not at the hip or total body. One-way analysis of covariance (controlling for body weight) indicated that athletes with menstrual irregularity had significantly lower BMD at the spine (1.03 ± 0.12 g·cm^2) compared to eumenorrheic athletes (1.12 ± 0.11 g·cm^2, $p<0.03$). These results indicate that female high school cross-country runners with menstrual irregularity have a greater risk of developing osteopenia/osteoporosis than their eumenorrheic peers. Screening for menstrual irregularity, and education to promote bone health in this population may be beneficial steps toward helping female athletes optimize bone mineral accrual during their adolescent years.

SU357

An Assessment Tool for Prediction of Non-Vertebral Fracture Risk in Postemenopausal Women. c. roux[1], k. briot*[1], a. varbanov*[2], s. horlait*[3]. [1]Rhumatology, Cochin hospital, PARIS, France, [2]Procter and Gamble, Cincinatti, OH, USA, [3]Procter and Gamble, Neuilly sur seine, France.

Non-vertebral fractures are common and responsible for the greatest amount of morbidity, mortality and cost attributable to osteoporosis. The risk of these fractures may play a key role in therapeutic decision-making as discrepancies remain regarding the effect of treatments on non-vertebral (NV) fractures. The objective of this analysis was to design a risk assessment tool for NV fracture risk. 2548 osteoporotic postmenopausal women included in the placebo groups of the phase III fracture endpoint risedronate trials (VERT-MN, VERT NA & HIP Group 1) were included (mean age 72, mean femoral neck T score -2.53, 60% and 53% of patients with prevalent vertebral and NV fractures, respectively). During a follow-up of 3 years, 206 NV fractures were observed including 50 hip fractures. Baseline data on 14 parameters (age, height, weight, body mass index, years since menopause, femoral neck T score, serum 25OHD3, prevalent vertebral and NV fractures, current alcohol intake and smoking, current use of thiazide diuretics, history of breast cancer and rheumatoid arthritis) were included in a logistic regression analysis. Baseline factors significantly associated with NV fracture risk included: Prevalent NV fracture ($p=0.006$), no.of prevalent vertebral fractures ($p<0.001$), femoral neck T score ($p=0.034$), 25OHD3 ($p<0.001$), age ($p=0.019$) and height ($p=0.037$) .The predicted NV fracture risk (probability) is given by the equation: risk =exp(x)/[1+exp(x)], where, x=-9.0733+0.0351*Age + 0.0240*Height - 0.2534*femoral neck T score - 0.0104*serum 25OHD3 + 0.1126* number of prevalent vertebral fractures - 0.2141*prevalent NV fractures. Prevalent NV fractures are assigned a value of 1 if the woman has no previous NV fracture, and -1 otherwise.The ROC results were used to define a subgroup of women with high risk of NV fracture. The cut-off value of 0.082 (i.e. 8.2% NV fracture risk at baseline) corresponded to sensitivity of 62.6% and specificity of 62.3%. In the subgroup of women with high risk of NV fracture (N = 1013), the incidence of NV and vertebral fractures was 12.7% and 22.3%, respectively, i.e. 1.6 and 1.5 times higher than the average of the population. The use of six parameters easily assessable in clinical practice can help to define patients at high risk of non-vertebral fracture. As a number of compounds approved for the treatment of osteoporosis have no or little demonstrated effect against non-vertebral fractures the risk assessment tool may be useful for the selection of optimal treatments.

Disclosures: ***C. Roux****, None.*

SU358

Changes in Weight and Body Composition Are Associated with Bone Loss and Incident Vertebral Fracture in Women Over 50. J. Finigan, D. M. Greenfield*, R. A. Hannon, A. Blumsohn, N. F. Peel, G. Jiang*, R. Eastell. University of Sheffield, Sheffield, United Kingdom.

It has been observed that weight loss is associated with loss of bone density and with incident non-spine frailty fractures. It is unclear whether it is the loss of fat mass or of lean mass that is significant for bone loss or whether weight loss is related to the risk of vertebral fractures. We carried out a 10-year prospective study of a population-based group of 375 women, ages 50 to 85 years. At baseline we measured height, weight, bone mineral density (BMD) by DXA of the femoral neck and total body for body composition. Incident vertebral fractures were determined for subjects with 2 or more study visits (n=314) by a single radiologist from spinal radiographs at 0, 2, 5, 7 and 10 years. BMD measurements were repeated at these visits, and the annual percentage rate of bone loss at the femoral neck (FN) was calculated from a regression line. Only those subjects who attended for 5 or more years were included in the bone loss analysis (n=254). Weight and body composition changes were calculated as annual percentages of baseline values for all subjects with at least 2 visits. Neither height, weight, BMI, fat mass nor lean mass at baseline predicted the rate of change of hip bone density, but older age was associated with greater annual bone loss ($rho=-0.16$, $p=0.012$). Rates of change in weight, fat mass and lean mass were all positively associated with rate of change of bone density ($r=0.41$, $r=0.32$, $r=0.38$ respectively, all $p<0.001$). By multiple linear regression, each of these was independent of age, and changes in fat mass and lean mass were independent of each other, with $p<0.001$ in each case. When subjects under or over age 65 (n=159, n=95) were analysed separately, the associations were similar in both analyses. By logistic regression, the rates of change of weight and fat mass were associated with incident vertebral fracture, with odds ratios of 1.66 (95% CI 1.13, 2.46) for weight change and 1.56 (1.05, 2.31) for fat change, for each SD decrease, but these were not independent of age. Change in lean mass was not associated with fracture. We have previously observed that a greater fat mass protects against vertebral fractures. When obese subjects (BMI>30, n=57) were excluded from the current analysis, the odds ratios for each SD decrease in weight change and fat change were 1.86 (1.20, 2.87) and 1.62 (1.07, 2.44), with both independent of age. We conclude that, regardless of baseline weight or body composition, weight loss is associated with greater bone loss, with changes in fat mass and lean mass making similar and independent contributions. Incident vertebral fractures, on the other hand, are associated with loss of weight and fat mass, but not lean mass, in non-obese subjects.

Epidemiology and Treatment Practices of Osteoporosis in Elderly Americans. M. A. Omar*[1], K. H. Kahler*[1], M. Edmonson*[2], K. Annunziata*[2]. [1]Novartis Pharmaceuticals Corporation, East Hanover, NJ, USA, [2]Consumer Health Sciences, East Hanover, NJ, USA.

Osteoporotic fractures are a major public health concern, resulting in substantial morbidity and mortality. The objective of this study was to determine the recent epidemiology of osteoporosis and related treatment practices of the elderly in the US. The study population consisted of respondents from the 2004 US National Health and Wellness Survey (NHWS). The NHWS is an annual cross-sectional survey of a nationally representative sample of the adult US population (≥ 18 years) that contains a broad range of health-related topics. The survey was fielded via the internet in June 2004 and completed by 40,730 US adults. Of all respondents who completed the NHWS, 3.8% reported being diagnosed with osteoporosis by a physician. Fifty percent of these were ≥ 65 years. Of the latter group, 93% were female, and about 11% were part of the workforce. Of the overall population ≥ 65 years (regardless of osteoporosis diagnosis), 20% reported having had ≥ 1 fracture(s) in the past. The proportion increased to 31% for all respondents diagnosed with osteoporosis. Of all NHWS respondents ≥ 65 years with past fracture(s), 38% had never had a bone mineral density scan, 19% had received a diagnosis of osteoporosis, and 12% were on prescription drug therapy for osteoporosis. Of the respondents ≥ 65 years who did not have a diagnosis of osteoporosis by a physician, 24% considered themselves at risk for the condition, while 59% reported taking no measures to prevent it. The results from this study suggest that under-treatment of osteoporosis in the elderly is an important concern. Patient education, adequate screening and appropriate treatment of those at risk for fractures may help reduce the clinical and economic burden of this disease.

Overweight, but not Obesity, Is Associated with Higher Bone Mineral Density in Women Across the Age-Span. R. A. Brownbill, J. Z. Ilich. School of Allied Health, University of Connecticut, Storrs, CT, USA.

Studies show that weight loss causes reduction in bone mineral density (BMD), however, it is not clear whether and to what extent higher body weight might contribute to higher BMD in women across the age span. This study was conducted to determine if degree of overweight/obesity was related to BMD of various skeletal sites in 311 healthy Caucasian women of wide age range (18.6-88.6 y, mean±SD 49.3±20.3 y). Weight and height were measured in indoor clothing by standard methods and body mass index (BMI, kg/m^2) was calculated. BMD and t-scores of the whole body, femur (neck, Ward's triangle, shaft, trochanter and total hip), lumbar spine and forearm were measured with Lunar DPX-MD densitometer. Subjects were classified according to their BMI as either normal weight (BMI<25 kg/m^2, n=141, age 50.6±19.8 y), overweight (BMI=25-29 kg/m^2, n=114, age 49.2 y), or obese (BMI>30 kg/m^2, n=56, age 47.1 y). ANCOVA, controlled for age, and pair-wise group comparisons with Bonferroni corrections were used to assess group differences in BMD and t-scores. Obese and overweight subjects had significantly higher BMD and t-scores for all skeletal sites ($p<0.05$) than normal-weight subjects. Whole body BMD for ascending BMI groups was 1.110±0.10, 1.163±0.11, and 1.193±0.10 g/cm^2, respectively, while hip t-scores were -0.92±1.28, -0.55±1.37, and -0.31±1.30, respectively. Although obese subjects had higher BMD than overweight subjects for most of the skeletal sites, results were not significant. The findings of this study indicate excess body weight is associated with higher BMD in women of wide age range, however, excess weight beyond BMI of 30 kg/m^2 is not associated with additional increase in BMD.

Bone Turnover and Micro-Architecture in Premenopausal Women with Idiopathic Osteoporosis. J. Fleischer[1], M. Donovan[1], H. Zhou[2], D. McMahon[1], D. Dempster[2], R. Müller[3], E. Shane[1]. [1]Medicine, Columbia University P & S, New York, NY, USA, [2]Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [3]ETH and University Zürich, Zürich, Switzerland.

Most young women with osteoporosis (OP) have an identifiable cause. Others have an idiopathic form (IOP) for which no cause can be found. To characterize histomorphometric features of IOP, 9 otherwise healthy premenopausal women who presented with OP and fragility fractures, underwent tetracycline-labeled transiliac bone biopsy. Secondary causes of OP were excluded. Compared to age and sex matched controls (n=18), significant differences in bone turnover were identified. Although osteoid thickness and surface did not differ, parameters that reflect bone formation were lower in IOP patients, wall width by 12% ($p<.01$), mineral apposition rate by 18% ($p<.01$), mineralizing surface by 42% ($p \leq 0.02$), bone formation rate by 52% ($p<.01$) and activation frequency by 54% ($p=.07$). Conversely, bone resorption variables were increased, including a markedly longer resorption period ($p=0.02$) and increased eroded surface ($p=.05$). Despite abnormalities in bone turnover, structural parameters assessed by 2-dimensional (2D) histomorphometry, such as cancellous bone volume (BV/TV) and trabecular width (Tb.Wi), did not differ, although there was a trend toward lower trabecular number (Tb.N; 1.7 ± .07 vs 1.9 ± .05; ± SEM; $p=.12$) and increased trabecular separation (Tb.Sp; 429 ± 20 vs 388 ± 17 μm; $p=.16$) in women with IOP. To further assess microarchitecture, biopsies were analyzed by microCT. Consistent with 2D results, BV/TV and bone surface/bone volume (BS/BV) did not differ between groups ($p=.59$ and $p=.46$, respectively), but bone surface/total volume (BS/TV; 3.74 ± .19 vs 4.34 ± .13 1/mm; $p=.01$) was significantly lower in IOP subjects. Trabecular thickness (Tb.Th; 226 ± 19 vs 194 ± 10 μm; $p=.11$) and Tb.Sp (551 ± 27 vs 464 ± 30 μm; $p=.06$) tended to be higher and Tb.N tended to be lower (1.6 ± .07 vs 2.3 ± .49; $p=.18$) in IOP. Moreover, there was significantly greater ($p<0.04$) intra-individual variability in Tb.Th and Tb.Sp in IOP subjects than controls. In summary, women with IOP have evidence of increased bone resorption and decreased bone formation compared to controls. Microarchitectural changes were less pronounced, although with more sensitive micro-CT analysis, significant decreases in BS/TV, increases in Tb.Sp and evidence of structural heterogeneity were detected. The microCT data suggest abnormal bone remodeling in premenopausal women with IOP is associated with loss of whole trabecular elements, rather than thinning of individual trabeculae, changes that may ultimately lead to abnormal bone quality and increased fragility.

Comparison of Male and Female Response to Regenerative Nerve Damage. A. M. Miesse*, T. A. Bateman. Bioengineering, Clemson University, Clemson, SC, USA.

It is known that different modes of nerve damage cause osteoporosis. This decrease in bone mass coincides with the loss of muscle stimulation, resulting in a measurable increase of bone resorption local to the affected limb. This study was designed to examine a potentially different response to nerve damage-induced bone loss between male and female mice. Twenty-four C57BL/6J mice were used in this study. At surgery, all animals were 105 days old and assigned to one of two groups: Sciatic nerve crush male (MAL, n=12); and sciatic nerve crush female (FEM, n=12). The sciatic nerve was surgically exposed and then crushed flat with mosquito forceps midway between the sciatic notch and patella for 30 seconds. The left limb was used as a control. The mice were sacrificed two weeks post-surgery and the hindlimbs excised. These analyses were performed on the femora: bone mass, 3-point bending, and microCT (μCT) of the diaphysis and epiphysis. For all comparisons, a t-test was performed comparing the right (surgical) limb to the left (non-surgery) limb within the MAL and FEM groups. The FEM group experienced an 8.0% ($p<0.001$) decrease in bone mass while the MAL group had a 6.3% ($p=0.16$) decrease. Yield strength was unchanged for both groups. Maximum strength decreased significantly for FEM (7.0%, $p=0.02$) but not for the MAL group (0.2%). Stiffness decreased significantly in both the FEM and MAL groups with mean decreases of 67% ($p<0.001$) and 32% ($p<0.001$), respectively. These data suggest that functionally FEM were more severely affected by the nerve damage compared to the MAL. Cortical diaphysis (9mm) was measured via μCT in order to quantify the effects of nerve crush on cortical volume and moment of inertia. The cortical volume decreased in the FEM group by 4.4% ($p=0.005$) but there was no significant decrease in the MAL group (2.2%). This decrease in cortical volume coincides with a trend of a decrease in average maximum principle moment of inertia (I_{max}) for FEM. I_{max} was diminished 6.4% ($p=0.06$) for the FEM group, while MAL had no difference in I_{max} (-0.2%). Trabecular bone density was measured at both the proximal and distal ends to assess the effects of nerve damage at different regions. Neither group had significant differences in bone density at the distal end, but both experienced differences at the proximal end (FEM 16%, $p=0.03$; MAL $p=0.009$, 16%). These data demonstrate that male and female mice experience a difference in functional bone loss due to regenerative damage to the sciatic nerve. These differences are primarily manifested in cortical bone, resulting in greater changes in mechanical strength for female mice.

Loading Influences the Size, Shape and the Architecture of the Bone Rather than its Mass. R. M. Zebaze[1], A. Jones*[2], M. Knackstedt*[2], E. Seeman[1]. [1]Endocrinology, Austin Health, Melbourne, Australia, [2]Department of Applied Maths, RSPhysSE, Australian National University, Australia.

The structural basis of femoral neck (FN) strength was studied using high resolution micro-CT. Two hundred cross-sectional slices were analyzed in each of 13 postmortem specimens from Caucasian women aged 29 to 85. At the FN-shaft junction (a region mainly subjected to bending), the section modulus was highest, the FN had a large ellipsoid total cross-sectional area (T-CSA) with a supero-inferior long axis. The bone at this junction was largely cortical with greater thickness inferiorly than superiorly. Moving proximally along the FN, T-CSA decreased then increased becoming less ellipsoid and more circular; while the cortical mass diminished, trabecular mass increased so that bone mass (represented by bone area) from section to section was almost constant along the FN but the proportions of cortical and trabecular bone varied in a reciprocal fashion. From the FN-shaft junction to FN- femoral head junction, cortical bone mass decreased by ~ 60% (199.6 ± 12.7 vs. 78.5 ± 8.6 mm^2), this was associated with a similar ~ 60% increase in trabecular bone mass (72.8 ± 9.4 vs. 174.2 ± 16.3mm^2) towards the femoral neck-head junction, a region subjected to mainly compressive and shear stresses. From the FN-shaft junction to the neck-head junction, the section modulus decreased by 67% (1491 ± 101.9 vs. 496 ± 66.1mm^3) while the coefficient of circularity (the degree to which the T-CSA approximates a circle) of the cross section increased from 59 to 87.5%. Thus, bone mass from slice to slice was relatively constant despite the change in T-CSA size and shape along the FN. Loading influences the structural and spatial organization of bone, but has little effect on its mass; adapting the size, shape and architecture to prevailing loads; ellipticity and cortical bone favours resistance bending, circularity and trabecular bone favours resistance to compression and shear stresses. The inability of bone to adapt its structural parameters (shape, relative distribution of cortical and trabecular bone) to prevailing loads may play an important role in the development of bone fragility. Understanding the mechanisms regulating these structural parameters independently of bone mass may be important in understanding the pathogenesis of bone fragility.

The Disproportionately Shorter Femoral Neck Length in Chinese Contributes to Higher Hip Strength than in Caucasians. X. Wang*[1], Y. Duan[1], M. J. Henry*[2], E. Seeman[1]. [1]Endocrinology and Medicine, Austin Health, the University of Melbourne, Heidelberg, VIC, Australia, [2]Clinical and Biomedical Sciences, Barwon Health, the University of Melbourne, Geelong, Australia.

Racial differences in femoral neck (FN) traits are the result of differences in structure rather than differences in volumetric bone mineral density (vBMD) (Wang et al, in press). We hypothesized that the lower hip fracture rate in Chinese than Caucasians may be partly due to Chinese having shorter FN length, a trait that contributes to the higher hip strength than in Caucasians. We studied 821 healthy Chinese (540 females) and 1052 Caucasians (692 females) aged 18-93 years living in Melbourne. Trunk length and leg length were measured by anthropometry. Using DXA hip strength analysis program, we calculated safety factor (SF), an estimate of hip strength expressing the ratio of estimated failure stress in tension to applied tensile stress during walking. In both sexes, 85% of the shorter stature in Chinese than Caucasians was due to their shorter leg length. FN length was 6% shorter in Chinese than Caucasians after adjusting for their shorter stature. SF decreased with age in all subjects but was 5-10% higher in Chinese than in Caucasians. About 13% of the racial difference in SF was independently attributed to the racial difference in FN length. Comparing sexes, shorter standing height in women was equally due to shorter leg and trunk length in both races while FN length was 4-6% shorter in women than men after adjusting for age, standing height and weight. Young adult women and men had a similar SF in both races. There was also no sex difference in SF in elderly Caucasian women and men, but SF was 7.8% lower in elderly Chinese women than men ($p < 0.01$). We infer the disproportionately shorter leg length and the shorter FN length may partly account for the lower hip fracture rates in Chinese than Caucasians. However, women also have shorter leg length and FN length but fracture more often than men. Whether deleterious structural abnormalities in women overwhelm any protective effect remains to be determined.

The Different Response to D-Galactose on Bone Tissue from Female and Male Rats. L. Cui, T. Wu*, H. M. Luo*. Pharmacology, Guangdong Medical College, Zhanjiang, China.

D-galactose is known to induce senescent animal models such as age-dependent cataractogenesis and brain senescence partially due to the oxidative damage and lipid peroxidation induced by D-galactose. Since osteoporosis are also involved in a senescent procedure, whether D-galactose induces bone loss is not being studied. The aim of current study was to examine the effects of D-galactose on rats bone tissue in order to duplicate D-galactose-induced bone loss as a senescent-related osteoporosis model. Fifty Sprague-Dawley rats at age of 3 months with half female and half male were divided into control, ovariectomized, orchiectomized or treated with D-galactose at doses of 50, 100 and 200mg/kg/d for two months respectively. Double in vivo fluorochrome labeling was given. The undecalcified longitudinal proximal tibial metaphyseal sections were processed for bone histomorphometric analysis. The testicles and the ovaries were processed for observation under microscope. As the results, D-galactose at three doses decreased bone mass (% Tb.Ar) by 53.5%, 53.6% and 64.4% respectively in male rats (parallel to ORX which decreased by 62.4%), decreased bone formation parameter (BFR/BV) by 24.1%, 65.5% and 89.1% respectively in male rats (parallel to ORX which had no changes on BFR/BV). However, D-galactose has no effects on female rats of bone tissue while OVX rats had a marked decrease of bone mass by 75% with increase of bone formation indices. Comparing with control rats, the interstitial cells of testicles were sparse and the convoluted seminiferous tubles were vacuous in D-galactose treated male rats but no changes in ovaries of D-galactose treated female rats. Our study suggested that D-galactose can induced cancellous bone loss and inhibit bone formation rate but have no effects on female rats probably due to the different response of D-galactose to gonad gland, this indicate D-galactose-induced bone loss can be an model of man osteoporosis. The mechanism of D-galactose on bone tissue in different gender rats need further investigating.

Texture Analysis of X-Ray Radiographs Is Correlated with 3D Ddescriptors of Bone Microcomputed Tomography. P. Guggenbuhl[1], F. Bodic*[2], L. Hamel*[2], M. F. Basle*[1], D. Chappard[1]. [1]INSERM, EMI 0335, ANGERS, France, [2]Faculté Chirurgie Dentaire, Nantes, France.

Alteration of bone trabecular architecture is an independent predictor of fracture risk in osteoporosis. Until now, microarchitecture can only be measured on a bone biopsy, thus limiting microarchitecture analysis in routine clinical practice for osteoporosis. Texture analysis on X-ray images has been shown a suitable means to assess 2D microarchitecture. But, little is known on the relationships between 3D architecture and texture analysis. In this study, the anterosuperior part of the iliac bone was removed from twenty-four cadavers. Large samples were prepared and comprised the crest and a stripe of bone approximately 3cm in width and 5cm in height. These large specimens were used in order to preserve bone architecture; they also corresponded to the location used by histomorphometrists for the diagnosis of metabolic bone diseases on iliac crest biopsies. Bone samples were examined with a microcomputed tomograph for 3D microarchitecture (BV/TV, C.BV/C.TV, Tb.Pf, SMI, Tb.Th, Tb.N, Tb.Sp). (cf figure with 3D reconstructions and corresponding textures). Texture analysis was done by several methods (skeletonization, run lengths, fractal techniques) from X-ray projection images. Significant correlations were found between bone mass parameters (BV/TV and C.BV/C.TV -which takes into account both cortical and trabecular bone) and other histomorphometric parameters (e.g., [BV/TV] /Tb.Pf, r=-0.875; /SMI, r=-0.849; /Tb.Th, r=0.6; /Tb.N, r=0.824; /Tb.Sp, r=-0.856) but no correlation was found with texture parameters. However, when specific descriptors of trabecular bone microarchitecture were used, several relationships with texture parameters were found ([Tb.N] /BOUND, r=0.628; /VGLN, r=0.596; / Fractal D, r = 0.569). When multiple correlations were used, the correlation coefficients were markedly improved with trabecular caracteristics. X-ray texture analysis seemed to be a suitable approach for 2D bone microarchitecture assessment. Furthermore, there is a good correlation between texture analysis of X-ray radiographs and 3D bone microarchitecture assessed by microcomputed tomography.

Bone Turnover, Bone Mass, Size and Volumetric Density Differences between Young Aadult and Senile Osteoporosis. D. Merlotti, L. Gennari, G. Martini, N. Dal Canto*, V. De Paola, R. Nuti. Internal Medicine, Endocrine-Metabolic Sciences and Biochemistry, University of Siena, SIENA, Italy.

Although osteoporosis predominantly affects older postmenopausal women, low bone mineral density also occurs in men and younger women. While most young people with osteoporosis have an identifiable cause, others have an idiopathic form for which no etiology can be found. In order to better characterize the structural and metabolic basis of reduced bone mass in young adults, we measured bone turnover markers (bone alkaline phosphatase, BALP and serum crosslaps, CTX), areal bone mineral density (aBMD), bone volume and volumetric BMD (vBMD) by dual-energy X-ray absorptiometry in 70 adult males (32-49 yrs) and 30 premenopausal females with low bone mass (<-2 SD), in 100 age-matched healthy subjects, in 150 elderly men (59-85 yrs) and 150 postmenopausal women (55-70 yrs). Body weight was reduced in young adult and elderly osteoporotic subjects with respect to controls. Average BALP was within the normal reference range both in young and elderly males and was significantly decreased in young adult than in elderly osteoporotic men. CTX levels appeared significantly lower in young adult than in elderly osteoporotic men, while did not significantly differ from those in healthy age-matched controls. Similarly, young women with osteoporosis had reduced BALP and CTX levels than healthy and osteoporotic postmenopausal women. No major differences were observed in parathyroid hormone and 25 hydroxy-vitamin D even though a trend for decreased levels was observed in elderly subjects. Smaller aBMD and vBMD were observed between young adult osteoporotic males and age-matched controls as well as between elderly osteoporotic and non osteoporotic men, at both femoral and lumbar sites. When we considered bone size, only the bone volume at the spine was significantly reduced in young osteoporotics compared with controls. Moreover, bone volume at the spine was also significantly reduced when young osteoporotic males were compared to healthy elderly subjects. A similar but more pronounced deficit in vBMD and bone size was observed in premenopausal women with osteoporosis as compared to age-matched controls as well as in postmenopausal osteoporotic women compared to healthy osteoporotic women. Even though the pathogenesis of low bone mass in young men and women may be heterogeneous, these results suggest that a low bone turnover with a possible osteoblast dysfunction may be responsible of these forms of osteoporosis in both sexes. Moreover, the reported differences in bone size between elderly osteoporotic and non osteoporotic subjects may be accentuated in young adult idiopathic osteoporosis as compared to normal controls.

Bone Formation in the Periosteal, Endocortical, and Trabecular Envelopes of the Ilium of Adult Women. S. Bare*[1], S. Recker*[1], R. Recker[1], D. Kimmel[2]. [1]Creighton University, Omaha, NE, USA, [2]Merck & Co., West Point, PA, USA.

Transilial biopsy (TIBx) specimens contain all bone envelopes (periosteal [Ps], Haversian, endocortical [Ec], and trabecular [Tb]); the Tb envelope is most frequently studied. Consistently orienting Haversian systems in TIBx sections is difficult. Though current therapeutic agents influence mainly the Tb and Ec envelopes, future ones may work elsewhere. Our purpose is to compare bone formation activity in the TIBx Ps and Ec envelopes to that of the Tb envelope. One unstained section from each of two levels of TIBx's from 55 untreated post-menopausal osteoporotic (PMO) women (16yrs post-menopause), 79 similar PMO alendronate (ALN)-treated (1-2yrs) women, and 42 women at one yr after last menses, were examined for total surface (BS), single (1XL), and double (2XL)-fluorochrome labeled surface, and mineral apposition rate (MAR) in Ps, Ec, and Tb envelopes. 2XL/BS was calculated omitted those individuals without 2XL. Differences were tested by Kruskal-Wallis ANOVA with Student Neuman-Keuls post-hoc analysis.

Ps, Ec, and Tb Envelopes of 55 Untreated PMO Women					
Env	Surface (mm)	% with 2XL	% with any Label	2X/BS (%)	MAR (μm/d)
Ps	29±10	38	70	1.59±1.36	0.88±0.33 (21)
Ec	31±10	90*	100	6.07±4.77*	0.73±0.19 (50)
Tb	79±26	98*	100	2.26±1.41	0.54±0.12 (54)
Ps Envelope (176 Post-Menopausal Women)					
-	29±9	33	73	1.43±1.26	0.79±0.35 (58)

The Tb envelope of a TIBx of untreated PMO women presents ~3X as much surface as the Ps or Ec envelopes. 90-98% of subjects had 2XL at the Ec and Tb envelopes; only ~40% had 2XL at the Ps envelope. Ec 2XL/BS was 2-3X higher than in the Tb and Ps envelopes. While ALN subjects had less 2XL at the Tb and Ec envelopes than untreated subjects (data not shown), Ps labeling was not ALN sensitive (Bare et al., 2005 [two ASBMR Abstracts]). Thus, the frequency of Ps 2XL was confirmed in a group of 176 post-menopausal women. **Conclusion:** The TIBx Ps envelope of PMO women forms bone at a lower rate than do the Tb and Ec envelopes. Considering that only ~35% of subjects had Ps 2XL when 30mm of surface was studied and 2X/BS was ~25% of that at the Ec envelope, Ps bone formation seems to be about 10X lower than at the Ec envelope. The T envelope also has three times lower 2X/BS than the Ec envelope. Since ~65% of TIBxs showed no Ps 2XL, about four-fold additional Ps surface should be examined to improve the accuracy of bone formation assessment at the iliac Ps envelope.

Structural and Density Changes following Injury to the Forearm Seen by Quantitative CT. J. A. Spadaro, C. Button*, A. Pennella*, W. H. Short*. Orthopedic Surgery, Upstate Medical University, Syracuse, NY, USA.

Loss of bone density in the radius following fracture or surgery has been reported, but it is not entirely clear what gives rise to it. Losses appear rapidly (average 8-10% or more distally 2-4 months after injury). The aim was to characterize the early post-injury structural/quality changes in the bone that may not be reflected in conventional densitometry. We used baseline data from an NIH funded trial of electromagnetic treatment of post-injury osteopenia (the 'e-Bone study'). The distal radius was studied in 53 consecutive subjects (34 females, 19 males, median age 42, range 18-78) (Upstate IRBPHS #4812). Peripheral quantitative computed tomography (pQCT) scans (Norland-Stratec XCT-2000) were made about 6 weeks after either a distal radius fracture or carpal surgery, requiring cast or external fixation. Bilateral axial scans were made at the 4%, 15% and 30% sites of the forearm from the distal end and determined 4 key parameters: the average total density of the slice, the trabecular density, the cross-sectional area of the cortex and the structural strength index (SSI) (~polar moment of inertia). Data was expressed as the % difference from the contralateral (uninjured) arm. Results for the entire group show the total density in the sections was unchanged on average, trabecular density was increased in the 4 % site (t-test, P<0.1)(Fig. 1). Cortical area was decreased at the 15% site and the structural strength index was decreased at all three test sites (P<0.05, 0.1). Changes were larger when subgroups were considered. The fracture subgroup had 12% increase in trabecular density at the 4% region and 2-5% decrease in cortical area and SSI at the more proximal sites. The surgery subgroup had only a 3% decrease in cortical area at the 4% site. Those whose non-dominant arm was injured had significant reductions (3-8%) in cortical area and SSI. We conclude that the pattern of these early changes following injury suggests an increase in trabecular bone associated with the distal radius fracture and decreases in cortical cross-sectional area and strength in all cases. These findings are consistent with endosteal resorption as an important part of the response to injury/disuse. pQCT provides an excellent insight into these changes.

Characterization of the Age-Dependent Osteoporotic Phenotype in Sca-1/Ly6A Null Mice. C. Holmes*[1], T. S. Khan*[1], C. Owen*[2], M. D. Grynpas[2], W. L. Stanford*[1]. [1]Institute of Biomaterials and Biomedical Engineering, University of Toronto, Toronto, ON, Canada, [2]Samuel Lunenfeld Research Institute, Toronto, ON, Canada.

Stem cell antigen-1 (Sca-1/Ly6A) is an 18-kDa glycosyl phosphatidylinositol-anchored cell surface protein expressed by a variety of stem cell populations, including those of the blood, muscle, liver, and mammary epithelium. Previous studies involving Sca-1 knockout (KO) mice implicate that Sca-1 is required directly for the self-renewal of mesenchymal progenitor cells and indirectly for the regulation of osteoclast differentiation. Sca-1 KO mice undergo normal bone development but by 12 months of age exhibit dramatically decreased bone mass and bone brittleness characteristic of age-dependent osteoporosis. The objective of this study was to further characterize the cellular, mechanical, and microarchitectural bone phenotype of Sca-1 KO mice at earlier time points to increase our understanding of its initiation and progression. To achieve this, we carried out both in vitro and in vivo analyses of the bone phenotype of 13 nine-month old Sca-1 KO mice and compared it to that of 16 Sca-1 wild type (WT) age matched controls. Colony-forming unit fibroblast assays revealed that KO mice exhibit an 81.8 % reduction ($p<0.01$) in the number of total mesenchymal progenitors compared with WT controls; a decrease that was mirrored by a similar dramatic reduction in colony-forming unit osteoblast assays. Whole body bone mineral density (BMD) analysis indicated that the KO mice displayed a 5.7% ($p<0.01$) reduction in BMD compared to WT controls. This was paralleled by 4.0% ($p<0.03$) and 4.4% ($p<0.02$) decreases in femoral and spinal BMD, respectively. This suggests that the reduction in total mesenchymal progenitor cells had a negative impact on the BMD of both cortical and trabecular bones in Sca-1 KO mice. Although femoral neck fracture and three point bending tests revealed no statistically significant differences in stiffness between WT and KO femurs, Sca-1 KO femurs required a lower ultimate load ($p<0.03$), as well as failure load ($p<0.03$) in three point bending tests, and less energy for failure ($p<0.01$) than the WT controls in femoral neck fracture tests. These results reinforce our previous findings in 12-month old Sca-1 KO mice, indicating that Sca-1 plays a role in maintaining self-renewal of mesenchymal progenitor cells, which in turn are important in maintaining normal bone mass and mechanical properties with age in mice.

Devastation of Skeletal Quality by Neuromuscular Degeneration. B. J. Lee*[1], S. Judex[1], G. A. Cox*[2], C. Rubin[1]. [1]Biomedical Engineering, SUNY - Stony Brook, Stony Brook, NY, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

A spontaneous autosomal recessive mutation in C57BL/6J mice, causing the degeneration of neuronal innervation of skeletal muscle fibers (Neuron, 1998), was used to study the skeletal consequences of neuromuscular degenerative disease (*nmd*). Comparing *nmd* and wild-type control (WT) at skeletal maturity (15-19wks of age, n=6 in each group), this study used microCT to determine how the reduction in locomotory activity caused by motor neuron dysfunction would influence cortical bone area (mm^2), trabecular bone volume fraction (%), and trabecular connectivity density ($1/mm^3$). These parameters of bone quality were evaluated at the diaphysis of the humerus and femur (cortical bone), and the metaphysis of the distal femur (trabecular bone). *nmd* mice were markedly less mobile and weighed 43% less ($p<0.001$) as compared to WT. This difference was paralleled by *nmd* mice having 41% less bone area ($p=0.001$) in the diaphyseal regions of the humerus, and 37% less bone area ($p=0.001$) in the diaphyseal regions of the femur. In the trabeculae of the metaphysis (table below), the *nmd* mice had 95% less bone area ($p=0.002$), 99% less connective density ($p=0.003$), and 91% less bone volume fraction ($p=0.003$) than WT.

comparison of bone quality parameters in trabecular bone				
	BA (mm^2)	**BV/TV**	**Conn. D. ($1/mm^3$)**	**Body Mass (g)**
WT	0.18	6%	148.5	25.6
nmd	0.009	0.5%	1.30	14.5
% difference	95%	91%	99%	43%
p value	0.002	0.002	0.003	<0.001

Neuromuscular dysfunction, as modeled by the *nmd* mice, occurs concurrently with a significant reduction in an array of parameters central to bone quality, with the largest consequences observed in the trabecular envelope. Of course, it is not yet clear if this reduction is caused by a systemic metabolic retardation of growth, as evidenced by the reduced body weight, elevated resorptive activity in bone tissue as permitted by diminished motor function, or some combination thereof. Nevertheless, these data imply that any pharmacologic or physical means of restoring bone quality, perhaps as an anabolic surrogate for functional activity, will result in a marked reduction in the risk of atraumatic fracture. *Work kindly supported by NIAMS.*

Ethnic Differences in Novel Markers of Bone Metabolism and Fracture Risk: The First Nations Bone Health Study. W. D. Leslie[1], J. Krahn*[1], C. N. Bernstein*[1], M. Sargent*[1], H. A. Weiler[2], C. J. Metge[3], M. Doupe*[1], E. A. Salamon[1], P. Wood Steiman*[4]. [1]Faculty of Medicine, University of Manitoba, Winnipeg, MB, Canada, [2]Human Nutritional Sciences, University of Manitoba, Winnipeg, MB, Canada, [3]Faculty of Pharmacy, University of Manitoba, Winnipeg, MB, Canada, [4]Assembly of Manitoba Chiefs, Winnipeg, MB, Canada.

Canadian Aboriginal (First Nations) women are at increased fracture risk compared with the general population (CMAJ 2004;171:869-73). The First Nations Bone Health Study (FNBHS) reported site-specific reductions in BMD among a random age-stratified (25-39, 40-59 and 60-75) sample of Aboriginal women compared with age-matched White women, lower serum 25OHD values and higher PTH (JBMR 2004;19(Suppl 1):S288 and S423) but these were insufficient to account for the large difference in fracture rates. Therefore, we looked at novel markers of bone metabolism and fracture risk. Morning fasting serum samples were assessed for serum OPG, homocysteine, vitamin B12 (cobalamin) and folate. Mean serum OPG was significantly greater in Aboriginals, the group known to have higher fracture risk and lower BMD. This may imply a counter-regulatory response as has been described with other conditions that adversely affect bone metabolism (such as aging and inflammatory bowel disease). Although mean serum homocysteine was similar, there were significant reductions in both B12 and folate. OPG correlated negatively with BMD at 4 of 5 sites (heel, spine, hip, total body; $P<0.05$, $r=-0.11$ to -0.14) while homocysteine correlated negatively with BMD at the heel only ($P=0.014$, $r=-0.12$). This study demonstrates that novel factors involved in bone metabolism may be important in explaining ethnic differences in fracture rates independent of their effects on BMD.

	Biochemical analyses Aboriginal (N=250)	White (N=177)	P
OPG (pg/mL)	1.29 ± 0.63	1.03 ± 0.71	0.00014
Homocysteine (umol/L)	8.7 ± 3.1	8.9 ± 3.0	>0.2
B12 (pmol/L)	291 ± 160	339 ± 177	0.00350
Folate (nmol/L)	28.7 ± 8.2	32.2 ± 9.1	0.00006

Blood Homocysteine Is Correlated with Bone Mass and Bone Turnover Rate, not with Bone Size in Postmenopausal Women. B. Kim[1], B. Ahn*[1], J. Son*[2], H. Choi*[3], K. Kim*[1], S. Kim*[4], D. Lee[5]. [1]Family Practice and Community Health, Ajou School of Medicine, Suwon, Republic of Korea, [2]Family Medicine, Eulji University School of Medicine, Suwon, Republic of Korea, [3]Family Medicine, Eulji University School of Medicine, Daejeon, Republic of Korea, [4]Family medicine, Sungkyunkwan Universityi School of Medicine, Suwon, Republic of Korea, [5]Family Medicine, Sungkyungkwan University School of Medicine, Suwon, Republic of Korea.

Hyperhomocysteinemia is related to fractures due to osteoporosis. We assessed the relation between blood homocystein and bone mass, size, bone turnover rate. This study included 2,670 postmenopausal wemen who underwent periodic health examination in ajou university health promotion center, from January 2002 to December 2003. Serum homocysteine, bone turnover marker and bone mineral density were measured. The age,osteocalcin,25-vit D,total lumbar BMD,total lumbar T- score,very low lumbar BMD,very low lombar T-score,femur neck BMD,femur neck T-score,femur trochanteric BMD and femur trochanteric T-score showed a significant correlation with the serum total homocysteine. However, after adjusting for age, the only osteocalcin is significantly correlated with the serum total homocysteine, At 3rd lumbar vertebra, the BMC,volumetric BMD and areal BMD showed a significant correlation with the serum total homocysteine but the bony size and the volume were not significant. Even after adjusting for age, the 3rd lumbar BMD is significantly correlated with the serum total homocysteine. Our study show that serum total homocysteine is correlated small but significantly with bone mass, bone turnover rate but not with bone size.

Circulating Levels of OPG, Colia1 Polymorphism and Bone Mass in Healthy Postmenopausal Women. P. Mezquita-Raya*[1], D. Fernandez-Garcia*[2], M. de la Higuera*[2], G. Alonso*[2], J. M. Quesada[3], G. Dorado*[3], F. Luque-Recio*[3], M. E. Ruiz Requena*[4], M. Muñoz-Torres[2]. [1]Endocrinology, Torrecardenas Hospital, Almeria, Spain, [2]Endocrinology, San Cecilio University Hospital, Granada, Spain, [3]Endocrinology, Reina Sofia University Hospital, Cordoba, Spain, [4]Biochemistry Division, San Cecilio University Hospital, Granada, Spain.

Background: Twin and family studies have suggested that BMD has a strong genetic component and is under polygenic control. Several candidate genes have generated considerable attention, although conflicting results have been published. Also, previous studies have revealed the critical role of the RANKL-OPG system on the regulation of bone resorption. To our knowledge no previous studies have investigated the links among genetic factors, serum OPG levels and bone mass in a population of postmenopausal women. **Aims:** To examine the relationship among circulating levels of OPG, COLIA1, VDR and ER genotypes and bone mineral density (BMD) in healthy postmenopausal women. **Subjects and Methods:** We determined anthropometric parameters, serum OPG levels, the COLIA1 (MlsI), VDR (BsmI, TaqI, FokI) and ER (Xba, Pvu) polymorphisms by PCR and BMD by dual X-ray absorptiometry in 134 ambulatory postmenopausal spanish women (61±7 yrs). **Results:** There were no significant differences in serum OPG levels or BMD according to VDR and ER genotypes. There was a strong overrepresentation of the "s" allele in osteoporotic women ($p=0.003$) and a significant association between serum OPG levels and COLIA1 polymorphism (SS[N=64]: 137±54 *vs.* Ss/ss[n=70]: 119±36; $p=0.028$). However, the association of serum OPG levels (OR: 3.2; CI95%: 1.3-7-6) and COLIA1 polymorphism (OR:2.8; CI95%: 1.2-6.6) with the osteoporotic densitometric criteria (T-score ≤-2.5) were significatively independent in the logistic regression model. **Conclusion:** these preliminary results show a significant relationship between serum OPG levels and COLIA1 polymorphism. However, the results of the logistic regression model suggest that these factors influence bone mass in an independent way.

Reduced Bone Mineral Density in Male Patients with Untreated Graves' Disease. T. Majima*[1], Y. Komatsu[2], K. Doi*[1], M. Shigemoto*[1], C. Takagi*[1], K. Nakao*[2]. [1]Endocrinology and Metabolism, Rakuwakai Otowa Hospital, Kyoto, Japan, [2]Medicine and Clinical Science, Kyoto University Graduate School of Medicine, Kyoto, Japan.

Introduction Although it has been established that hyperthyroidism leads to a reduction in bone mineral density (BMD) with accelerated bone turnover promoting bone resorption in female patients, there is a dearth of data for male patients with hyperthyroidism. The purpose of this study was to evaluate bone mineral density and bone metabolism in male patients with Graves' disease. **Subjects and Methods** This study included 56 Japanese male patients with newly diagnosed Graves' disease (mean age 43.6±10.0 years, mean BMI 22.9±2.1 kg/m^2), and 34 normal Japanese male control subjects of similar age (mean age 43.8±10.5 years) and body mass index (mean BMI 22.9±2.0 kg/m^2). We used dual energy X-ray absorptiometry to measure BMD at sites with different cortical/cancellous bone ratios (lumbar spine (LS), femoral neck (FN), and distal radius (DR). **Results** In patients with Graves' disease, the levels of thyroid hormones were elevated (mean free triiodothyronine (FT3) 11.71±4.0 pg/ml, mean free thyroxine (FT4) 4.36±1.4 ng/dl), while thyroid-stimulating hormone (TSH) levels were suppressed below sensitivity. Urinary N-terminal telopeptide of type I collagen normalized by creatinine (U.NTx) and bone-specific alkaline phosphatase (BAP) levels of the GD patients were significantly higher than those of controls ($p<0.0001$ for both). At the LS and the DR, BMD and T scores were significantly lower for patients than for controls. At the FN, on the other hand, the same values were relatively, but not significantly, lower in patients than in controls. However, Z scores at all three sites were siginificantly lower for patients than for controls. The Z score at the DR was significantly lower than those at the LS and FN ($p<0.0001$ for both), whereas no marked difference in Z score was found between the LS and the FN. In addition, the Z-score at the DR, but not at the LS or the FN, correlated negatively with age, FT4, TSH receptor antibodies (TRAb), thyroid stimulating antibody (TSAb) and U.NTx. **Conclusion** These results indicate high prevalence of cortical bone loss in male patients with Graves' disease, especially in elderly patients. We conclude that BMD measurement is crucial in all Graves' patients regardless of their gender, and that the radial BMD as well as those in the LS and FN should be monitored to effectively prevent bone loss and subsequent fracture.

SU376

Factors of Importance for the Age Related Increase in Fragility Fractures of the Hip. H. Christoffersen, S. N. Holmegaard*. Orthopaedic, Hospital Nord / Thisted, Thisted, Denmark.

Age is a BMD-independent risk factor for fragility fracture (FF). In order to evaluate the influence of co morbidity we analyzed laboratory investigations for secondary osteoporosis (OPO) in 302 patients, 221 females (F) and 81 males (M), consecutively admitted due to FF of the hip (FFH). Mean age for F was 80.9 years, for M 77.6 years. One or more previous FF was present in 26% of F and in 29% of M. Laboratory tests comprised Haemoglobin (Hgb), Leucocytes (Leu), ESR, Sodium (Na), potassium (K), Calcium (Ca), phosphate (P), Creatinine (Cr), Albumin (Alb), Alkaline phosphatase (AP) and thyrotrophin (TSH). Considering the age and presence of fracture, limits for abnormality were set at Hgb < 7 mmol/L; Leu > 18 or < 3 /10^{-9}L; ESR > 60 mm/h; Cr > 150 mmol/L and AP > 10% above the upper normal reference value. Normal reference values were used for the rest. The table shows number of patients with abnormal values expressed as percentage of the total number of patients investigated.

	Hgb	Leu	ESR	Na	K	Ca	P	Cr	Alb	AP	TSH
F	29,4	4,3	4,9	2,3	2,7	42,6	16,4	4,1	64,3	9,6	14,7
M	24,7	0,0	7,7	4,9	3,7	59,6	11,4	8,6	73,1	18,8	6,4

Most frequently encountered abnormal results were low Hgb, Ca and Alb, but other abnormalities were also found with high frequency. A significant correlation was observed between Alb and Hgb (F: $p < 0.01$, M: $p < 0.05$), Alb and Ca ($p < 0.01$) and Ca and Hgb ($p = 0.011$). Except for Hgb and TSH, M generally had more abnormal results than F. Surprisingly mean age for M was less than for F, though this was not statistically significant. Previously unrecognized elevation of ESR was rarely encountered. Since ESR seldom is of informative value and more time consuming than other laboratory tests it can be omitted in the screening procedure. Our results suggest that the age related increase in FFH is as much a sign of underlying disease and poor nutrition as of idiopathic OPO. This is supported by the observation that the mean age of males unexpectedly was lower than for females.

Chronic Mild Stress Induces Depression and Bone Loss in Mice: Pharmacological Attenuation by Anti-Depressant Therapy and Possible Involvement of the Sympathetic Nervous System and Hypothalamic-Pituitary-Adrenal Axis. A. Bajayo*[1], I. Goshen*[2], S. Feldman*[3], T. Kreisel*[2], V. Csernus*[4], J. Weidenfeld*[5], E. Shohami*[6], R. Yirmiya*[2], I. Bab[1]. [1]Bone Laboratory, The Hebrew University of Jerusalem, Jerusalem, Israel, [2]Department of Psychology, The Hebrew University of Jerusalem, Jerusalem, Israel, [3]Bone Laboratory and Department of Pharmacology, The Hebrew University of Jerusalem, Jerusalem, Israel, [4]Department of Anatomy, University Medical School Pécs, Jerusalem, Hungary, [5]Department of Neurology, Hadassah University Hospital, Jerusalem, Israel, [6]Department of Pharmacology, The Hebrew University of Jerusalem, Jerusalem, Israel.

In humans, osteoporosis is often accompanied by major depression. However, it is unclear whether bone loss and the associated morbidity and incapacitation induces depression or vice versa. To determine the cause-effect relationship in this case, we examined the bone status in mice subjected for five weeks to chronic mild stress (CMS), a model for depression in rodents. CMS-induced depression was confirmed by reduced sucrose consumption, an established indicator of anhedonia, and reduced social exploration. The CMS mice exhibited normal motility. Micro-computed tomographic measurements of femora and lumbar vertebrae showed a marked bone loss in CMS mice, reflected by a significant decrease in overall bone mass, in particular trabecular bone volume density (30% loss). A further histomorphometric analysis showed CMS-induced decreases in osteoblast number and bone formation rate and increased osteoclast number. While serum testosterone levels were similar in the CMS and control mice, serum corticosterone was almost twice higher under CMS. The anti-depressant drug imipramine, administered in the drinking water throughout the experimental period, attenuated both the depressive symptoms and bone loss. CMS mice responding to imipramine by increased sucrose preference had normal bone mass as compared to non-responders that displayed bone loss. The CMS-induced bone loss was blocked by propranolol, a β-adrenergic receptor antagonist. These results demonstrate that CMS induces bone loss in mice possibly via activation of the sympathetic nervous system and hypothalamic-pituitary-adrenal axis, and are consistent with a causal relationship between depression and bone loss in human osteoporosis.

The Effects of Recombinant TSH on Bone Turnover Markers and Serum Osteoprotegerin and RANKL Levels. G. Martini[1], F. Pacini*[2], M. S. Campagna*[1], B. Franci*[1], A. Avanzati*[1], B. Lucani*[1], S. Salvadori*[1], L. Gennari[1], R. Valenti[1], V. De Paola[1], T. Pilli[2], R. Nuti[1]. [1]Department of Internal Medicine, University of Siena, Siena, Italy, [2]Endocrine Unit, University of Siena, Siena, Italy.

The only established biologic function of thyroid stimulating hormone (TSH) is to regulate the synthesis and secretion of thyroid hormone from thyroid follicle cells. Recently it has been found that TSH-receptors are present both in osteoclast and osteoblast and that THS can modulate bone remodeling independently of thyroid hormones (T3 and T4). In mice TSH inhibits both osteoclast and osteoblast activity, while rhTSH administration in postmenopausal thyroidectomized women causes a rise in bone specific alkaline phosphatase (BSAP) and a decrease of C-telopeptide of Type-I collagen (CTX) without any change in Osteoprotegerin (OPG) serum levels. Moreover older women with low levels of TSH showed an high risk of vertebral and hip fractures. The aim of this study was to evaluate: 1) the role of TSH on bone remodeling both in men than women 2) the role of serum levels of Osteoprotegerin and RANKL regarding the effect of TSH on bone turnover. We studied 30 thyroidectomized patients affected by thyroid carcinoma on L-thyroxine therapy: 10 premenopausal women (aged 32.9 ± 7.6), 10 postmenopausal women (aged 67.2 ± 7.9) and 10 men (aged 49.5 ± 13.9). A blood sample was drawn from each patient at baseline and three and five days after the rhTSH administration (0.9 mg i.m. once daily for the first two days). Sera were assayed for thyroid function (TSH, fT3, fT4) and bone turnover: BSAP, osteocalcin (BGP), N-terminal propeptide of type-I procollagen (PINP) as markers of bone formation, and CTX as marker of bone resorption. Serum OPG and RANKL were assessed using a sandwich enzyme immunoassay (Osteoprotegerin and RANKL, Biomedica, Austria); precision intra and interassay was lower than 10%. In basal conditions serum TSH values were in low-normal range or suppressed with no differences between the three groups. Postmenopausal patients had significantly higher basal values of OPG and BSAP compared to premenopausal women and men. After the rhTSH administration, serum TSH values peaked at day 3, but we were not able to find any significant changes on bone turnover markers in all groups. Serum RANKL levels significantly increased after three days in postmenopausal patients and men returning to baseline values at day 5, while serum OPG levels did not change significantly. These preliminary data showed that TSH has not effect on bone markers; on the other hand the increase of RANKL could suggest an osteoblast activation which only later can lead to bone turnover adjustement.

SU379

Serum Brain Natriuretic Peptide (BNP) Correlates with OPG Levels and Influences Bone Mass and Body Segment Lengths in Elderly Subjects. L. Gennari, R. Valenti, A. Palazzuoli*, B. Franci*, S. Campagna*, D. Merlotti, F. Valleggi*, G. Martini, A. Calabrò*, V. De Paola, A. Avanzati*, B. Lucani*, R. Nuti. Internal Medicine, Endocrine-Metabolic Sciences and Biochemistry, University of Siena, SIENA, Italy.

Natriuretic peptide family consists of 3 structurally related endogenous ligands, atrial, brain, and C-type natriuretic peptides (ANP, BNP, and CNP), and is thought to be involved in a variety of homeostatic processes, including longitudinal bone growth. BNP is a 32-aminoacid peptide that is markedly elevated in patients with congestive heart failure and acute coronary syndrome (ACS). Even though cardiac myocytes constitute the major source of BNP, this peptide is synthesized and released by bone marrow stromal cells at physiologically relevant levels in vitro. Moreover, BNP receptors have been described in osteoblasts and BNP knockout mice exhibit cardiac fibrosis and bone malformations. The aim of this study was to characterise the relationship between plasma BNP, bone mineral density (BMD), and bone turnover markers in 150 subjects. BNP levels significantly increased with age ($r= 0.25$; $p<0.01$) both in males and females and were higher in postmenopausal than premenopausal women. Of interest, BNP highly correlated with OPG levels ($r=0.85$; $p<0.0001$) and total body BMD ($r=0.30$, $p<0.001$). Negative correlations between BNP and urinary calcium or phosphate excretion were also observed in both sexes. When subjects were grouped according to BNP quartiles, we observed significantly higher OPG levels and RANKL/OPG ratio in subjects within the high BNP quartile. No major differences were observed concerning bone alkaline phosphatase and serum CTX. Moreover, in postmenopausal women with BNP in the highest quartile, the average total body BMD was from 4% to 14% higher than in men in the other BNP quartiles ($p<0.005$). A similar but not significant trend was observed in men. Sitting height measured by a stadiometer was significantly related to BNP levels ($r=0.24$; $p<0.05$). Finally, to further explore the relationship between OPG and BNP we evaluated their levels in 50 patients affected with ACS. A similar positive correlation between OPG and BNP was observed ($r=0.38$; $p<0.01$) and both markers significantly correlated with left ventricular systolic function and the severity of disease. These data confirm experimental observations demonstrating a skeletal effect of BNP and further support the reported link between bone and cardiovascular disorders.

Uncoupled Bone Remodeling in Hyperhomocysteinemia-Restoration by Folate Therapy Possibly Involving OPG/RANKL/RANK-Related Mechanisms. T. Ueland*, P. Aukrust*, L. Ose*, J. Bollerslev, M. Nenseter*, K. Holven*. Rikshospitalet University Hospital, Oslo, Norway.

Background Osteoporosis is characterized by a combination of low bone mass and deterioration of the microarchitecture of bone, resulting in increased risk of fractures in the elderly. Critical for the bone remodeling process is the balance between the newly discovered OPG and RANKL, which mediate the effects of many upstream regulators of bone metabolism. Recently, an association between osteoporotic fractures and increased serum levels of homocysteine was demonstrated. **Purpose** To further elucidate the association between homocysteine and bone metabolism we hypothesized that subjects with hyperhomocysteinemia may display disturbances in bone turn-over and the OPG/RANK/RANKL axis. **Methods** This was investigated by measuring biochemical markers of bone turn-over (osteocalcin and CTX-1) and OPG in serum from 35 patients with hyperhomocysteinemia (age 47±13; 20 men) as well as mRNA expression of RANK and RANKL in peripheral blood mononuclear cells (PBMC). The effect of intervention with folate was also assessed. Age- and sex-matched controls were analyzed in parallel. **Results** At baseline no disturbances in bone turn-over were found although OPG was higher and osteocalcin lower in patients. A strong correlation was observed between baseline osteocalcin and CTX-1 in controls ($r=0.59$, $p<0.001$), but not patients ($r=0.20$, p=NS). Quantitative RT-PCR revealed that subjects with hyperhomocysteinemia had higher mRNA expression of both RANK and RANKL in PBMC compared to controls ($p<0.05$). Following folate treatment a significant increase was observed for osteocalcin, while circulating osteoprotegerin decreased ($p<0.05$). Furthermore, osteocalcin and CTX-1 were correlated ($r=0.43$, $p<0.05$) and mRNA levels of RANK and RANKL decreased following folate treatment ($p<0.05$). **Conclusion** Our data suggest that patients with hyperhomocysteinemia are characterized by normal bone turn-over quantitively, however the lack of correlation between bone markers may suggest a uncoupling of the remodeling process. Furthermore, the enhanced RANK/RANKL mRNA expression in circulating immune cells may indicate an increased pro-resorptive potential in these patients. Importantly, both RANK and RANKL were modulated, and the coupling process was restored by folate treatment suggesting that intervention aimed at lowering the serum homocysteine level may be a treatment option for reducing fracture rates.

SU381

Bone Loss following Ovariectomy Is Maintained in Absence of Adrenergic Receptor ß1 and ß2 Signaling. D. D. Pierroz[1], M. L. Bouxsein[2], P. Muzzin*[3], R. Rizzoli[1], S. L. Ferrari[1]. [1]Rehabilitation and Geriatrics, Div of Bone Diseases, University Hospital, Geneva, Switzerland, [2]Beth Israel Deaconess Medical Center, Orthopedic Biomechanics Laboratory, Boston, MA, USA, [3]Cellular Physiology and Metabolism, Geneva University Hospital, Geneva, Switzerland.

Whether ß-blockers may increase bone mass in post-menopausal women remains controversial. Compared to wild-type (WT) mice, ß2-adrenergic receptor (ß2AR) KO mice were reported to have greater trabecular (Tb) bone volume (BV/TV) by 6 months of age, and also following ovariectomy (OVX) during growth. However, intact ß2AR KO mice apparently do not have greater BV/TV before 6 months of age nor do they have higher cortical bone volume. Moreover, we previously reported vertebral Tb BV/TV is not increased in growing and adult ß1ß2 adrenergic receptor (ß1ß2AR) KO mice, and that bone mass and cortical microarchitecture are actually lower in these mice compared to WT. Therefore it remains unclear whether inhibition of adrenergic-mediated signaling may prevent OVX-induced bone loss in adults. For this purpose, 15-week-old ß1ß2AR KO and WT mice were OVX and pair-fed to a non-OVX group (Sham) (n=7-10/group). Bone mineral density (BMD) was evaluated 0, 4 and 8 wks after OVX by pDXA, trabecular (Tb) and cortical (Cort.) micro-architecture at the distal and mid-femur after 8 wks by µCT, and biochemical markers of bone turnover (TRAP5b and osteocalcin, OC) at 0, 4 and 8 wks. Adult ß1ß2AR KO mice were confirmed to have lower total body (TB, -16%), spine (Sp, -21%) and femur (Fem, -26%) BMD compared to WT ($p<0.0001$ for all by repeated measures ANOVA). Compared to Sham, OVX significantly decreased TB and Sp BMD ($p<0.001$) and to a lesser extent Fem BMD ($p=0.02$) after 4 and 8 weeks, with a non-significant trend for greater decrease in WT (TB BMD: WT -6.8%, KO =-2.7%, ns; Sp BMD: WT -12.3%, KO -6.7%; Fem BMD: WT -7.3%, KO -5.4%). OVX also significantly decreased Tb BV/TV and Tb number ($p<0.003$) and increased Tb separation ($p<0.0001$) without changes in Tb thickness. These effects were more prominent in KO than WT (Pinteraction=0.04-0.005). Moreover, OVX significantly decreased Cort bone volume in KO ($p=0.046$ vs Sham), but not in WT. Osteocalcin levels were significantly lower in KO than WT ($p=0.013$ by repeated measures ANOVA) and were transiently increased 4 wks after OVX in both genotypes ($p<0.0001$), whereas TRAP5b did not significantly differ between WT and KO. Altogether these data indicate that non-selective inhibition of ß1ß2 adrenergic receptor signaling may not prevent increased bone remodeling nor bone loss due to estrogen deficiency.

Evidence that Gut Hormone Receptors Are Expressed on Circulating Peripheral Blood Cells. J. A. Clowes[1], J. Xiao*[1], R. Eastell[2], S. Khosla[1]. [1]Endocrine Research Unit, Mayo Clinic College of Medicine, Rochester, MN, USA, [2]University of Sheffield, Sheffield, United Kingdom.

Recent studies have identified a nutrient regulated decrease in bone resorption. The mechanism for this effect is currently unclear. The intestinal hormone, glucagon-like polypeptide 2 (GLP2), has been shown to decrease bone resorption *in vivo*. In addition, leptin and ghrelin are expressed on peripheral blood mononuclear (PBMN) cells and are important hormones involved in regulating immune function and energy homeostasis. To investigate the potential mechanisms involved, we examined the expression of GLP2 receptors (GLP2R) on PBMN cells and determined the co-expression with osteoclast (OC) precursors using CD14, a monocyte marker, and RANK. Osteoblast (OB) precursors were characterized using an anti-osteocalcin (OCN) antibody. We also examined the co-expression of GLP2R with leptin receptor (ObR) and ghrelin receptor (GHS-R). We identified approximately 2% of PBMN cells in the circulation of adult humans that express GLP2R (A). The majority of the GLP2R+ cells co-expressed CD14 (B), but not RANK. A small but consistent percentage of GLP2R+ cells were OCN+, and none of these cells expressed T- or B-cell markers (CD-3 or -19, respectively). ObR was expressed on 1.8% of PBMN cells, but ObR did not co-localize with GLP2R+ cells, suggesting these are distinct populations. We were unable to identify GHS-R on PBMN cells. We conclude that GLP2R+cells circulate in small but significant numbers in the peripheral circulation. The co-expression of GLP2R with CD14, but not RANK, suggests potentially distinct subpopulations of OC precursors. The GLP2R+/OCN+ cells suggest a potential nutrient-induced role in differentiation of OB lineage cells. These findings need to be confirmed using bone marrow and functional studies are required. Clearly, however, these techniques represent a powerful new tool for investigating the effect of nutrition on the pathophysiology of osteoporosis and other metabolic bone diseases.

Immobilization Inhibits Sensory Neuropeptide Signaling in Bone at a Post-Junctional Level. W. S. Kingery[1], W. Yao[1], W. Zhao*[1], X. Jia*[1], T. Guo*[1], T. Wei*[1], D. Lindsey*[2], C. Jacobs[2]. [1]PM&R service (117), VAPAHCS, Palo Alto, CA, USA, [2]RR&D Service, VAPAHCS, Palo Alto, CA, USA.

We recently observed that lesioning substance P (SP) and calcitonin gene-related peptide (CGRP) containing sensory neurons in rats caused a loss of trabecular bone integrity, an effect that we attributed to impaired sensory neurotransmitter signaling in bone. Immobilization also causes a loss of trabecular mass, structure, and strength, and in the current study we tested the hypothesis that these deleterious effects of immobilization could be due to impaired sensory neuropeptide signaling. The right hindlimbs of skeletally mature Sprague Dawley male rats were casted for 4 weeks. After 4 weeks immobilization there was no change in SP and CGRP gene expression in the sensory neurons innervating either hindlimb, but in trabecular bone there was a dramatic reduction in gene expression for the SP and CGRP receptors in the immobilized hindlimb, and to a lesser extent, the contralateral hindlimb. Electrically and SP evoked extravasation responses were impaired in both hindpaws, indicating a bilateral post-junctional inhibition of SP signaling after immobilization. Immunocytochemical and PCR studies demonstrated the presence of SP and CGRP receptors on osteoblasts and osteoclasts in vitro, while immunohistochemical studies in bone sections demonstrated SP and CGRP containing neurons innervating trabecular bone, evidence that sensory neuropeptides released in trabecular bone could have a direct effect on bone cells. Immobilization also caused a reduction in bone mineral density (by DXA scanning at 4 weeks after cast removal) in the of the ipsilateral, and to a lesser extent, contralateral distal femur. There was no effect on diaphyseal bone density in either limb. Microcomputed tomography (µCT) in the distal femur demonstrated bilateral loss of trabecular bone volume and connectivity after unilateral immobilization. On biomechanical testing bone strength was also reduced bilaterally. These results support the hypothesis that the widespread osteoporotic effects of unilateral limb immobilization are a consequence of impaired neural-osseal signaling at the post-junctional level in the trabecular bone.

Chronic Inflammation-Induced Bone Loss and Coronary Artery Disease in Aged Rat Model. S. Y. Bu*[1], M. R. Lerner*[2], D. Morgan*[2], K. Denson*[2], M. S. Bronze*[3], S. A. Lightfoot*[4], D. J. Brackett*[2], B. J. Smith[2]. [1]Department of Nutritional Sciences, Oklahoma State University, Stillwater, OK, USA, [2]Department of Surgery, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA, [3]Department of Medicine, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA, [4]Department of Pathology, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA.

Epidemiological evidence indicates a link exists between osteoporosis and cardiovascular disease. Inflammatory processes have been shown to play a pivotal role in both of these conditions. The purpose of this study is to assess the skeletal and cardiovascular changes in old animals in response to chronic inflammation. Eighteen-month old male Sprague Dawley rats (n=8/group) were implanted subcutaneously with time-release pellets designed to deliver either 33.3 µg or 0 µg of LPS/day for 90 days. Analysis of bone microarchitectural properties was performed using µCT imaging on the proximal tibia and the tibia middiaphysis. Trichrome stains were used for histological examination of atherosclerotic fibrosis within the coronary arteries and arterioles. Although at the end of 90 days there was no significant change in bone volume (BV/TV) in the proximal tibial metaphysis, deleterious effects on trabecular number (TbN; $p=0.0039$) and separation (TbSp; $p=0.0038$) were observed in the LPS group. Trabecular thickness was also increased ($p=0.0143$) in response to chronic LPS. Furthermore, in the tibia midshaft, the LPS-treated group experienced an increase in cortical bone porosity ($p=0.0377$). In addition to these alterations in bone, trichrome staining indicated that chronic LPS administration increased fibrosis within the coronary arteries and arterioles. Additionally, infiltration of lymphocytes was observed which is consistent with coronary vascular disease. In conclusion, utilization of LPS time-release pellets appears to provide an *in vivo* model of chronic inflammation-induced bone loss and a potentially novel system to study concurrent development of osteopenia and vascular disease.

Urinary Calcium Loss, Independent of Calcium and Sodium Intake, Leads to Reduced Forearm Bone Mineral Density in Postmenopausal Women Over a 3-Year Period. J. Z. Ilich[1], R. A. Brownbill[1], T. V. West*[2], A. H. N. Cillessen*[2]. [1]School of Allied Health, University of Connecticut, Storrs, CT, USA, [2]Department of Psychology, University of Connecticut, Storrs, CT, USA.

It is well established in animals and humans of all age groups that dietary sodium (Na) decreases renal calcium (Ca) reabsorption leading to greater urinary Ca excretion. The positive association between dietary and urinary Ca in postmenopausal women has been established as well. However, the effect of increased urinary Ca excretion on BMD in this population is not clear. The purpose of this study was to evaluate effects of urinary Ca loss, controlling for dietary Ca and urinary Na, on forearm BMD in over 100 generally healthy, Caucasian, postmenopausal women enrolled in a 3-year longitudinal evaluation. After the baseline screening, half of the subjects were instructed to reduce their Na intake to about 1500 mg/day. The other half remained on a habitual Na intake of about 3000 mg/day. All subjects were given Ca (~600 mg/day) and vitamin D (~400 IU/day) supplements to bring

their total Ca intake at ~1300 mg/day. The average age at enrollment was 68.6±7.1y (mean±SD) and subjects' anthropometries, bone mass measurement, 24-h urine analyses and dietary and activity records were assessed every 6 months, totaling 7 evaluations. Data were analyzed using multilevel growth curve modeling to examine the changes over-time in bone variables of interest and their predictors. The following covariates were controlled for in all analyses: age, body mass index, total body fat and lean tissue, systolic blood pressure, physical activity, alcohol and caffeine consumption, as well as calcium, energy, protein, and vitamin D intake. Statistically significant linear and curvilinear effects were found for proximal radius and total forearm (ulna and radius at proximal and ultradistal sites) BMD. After controlling for all significant covariates, a main effect for age indicated that, as expected, it was negatively associated with BMD, $p < 0.001$. A main effect for Na indicated that higher urinary Na was associated with higher BMD, $p = 0.02$. However, this effect was modified by interactions with time and with urinary Ca. These interactions indicated that at all levels of Na intake, increased urinary calcium was associated with a curvilinear decrease in BMD over time, $p < 0.01$. Results also revealed a statistically significant lower forearm BMD in women with higher urinary Ca in both younger and older subjects, regardless of urinary Na. We conclude that higher urinary Ca, independent of Ca and Na intake, leads to loss of BMD over time in postmenopausal women. This effect might increase risk of developing osteoporosis in this population.

The Rate that Family Physicians Prescribe Osteoporosis Medications to their Patients: Canadian Quality Circles (CQC) Project. A. Hodsman[1], G. Ioannidis[2], A. Papaioannou[2], B. Kvern*[3], D. Johnstone*[4], C. Crowley[4], J. D. Adachi[2]. [1]University of Western Ontario, London, ON, Canada, [2]McMaster University, Hamilton, ON, Canada, [3]University of Manitoba, Winnipeg, MB, Canada, [4]Procter and Gamble Pharmaceuticals, Toronto, ON, Canada.

The CQC Pilot Project was designed to facilitate family physicians' adoption of the Osteoporosis Society of Canada (OSC) 2002 clinical practice guidelines for osteoporosis (OP) and included training, a first wave of data collection (wave 1), an educational intervention, a second wave of data collection, using different patients (wave 2), and strategy implementation. 52 physicians were recruited as members of 7 Quality Circles. Each wave of data collection consisted of recording OP risk factors, diagnosis and treatment information on separate patients via chart reviews and knowledge of their patients using the CQC data collection form. All patients were women 55 years of age and older and attended at least 2 visits to the member's practice in the previous 24 months. 1505 and 1359 patients comprised waves 1 and 2, respectively. Individual and QC data were collated in profiles and provided to the members. The QC's then met to discuss the profiles, identify and analyze problems, recommend solutions, and participate in an OP workshop. The primary focus of the workshop was to assess postmenopausal OP and risk factor identification. The second wave of data collection occurred after the intervention. Our analyses examined the rate that family physicians prescribe OP medications to their patients who had a prior osteoporotic fracture of the hip, wrist, or spine according to their BMD status. The OSC guidelines recommend treating those with a prior fracture in association with osteopenia (BMD T-score< -1.5). The medications examined were divided into two groups: Bisphosphonate Therapy (etidronate, alendronate, or risedronate) and Any Therapy (bisphosphonates, raloxifene, or hormone replacement therapy). A total of 139 patients from wave 1 and 129 from wave 2 had a prior fracture. The table shows the rate therapy was prescribe in these patients.

Table: Treatment Given For Patients with Fractures According to Their BMD Status (Wave 1, Wave 2)

BMD T-score	Bisphosphonate Therapy	Any Therapy
Osteoporosis (≤ -2.5)	(87%, 88%)	(91%, 93%)
Osteopenia (≤-1 to > -2.5)	(51%, 66%)	(56%, 72%)
Normal (>-1)	(9%, 29%)	(9%, 29%)
BMD not Tested	(27%, 30%)	(27%, 39%)

In conclusion, most patients with a fracture and BMD in the osteoporosis range were given therapy. More than a third of the patients did not receive therapy if they had a fracture and osteopenia. Future QC interventions should focus on the use of therapy in patients with fractures and osteopenia.

The Evaluation of Process Factors Involved in Performing the Canadian Quality Circle (CQC) Pilot Project for the Care of Patients at Risk for Osteoporosis. B. Kvern*[1], G. Ioannidis[2], A. Papaioannou[2], A. Hodsman[3], D. Johnstone*[4], C. Crowley[4], S. Glezer*[5], J. D. Adachi[2]. [1]University of Manitoba, Winnipeg, MB, Canada, [2]McMaster University, Hamilton, ON, Canada, [3]University of Western Ontario, London, ON, Canada, [4]Procter and Gamble Pharmaceuticals, Toronto, ON, Canada, [5]Sanofi-Aventis, Laval, PQ, Canada.

The CQC project was planned in two phases, the Pilot and the National study, to facilitate family physicians' adoption of the Osteoporosis Society of Canada 2002 clinical practice guidelines for osteoporosis. One specific aim of the Pilot was to examine the process factors involved to determine if a planned National study was feasible. Current analyses of the Pilot evaluated the success of the processes and physicians' self perceptions of the effectiveness of the study. During recruitment, 52 physicians from two provinces were recruited as members of 7 Quality Circles (QC). Members collected data at random on different patients during two waves (wave 1, wave 2) via chart reviews and the completion of the CQC form that captures data on osteoporosis. Physicians were responsible to assess 30 patients during wave 1 and 30 during wave 2 using the CQC chart-audit form. Individual and QC data were collated in profiles and provided to the members. An individualized profile was only seen by the individual who collected the data from their own practice; data was compared to circle and the entire project sample. The QC then met to discuss the profiles and participate in an OP workshop. The primary focus of the workshop was to assess postmenopausal osteoporosis and risk factor identification. Wave 2 data collection occurred after the intervention and was used to provide feedback and to gauge overall progress. The evaluation process indicated that 96% of the circle members agreed that the format of the CQC meetings was conducive to learning, 98% agreed that the meetings permitted them to compare their profiles to their peers, and 98% felt that the information they learned was practical and could be immediately implemented in their practice. A total of 98% of participating physicians felt that the CQC initiative had either "some" or a "great deal" of influence on the manner in which they provided care to patients with or at a high risk of developing osteoporosis. In addition, 45% and 53% of physician respondents felt that their patients had benefited "a little" or "most definitely" from their involvement in the research, respectively. In conclusion, the use of QC is a feasible stepwise approach to education that provides the opportunity for physicians to systematically analyze patient-related problems and develop solutions to these problems.

Persistent Bisphosphonate Usage Reduces the Risk of Hospitalizations for Osteoporotic Fractures. W. G. Goettsch*[1], F. Penning*[1], J. E. Erkens*[1], N. O. Lynch*[2], A. Novak*[3], R. M. C. Herings*[1]. [1]PHARMO Institute, Utrecht, The Netherlands, [2]GSK, Greenford, United Kingdom, [3]Roche Products Ltd, Woerden, The Netherlands.

Bisphosphonates are widely used to treat osteoporosis and have been proven to reduce the risk of osteoporotic fractures. However, suboptimal compliance and treatment discontinuation might lead to gradual loss of this effect. This study aimed to investigate the effect of persistent bisphosphonate usage on the risk for hospitalization due to osteoporotic fractures. The PHARMO database, which includes linked drug-dispensing records and hospital discharge records of more than one million subjects in defined areas in the Netherlands, was used to identify new female users of alendronate, etidronate or risedronate ≥50 years in the period Jan '96 - Jan '03. Persistence of treatment was determined by using episodes of bisphosphonate treatment based on the method of Catalan. Within the cohort a matched case control study was performed. Cases were selected on the basis of a first hospitalization for an osteoporotic fracture (index date). Controls were matched 10:1 to cases on month of inclusion in the cohort and were assigned a random index date. The association with risk for fractures was assessed for bisphosphonate use at the index date and for persistent bisphosphonate use before the index date. The study cohort included 8,845 new female bisphosphonate users; 334 patients (3.8%) were hospitalized for a fracture after inclusion in the cohort. 3280 controls were matched to the 334 cases. Bisphosphonate use at the index date significantly reduced the risk for osteoporotic fractures (RR 0.78; 95%CI 0.61-0.99, adjusted for age, previous fractures and co-medication). At least one year of persistent bisphosphonate usage reduced the risk for osteoporotic fractures even more evidently (adjusted RR 0.70; 95%CI 0.50-0.99). Patients who were persistent on their bisphosphonate treatment reduced their risk of hospitalization for osteoporotic fractures by 20-30%. The protective effect was highest (30%) in patients who used bisphosphonates consistently for more than one year. These results emphasize the importance of persistent bisphosphonate usage to obtain the maximal protective effect. Previous studies have demonstrated that persistence with bisphosphonates is higher with less frequent dosing regimens but still suboptimal. This study has demonstrated that improving persistence will result in reduced fracture rates.

Alendronate 35mg Once-Weekly Treatment Increased Bone Mineral Density in Japanese Patients with Osteoporosis. S. Uchida[1], T. Taniguchi*[1], T. Shimizu*[1], T. Kakikawa*[1], K. Okuyama*[1], M. Okaniwa*[2], H. Arizono*[2], K. Nagata*[2], A. Santora[3], M. Shiraki[4], M. Fukunaga[5], T. Tomomitsu*[5], Y. Ohashi*[6], T. Nakamura[7]. [1]Clinical Development Institute, Banyu Pharmaceutical Co., Ltd., Tokyo, Japan, [2]Pharmaceutical Business Unit, Teijin Pharma Ltd., Tokyo, Japan, [3]Merck Research Laboratories, Rahway, NJ, USA, [4]Research Institute and Practice for Involutional Diseases, Nagano, Japan, [5]Kawasaki Medical School, Okayama, Japan, [6]Biostatistics, University of Tokyo, Tokyo, Japan, [7]University of Occupational and Environmental Health, Kitakyushu, Japan.

The therapeutic equivalence of 70 mg alendronate (ALN) once weekly and 10 mg ALN daily was demonstrated in postmenopausal patients with osteoporosis (~96% Caucasians), based on percent changes in bone mineral density (BMD) and bone markers. However, the effects of 35 mg ALN once weekly have not been compared with those of 5 mg daily, the approved daily dose in Japanese patients with osteoporosis. The present study was carried out in a double-blind manner in a Japanese patient population with involutional osteoporosis, to compare the efficacy and safety of oral ALN 35 mg once-weekly to 5mg once-daily over a 52 week period. The primary efficacy endpoint was the percent change from baseline in lumbar spine (L1~L4) BMD after 52 weeks treatment. Three hundred twenty eight patients were randomized to ALN 5 mg once-daily (160 patients) or ALN 35 mg once-weekly (168 patients). The adjusted mean percent change from baseline in spine BMD after 52 weeks treatment was 5.8% and 6.4% in the once-daily group and the once-weekly group, respectively. The 95% confidence interval for the difference in spine BMD

change between the two treatment groups was -0.31~1.48%, indicating that the two regimens are therapeutically equivalent, since it fell entirely within the predefined equivalence criterion (±1.5%). The time-course of the spine BMD increase was also similar for both regimens. When the results of this study were compared with the results from the earlier (primarily Caucasian) study, the percent changes from baseline in the L1~L4 BMD were similar. Mean changes in total hip BMD from baseline at 52 weeks were 2.8% and 3.0% in the once-daily group and the once-weekly group, respectively. In addition, the bone markers (urinary deoxypyridinoline, urinary Type-I collagen N-telopeptides and serum bone-specific alkaline phosphatase) were reduced to a similar level by either treatment throughout the treatment period. The tolerability and safety profiles were also similar between the treatment groups. These findings suggest that the efficacy and safety of ALN 35 mg once-weekly are similar to ALN 5 mg once daily in Japanese patients with osteoporosis.

Persistence and Adherence to Alendronate and Risedronate among Chronic Glucocorticoid Users. J. R. Curtis[1], A. O. Westfall*[2], J. J. Allison*[3], C. I. Kiefe*[3], K. G. Saag[1]. [1]Division of Rheumatology, University of Alabama Birmingham, Birmingham, AL, USA, [2]Department of Biostatistics, University of Alabama Birmingham, Birmingham, AL, USA, [3]Division of Preventive Medicine, University of Alabama at Birmingham, Birmingham, AL, USA.

Purpose Adherence to oral bisphosphonates (BPs) is often suboptimal. Based on anecdotal data, we hypothesized differences between alendronate and risedronate in adherence and persistence among glucocorticoid (GC) users enrolled in managed care. **Methods** Using claims and pharmacy data from a U.S. managed care plan, we identified new alendronate or risedronate users (no BP Rx within 180 days) receiving 60+ GC days filling >1 BP Rx during 7/01 - 6/04. GI events, GI Rx, and NSAIDs prior to 1st BP and during 1/01-6/01 were examined to evaluate channeling (i.e. patients at high GI risk preferentially prescribed one drug over another). Adherence defined as BP days filled / (first BP fill date - last BP fill date). Persistence defined as ongoing BP Rx through 6/04 without discontinuing (> 180 day gap after last Rx). Survival analysis evaluated BP discontinuation (1- persistence) and a combined endpoint of (BP discontinuation or GI event). **Results** Of 1483 GC users filling ≥1 BP Rx, new alendronate (n = 609) and risedronate (n = 314) users filling >1 BP Rx had similar mean ± SD age (54 ± 13 yrs); sex (22% men), # of comorbidities (7 ± 3); BMD (65%); fracture claims (12%), and prior NSAID Rx (50%). Alendronate users filled more days (353 ± 254 vs. 316 ± 228, p < 0.05) and more often received weekly BP (91% vs. 79%, p < 0.0001). Prior to 1st BP Rx, risedronate users were more likely to have a GI event (OR 1.40; 95% CI 1.04 - 1.88) or receive GI Rx (OR 1.41; 1.07 - 1.86), suggesting channeling. Alendronate and risedronate users had similar adherence (73 ± 26%) and persistence (Figure). Factors associated with discontinuing BPs included age (hazard ratio 0.86, 95% CI 0.78 - 0.93 per 10yrs), BP days dispensed (0.91, 0.86 - 0.96 per 90 days), BMD test (0.82, 0.67 - 0.99), and comorbidity count (1.04, 1.00 - 1.07). **Conclusions** Despite adjustment for potential channeling, no difference in adherence or persistence between oral BPs was observed among chronic steroid users enrolled in managed care. At 2 years, > 50% of new users discontinued BP Rx. Alternate medications, new BP formulations, and new monitoring mechanisms are needed to improve adherence to osteoporosis therapies.

Consistent 60% Risk Reduction of New Vertebral Fractures in Men with Osteoporosis after the First and Second Year of Risedronate Therapy. J. D. Ringe, A. Dorst*, H. Faber*. Medizinische Klinik IV, Klinikum Leverkusen, University of Cologne, Leverkusen, Germany.

Background: Clinical studies in postmenopausal osteoporosis with risedronate have shown rapid reduction of vertebral and non-vertebral fractures. Vertebral fracture reduction during risedronate treatment was equally proved in glucocorticoid-induced osteoporosis and interestingly, the risk reduction observed in male and female subgroups was not different. **Purpose of the study:** To examine the effects of risedronate on vertebral fractures and mean changes in lumbar spine, femoral neck and total hip BMD only in men with primary and secondary osteoporosis. Secondary endpoints include non-vertebral fractures, height loss, pain, safety, and tolerability. **Patients and methods:** In this single center, open label, controlled prospective two year trial we enrolled 316 male patients with T-score values of lower than -2.5 SD at lumbar spine (LS) and lower than -2.0 SD at the femoral neck (FN) with or without prevalent vertebral fractures (vert.-fx). Patients in group A (n=158; 81 with, 77 without prevalent vert.-fx) received risedronate 5 mg plus calcium 1000 mg and 800 IU Vit. D daily. Group B comprised equally 158 men. Those with a prevalent vert-fx (subgroup B1 n=81) were treated with alfacalcidol 1 µg plus calcium 500 mg daily, whereas patients without prevalent vert.-fx (subgroup B2, n=77) were treated with 800 IU plain vitamin D plus calcium 1000 mg daily. BMD measurements and x-rays were performed at baseline and 12 and 24 months thereafter. **Results:** The LS-BMD increase after 12 and 24 months amounted to 4.7% and 6.5% resp. in risedronate patients compared with a mean resp. increases of 1.0% and 2.2% in controls ($p<0.001$). The mean changes at the total hip site were 2.7% and 4.4% for group A after the first and second year. For group B an average change of 0.4% was documented after one year and unchanged after the second ($p< 0.001$). In the first year 8 patients of group A and 20 of group B sustained new vert.-fx (risk reduction 60%). The cumulative patient numbers with new vert-fx after 2 years were 14 and 35 in the resp. groups, i.e. an unchanged fracture reduction of 60% (Fisher's exact test 0.0026). **Conclusion:** Risedronate therapy in men with established primary or secondary osteoporosis consistently reduces the risk of new vertebral fractures by 60% over two years and significantly increases BMD at the lumbar spine and proximal femur.

SU392

Alendronate 70 mg Once-Weekly Is More Effective and Has a Better Tolerability than Alendronate 10 mg Daily in the Treatment of Osteopenia Aassociated with Primary Biliary Cirrhosis. N. Guanabens[1], I. Vazquez*[1], L. Alvarez[1], F. Pons*[1], L. Caballeria*[2], D. Cerda*[1], P. Peris[1], A. Monegal*[1], A. Pares*[2]. [1]Metabolic Bone Diseases Unit, Hospital Clinic, IDIBAPS, Barcelona, Spain, [2]Liver Unit, Hospital Clinic, IDIBAPS, Barcelona, Spain.

The treatment of osteoporosis in patients with primary biliary cirrhosis (PBC) has been poorly analyzed. We have described that alendronate 10 mg daily is more effective than cyclical etidronate for increasing bone mass in osteopenic patients with PBC. The objective of this study was to evaluate the efficacy and tolerability of once-weekly alendronate 70 mg compared with alendronate 10 mg daily on bone mineral density (BMD) and bone markers. 32 women with PBC (age: 63 ± 2 years) were randomly assigned to receive 70 mg once-weekly (n=16) or 10 mg daily (n=16) for one year. BMD of the lumbar spine and proximal femur (DXA), liver function tests, 25-hydroxyvitamin D and bone markers (serum OC, bone ALP and P1NP, and urinary NTX) were measured initially and every 6 months. At entry, women assigned to the two treatment groups were similar with respect to age, BMD and severity of cholestasis. All patients in the once-weekly group completed the 1-yr trial whilst only 10 of 16 patients in the daily group (in 4 patients because minor gastrointestinal events). 18 patients (62%) had osteoporosis by densitometric criteria and/or fragility fractures and the others met criteria of osteopenia. At month 12, there were significant increases in BMD at the spine (from 0.920 ± 0.03 to 0.950 ± 0.04 g/cm^2, $p<0.01$) and at the total hip (from 0.841 ± 0.029 to 0.851 ± 0.29 g/cm^2, $p=0.02$) in the once-weekly group, with no significant changes in the daily group (spine: from 0.890 ± 0.03 to 0.901 ± 0.03 g/cm^2, p:ns; total hip: from 0.842 ± 0.03 to 839 ± 0.04 g/cm^2, p:n.s). Both regimens induced early and significant reductions in bone markers, although NTX was only significantly reduced by 12 months in the once-weekly group (from 46.8 ± 6.4 to 27.7 ± 5.2 nM/mM, $p<0.01$). Compliance, monitored by % remaining pills, was 86 ± 5% and 70 ± 12% in the once-weekly and daily groups, respectively (p:n.s). Neither treatment impaired liver function or cholestasis. When patients were classified according to spine BMD changes at 12 months, those who maintained or experienced a loss of BMD (n=9)) had higher bilirubin levels than patients who experienced gains in BMD (n=17) (1.2 ± 0.2 vs 0.7 ± 0.1 mg/dl, $p<0.01$) without significant differences in compliance, age or baseline BMD. These results suggest that once-weekly alendronate is more effective and has a better tolerability profile than daily dosing in the treatment of low bone mass in patients with PBC. The effects of alendronate on BMD are lower in patients with higher indices of cholestasis.

Disclosures: ***N. Guanabens****, Novartis 5.*

Effect of Alendronate on Cortical and Trabecular Bone of the Transilial Biopsy as Measured by Micro-CT. P. J. Masarachia[1], R. Recker[2], A. Santora[3], P. Chavassieux*[4], M. Arlot*[4], D. Kimmel[1]. [1]Molecular Endocrinology, Merck Research Laboratories, West Point, PA, USA, [2]Osteoporosis Research Center, Creighton University, Omaha, NE, USA, [3]Merck & Co., Whitehouse Station, NJ, USA, [4]INSERM, Lyon, France.

The purpose of this study is to use micro-CT (m-ct) endpoints to compare cortical (Ct) and trabecular (Tb) bone microarchitecture (MA) of transilial biopsies obtained from post-menopausal osteoporotic women treated with alendronate (ALN, N=29) or PBO (N=59) for 2-3 years (Curr Med Res Opin 21:185-194 (2005)). M-CT variables obtained from scans at 19 μm resolution (GE Healthcare, Explore Locus SP, Explore MicroView V.2.0) included bone volume (BV/TV); trabecular thickness (TbTh); trabecular number (TbN); trabecular spacing (TbSp) [plate model]; trabecular thickness [fitting of maximum spheres] (TbTh-3D); Structure Model Index (SMI); Degree of Anisotropy (DA); and "purified" Euler number (PEuler#). Thickness of each cortex of each specimen was measured at four equidistant points in each of two planes separated by 2mm. The two cortices were of significantly different thickness (P<.0001). The thicker cortex (CtTk) and all thinner cortex (CtTn) from each sample were grouped. Mean thickness of the combined cortices was calculated (CtTh). T-test of means, based on treatment groups, was executed for all endpoints. All Tb m-ct endpoints were correlated to BV/TV (Pearson R).

Table 1.	Mean ± S.D.		
	ALN	PBO	P=
BV/TV (%)	19.6±6.3	16.0±6.6	0.017
TbTh (μm)	132±29	120±30	0.070
TbSp (μm)	580±181	705±260	0.034
TbN (#/mm)	1.47±0.31	1.30±0.33	0.022
TbTh-3D (μm)	192±46	171±50	0.063
SMI	1.12±0.57	1.30±0.73	0.251
DA	1.61±0.35	1.66±0.69	0.693
PEuler# (#/cc)	4.94±2.26	4.30±1.77	0.148
CtTh (mm)	0.896±0.299	0.865±0.242	0.626
CtTk (mm)	1.035±0.398	1.079±0.347	0.615
CtTn (mm)	0.745±0.274	0.651±0.218	0.100

As previously shown (CMRO), BV/TV and TbN were greater, and TbSp was less, in ALN than in PBO patients; TbTh tended to be greater. For 3D-specific m-ct algorithms, TbTh-3D also tended to be greater. However, SMI, DA, and PEuler# did not differ between groups. In addition, a trend for the thin cortex of the ALN group to be thicker than the thin cortex of the PBO group was found. TbTh-3D values were ~50% greater than TbTh, with high correlation (r = 0.924). BV/TV was highly correlated to TbTh (r = 0.82), TbSp (r = 0.71), TbN (r = 0.82), TbTh-3D (r = 0.61) and SMI (r = -0.75); moderately with PEuler# (r = 0.24) and CtTn (r = 0.28); and mildly with DA (r = -0.20). **Conclusion:** ALN treated patients have significantly higher bone volume and better Tb MA (plate method) than PBO patients. However, 3D-specific endpoints (SMI, DA, PEuler#) did not differ between ALN and PBO groups. Most Tb MA endpoints were solidly related to bone volume.

Low Doses of Pamidronate for the Treatment of Osteoporosis in Children with Cerebral Palsy. H. Plotkin[1], M. Bruzoni*[2], S. Coughlin*[3], G. Lerner*[3], S. Allbery*[3], B. Schroeder*[3], K. Heldt*[3], L. Grovas*[3], R. Kreikemeier*[3]. [1]Pediatrics, University of Nebraska Medical Center, Omaha, NE, USA, [2]Surgery, University of Nebraska Medical Center, Omaha, NE, USA, [3]Children's Hospital, Omaha, NE, USA.

Cerebral palsy (CP) is a non-progressive motor disorder resulting from a defect or lesion in the developing brain. It is the most common physical disability of childhood. Patients often have low bone density and fractures. Pamidronate treatment has been successfully tried in these patients at 9.0 mg/kg/year. This dose has caused retention of calcified cartilage within secondary spongiosa in children with OI. Higher doses have leaded to osteopetrosis in a patient, suggesting a dose-related effect. We have evaluated the effects of 4.12 mg/kg/yr of IV pamidronate on lumbar spine (LS) and femoral neck (FN) bone density in 25 children (age 3.5 to 17.9 years) with severe CP. IV Pamidronate (0.75 mg/kg/day for two days) was administered every 4 months. On the first day of treatment patients received 0.37 mg/kg, to minimize the acute phase reaction, and acetaminophen was administered every 6 hours during the first 2-day infusion. LS and FN BMD (DEXA, Hologic Delphi) was obtained at baseline, 4 months and 12 months. All patients had adequate calcium and vitamin D intakes for age. The study was approved by Children's Hospital IRB. FN BMD increased from 0.272 ±0.14 at baseline to 0.355 ±0.13 at 4 months (p=0.04), and to 0.386 ±0.12 at 12 months (p=0.01). Z-scores increased from -4.8 ±1.2 at baseline to -3.8 ±1.0 at 4 months (p NS) and -3.2 ±1.1 at 12 months (p=0.02). FN BMC increased from 0.9 ±0.6 at baseline to 1.6 ±0.5 at 12 months (p= 0.02) and FN area increased from 3.2 ±1.2 at baseline to 3.4 ±0.9 at 12 months (p= NS). LS BMD increased from 0.348 ±0.17 at baseline to 0.412 ±0.15 at 4 months (p NS), and to 0.485 ±0.16 at 12 months (p=0.02). Z-scores increased from -3.9 ±1.6 at baseline to -3.2 ±1.2at 4 months (p NS) and -2.3 ±1.5 at 12 months (p=0.03) LS BMC increased from 11.2 ±9.8 at baseline to 15.3 ±5.0 at 12 months (p=NS) and LS area increased from 23.4 ±13.7 at baseline to 31.3 ±3.1 at 12 months (p=NS). Femoral neck is more severely affected than lumbar spine in children with CP. Bone density should always be measured in more than one region in the pediatric population. Low doses of pamidronate are effective to increase bone mineral density in young patients with CP.

SU395

Comparative Effects of Alendronate and Risedronate Treatment on Bone Mineral Density and Bone Resorption and New Incident Vertebral Rractures. T. Tsuchida[1], T. Kobayashi*[2], N. Konno*[2], M. Ogino*[2]. [1]Orthopedic Surgery, Akita University School of Medicine, Akita, Japan, [2]Orthopedic Surgery, Koto General Hospital, Akita, Japan.

The purpose of this study was to compare the effects of alendronate (ALN) and risedronate (RIS) treatment on bone mineral density (BMD) and bone resorption marker and incidence of vertebral fractures in patients with involutional osteoporosis. In this study, a total of 249 postmenopausal women with osteoporosis were randomized to receive either treatment with 5 mg/day of alendronate or 2.5 mg/day of risedronate for 12 months. Dual-energy x-ray absorptiometry (DXA) was used to measure patients' BMD (distal radius) at baseline and 12 months later. Lateral thoracic and lumbar spine radiographs were obtained at baseline and at 12 months to find new incident vertebral fractures. Urine N-telopeptides of type 1 collagen (NTx) corrected for creatinine level were measured at baseline and at 6 months. A significant increase in BMD (distal radius) was observed at 12 months after initiation of therapy in both ALN (1.6%) and RIS (1.1%) groups. However, the difference in percentage increase in BMD measurements was not statistically significant between the two groups. ALN produced a significantly greater mean reduction in urine NTx than did RIS (-51% vs -42%, $p < 0.05$) at 6 months. Incidence rates of patients who had at least one new vertebral fracture during the 12-months period were 7.9% for ALN and 9.4% for RIS. However, there was no statistically-significant difference between both groups. These results suggest that there are no differences in enhancing the BMD and in anti-vertebral fracture efficacy between the two agents, although ALN (5 mg) exhibited efficacy superior to that of RIS (2.5 mg) in suppression of bone resorption.

Long-Term Effects of I.V. Bisphosphonates after their Discontinuation in Pediatric Patients. K. M. Waterhouse*, C. Haney*, T. Srivastava*, G. Colgan*, U. S. Alon. Nephrology, Children's Mercy Hospital, Kansas City, MO, USA.

Purpose: To determine the long-term effects of bisphosphonates after their discontinuation in a pediatric patients cohort. Methods: Retrospective analysis of all 17 children with metabolic bone disorders, seen in our clinic, in which I.V. bisphosphonate therapy was discontinued for at least 12 months. Data of fracture rate, musculoskeletal pain, height (SDS), weight (SDS), DEXA's Z-scores of total body (T.B.) and spine L^{2-4}, urine N-telopeptides (NTX), serum bone specific Alk. Phos. (BSAP) and osteocalcin were compared between (a) before treatment, (b) end of treatment, (c) at last follow-up visit, utilizing two-tailed paired T test. Results: Are shown in the Table below.

Long-term effects of I.V. bisphosphonate therapy in children (mean±SE)

	Before Treatment	End of Treatment	Follow-up
Median Age (y)	7.6	9.6	11.0
Fractures (/y)	0.74 ± 0.21*	0.35 ± 0.11	0.31 ± 0.15
Height (SDS)	-1.78 ± 0.52	-1.43 ± 0.38	-1.23 ± 0.32
Weight (SDS)	-1.42 ± 0.57	-1.39 ± 0.50	-1.29 ± 0.59
DEXA T.B. (Z-score)	-1.24 ± 0.50*	-0.37 ± 0.44	0.23 ± 0.37
DEXA Spine (Z-score)	-1.65 ± 0.57*	-0.34 ± 0.56	0.31 ± 0.48*
NTX	684 ± 121*	192 ± 28	196 ± 27
BSAP	172 ± 51*	51 ± 8	55 ± 5
Osteocalcin	32 ± 5	15 ± 3*	34 ± 7

*P<0.05 in comparison to the two other periods.
Three children had bone pain before treatment, 6 during treatment with bisphosphonates, and 0 at the last follow-up (Chi-square, P<0.05). Summary of Results: Treatment with I.V. bisphosphonates had no adverse effect on height or weight. There was a significant and sustained reduction in fracture rate and pain. Bone density showed a significant improvement with therapy which was maintained after its discontinuation, with further gain in the spine. Bone remodeling markers showed sustained effect of bisphosphonates, with potential recovery of osteocalcin levels. Conclusion: I.V. bisphosphonates continue to exert their effect for at least 17 months after their discontinuation. Further observations are required to evaluate long-term outcome with the potential in the future to lower therapeutic doses.

Adherence with Weekly Versus Daily Bisphosphonate Therapy among Women with Postmenopausal Osteoporosis. D. Weycker*[1], D. Macarios*[2], G. Oster*[1]. [1]Policy Analysis Inc., Brookline, MA, USA, [2]Amgen Inc., Thousand Oaks, CA, USA.

Adherence with daily bisphosphonate therapy is relatively poor; it is unknown whether it improves with less frequent (i.e., weekly) administration. Data were obtained from a medical claims database containing information from over 30 US health plans on 15 million lives annually. Study subjects consisted of all women aged ≥45 years with postmenopausal osteoporosis (PMO) who initiated bisphosphonate therapy between July 1998 and December 2003; those with secondary causes of osteoporosis were excluded. Subjects were stratified according to whether they received daily or weekly therapy, and adherence was assessed for each patient based on the ratio of the number of therapy-days to the number of calendar days over time ("adherence ratio"); adherence failure was defined as an adherence ratio <80%. Unadjusted "survival curves" describing time to

adherence failure were estimated for patients in each group using Kaplan-Meier methods. A Cox proportional hazards (PH) model was employed to examine the relationship between regimen and time to adherence failure, controlling for age, drug received, history of fracture, and other potential confounders. The study sample consisted of 12,538 women with PMO initiating weekly (n=9,117) or daily (n=3,421) bisphosphonate therapy. Weekly therapy patients were younger (mean age: 62 years vs. 67 years for daily therapy, p<0.01), and were less likely to be hospitalized during the six months prior to therapy initiation (5.5% vs. 6.9% respectively, p<0.01); history of fracture was similar (4.2% vs. 4.9%, p=0.06). By month 6 following therapy initiation, 57% of women receiving weekly therapy and 62% of those receiving daily therapy experienced adherence failure (Figure). In Cox PH regression, risk of adherence failure did not differ between women initiating weekly versus daily therapy (HR: 1.01, p=0.81); risk of adherence failure was higher among women aged ≥65 years (HR: 1.23, p<0.01) and was lower among those with a history of fracture (HR: 0.84, p<0.01). Adherence with weekly bisphosphonate therapy is poor, and appears to be no better than adherence with the daily regimen among women with PMO.

Figure. Kaplan-Meier (unadjusted) estimates of time to adherence failure following therapy initiation*

Calcium Supply in Women with Postmenopausal Osteoporosis on Bisphosphonate Therapy in Daily Practice. J. D. Ringe[1], G. Möller*[2], B. C. Wick*[3]. [1]Medizinische Klinik IV, Klinikum Leverkusen, Leverkusen, Germany, [2]Medical Affairs, Procter&Gamble Pharmaceuticals-Germany GmbH, Weiterstadt, Germany, [3]European Medical&Technical Affairs, Procter&Gamble Pharmaceuticals-Germany GmbH, Weiterstadt, Germany.

The objective of the study was to assess whether women with postmenopausal osteoporosis on bisphosphonate therapy have a sufficient calcium intake. 264 community-based physicians were asked to interview patients with postmenopausal osteoporosis on bisphosphonate therapy regarding their knowledge about the importance of calcium and their daily calcium intake using a questionnaire. The survey was conducted from July to September 2004. Questionnaires were analyzed from 726 patients. The importance of calcium for their osteoporosis therapy was rated as important or very important by 678 (93.4%) of the patients. Patients estimated their required daily calcium intake to be 1000 mg (median, 25% 500, 75% 1000); 75.5% believed that they take enough calcium per day. Calculation based on the reported intake of calcium-rich foods showed a median of 913.2 mg calcium per day (25% 466.7; 75% 1514.7). 157 (21.6%) patients reported that they take no additional calcium, and of these patients, 54.8% believed that they take sufficient calcium with their dairy products. A regular calcium supplement was considered too expensive by 17.8%, too cumbersome by 17.8%, and 16.6% admitted that they forget to take it. Although more than 90% of the women interviewed rated the intake of calcium for their osteoporosis therapy as important or very important, they underestimated their required calcium intake. The German Dachverband Osteologie (DVO) recommends 1500 mg daily calcium intake for women with postmenopausal osteoporosis (http://www.lutherhaus.de/osteo/leitlinien-dvo/index.php). Studies show that the daily calcium intake from food for women aged ≥50 years is below the recommended amount (DGE Report, 2000). Our results confirm these findings, identifying a deficit in daily calcium of 500-600 mg versus the required intake. More than 20% of patients took no supplemental calcium to reach the daily requirement. When asked for the reason, more than half considered extra calcium supplementation too expensive or too inconvenient. Osteoporosis therapy with bisphosphonates requires a sufficient calcium level. We conclude that a simplified way to supply calcium to patients on bisphosphonate therapy could ensure greater compliance to this evidence-based osteoporosis therapy and, thereby, could be more cost-effective.

Cbfa1/Runx2 Overexpressing Mice: A New Animal Model for Evaluation of Bisphosphonates Efficacy on Bone Quality, Bone Strength and Fractures. V. Geoffroy[1], R. Phipps*[2], M. de Vernejoul[1]. [1]INSERM U606, Paris Cedex, France, [2]P & G Pharmaceuticals, Mason, OH, USA.

Mice overexpressing Cbfa1/runx2 specifically in cells of the osteoblastic lineage (cbfa1+) exhibit an increase in bone remodeling leading to severe osteopenia and spontaneous vertebral fractures after 1 mo of age (Geoffroy et al, MCB, 2002). The objective of the current study was to determine whether an antifracture effect could be demonstrated in caudal vertebral fractures of this mouse model after therapy with the bisphosphonates risedronate (RIS) and alendronate (ALN). Five-wk old female Cbfa1 mice were randomized to receive RIS at 4 or 20μg/kg/wk (RIS4 and RIS20), or ALN at 4 or 20μg/kg/wk for 12 wk (ALN4 and ALN20). Cbfa1 and age- and background-matched wild type mice received vehicle as controls (VEH and WT groups, respectively). Only Cbfa1 mice exhibiting fewer than 3 fractures in the tail vertebrae at baseline were included in the study. We measured BMD of whole body (WB) and caudal vertebrae (CV) (PIXImus, Lunar, France) and the number of fractures in the caudal vertebrae (via X-ray; FAXITRON). Fractures were also scored for severity (0 to 3). Compared to WT VEH treated mice, Cbfa1 VEH treated mice had significantly lower BMD (19% in WB and 24% in CV) at end of 12-wk treatment period. RIS20 significantly increased BMD of WB (12%) and CV (12%) compared to Cbfa1 VEH controls (p<0.001). There was no significant effect on BMD in the other treatment groups. RIS20 significantly reduced (by 43%) the average number of new fractures compared to Cbfa1 VEH treated controls (3.13 ± 0.42 vs 5.48 ± 0.53 fractures/mouse). There was no significant effect on the number of fractures with RIS4 (-9%), or ALN4 and ALN20 (-9% and -10%, respectively). The fracture severity score per vertebrae was unchanged by treatment.

Group	Mean fractures	Severity	WB BMD	CV BMD
WT VEH	0	0	0.048	0.054
Cbfa1 VEH	5.48	1.41	0.039	0.041
ALN 4 μg/kg/wk	5.00	1.44	0.040	0.041
ALN 20 μg/kg/wk	4.91	1.58	0.039	0.042
RIS 4 μg/kg/wk	5.00	1.52	0.038	0.042
RIS 20 μg/kg/wk	3.13*	1.39	0.044**	0.046**

Values are means; *, p<0.01 and **, p<0.001 vs Cbfa1 VEH

In conclusion, we describe here a transgenic mouse model that allows for the first time the assessment of bone fragility and fractures in vivo. In this study RIS had a dose related effect, and at 20 μg/kg/wk significantly increased vertebral BMD and reduced the occurrence of vertebral fractures. ALN at an equal dose had no significant effect. Further analyses are being performed to determine the roles of BMD, architecture, matrix composition and mechanical properties to this RIS-induced reduction in bone fragility.

Change in Bone Turnover Markers Following Discontinuation of Long-Term Alendronate in FLEX. A. V. Schwartz[1], D. C. Bauer[1], P. Garnero[2], A. C. Santora[3], L. Palermo*[1], D. M. Black[1]. [1]Epidemiology and Biostatistics, UCSF, San Francisco, CA, USA, [2]Synarc, Lyons, France, [3]Merck Research Laboratories, Rahway, NJ, USA.

Limited information is available on the response of bone turnover markers to alendronate (ALN) discontinuation after long-term use. Effects of discontinuation of ALN on bone turnover markers were investigated in the FIT Long-Term Extension (FLEX) Trial among women who had previously used ALN for an average of 5 years. 1099 women who had previously been randomized to receive ALN during the Fracture Intervention Trial (FIT) were re-randomized to receive placebo (40%), ALN 5 mg (30%) or 10 mg (30%) for an additional 5 years. Participants received a daily supplement of calcium (500 mg) and vitamin D (250 IU). At FLEX baseline, the mean duration of previous ALN was 5 years and 80% were still taking ALN. The mean age was 73 5.8) years; total hip BMD 0.73 (0.09) g/cm^2 and t-score -1.8 (0.7); lumbar spine BMD 0.90 (0.14) g/cm^2 and t-score -1.6 (1.3). Samples were obtained at the FIT baseline visit before any ALN treatment and at FLEX baseline and 5-year visits. Only the FIT baseline visit was fasting. Bone ALP (Ostase, Hybritech) and U-NTX (Ostex) were assayed at different times over a period of 10 years at two commercial labs. To eliminate possible assay drift or lab differences, at the end of the study we also performed concurrent measurements of Bone ALP, PINP, and S-CTX at one specialized lab using stored serum specimens. Participants selected for concurrent measurements were compliant with the FLEX protocol. 41 participants had complete data available for the separate and concurrent assays. Bone Turnover Markers in Women Who Discontinued ALN (N=41)

Timing of assays	Marker	Geometric mean			% change FIT baseline to FLEX 5yr (95% CI)
		FIT baseline	FLEX baseline	FLEX 5 yr	
Separate	Bone ALP (ng/ml)	11.0	8.6	11.2	4.1 (-11, 22)
	U-NTX (nmol/ mmol Cr)	57.8	16.4	23.5	-54.5 (-66, -38)
Concurrent	Bone ALP (ng/ml)	12.0	8.4	11.2	-6.9 (-17, 4.3)
	PINP (ng/ml)	52.9	23.2	38.2	-23.2 (-37, -6.0)
	S-CTX (pg/ml)	210	110	200	2.3 (-20, 31)

After an average of 5 years of ALN use followed by 5 years of placebo, there was little continuing effect of ALN on Bone ALP (in separate and concurrent assays) or S-CTX. PINP and U-NTX increased after discontinuation of ALN, but their levels remained below pre-treatment levels. The large difference between change in U-NTX (separate assays) and S-CTX (concurrent) may be due to assay drift in U-NTX measurements or possible biological differences between NTX and CTX. In conclusion, marker levels increased in women who discontinued ALN after long-term use and some, but not all, returned to pre-treatment levels, possibly because of biological differences in response to ALN discontinuation or to calcium supplementation.

Bone after Cessation of Alendronate Use in Children with Fracturing Osteoporosis. C. B. Langman, A. L. Arwady*, H. Price. Pediatric Kidney Diseases, Northwestern University, Childrens Memorial Hospital, Chicago, IL, USA.

We report on bone mineral density (BMD), somatic growth, and bone markers in blood and urine in children with fracturing osteoporosis after cessation of a therapeutic course of oral alendronate. Forty-six consecutive children (23 girls, 23 boys) of normal growth for age (-0.6 Z score for height by chronologic age; -1.0; +1.0 [median; 25%ile; 75%ile]) and pubertal status were treated for 672 (513; 959) days with 70 or 35 mg/week oral alendronate, depending on body mass (≥30 kg, or below, respectively) for fracturing osteoporosis (88% with radiographically-confirmed fracture). No patients were growth-hormone or vitamin D deficient during or after alendronate therapy. Initial DXA Z-BMD in the L1-L4 spine = -1.8 (-2.4; -1.3), and at conclusion of therapy, the Δ Z BMD in the spine = +1.7 (+1; +2.2) differed (p 365 days of follow-up as of end of 2004, the most recent evaluation of BMD spine Z-score after 410 (373; 797) days of absence of alendronate use = -0.2 (-0.9; +0.33) did not differ from the value at the time of discontinuation of the drug. Height Z-score at this time = -0.5 (-1.1; +0.7) did not differ from either alendronate initiation or discontinuation time points. Urinary N-linked telopeptides (NTx) were reduced from 372 (184; 504) at initiation of alendronate to 105 (71; 221) at drug discontinuation (p < 10-3), and remained at 110 (77; 309) at most recent evaluation (p < 10-3), while serum bone-specific alkaline phosphatase activity (BsAP) was unchanged (median values at the 3 time points: 90; 128; 77; p = NS). During and after alendronate therapy, 4% of children sustained a fracture. In conclusion, alendronate therapy in children of normal growth with fracturing osteoporosis did not affect subsequent somatic growth while placing BMD of the lumbar spine into the normal range. Subsequently, BMD and growth have remained normal. Analysis of bone markers suggest a more profound effect of alendronate on remodeling than modeling space dynamics. Appropriate algorithms for the use of alendronate must take into account subsequent effects on bone after its discontinuation, and the data provided here lend support for its time-limited utility in children of normal growth but with fracturing osteoporosis.

SU402

Characteristics Associated with Non-Persistence during Daily Therapy - Experience from the Placebo Wing of a Community-Based Clinical Trial. E. McCloskey[1], D. deTakats*[1], J. Orgee*[1], S. Aropuu*[2], T. Jalava*[2], J. Cliffe*[1], L. Reaney*[1], C. McGurk*[1], D. Charlesworth*[1], J. A. Kanis[1]. [1]University of Sheffield, Sheffield, United Kingdom, [2]Schering Oy, Helsinki, Finland.

Despite well-proven efficacy, long-term persistence with therapy for osteoporosis is reported to be poor, at least partly related to drug-specific adverse events. Other factors underlie poor persistence, however, and need to be identified and addressed to improve management strategies. For this reason, we compared the baseline characteristics of elderly women who persisted or failed to persist with placebo capsules throughout a 3-year double-blind study of daily oral clodronate (Bonefos®). Of 2248 women aged 75 years or more, recruited from the general community and unselected for osteoporosis, 706 (31%) failed to persist with the placebo capsules during a follow-up of at least 1000 days. The analysis excluded women who discontinued the capsules following hip fracture. Half of the women stopping treatment did so within the first 6 months and 71% had discontinued by one year. At baseline, the women who subsequently discontinued treatment were slightly but significantly older (79.8 vs. 79.1yrs, P<0.001) than women who persisted with treatment and they also had significantly lower total hip BMD (0.74 vs. 0.76gcm^{-2}, P=0.003). BMI was similar in the two groups. Non-persistence was significantly associated with poor health as judged by increased reports of hospital admissions within the previous year (20.3 vs. 14.3%, P=0.002), increased out-patient attendances (34% vs. 25%, P<0.001) and lower health-related quality of life as judged by higher scores in all 5 dimensions of the Euroqol-5D questionnaire and lower self-rated health score on the Euroqol VAS (67 vs. 73, P<0.001). There were, however, no significant differences in reports of prior fractures in the two groups or the prevalence of vertebral fractures on spine images (15% vs. 14%, NS). Furthermore, despite poorer health as described above, non-persistence was not associated with an increased risk of incident hip fracture (RR 1.02, 95%CI 0.59-1.74). We conclude that extraskeletal health-related factors contribute to non-persistence with therapy in elderly women unselected for osteoporosis. Management strategies need to address these issues by either overcoming the influence of such factors (by contact, feedback etc) or through novel dosing regimens.

SU403

Greater Adherence to Bisphosphonate Therapy Is Associated with Greater Fracture Risk Reduction in Postmenopausal Women. E. Siris[1], C. Rosen[2], S. Silverman[3], T. Abbott[4], C. Barr*[5], S. Harris[6]. [1]Department of Medicine, Columbia University College of Physicians and Surgeons, New York, NY, USA, [2]Maine Center for Osteoporosis Research and Education, St. Joseph's Hospital, Bangor, ME, USA, [3]Cedars-Sinai Medical Center, David Geffen School of Medicine UCLA, Beverly Hills, CA, USA, [4]Thomson-Medstat, Philadelphia, PA, USA, [5]Medical Affairs, Roche Laboratories Inc., Nutley, NJ, USA, [6]Department of Metabolism and Endocrinology, University of California, San Francisco, San Francisco, CA, USA.

Purpose: The Medstat MarketScan® Research Databases encompass 6 million members, 45 employers, and 100 health plans, and include both managed care claims and Medicare claims. We have analyzed data from these large claims databases and investigated the association between refill compliance with bisphosphonate dosing regimens and fracture risk in women who had received a prescription for bisphosphonate therapy. *Methods:* Data were extracted from the Medstat MarketScan® Research Databases on 37,698 women ≥45 years of age who had received a first (index) prescription for alendronate or risedronate. The relationship between refill compliance and fracture risk was analyzed over 24 months following the index prescription. Exclusion criteria included Paget's disease of bone, cancer, HIV, and prior bisphosphonate therapy. Patients were categorized by the percent of time during which drug was available, based on number of prescription refills, to yield a Medication Possession Ratio (MPR). MPR was calculated as the sum of days' supply divided by the total follow-up period (24 months). A new occurrence of osteoporotic fracture was determined by a subset of ICD-9 codes. *Results:* The probability of fracture decreased with higher rates of refill compliance, with the greatest decline in fracture risk related to increases in MPR from 75% to 100%. For example, the fracture rate was 11.45% for women with 70% to 75% MPR versus 8.07% for those with 95% to 100% MPR. Overall, fracture risk was reduced by 19.6% over 24 months for women with ≥75% refill compliance and by 20.4% for women with ≥80% refill compliance compared to those with lower MPR. Comparable reductions in fracture risk were similarly associated with better adherence, a measure that includes persistence with medication over time, as well as refill compliance. *Conclusion:* Greater refill compliance was associated with a significantly lower fracture risk in women taking bisphosphonates. The largest decline in fracture risk occurred for compliance >75%. Strategies are needed to help women with osteoporosis increase their compliance to therapy.

Oral Risedronate Treatment in Men with Osteoporosis: Study Design and Baseline Characteristics. S. Boonen*[1], D. Wenderoth[2], P. J. Schofield*[3], D. Cahall[4], E. S. Orwoll*[5]. [1]University Hospital Leuven, Leuven, Belgium, [2]Procter & Gamble Pharmaceuticals, Schwalbach a. Ts., Germany, [3]Procter & Gamble Pharmaceuticals, Mason, OH, USA, [4]Sanofi-Aventis, Bridgewater, NJ, USA, [5]Oregon Health and Sciences University and Veterans Administration Medical Center, Portland, OR, USA.

Epidemiological studies have shown that osteoporosis is a significant medical health issue facing men. If one uses the WHO suggested diagnostic threshold for women but uses male reference data (i.e., -2.5 SD below the peak bone mass reference standard for young men), it is estimated that 1-2 million men in the United States have osteoporosis and 8-13 million have osteopenia. More importantly, according to the EPOS study one-third of all vertebral fractures occur in men. In the United States and Northern Europe approximately 25% of all hip fractures occur in men, with men reaching the same incidence as women when they are 5-10 years older. Men have a higher mortality (31%) than women (17%) during the first year after a hip fracture. Risk factors for male osteoporosis include: history of a nontraumatic fracture, osteopenia, family history, excess alcohol consumption, tobacco use, and glucocorticoid use.A 24-month, double-blind, placebo-controlled multinational study with 35 mg weekly oral risedronate is ongoing. All patients are being supplemented with 1000 mg calcium and 400-500 IU of vitamin D. Male patients at least 30 years old, with a femoral neck BMD T-score ≤-2 and lumbar spine BMD T-score ≤-1, or with a femoral neck BMD T-score ≤-1 and lumbar spine BMD T-score ≤-2.5, were included. DXAs of the spine and hip are performed at screening, and months 6, 12, and 24; bone turnover markers (serum CTX and BAP and urine NTX) are performed at baseline, and months 3, 6, 12, and 24; spine radiographs are performed at screening, and months 12 and 24. Bone biopsies are performed in a subset of patients at month 24. 285 patients were randomized into the trial and 95%were Caucasian. Preliminary baseline characteristics for the patients that entered the study are presented in the table below.

Baseline Characteristics	
Age - (years) - n	285
Mean (SD)	60.5 (10.65)
Min-max	36 - 80
Lumbar Spine BMD T-score - n	282
Mean (SD)	-2.8 (0.79)
Femoral Neck BMD T-score - n	282
Mean (SD)	-2.1 (0.48)
Tobacco Use - n (%)	
Current	71 (25%)
Previous	114 (40%)
Never	100 (35%)
Alcohol Use - n (%)	
Current	160 (56%)
Previous	101 (35%)
Never	24 (8%)

Upon completion of the initial 24-month study, all eligible patients are being invited to continue in a 2-year, open-label extension where all patients will receive 35 mg risedronate weekly.

Risedronate Demonstrates Favorable Safety Profile in Postmenopausal Osteoporosis over Wide Range of Serum Concentrations. P. Miller[1], S. Magowan[2], I. Barton*[2], S. Boonen*[3]. [1]Colorado Center for Bone Research, Lakewood, CO, USA, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA, [3]Leuven University for Metabolic Bone Diseases, Leuven, Belgium.

Risedronate's serum steady state levels during therapy are determined by renal clearance (CrCl) of risedronate, the daily drug dose, and body weight. Therefore, studies of patients varying in CrCl and body weight provide useful information for clinicians. This analysis investigated the safety profile of risedronate over a wide range of drug serum concentrations in postmenopausal women. Patients who took at least one dose of daily risedronate (2.5 mg or 5 mg) in the risedronate phase III clinical trials investigating postmenopausal osteoporosis for up to 3 years were included. Because the serum drug concentration is inversely proportional to CrCl and body weight, and directly proportional to drug dose, these variables were incorporated for each patient to estimate a serum concentration ratio (SCR). The patient with the maximum combination of both CrCl and body weight, and receiving the lowest dose of risedronate (2.5 mg/day), was given an arbitrary value of 1. All other patient SCR values were calculated relative to this index case. Patients were then ranked according to SCR decile (1=lowest, 10=highest). For patients in each of these SCR deciles, the adverse event rate per 100 patient years and corresponding 95% confidence interval was calculated using a Poisson regression model. The analysis identified 9,606 postmenopausal women randomized to daily risedronate. Serum steady states ranged from an arbitrary value of 1 to 57 with a median of 7.9 (interquartile range from 5.3 to 11.9). The adverse event (AE) rate per 100 patient years for risedronate-treated patients (Table) was 323 (95% CI=318 to 328). There was no increase in the adverse event rate experienced over the deciles of serum concentration of risedronate. This analysis demonstrates that risedronate has an excellent safety profile across a wide spectrum of serum drug concentrations in postmenopausal women.

AE Rate (per 100 patient years) for Each Decile of Risedronate Baseline SCR

Decile	SCR Midpoint	N	AE Rate/100 Yrs (95% CI)
1	2.9	960	344 (327, 362)
2	4.3	961	317 (300, 334)

Risedronate Demonstrates Favorable Renal Safety Over a Wide Range of Serum Concentrations. P. Miller[1], S. Magowan[2], I. Barton*[2], J. Beary*[2], S. Boonen*[3]. [1]Colorado Center for Bone Research, Lakewood, CT, USA, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA, [3]Leuven University Center for Metabolic Bone Diseases, Leuven, Belgium.

Important factors that determine risedronate's serum steady state level include renal clearance of risedronate (CrCl), the daily drug dose, and volume of distribution (i.e. body weight). This analysis was designed to investigate the renal safety of risedronate over a wide range of drug steady state serum concentrations. Patients who took at least one dose of daily risedronate from the risedronate clinical trial programme (investigating postmenopausal osteoporosis, osteoarthritis and Paget's disease) were included. Serum drug concentration is inversely proportional to CrCl and body weight, and directly proportional to daily drug dose. These variables were incorporated for each patient to estimate a serum concentration ratio (SCR). The patient with the maximum combination of both CrCl and body weight and the lowest dose of risedronate (2.5 mg/day) was given an arbitrary value of 1. All other patient SCRs were calculated relative to this reference case. CrCl was estimated using the Cockcroft-Gault methodology. For each disease state, patients were ranked according to SCR decile. For these SCR deciles, the average of the maximum percent creatinine change from baseline was calculated. The analysis identified 11,193 patients who were randomized to risedronate in daily doses ranging from 2.5 to 30 mg/day: 9679 postmenopausal osteoporosis patients (2.5 mg/day=4833 and 5 mg/day=4846), 1237 osteoarthritis patients (5mg/day=628 and 15mg/day=609), 277 Paget's (30 mg/day). Risedronate SCRs (Figure) ranged from 1 to 175 with a median value of 8.1 (inter-quartile range=5.3 to 12.4). There was no observed deleterious change in renal function as a function of risedronate drug concentration over a range of 1 - 175 serum concentrations. This analysis suggests that risedronate over a range of SCRs from 1 to 175 has no deleterious effect on renal function. This is reassuring data for the clinician providing osteoporotic care to the elderly population with mild to moderate renal function.

Fast Reduction of Bone Resorption with Risedronate Treatment within Two Weeks. C. Günther[1], A. Kapner*[1], H. W. Schultis*[2], G. Moller[3], O. Günther*[1], S. Günther*[1]. [1]Deutsches Zentrum für Osteoporose, Fachklinik Johannesbad, Bad Füssing, Germany, [2]Gemeinschaftspraxis für Laboratoriumsmedizin und Mikrobiologie, Weiden, Germany, [3]Dept. of Bone Pathology / Center for Biomechanics, Hamburg University School of Medicine, Hamburg, Germany.

The risk of a subsequent fracture after an osteoporotic fracture is highest immediately after the fracture event. Therefore, a very early intervention after fractures can avoid recurrent fractures. Risedronate 5 mg is an important antiresorptive drug in postmenopausal osteoporosis and reduces the risk of clinical vertebral and nonvertebral fractures in postmenopausal women with osteoporosis within 6 months. Short-term changes in bone turnover markers can prove fast onset of an antiresrorptive therapy. Aim of this study is to determine how fast risedronate 35 mg once a week can reduce the bone turnover markers in patients with osteoporosis after treatment in clinical practice. 31 patients (26 women, 5 men, mean age 67 years) with a LWS BMD T-score < -2.5 and strong osteoporotic risk factors according to the German guidelines for osteoporosis (DVO) were enrolled. The patients were treated with calcium supplementation (800mg/d) and vitamin D (1000-1200 I.U./d) and received one dose of risedronate 35 mg per week. β-CTX levels were measured fasting in the morning at baseline and after 14 days of treatment using the Elecsys® β-CrossLaps test (Roche Diagnostics GmbH, Mannheim). Statistical analyses were determined by the sign-test. $p<0.05$ was considered statistically significant. β-CTX levels were significantly reduced by 42.1% ($p<0,001$) compared to baseline in osteoporotic patients two weeks after beginning treatment with risedronate 35 mg once a week. Risedronate 35 mg once a week significantly reduces bone resorption markers in osteoporotic patients as soon as two weeks after treatment. This fast reduction of bone resorption markers by risedronate 35 mg once a week is consistent with its fast reduction of vertebral and nonvertebral fractures in postmenopausal women with osteoporosis within 6 months. Treatment of postmenopausal osteoporosis with risedronate 35 mg once a week provides therefore an opportunity for early intervention in osteoporotic patients to avoid further osteoporotic fractures.

Comparative Study of Bone Turnover and BMD Response to Treatment with Risedronate, Vitamin D, or Vitamin K in Japanese Osteoporosis Patients. H. Iwata*, S. Yamada*, H. Takagi*. Rheumatology and Joint Replacement Center, Nagoya Kyoritsu Hospital, Nagoya, Japan.

The Japanese have the world's longest average life span (85 years for women, 78 years for men) and the elderly population of Japan is rapidly rising. Measures to counter diseases specific to the elderly, particularly osteoporosis, are important. We compared changes in bone turnover markers and bone mineral density (BMD) with the administration of risedronate (RIS) with those of vitamin D and vitamin K. Japanese patients with primary osteoporosis (6 men, 117 women) were enrolled at Nagoya Kyoritsu Hospital between May 2002 and May 2003 and were randomly assigned to one of three oral treatment groups: risedronate (Actonel®, RIS) 2.5 mg/d (n=37), vitamin D3 (Alfarol®, VD3) 1.5 μg/d (n=45), vitamin K (Glakey®, VK2) 45 mg/d (n=41). The mean (SD, P-value vs RIS) changes in bone turnover markers and BMD from baseline to 48 weeks are shown in the table below:

Variables	% Changes from Baseline		
	RIS (SD)	VD3 (SD, P-value vs RIS)	VK2 (SD, P-value vs RIS)
Urinary NTX	-46.8 (17.7)	-0.01 (62.6, <0.001)	18.3 (55.7, <0.001)
Serum NTX	-44.8 (11.6)	-16.1 (70.1, 0.207)	-7.2 (23.8, 0.002)
Urinary DPD	-35.4 (29.5)	-5.7 (41.3, 0.004)	14.4 (60.6, 0.001)
Serum OC	-44.4 (31.2)	-27.8 (30.0, 0.049)	-6.8 (30.0, <0.001)
Serum BAP	-34.6 (19.9)	-25.9 (16.4, 0.083)	-4.1 (18.6, <0.001)
BMD	5.1 (3.9)	1.2 (4.6, 0.013)	1.0 (5.3, 0.008)

NTX=cross-linked N-telopeptides of type I collagen; DPD=deoxypyridinoline; OC=osteocalcin; BAP=bone alkaline phosphatase; BMD=bone mineral density.
Beginning 4 weeks after the initiation of therapies, significant differences were observed for urinary and serum NTX, urinary DPD and serum OC with RIS compared to both VD3 and VK2. For serum BAP, similar decreases were observed for RIS and VD3; the decrease was greater for RIS compared with VK2. At 48 weeks, the BMD increase was significantly greater with RIS compared with VD3 or VK2. After These findings indicate that after 48 weeks of treatment in Japanese patients, risedronate was a more effective treatment for osteoporosis than VD3 or VK2.

Short-Term Monitoring of Bone Turnover Markers Improves Compliance in Postmenopausal Osteoporotic Patients under Antiresorptive Therapy. O. Günther*[1], A. Kapner*[1], S. Günther*[1], H. W. Schultis*[2], C. Günther[1]. [1]Deutsches Zentrum für Osteoporose, Fachklinik Johannesbad, Bad Füssing, Germany, [2]Gemeinschaftspraxis für Laboratoriumsmedizin und Mikrobiologie, Weiden, Germany.

To control the onset of an antiresorptive therapy for treatment of postmenopausal osteoporosis bone turnover markers are usually measured 3-6 months after beginning treatment. We could recently show (Osteoporose & Rheuma aktuell 1/03, 12-13) that short-term monitoring of bone turnover markers as soon as 14 days after beginning antiresorptive treatment in patients with postmenopausal osteoporosis is a useful tool for proving the onset of treatment in rehabilitation. Aim of this study was to determine if short-term bone turnover marker monitoring can further improve long-term compliance in patients with postmenopausal osteoporosis on risedronate treatment. 31 patients (26 women, 5 men, mean age 67 years) with a LWS BMD T-score < -2.5 and strong risk factors according to the German guidelines for osteoporosis (DVO) were enrolled. The patients were treated with calcium supplementation (800mg/d) and vitamin D (1000-1200 I.U./d) and received one dose of risedronate 35 mg per week. β-CTX levels were measured fasting in the morning at baseline and after 14 days of treatment using the Elecsys® β-CrossLaps test (Roche Diagnostics GmbH, Mannheim). The results were discussed with the patients immediately after the measurement of bone turnover markers. To assess the compliance patients were called by telephone 12 months after first prescription. Compliance data could be collected from 83.9% of the 31 patients. 19.2% of this population stopped treatment with risedronate 35 mg once a week 4 weeks after the first prescription because the therapy was not continued by their family physicians. But 12 months after beginning of the risedronate treatment a great majority of the patients (80.8%) took their medication as prescribed. Short-term monitoring of bone turnover markers 14 days after beginning of bisphosphonate treatment can further improve long-term compliance in patients with postmenopausal osteoporosis on antiresorptive therapy and is therefore a great tool in rehabilitation medicine.

Once-Monthly Oral Ibandronate Effectively Normalizes Biochemical Markers of Bone Resorption in Postmenopausal Osteoporosis: MOBILE 2-Year Analysis. P. D. Miller[1], D. L. Kendler[2], P. Garnero[3], S. Silverman[4], C. Hughes*[5], N. Mairon[5], B. Bonvoisin[5], C. Christiansen[6]. [1]Colorado Center for Bone Research, Lakewood, CO, USA, [2]University of British Columbia, Vancouver, BC, Canada, [3]INSERM Research Unit 403 and Synarc, Lyon, France, [4]Cedars Sinai Medical Center, Los Angeles, CA, USA, [5]F. Hoffmann-La Roche Ltd, Basel, Switzerland, [6]Center for Clinical and Basic Research, Ballerup, Denmark.

When administered daily or weekly, oral bisphosphonates effectively normalize the elevated rate of bone resorption associated with postmenopausal osteoporosis (PMO). Ibandronate (Boniva) is a potent, nitrogen-containing bisphosphonate that can be effectively administered with extended dosing intervals.[1,2] In MOBILE, an ongoing, randomized, double-blind, phase III study, the influence of once-monthly (50+50mg [single doses, consecutive days], 100mg [single day] and 150mg [single day]) and daily (2.5mg) oral ibandronate dosing schedules on bone turnover is being evaluated in 1,609 women (aged 55-80 years, ≥5 years postmenopausal) with PMO (lumbar spine BMD T-score <-2.5 and ≥-5). Calcium (500mg) and vitamin D (400IU) supplements are provided. Median change (%) in the biochemical marker of bone resorption serum CTX (sCTX) was assessed as a secondary efficacy endpoint at 3, 6, 12 and 24 months. Values in the once-monthly arms were obtained by sampling at the end of the dosing interval. In all treatment arms, pronounced decreases in sCTX were observed at the 3 month time point, and were maintained for the duration of study (**Table**). At all time points, median decreases in sCTX with the 150mg once-monthly regimen were substantially greater than those with the daily and 100mg regimens (by 6.2-12.8% and 7.2-13.2%, respectively). These data demonstrate that the once-monthly ibandronate dosing schedule is similar to the daily dosing schedule in normalizing bone resorption, which has shown strong antifracture efficacy in a prior placebo-controlled fracture study.[1,2]

Bisphosphonate Augments PTH Effect on Trabecular Bone in Rats but Attenuates the Effect in Humans; How Relevant Is the Therapeutic OVX Model in Rat for Bisphosphonates? R. J. Arends*, H. v. Oudheusden*, A. G. H. Ederveen. Pharmacology, N.V. Organon, Oss, The Netherlands.

Osteoporosis can be therapeutically approached in two different ways; by use of anti-resorptive agents or by use of anabolic agents. Nowadays, anti-resorptive agents like bisphosphonates (BP), estrogens and SERMs are widely used to prevent menopause related bone loss. However, these treatments are only limited in preventing bone loss and do not restore the lost bone. Daily administration of parathyroid hormone (PTH) has been found to possess this anabolic quality and is therefore a promising agent to treat osteoporosis. However, stopping PTH treatment results in a rapid loss of newly gained bone. Preclinical studies have been described in literature to address the hypothesis that there may be an advantage in using PTH in combination with anti-resorptive agents. The results published so far are inconclusive, partially due to the large variety of different experimental set-ups used. In the present study, we evaluated the effect of PTH (16.5 µg/kg.d.sc) alone, BP (10, 50, 100 µg/kg.d.sc) or the combined treatment of PTH with BP on the bone mass and bone strength of ovariectomized female rats (OVX). Eighty-eight three-month-old female Wistar rats were ovariectomized and randomized in 11 groups (n=8). The animals were left untreated for two weeks to await development of moderate osteopenia. The sham-operated and the control OVX animals were treated with vehicle starting two weeks after surgery, while other groups received PTH, BP or a combination of PTH plus BP. All animals were sacrificed after 6 weeks of treatment. Both femurs were collected for bone mineral density measurement by pQCT and biomechanical testing by use of an indentation test, three-point bending test and cantilever bending test. In addition, the vertebral body L4 was dissected for a compression test. Our study demonstrated that treatment with either PTH or BP alone, or combined treatment of PTH with BP significantly restored the ovariectomy-induced loss of bone mass and trabecular bone strength in rats. Moreover, combined treatment of PTH with BP strongly augmented the effect of PTH alone. In conclusion, these preclinical in vivo data suggest that a bisphosphonate and PTH may act synergistically on bone mass and bone strength in rats thereby improving bone quality. This, however, is in contrast to recent clinical studies that failed to demonstrate any additive effect of the combined treatment of both agents on trabecular BMD in men and women. The fact that the above described results in rats are not in line with human data warrants carefulness in extrapolating these data to clinical outcome. Further animal studies to evaluate this discrepancy are ongoing.

SU412

Renal Tolerability of Ibandronate When Administered by Intravenous Injection: DIVA 1-Year Analysis. R. Civitelli[1], L. B. Tankó[2], V. Vyskocil[3], C. Leigh*[4], P. Ward*[4], D. Masanauskaite*[4], R. R. Recker[5]. [1]Washington University School of Medicine, St Louis, MI, USA, [2]CCBR, Ballerup, Denmark, [3]University Hospital, Plzen, Czech Republic, [4]F. Hoffmann-La Roche Ltd, Basel, Switzerland, [5]Creighton University, Omaha, NE, USA.

Currently, intravenous (i.v.) bisphosphonates need to be administered as extended infusions to ensure renal tolerability. The ability to administer an intravenous bisphosphonate with a shorter dosing time without compromising renal function may be beneficial in some clinical situations. In prior clinical studies, ibandronate (Boniva), a potent, nitrogen-containing bisphosphonate, has demonstrated a favourable renal safety profile in women with postmenopausal osteoporosis (PMO) when administered as an i.v. injection. In the DIVA study, an ongoing, randomised, double-blind, double-dummy, phase III clinical trial, 2mg q2mo and 3mg q3mo i.v. ibandronate injections are being compared with an established 2.5mg daily oral ibandronate regimen in 1,395 women with PMO. In DIVA, renal safety parameters were assessed by continuously monitoring for renal adverse events (AEs), measuring serum creatinine concentrations and estimating creatinine clearance at baseline and every 4 and 3 months thereafter in the q2mo and q3mo treatment arms, respectively. Increases in serum creatinine concentrations were considered clinically important if they doubled during treatment or increased by >0.5mg/dl or >1mg/dl from baseline levels of <1.4mg/dl or >1.4mg/dl, respectively. In the 1-year safety analysis, baseline creatinine clearance was <90mL/min in all and <60mL/min in approximately half of the 1,382 women included. There were no reports of acute renal failure. Renal adverse events showed a low incidence, with no difference across all treatment groups (2%, 3% and 2% in the daily arm, q2mo arm and q3mo arm, respectively). Clinically important changes in serum creatinine occurred in only six participants (n=4 in the q2mo arm and n=2 in the q3mo arm), none of which were regarded as treatment-related, mostly due to the presence of concomitant conditions known to compromise kidney function. Only 14.2%, 14.1% and 17.4% of participants in the daily, q2mo and q3mo groups, respectively, showed any fall in creatinine clearance at any time point during the study. When administered as an

intermittent i.v. injection, ibandronate has a good renal safety profile in PMO, which is comparable to that of the established daily oral ibandronate regimen that has previously shown tolerability similar to placebo.

SU413

Consistent Bone Mineral Density Gains with Intravenous Ibandronate Injections: Results from the DIVA Study. R. Emkey[1], J. Halse[2], H. P. Kruse*[3], C. Hughes*[4], P. Ward*[4], D. Masanauskaite*[4], R. R. Recker[5]. [1]Radiant Research, Wyomissing, PA, USA, [2]Osteoporoseklinikken, Oslo, Norway, [3]Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany, [4]F. Hoffmann-La Roche Ltd, Basel, Switzerland, [5]Creighton University, Omaha, NE, USA.

DIVA is an ongoing randomized, double-blind, double-dummy, phase III, non-inferiority study. In this study, 2mg q2mo and 3mg q3mo intravenous (i.v.) ibandronate injections were at least as effective (for BMD endpoints) as an established 2.5mg daily oral ibandronate regimen (3-year vertebral fracture risk reduction: 52%) in 1,395 women with postmenopausal osteoporosis (PMO). In DIVA, a prospective analysis explored the influence of the following baseline patient characteristics on bone mineral density (BMD) gain: BMD T-score, prevalent fracture, and age (**Table**). Each subgroup comprised approximately 20% of the total study population. Although formal non-inferiority tests were not performed, spinal BMD gains in the i.v. groups were compared with the oral group using 95% confidence intervals (CI) in a post-hoc analysis. At 1 year, sizeable gains in lumbar spine BMD were observed in all patient subgroups, independent of the dosing route or schedule (**Table**). Increases in BMD were generally similar across the patient subgroups and between the i.v. regimens (**Table**). For each of the subgroups analysed, gains in lumbar spine BMD in the i.v. treatment arms were non-inferior (1% margin) to those observed in the daily arm (**Table**). In all study subgroups, i.v. ibandronate injections provided sizeable and comparable gains in lumbar spine BMD, which were at least as large as those observed with the established daily oral regimen. I.v. ibandronate injections have a consistent effect on BMD, regardless of baseline patient characteristics.

Table. Mean change (%, n) from baseline in lumbar spine BMD (plus 95% CI for difference versus daily) with i.v. ibandronate injection in the overall population and by patient subgroup.

	2.5mg daily oral	2mg q2mo i.v.	3mg q3mo i.v.

Risedronate Inhibits Spontaneous Osteoclastogenesis from Peripheral Blood Mononuclear Cells in Post Menopausal Osteoporosis. P. D'Amelio*[1], A. Grimaldi*[1], C. Tamone*[1], S. Di Bella[1], G. P. Pescarmona*[2], G. C. Isaia[1]. [1]Department of Internal Medicine, University of Torino, Torino, Italy, [2]Department of Genetics, Biology and Biochemistry, University of Torino, Torino, Italy.

In our previous study we demonstrated an increased osteoclastogenesis from peripheral blood mononuclear cells (PBMC) in postmenopausal osteoporosis: the aim of this study is to evaluate a possible reduction of osteoclastogenesis in osteoporotic women after treatment with risedronate, and possible differences in osteoclasts formation in wells treated or not with vitamin D. Furthermore we will investigate possible effects of risedronate on the serum level of IL1 β, TNFα, IL6. 15 osteoporotic women and 13 controls were enrolled in the study. In all the subjects circulating PBMC were obtained with Ficoll-Pacque method. All cell incubations were performed in triplicate in 96 well/ plates (2 x 10^5 cell/well) using the alpha minimal essential medium with or without 1,25-OH vitamin D_3 [10^{-8} M]. On the 10^{th} day the cells were fixed and stained for Tartrate resistant acid phosphatase (TRAP) and for the expression of vitronectin receptor (VNR). In order to quantify the formation of TRAP+ and VNR+ multinucleated cells, the number of stained cells in each well was counted and identified as osteoclast. In all the subjects we measured the serum level of TNF α, IL-1β and IL-6 with ELISA method. All the patients received risedronate 5 mg/day for three months; after three months the patients were recalled and the above mentioned exams were repeated. After therapy there is an important decrease in the number of osteoclasts, the difference in osteoclasts number between wells treated or not with 1,25-OH vitamin D_3 was not significant before therapy, while after therapy 1,25-OH vitamin D_3 significantly reduced osteoclasts number (table). The comparison between calcium, phosphorus, markers of bone turnover and levels of measured cytokines before and after therapy is not significant. In conclusion our data demonstrate that:

1. Osteoclast formation is significantly decreased by the administration of risedronate 5 mg/day for three months
2. The number of osteoclasts is reduced by the addition of vitamin D_3 *in vitro* only after treatment with risedronate *in vivo*.
3. Levels of TNFα , IL-1β and IL-6 are not significantly different in patients with respect to controls, and are not significantly modified by therapy

	Patients at baseline	Patients after theraphy	p
Number of OC without 1,25-OH vitD_3	50.23±30.97	20±24	0.008
Number of OC with 1,25-OH vitD_3	37.44±26.44	5.11±11.4	0.000

Once-Monthly Oral Ibandronate Is Safe and Well Tolerated in Women with Postmenopausal Osteoporosis: MOBILE 2-Year Analysis. E. M. Lewiecki[1], R. Emkey[2], S. Adami[3], L. Rowell*[4], N. Mairon*[5], B. Bonvoisin[4], D. Felsenberg[6]. [1]New Mexico Clinical Research & Osteoporosis Center, Albuquerque, NM, USA, [2]Radiant Research, Wyomissing, PA, USA, [3]University of Verona, Verona, Italy, [4]F. Hoffmann-La Roche Ltd, Basel, Switzerland, [5]F. Hoffman-La Roche Ltd, Basel, Switzerland, [6]Charité-University Medicine Berlin, Berlin, Germany.

Post-dose upper gastrointestinal adverse events (AEs) are a major reason for the discontinuation of oral bisphosphonates.[1,2] An effective oral bisphosphonate that combines favorable safety with a reduction in the opportunity for post-dose AEs may improve adherence to therapy. When administered orally, the potent, nitrogen-containing bisphosphonate, ibandronate (Boniva), has shown a safety profile similar to placebo. In the MOBILE study, a favorable and comparable safety profile was observed at 1 year with once-monthly (50+50mg [single doses, consecutive days], 100mg [single day] and 150mg [single day]) and daily (2.5mg) oral ibandronate regimens in 1,609 women (aged 55-80 years; ≥5 years since menopause) with postmenopausal osteoporosis (PMO; lumbar spine BMD T-score <-2.5 and ≥-5). Safety and tolerability parameters were continuously monitored throughout 2 years of treatment. At 2 years, as at 1 year, once-monthly and daily oral ibandronate were well tolerated, with no meaningful differences between groups in the overall incidence of AEs (76.5-80.3%), treatment-related AEs (30.1-36.9%) or treatment-related AEs resulting in withdrawal (5.1-7.6%). Most serious AEs were considered unrelated to treatment, with the incidence and number of related serious AEs being very low over the 2-year study period (0.3-0.8%; n=8). No imbalance in the overall incidence of upper GI adverse events was observed across the daily (22.8%) and once-monthly (19.9-25.8%) treatment arms, with most events mild to moderate in intensity. The incidence of clinical fractures was comparable across the treatment arms. At 2 years, the safety profile of once-monthly and daily oral ibandronate in MOBILE was similar, and consistent with that reported at 1 year. Importantly, no tolerability disadvantage was observed with the 150mg once-monthly dose versus the 2.5mg daily dose and 100mg once-monthly dose.

Comparison of the Persistence of Daily and Weekly Bisphosphonates in French Female Patients Treated for Osteoporosis. P. Fardellone*[1], A. F. Gaudin*[2], F. E. Cotte*[2], A. Lafuma*[3], C. Marchand*[3], A. El Hasnaoui*[2]. [1]CHU Nord, Amiens, France, [2]GlaxoSmithKline, Marly le Roi, France, [3]CEMKA - EVAL, Bourg la Reine, France.

The aim of this study was to compare the persistence of treatment with bisphosphonate (BP) according to their administration regimen. Persistence was assessed by the time to discontinuation of therapy. Two cohorts of female patients treated for osteoporosis with BP were retrospectively selected in a national computerized database representative of the French GPs prescriptions. Included women have consulted their GP at least twice a year for any reasons.The first cohort consisted of women whose treatment with daily BP (DBP) was first prescribed in 2000 or 2001 without prior treatment with SERMs or BP the previous year. Alendronate 5mg treatment was excluded because it is indicated in prevention of osteoporosis and etidronate was excluded because of its particular administration regimen. The second cohort included women with first weekly BP (WBP) treatment during the period 2002 and 2003. These periods were selected because in France, DBP were available from 2000 and WBP from October 2002 and this allowed us to have comparable cohorts. Duration of follow-up was as far as October 2002 for DBP cohort and October 2004 for WBP cohort. Survival analyses were performed in both cohorts using the end of treatment as endpoint. End of treatment was defined as the non-renewal of prescription 30 days after the length of the previous prescription. DBP cohort included 1,363 female patients, aged 69.7 years on average and WBP cohort included 3,969 patients, aged 69.7 years. Median duration of persistence was substantially higher in the WBP cohort than the DBP cohort during the 24 months of follow-up (391 days vs 301 days to discontinuation, respectively). The actuarial survival analysis curves below showed that after 12 months, 50.5% of women with the WBP regimen and 43.6% of women with the DBP regimen persisted with therapy. These rates decreased to 41.1% and 31.5% respectively at the end of 24 months. These results indicated that persistence differences between daily and weekly regimen appeared from three months and increased as far as two years of follow-up. Weekly regimen allowed a better persistence rate than daily regimen for the osteoporosis treatment but was still sub-optimal.

Adherence to Bisphosphonate Therapy Is Associated with Decreased Nonvertebral Osteoporotic Fracture Risk. S. Silverman[1], E. Siris[2], T. Abbott[3], C. Barr*[4], S. Harris[5], C. Rosen[6]. [1]David Geffen School of Med UCLA, Beverly Hills, CA, USA, [2]Columbia Univ Coll of Physicians and Surgeons, New York, NY, USA, [3]Thomson-Medstat, Philadelphia, PA, USA, [4]Roche Laboratories Inc., Nutley, NJ, USA, [5]UCSF, San Francisco, CA, USA, [6]St. Joseph's Hosp, Bangor, ME, USA.

Purpose: Nonvertebral fractures account for a substantial proportion of the morbidity and mortality associated with postmenopausal osteoporosis (PMO). One in 4 hip fracture patients dies within 1 year of the incidences.[1] The US Surgeon General emphasized the importance of treatment adherence to improve suboptimal clinical outcomes in PMO. The present study examines the association between adherence to newly prescribed bisphosphonate therapy and the risk of nonvertebral osteoporotic fractures, including hip and wrist, in postmenopausal women. *Methods*: A medical and pharmaceutical claims database (Medstat MarketScan®, covering 6 million lives) was analyzed to assess the relationship between adherence and the risk of nonvertebral fracture over 24 months in 37,698 women ≥45 years of age who received a first prescription for a bisphosphonate. Exclusion criteria included Paget's disease of bone, prior bisphosphonate use, prior cancer, or HIV infection. Two adherence measures based on claims data were evaluated: refill compliance (drug available ≥80% of the time) and persistence (no gaps in refills >30 days). *Results*: A total of 3,441 new nonvertebral fractures were reported during the study period. Of these, 1463 occurred at typical osteoporotic sites (734 hip and 732 wrist). Overall nonvertebral fracture risk was 25% lower in persistent versus nonpersistent subjects (*P*<.0001) and 21.2% lower in compliant vs poorly compliant subjects (*P*<.0001). Hip fracture risk was reduced by 33% among compliant subjects (*P*<.0001) and by 36% among persistent subjects (*P*<.0001). The risk of wrist fracture was reduced by 19% among persistent subjects (*P*=.0357) and by 13% among compliant subjects (*P*=.0596).

Influence of Adherence on Hip Fracture Risk (N=37,698)

Adherence Status	n (%)	24-mo Hip Fracture Risk, %	% of Relative Risk Reduction	*P* value*
Compliant	16,350 (43)	1.5	33	<.0001
Noncompliant	21,348 (57)	2.3		
Persistent	7,113 (19)	1.3	36	<.0001
Nonpersistent	30,585 (81)	2.1		

*Fisher Exact Test

Conclusions: Adherence to bisphosphonate therapy is associated with a significant reduction in the risk of nonvertebral fracture, particularly hip and wrist, within 24 months of treatment initiation. Fewer nonvertebral fractures may minimize the morbidity and mortality associated with PMO.

Diet, Not Genotype, Affects Bone Size in Ovariectomized Estrogen Receptor Alpha Knockout Mice. C. A. Peterson, N. Bagegni*. Nutritional Sciences, University of Missouri-Columbia, Columbia, MO, USA.

Several studies have shown beneficial effects of soy protein and soy isoflavones (IF) on bone during states of compromised estrogen status, yet the mechanisms are not yet fully elucidated. Using bones collected from a colon tumorigenesis experiment involving a unique estrogen receptor alpha knockout (ER-alpha KO) mouse model, we tested the following hypothesis: Ovariectomized (OVX), ER-alpha KO mice fed a soy protein diet with added IF will have greater bone mineral content (BMC) than those fed a soy protein diet without IF which in turn, will have greater BMC than mice fed a casein diet. Because IF have a purported greater affinity for the estrogen receptor beta in bone, we also hypothesized that there will be no significant difference in BMC between wild-type and ER-alpha KO mice. Mineral analysis of whole mouse tibias revealed significant diet effects, but no genotype effect. Consumption of soy protein with added IF resulted in greater bone weights and greater total tibia Ca than soy protein without IF or casein controls; total tibia P and Mg were not different between soy groups, both of which were greater than casein. Furthermore, the *proportion* of Ca, Mg and P in bone remained rather constant regardless of diet. Our results support the observation that soy IF act through the ERB to affect bone growth and mineralization, while soy protein alone (without IF) appears to have limited effects.

Dietary Calcium Intake in Women with Early Postmenopausal Osteoporosis in Zurich Is Insufficient. M. A. Dambacher*[1], M. Neff*[2], F. Brunner*[3], G. Moeller[4]. [1]Dept. of Rheumatology and Rehabilitation, University Clinic Balgrist, REKO Südbaden-Südwürttemberg, Zürich, Switzerland, [2]Center of Osteoporosis, Zürich, Switzerland, [3]Dept. of Rheumatology and Rehabilitation, University Clinic Balgrist, Zürich, Switzerland, [4]Medical Affairs, Procter & Gamble Pharmaceuticals–Germany GmbH, 65824 Schwalbach am Taunus, Germany.

Introduction: All large bisphosphonate trials have added calcium in amounts ranging from 500 to 1000 mg/day above individual dietary intake. Accordingly calcium supplements or calcium/vitamin D combinations are recommended today as co-medication to antiresorptive therapy in all recently published national or international guidelines on the care strategy for osteoporosis. In our experience general practitioners often disregard this important supplementation. Objective of this examination was to assess the dietary mean calcium intake of early postmenopausal osteoporotic (osteoporotic according to the WHO definition) women in Zurich. **Patients and Methods:** We assessed the daily calcium intake of 500 early postmenopausal osteoporotic (osteoporotic according to the WHO definition) women in Zurich. The calcium intake was determined by direct inquiry and calculated according to standardized tables (from Novartis and Roche). **Results:** Less then 3% of these 500 postmenopausal women (mean age: 58 years) reached the WHO recommendation for daily calcium intake for postmenopausal women which is 1300 mg. The mean daily calcium intake was 590 mg. **Conclusions:** There is an insufficient dietary mean calcium intake of the vast majority of early postmenopausal osteoporotic women in the (small big) town of Zurich. An addional calcium supplementation is highly recommended to achieve the recommended co-medication to antiresorptive therapies in all recently published national or international guidelines on the care strategy for osteoporosis. Integrated packaging that combined antiresorptive therapy with calcium (e.g., a bisphosphonate with calcium) could simplify and therefore improve current osteoporosis therapy.

Effects of Vitamins B6 and K2 on Bone Mechanical Properties and Collagen Cross-Links in Spontaneously Diabetic WBN/Kob Rats. M. Saito, S. Soshi*, T. Tanaka*, K. Fujii*. Orthopaedic Surgery, Jikei University School of Medicine, Tokyo, Japan.

Diabetes is associated with an increased risk of fracture, although type 2 diabetes is often characterized by normal bone mineral density (BMD). It is generally thought that latent vitamin B6 deficiency in diabetic patients is due to upregulated gluconeogenesis. Cross-links involves two different mechanisms, lysyl oxidase (LOX) mediated cross-links and non-enzymatic cross-linking (Advanced glycation end products; AGEs). LOX cross-links play important roles in the expression of proper physiologic function of collagen, whereas AGE accumulation has opposite effects. We recently demonstrated that low serum vitamin B6 was associated with a decrease in LOX-mediated cross-link and a sharp increase in AGEs (Pentosidine) cross-links, which correlated with bone fragility despite a lack of change in BMD in spontaneously diabetic WBN/Kob rats. Vitamin B6 is believed to act as both a coenzyme of LOX and as an inhibitor of AGE formation. In this study, we determined the effects of administration of vitamin B6 (pyridoxal 5-phosphate; PLP) or vitamin K2 (menatetrenone; MK-4) on bone mechanical properties and collagen LOX and AGE cross-link formation in male WBN/Kob rats. The onset of diabetes in these rats was observed at 12 months of age with mean fasting blood glucose levels of 493±119 mg/dl thereafter. Fourteen-month old male WBN/Kob rats were given either vehicle, PLP (250mg/kg bw/day) or MK-4 (50mg/kg bw/day) for 8 or 16 weeks. Low serum PLP levels were restored in the PLP-treated group. Femoral 3-point bending tests showed a significant increase in elastic modulus and toughness in rats treated with PLP or MK-4, despite no change in femoral BMD. The mechanical test results coincided with LOX and AGE cross-linking levels in bone collagen, such that the sum of LOX examined cross-linking components (DHLNL, HLNL, LNL, PYD, and DPD) was increased in the PLP (148%) and MK-4 (141%) groups over the vehicle-treated group. In contrast, Pentosidine levels were reduced in both PLP (49%)- and MK-4 (78%)-treated rats compared with the vehicle treated group. Bone collagen and serum intact osteocalcin levels were significantly greater in the MK-4 group than either the vehicle or PLP groups. These findings suggest that PLP stimulated not only LOX cross-link formation due to amelioration of the vitamin B6 deficiency, but also inhibited AGE cross-link formation in diabetic male rats. In contrast, MK-4 increased collagen accumulation in bone, suggesting that MK-4 improved the bone turnover rate without forming AGEs. These results indicate that both PLP and MK-4 increased collagen cross-link profiles and increased bone strength in diabetic osteopathy, but via different mechanisms.

Bone Mineral Density (BMD) Evolution in Young Premenopausal Women with Idiopatic Osteoporosis. P. Peris[1], A. Monegal*[2], C. Moll*[2], J. Mundo*[2], A. Martinez*[2], S. Vidal*[3], F. Pons*[3], M. Martinez de Osaba*[4], N. Guañabens[2]. [1]Rheumatology. IDIBAPS, Hospital Clinic, Barcelona, Spain, [2]Rheumatology, Hospital Clinic, Barcelona, Spain, [3]Nuclear Medicine, Hospital Clinic, Barcelona, Spain, [4]Hormonal Laboratory, Hospital Clinic, Barcelona, Spain.

Idiopatic osteoporosis is one of the most frequent causes of osteoporosis in young premenopausal women. However, there are no data about the therapy and the spontaneous evolution of BMD in these patients. The aim of this study was to analyse the evolution of BMD in premenopausal women with idiopatic osteoporosis treated with calcium and vitamin D supplements. Methods: Retrospective study of 16 premenopausal women with idiopatic osteoporosis (aged 35.7±7 years) with a mean follow-up period of 4 years (1-7 years). BMD measurements at the lumbar spine and femoral neck (DXA) were obtained in all patients at baseline and yearly. All patients had one or more fragility fractures and/or a Z-score < -2 in the lumbar spine or femur. In all patients secondary causes of osteoporosis were excluded. In addition, serum Ca, P, total alkaline phosphatase (TAP), 25-OH vitamin D and PTH were determined as well as urinary calcium and hydroxyproline. Patients were treated with calcium (500mg/d) and vitamin D (400 UI) supplements and were advised to increase physical activity. Results: 25% of patients had associated fragility fractures and 50% had family history of osteoporosis. The mean calcium intake was 734±62 mg/day. The mean lumbar BMD at baseline was 0.909±0.04 g/cm^2 (Z-score -2.04±0.1), and in femur it was 0.766±0.06 g/cm^2 (Z-score -1.47±0.1). A significant increase in lumbar and femoral BMD was observed after 2 and 3 years of follow-up, respectively (1.9±1.9% mean increase in lumbar spine, p= 0.021, at 2 years) (5.6±4.5% mean increase in femur, p=0.04, at 3 years). Although no significant changes were observed in the other variables analysed (Ca, P, TAP, 25-OH vitamin D and PTH), the TAP values tended to increase at 2 years (122±46 vs 140±36 U/l, p=0.054). In addition, a negative correlation between baseline TAP serum values and lumbar BMD evolution at 2 years was observed (r=-0.748, p=0.013). No patient developed new skeletal fractures during the follow-up period. Conclusion: In young premenopausal women with idiopatic osteoporosis the conservative treatment with supplements of calcium and vitamin D associated with an increase of physical activity is associated with an increase in BMD without evidence of further skeletal fractures after more than 4 years of follow-up.

Bisphosphonate Users Do not Purchase Enough Calcium to Ensure Sufficient Supplementation. B. Dawson-Hughes[1], M. P. Bradshaw*[2]. [1]Bone Metabolism Lab, Tufts University, Boston, MA, USA, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

The Surgeon General's Report on Bone Health suggests the average calcium intake of women 50 years and older is far below recommended levels for optimal bone health. The 1994-1996 Continuing Survey of Food Intakes by Individuals (CSFII) reports over 90% of women over 50 consume less than the dietary reference intake (DRI) of 1200 mg calcium. Recent NHANES data (2004) report average daily intake of 660 mg/day. This indicates a large percentage of the population will need dietary supplements to reach the DRI for calcium. Most postmenopausal osteoporotic women claim to understand calcium is a necessary part of osteoporosis treatment, but it is unknown how many actually take enough calcium supplements to meet the DRI of 1200 mg. This study analyzed calcium purchasing practices of current bisphosphonate users (Actonel® and/or Fosamax®) over a one-year period. 498 households of women who filled a prescription for either Actonel and/or Fosamax one year prior to and at least once during the current 52-week period were included in this study. These households were part of Information Resources Inc (IRI) RxPulse™ Patient Panel. This panel is a subset of IRI's Consumer Network Panel, a nationally representative set of 70,000 households that scan all their bar-coded purchases at home. Households within the RxPulse Patient Panel use their scanning device to record prescription information, including name of drug, strength and dose frequency, for each individual in their households. Data for supplement purchases included brand, calcium content (mg) and total tablet count. This panel provided a single source of data for bisphosphonate usage as well as total number of calcium supplement tablets (including Tums®) purchased. Panel data are weighted to match US demographics, and aggregate claimed purchases are verified through a comparison to store level scanner data. For this study, the supplement category was specifically examined and confirmed to fit within standard limits. 73% of bisphosphonate users' households did not purchase enough calcium supplements for them to take at least one tablet every day. Moreover, 40% of bisphosphonate users did not purchase any calcium supplements at all during the year. Calcium intake in osteoporotic women currently taking bisphosphonates is far below the recommended levels. Only about one in four patients currently taking a bisphosphonate purchases enough calcium to take one tablet every day. Providing osteoporotic women a convenient source of calcium with their osteoporosis treatment may help increase the percentage who actually take calcium on a regular basis, thereby improving the fracture risk reduction benefits of osteoporosis therapy.

No Effect of Vitamin K_1 Intake on Bone Mineral Density and Fracture Risk in Perimenopausal Women. L. Rejnmark[1], P. Vestergaard[1], P. Charles*[1], A. P. Hermann*[2], C. Brot*[3], P. Eiken*[4], L. Mosekilde[1]. [1]Dept. of Endocrinology and Metabolism C, Aarhus Sygehus, Aarhus University Hospital, Aarhus, Denmark, [2]Dept. of Endocrinology, Odense University Hospital, Odense, Denmark, [3]The Osteoporosis Research Centre, Hvidovre Hospital, Hvidovre, Denmark, [4]Dept. of Endocrinology and Clinical Physiology and Nuclear Medicine, Hilleroed Hospital, Hilleroed, Denmark.

Vitamin K functions as a cofactor in the posttranslational carboxylation of several bone proteins including, osteocalcin. In recent studies from the USA, a high vitamin K_1 intake has been associated an increased bone mineral density (BMD) and a decreased fracture risk. However, in the populations previously studied, the averages vitamin K_1 intake estimated by the food frequency method was approximately three times the recommended daily intake. We the present study, we investigated relations between vitamin K_1 intake and BMD and fracture risk in a European population. Within the Danish Osteoporosis Prevention Study (DOPS), including a population-based cohort of 2016 perimenopausal women, associations between vitamin K_1 intake and BMD was assessed at baseline and after 5-years of follow-up (cross sectional design). Moreover, associations between vitamin K_1 intake and 5- and 10-years changes in BMD were studied (follow up design). Finally, fracture risk was assessed in relation to vitamin K_1 intake (Nested case control design). In our cohort, dietary vitamin K_1 intake (0.6 µg/day) was close to the daily intake recommended by the FAO, but substantively lower than the intake reported in previously studied populations. Cross-sectional and longitudinal analyses showed no associations between intake of vitamin K_1 and BMD of the femoral neck or lumbar spine. Neither did BMD differ between those 5% who had the highest- and those 5% who had the lowest vitamin K_1 intake. During the 10-years of follow-up, 360 subjects sustained a fracture (cases). Compared to 1440 controls, logistic regression analyses revealed no difference in vitamin K_1 intake between cases and controls. Thus, in a Danish population, with an average vitamin K_1 intake close to the recommended daily intake, vitamin K_1 intake is not associated with effects on BMD or fracture risk.

DHEA Supplementation Does not Change Bone Turnover in Postmenopausal Osteopenic Women. M. R. Rubin, J. Sliney*, M. Johnson*, S. J. Silverberg. Columbia University College of Physicians & Surgeons, New York, NY, USA.

Dehydroepiandrosterone (DHEA) is an endogenous steroid that declines with age. On the basis of mainly anecdotal data, supplemental DHEA has become popular for putative anti-aging effects. Although DHEA administration has been associated with an increase in femoral neck BMD in postmenopausal women with normal BMD, no data exist on the effects of DHEA supplementation on skeletal metabolism in postmenopausal osteopenic women. We conducted a double-blind randomized placebo-controlled trial to investigate the effects of DHEA treatment on bone turnover in postmenopausal women with osteopenia. 37 postmenopausal women with osteopenia at the lumbar spine (LS) and/or total hip (TH) were randomized to 1 yr of DHEA (50 mg/d) or placebo (PLB). At baseline, the groups were well matched (mean ± SEM) in terms of age (DHEA: 63.2 ± 2 vs PLB: 62 ± 1 yrs; p=NS), time since menopause (DHEA: 10.3 ± 1 vs PLB:11.5 ± 1 yrs; p=NS), LS T-score (DHEA:-1.2 ± 1 vs PLB: -1.8 ± 1; p= 0.1), TH T-score (DHEA -1.4 ± 1 vs PLB:-1.1 ± 1; p=NS), serum NTX (DHEA: 13.9 ± 1 vs PLB: 15.9 ± 2; nl range: 8.7-19.8 nmol BCE/ liter; p=NS) and BSAP (DHEA: 27.4 ± 2 vs PLB: 26.4 ± 2 ng/ml; nl range: 8.0-16.6 ng/ml; p=NS). Osteocalcin was higher in the DHEA group at baseline (7.0 ± 1 vs 5.6 ± 1; nl range: 2.4-10.0 ng/ml; p = 0.006). Data are presented from an efficacy analysis of the subjects who continued in the study after the first baseline visit. 11 women (4 DHEA, 7 PLB) dropped out after the baseline visit, but they did not differ from the remaining 26 subjects (14 DHEA, 12 PLB) in terms of age, years since menopause, LS and TH BMD, serum NTX, BSAP or osteocalcin. After 1 year, there was no evidence of DHEA effect (assessed as % change) on levels of bone turnover markers (serum NTX-DHEA: -7.3 ± 9%; PLB: 4.2 ± 19%, p=NS; BSAP-DHEA: 1.8 ± 8%; PLB: -0.7 ± 8%, p=NS; or osteocalcin- DHEA: -9.6 ± 5%; PLB: 0.7± 8%, p=NS), nor did the rate of change in bone markers differ among the two groups. The time x treatment interaction was not significant (serum NTX: F(6,47) = 1.03, p =0.4; BSAP: F(6,42) = 0.97, p= 0.5; osteocalcin: F(6,69) = 2.0, p=0.08) in a mixed model analysis with fixed effect of treatment and random effects of time and subject, adjusted for the baseline difference in osteocalcin. In conclusion, this small, preliminary study suggests that DHEA supplementation does not significantly influence bone turnover in postmenopausal osteopenic women. Whether a larger study might detect smaller changes in bone turnover remains to be seen.

Vitamin K Treatment Reduces Undercarboxylated Osteocalcin but Does not Alter Bone Turnover or Density in Postmenopausal North American Women. J. M. Harke[1], D. Krueger[1], D. Gemar[1], M. Checovich[1], S. Zeldin*[1], J. Engelke*[1], R. Chappell*[2], J. Suttie*[3], N. Binkley[1]. [1]University of Wisconsin Osteoporosis Clinical Research Program, Madison, WI, USA, [2]Biostatistics and Medical Informatics, University of Wisconsin, Madison, WI, USA, [3]Biochemistry, University of Wisconsin, Madison, WI, USA.

Prior data suggest that vitamin K may improve skeletal health by enhancing osteocalcin carboxylation. For example, low vitamin K status, as measured by elevated undercarboxylated osteocalcin concentration, is associated with increased osteoporotic fracture risk. Additionally, some studies find vitamin K treatment to reduce vertebral fracture risk. However, whether vitamin K plays a role in the skeletal health of North American women remains unclear. Moreover, it is possible that various K vitamers (phylloquinone [K1] and menatetrenone, [MK4]) have differing skeletal effects. The purpose of this study was to evaluate the effect of K1 or MK4 treatment on markers of skeletal turnover and bone density in non-osteoporotic postmenopausal North American women. As such, in this randomized, double-blind, placebo-controlled study, 381 women not meeting the National Osteoporosis Foundation criteria for receipt of osteoporosis medications received K1 (1 mg daily), MK4 (45 mg daily) or placebo for 12 months. All participants received calcium citrate with vitamin D_3 (315 mg/200 IU) twice daily for two months prior to randomization and for the study duration. Serum markers of bone turnover (bone specific alkaline phosphatase [BSAP] and n-telopeptide of type 1 collagen [NTx]) were measured at baseline, 1, 3, 6 and 12 months. Bone mineral density (BMD) of the lumbar spine and proximal femur was measured by dual-energy x-ray absorptiometry at baseline, 6 and 12 months. 176 women are included in this preliminary analysis, their mean age and spine BMD was 62.3 years and 1.188 g/cm^2. At baseline, the three treatment groups did not differ in age, albumin, creatinine, AST, BSAP, NTx, percent undercarboxylated osteocalcin or BMD. Median compliance with calcium supplements, K1 and MK4 treatment was 95%, 95% and 91% respectively. K1 and MK4 treatment reduced serum undercarboxylated osteocalcin by 72% and 74% respectively, averaged over all follow-up visits; the decreases were immediate and stable. No effect of either K1 or MK4 treatment was observed on BSAP or NTx. Moreover, no effect of K1 or MK4 on lumbar spine or total proximal femur BMD was demonstrated. This preliminary analysis does not support a role for vitamin K treatment in bone turnover or density among postmenopausal North American women receiving calcium and vitamin D supplementation.

A Controlled Trial of the Effect of Milk Basic Protein (MBP) Supplementation on Bone Metabolism in Healthy Menopausal Women. A. Itabashi[1], S. Aoe*[2], Y. Toba*[3], Y. Takada*[4], T. Koyama*[5]. [1]Central Clinical Laboratory, Saitama Medical School, Saimata, Japan, [2]Department of Home Economics, Otsuma Women's University, Tokyo, Japan, [3]Functional Products Business Development, Snow Brand Milk Products Co.,Ltd, Tokyo, Japan, [4]Product Planning Department, Snow Brand Milk Products Co.,Ltd, Tokyo, Japan, [5]Koyama Takao Clinic, Tokyo, Japan.

Milk has more beneficial effects on bone health than other food sources. Recent in vitro and in vivo studies have showed that milk whey protein, especially its basic protein fraction (milk basic protein, MBP), contains several components capable of promoting bone formation and inhibiting bone resorption. The object of this study was to examine the effect of MBP on bone metabolism of healthy menopausal women. Thirty-two healthy menopausal women were randomly assigned to treatment with either placebo or MBP (40 mg per day) for six months. The bone mineral density (BMD) of the lumbar vertebrae L2-L4 of each subject was measured by dual-energy x-ray absorptiometry (DXA) at the beginning of the study, and after six months of treatment. Serum and urine indexes of bone metabolism were measured at baseline, after three months, and at the end of the study. Daily intake of nutrients was monitored by a three-day food record at the beginning of the study, and after three and six months. Twenty-seven subjects who completed the study according to the protocol were included in the analysis. The mean rate of gain of lumbar BMD of women in the MBP group (1.21%) was significantly higher than for women in the placebo group (-0.66%, p=0.046). When compared with the placebo group, urinary cross-linked N-telopeptides of type-I collagen (a biochemical marker of bone resorption), adjusted for creatinine excretion, was significantly decreased in the MBP group at six months, but no significant difference in serum osteocalcin (a biochemical marker of bone formation) was observed between the two groups. The urinary NTx excretion was found to be related to serum osteocalcin in the MBP group at the 3 and 6 months. Daily MBP supplementation of 40 mg in women can significantly increase their BMD, independently of dietary intake of minerals and vitamins. These results suggested that MBP supplementation was effective in preventing bone loss in menopausal women, and that this improvement in BMD may be primarily mediated through inhibition of osteoclast-mediated bone resorption, while maintaining the balance of bone remodeling, by MBP supplementation.

Safety and Bone Mineral Density Effects of Bread Fortified with 125 mcg Vitamin D_3/day in Romanian Nnursing-Home Residents. V. Mocanu[1], P. A. Stitt*[2], A. Costan*[3], E. Zbranca*[3], V. Luca*[1], R. Vieth[4]. [1]Department of Pathophysiology, University of Medicine and Pharmacy, Iasi, Romania, [2]Nutritional Resource Foundation, Madison, WI, USA, [3]Endocrinology, University of Medicine and Pharmacy, Iasi, Romania, [4]Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada.

If older men and women maintain serum levels of 25(OH)D higher than the threshold of 75 nmol/L, they should be at lower risk of fracture (Dawson-Hughes et al, Osteoporosis Int. online Mar 2005). The European OPTIFORD Study proposes bread as a useful vehicle for vitamin D fortification. However, both groups propose vitamin D intakes of 25 mcg/d or less, which we regarded as unrealistically low for vitamin D deficient elderly. We carried out a single-arm trial to evaluate the safety and efficacy of vitamin D_3 bread fortification in 45 Romanian nursing residents (age 71.02±6.73 years). Their basal serum 25(OH)D in Dec 2003 was 28.5±10.3 nmol/L (11 ±4 ng/mL), and in 86% of them it was <40 nmol/L (<16 ng/mL). Each day, each resident consumed one bun whose dough had been enriched with 250 mcg of vitamin D_3 and 315 mg calcium. After baking, the vitamin D content averaged 125 mcg per 100-g bun. Serum calcium, parathyroid hormone, bone markers, 25(OH)D, urinary calcium/creatinine ratio and C-telopeptide were measured every 3rd month for 1-yr. At baseline and 12 mo, bone-mineral density (BMD) was measured at the hip, spine, and total body by dual-energy x-ray absorptiometry (Hologic Delfi A densitometer). After 12 mo, serum 25(OH)D levels were 125.6±38.8 (SD) nmol/L, but in 10% of subjects it was <75 nmol/L. The vitamin D and Ca-fortified bread lowered serum PTH (basal vs 12 mo: 64. ± 19 pg/ml vs 21.17±23.1 pg/ml; p=0.0001). At every follow-up, there were no changes in serum calcium (basal vs 12 mo: 2.29±0.15 mmol/L vs 2.29±0.15 mmol/L), urinary calcium (3.72±0.3 mmol/d vs. 3.16±0.3 mmol/l) or calcium/creatinine ratio (0.378 ± 0.18 mmol/mmol vs. 0.357±0.20 mmol/mmol). However, at 12 mo, there were significant increases in lumbar spine BMD (+4%, 0.831±0.128 g/cm^2 vs 0.863+0.146 g/cm^2; p=0/037) and hip BMD (+24%, 0.734±0.126 g/cm^2 vs 0.907±0.156 g/cm^2). The gain in BMD may be explained by mineralization of osteoid, and closure of the remodeling space because of sharply lower PTH concentrations that would have reduced bone remodeling. Fortification of bread with much more vitamin D than previously studied was safe and appears to be appropriate for sun-deprived nursing-home residents.

Daily, Weekly or Monthly Protocols to Reach the Desired Serum 25-Hydroxyvitamin D Concentration for the Elderly. S. Ish-Shalom[1], T. Salganik*[2], E. Segal*[2], B. Raz*[2], I. Bromberg*[3], R. Vieth[3]. [1]Calcium and Bone Unit, Rambam Medical Center, Haifa, Israel, [2]Calcium and Bone Unit, Technion Faculty of Medicine, Haifa, Israel, [3]Pathology and Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada.

A recent consensus about vitamin D_3 for prevention of hip fractures in the elderly stated that serum 25-hydroxyvitamin D (25(OH)D) concentrations should be higher than 30 ng/mL (75 nmol/L) (Dawson-Hughes et al, Osteopor Int. Mar 18, 2005). To achieve this goal, the consensus was that all elderly should be supplemented with 1000 IU/day. We investigated whether the 25(OH)D response to supplementation might differ when the same total dose of vitamin D was given daily, weekly or monthly. We randomly allocated 48 patients (age 81 ±8 SD yrs) to three different regimens of vitamin D supplementation; delivering the same total dose: 1500 IU/daily; 10500 IU/weekly; or 45000 IU/monthly as crystalline USP vitamin D_3 in USP ethanol (diluted so that mixing 1 mL into a drink delivered 1500 IU, 10500 IU or 45000 IU). Before starting, mean serum 25(OH)D of all subjects was 19 ±9 SD ng/mL, and in 95% of them it was < 30 ng/mL. At the end of the 8-week protocol, mean increases in 25(OH)D approached a plateau. Concentrations did not differ between dosing strategies (Table). The major difference was that the monthly protocol produced distinctive jumps in 25(OH)D during the week after each dose. After 8 wk, for all 48 subjects, mean serum 25(OH)D was 36 ±11 SD ng/mL. This was significantly higher than 30 ng/mL (p=0.001), yet in 35% of the subjects, serum 25(OH)D was < 30 ng/mL despite the intake of 1500 IU/day. We conclude that a dose of vitamin D_3 higher than 1500 IU/day is required to ensure that within 2 months, essentially all treated patients achieve serum 25(OH)D levels higher than the minimum concentration desired for fracture prevention.

Increases in serum 25(OH)D ng/mL after 8 weeks of vitamin D3				
Regimen	N	25(OH)D Mean Increase	25(OH)D 2.5 percentile	25(OH)D 97.5 percentile
1500 IU/day	16	18	6	33
10500 IU/wk	17	13	7	20
45000 IU/mo	15	21	-2	40
Overall data	48	17	-2	40

Neutralization of the Acidogenic Western Diet With K Citrate Increases DXA BMD in Postmenopausal (PM) Osteopenic Women: Results of a DBRCT. S. Jehle*[1], A. Zanetti*[1], J. Muser*[2], H. N. Hulter[3], R. Krapf[1]. [1]Medicine, Kantonsspital Bruderholz, Bruderholz/Basel, Switzerland, [2]Laboratory Medicine, Kantonsspital Bruderholz, Bruderholz/Basel, Switzerland, [3]Genentech Inc, South San Francisco, CA, USA.

The effect of alterations in either acid or protein intake on bone mass remains controversial. Both net anabolic and catabolic (via chronic acid loads) effects on bone have been attributed to the high animal/grain protein content of the Western diet. There are no reported controlled trials on the effects of altered acid intake on bone mass in humans. In a single-center, prospective DBRCT, PM non-vegetarian osteopenic (T-score -1 to -4 at L2-L4) women (n = 161) were randomized 1:1 to receive either blinded 10 mmol of trivalent Kcitrate or KCl (30 mmol) p.o. daily in 3 div doses for 12 mos. All subjects received Ca 500 mg and D3 400 IU daily. The primary endpoint was DXA (Lunar DPXL) BMD % change, L2-L4 at mo 12. There were no significant baseline differences among the 2 groups with regard to BMD (all sites), 25-OHD, intact PTH, acid-base parameters, Ca, Pi or markers.

	Month 6		Month 12	
	%Δ KCl	%Δ K Cit	%Δ KCl	%Δ K Cit
L2-L4 BMD	**-0.4**	**+0.5***	**-1.0**	**+0.9#**
THip BMD	**-0.8**	**+0.2***	**-1.5**	**+0.5#**
FN BMD	**-1.2**	**-0.3**	**-1.9**	**-0.5***
S BSAP	**+9.2**	**+10.4**	**+5.9**	**+9.1**
S osteocal	**-9.1**	**-7.7**	**-6.8**	**-11.7**
S Ctx	**-12.1**	**-33.5**	**+37.6**	**+20.2**
U Pyr/Cr	**+0.5**	**-5.6**	**-3.8**	**-5.0**
U DPD/Cr	**+2.7**	**-6.4**	**-7.3**	**-10.3**

* p<0.05, # p<0.001

%Δ BMD at L2-L4 was significantly higher in K Cit group by month 6 and differences increased progressively to mo 9 and 12. Bone marker changes showed a non-significant trend to decreased resorption and increased formation at mo 6 assessment. K Cit induced a sustained and significant reduction in urinary Ca and Pi excretion: U Ca/creat in Kcit at mo 6 was -0.065 (p = 0.033) and -0.073 at mo 12 (p = 0.040). In addition, the increases in Ucit excretion correlated directly and significantly with Δ%BMD at L2-L4, while the Δ net acid excretion (an estimate for endogenous acid production) correlated inversely and significantly with the %Δ L2-L4 BMD in a subset (N=22). In conclusion, Kcitrate - by neutralizing the dietary acid load - induced large (+1.9% net of control, L2-L4) mo 12 BMD increases, intermediate in magnitude between raloxifene and bisphos. The progressive BMD increases at mo 12 with small marker trends persisting only to mo 6 and the sustained effects on urinary Ca excretion suggest improved mineralization as part of the underlying mechanism, in addition to cellular mechanisms.

Polyphenolic Compounds in Dried Plum Enhance Bone Recovery Following Skeletal Unloading. E. A. Lancaster*[1], E. A. Lucas[1], J. Collins*[2], L. Howard*[3], N. O. Maness*[4], B. H. Arjmandi[1], B. J. Smith[5]. [1]Department of Nutritional Sciences, Oklahoma State University, Stillwater, OK, USA, [2]South Central Agricultural Research Laboratory, USDA ARS, Lane, OK, USA, [3]Department of Food Science, University of Arkansas, Fayetteville, AR, USA, [4]Department of Horticulture and Landscape Architecture, Oklahoma State University, Stillwater, OK, USA, [5]Department of Surgery, University of Oklahoma Health Sciences Center, Oklahoma City, OK, USA.

Dried plums have been used medicinally for many years, but recently have been shown to enhance the recovery of bone in osteopenic animal models. The aim of this study was to begin to investigate the bioactive components of dried plum, i.e. polyphenols and boron, on bone recovery following hindlimb unloading (HU). Fifty-four, 6-month-old, female Sprague Dawley rats were randomly assigned to either HU (5 groups) or ambulatory (AMB=1 group). Following 4 wks of HU and confirmation of bone loss by DXA, rats were returned to normal ambulation and treatments initiated: HU-control diet (HU-Con); HU-control diet with 15% (w/w) dried plum (HU-DP); or HU-control diet with a comparable dose of boron (HU-B) or polyphenol (HU-PP) extract to that found in dried plum. One HU group was fed control diet and received subcutaneous parathyroid injections (80 ug/kg body wt; 3 x wk) (HU-PTH) to serve as a positive control. Bone recovery of the 4th lumbar vertebrae (L4) was evaluated in terms of bone mineral density, trabecular microarchitecture, and bone strength. The recovery of L4 BMD in the HU-PP and HU-B animals was the same as that observed in the HU-DP and HU-PTH groups. Furthermore, the HU-PP had similar effects on trabecular bone volume (BV/TV), thickness (TbTh) and linear attenuation as the dried plum, but was not able to enhance recovery to that of the HU-PTH. While the HU-B group was statistically similar the HU-PP group on a number of microarchitectural parameters, it was not able to have the same effect as the dried plum. Bone strength of the L4 was increased in the HU-DP group, but the HU-PP and HU-B were not able to enhance overall bone strength. At the end of the 12 weeks no alterations in bone biomarkers were observed, but urinary calcium was elevated in HU-DP and HU-groups. We conclude that the extracted polyphenols account for large proportion of the effects observed with dried plum on trabecular bone and appear to be one of the primary bioactive components in dried plum.

Sevelamer Prevents Bone Loss in Ovariectomized Rats. P. Simic*[1], S. Vukicevic[1], N. Draca*[1], A. Blair[2], S. Burke[2], K. T. Sampath[2]. [1]Laboratory for Mineralized Tissues, Zagreb Medical School, Zagreb, Croatia, [2]Drug Discovery and Development, Genzyme Corporation, Waltham, MA, USA.

In patients with chronic kidney diseases (CKD), hyperphosphatemia is associated with renal osteodystrophy, vascular and soft-tissue calcification, and mortality. In a randomized clinical trial, we recently reported that sevelamer hydrochloride (Renagel®), a non-calcium phosphate binder, is capable of reducing progressive coronary artery and aortic calcification and significantly increasing trabecular bone mineral density (BMD) in CKD (stage 5) patients as compared to calcium containing phosphate binders (acetate and carbonate salts) (Raggi P, et.al., JBMR., in press). In the present study, we examined whether sevelamer could also prevent and restore bone loss that follows ovariectomy in rats (an animal model of osteoporosis). Sprague Dawley rats were ovariectomized (OVX) at 6 months and the sevelamer therapy was started immediately (prevention model), and 3 months following OVX (restoration model). Six months old rats (n=96) were ovariectomized (OVX) and divided into following groups: (1) Sham; (2) Sham + sevelamer 3%; (3) OVX; (4) OVX + sevelamer 1%; (5) OVX + sevelamer 3%. Sevelamer was mixed with food immediately following OVX and therapy was continued for 25 weeks. The whole body, hind limbs and lumbar spine bone mineral density (BMD) was monitored by DEXA in vivo throughout the study. Ex vivo measurements of femur, tibia and lumbar spine were performed using DEXA, pQCT and μCT. At 4 and 8 weeks following administration, sevelamer (at both doses) significantly increased BMD at all measured sites. Although sevelamer did not maintain the increased BMD at later time intervals (above 20 wks), at 3% in OVX animals it progressively increased BMD of sham animals towards 20 weeks following administration which was maintained until the termination at week 25, and then confirmed by ex vivo measurement of BMD. In a restoration model, sevelamer (3%) was mixed with food and therapy started at 3 months following OVX and continued for another 12 weeks. Results show that Sevelamer increased BMD of hind limbs and lumbar spine for 8% and 5%, respectively thus restoring lost bone. These results suggest that sevelamer has a positive effect on bone mineral density by preventing bone loss and restoring bone volume in aged OVX rats.

Additive Bone Protective Effects of Fuctooligosaccharide and Soy Isoflavones. L. Devareddy*, D. A. Khalil, D. Y. Soung, E. A. Lucas, S. C. Chai*, K. Korlagunta*, S. S. Mahajan*, B. H. Arjmandi. Nutritional Sciences, Oklahoma State University, Stillwater, OK, USA.

We have previously reported that the addition of fructooligosaccharide (FOS), an indigestible fermentable polysaccharide, to soy protein (Soy) reverses the loss of BMD in ovariectomized (Ovx) osteopenic rats. In this study, we examined the effects of Soy, FOS, and their combination on microstructural properties of tibiae. For this, 60 nine-month old female Sprague-Dawley rats were either sham-operated (sham) or Ovx and then maintained for 90 days to establish bone loss. Thereafter, rats were divided into five groups (n=12; one Sham and four Ovx): Sham, Ovx (control), Soy, FOS+casein, and FOS+Soy. After 125 days of dietary treatment, rats were necropsied and bones were analyzed. Treatment effects on selected bone microstructural properties were assessed using microcomputed tomography (Scanco Medical). Below is a summary of our findings.

Measures	Sham	Ovx	Soy	FOS	FOS+Soy	P Value
BV/TV	0.111^{a}	0.069^{b}	0.061^{b}	0.069^{b}	0.075^{b}	0.0007
ConnD	20.1^{a}	5.7^{b}	5.3^{b}	6.1^{b}	8.1^{b}	<.0001
SMI	1.98^{b}	2.50^{a}	2.71^{a}	2.61^{a}	2.59^{a}	0.0003
TbN	2.03^{a}	1.54^{bc}	1.50^{c}	1.61^{bc}	1.81^{ab}	0.0003
TbTh	0.078^{b}	0.090^{a}	0.088^{a}	0.087^{a}	0.085^{ab}	0.0234
TbSp	0.507^{c}	0.668^{a}	0.691^{a}	0.634^{ab}	0.559^{bc}	0.0057

Data are mean (n=12). Values in a row that do not share the same superscript letters are significantly (P<0.05) different from each other. In terms of certain trabecular microstructural properties, the results of this study indicate that the combination of these two agents is better than either alone. FOS, in part, may enhance the bone protective effects of soy isoflavones by altering gut microflora that improves calcium and isoflavone bioavailability.

A Novel Method for Monitoring of Neuromuscular Function as a Potential Factor for Risk of Fall. P. Schneider, H. Haenscheid*. Clinic for Nuclear Medicine, University of Wuerzburg, Wuerzburg, Germany.

According to epidemiological studies bone mineral density accounts for only 15% of fracture risk in elderly. The risk of fall, the primary factor leading to fracture depends largely on neuromuscular function. Therefore a method is required to directly assess the risk of fall instead of indirect questionnaire approaches. The device developed is capable of tracing force vectors during a provoked tandem stand test (TST) and tracing muscle force during a series of enforced knee-bends (KB), simulating the chair-rising test (CRT). During the measurement time the novel device assesses the forces and activation velocity (power) exhibited by the muscle groups essential for walking and balance. The time series is analysed and displayed as a power spectrum. Average power to maintain the gravity´s center of body mass is calculated. The test can be repeated as one leg test, with eyes open or closed. Sensitivity is +/- 2N. Measurement time for the TST and KB test, the surrogate

for the CRT is e.g. 10 seconds each. The number of bends with maximum force is registered and the maximum power is calculated by analysis of the recorded time series. The methods show clear differences in muscle activation frequencies which are generally in a range of 0-20 Hz, and power, depending on training, age, disease or neurotropic drug status. There is an inverse relation between the individuals capability to maintain balance, the power to remain in the neutral center of gravity, leading to muscle fatigue. The balance and KB tests show considerable differences in muscle frequency and power, related to age, training status or drug intake in individuals. The figure shows a patient with vertebral osteoporosis (89 y., female, top), a soccer player (19 y., female, middle), and a patient on 20 mg prednisolon (54 y., female, bottom). The novel method described° is able to monitor an individual's capability of keeping balance depending on different influences, to measure the muscle power required for the test, to display muscle activation frequencies and to measure gross and maximum muscle power during the KB test. Other than the classic stopwatch versions, the tests are digitally recorded and analysed. According to the bone mechanostat the results should be associated with bone health and fracture risk via the functional bone-muscle unit, which yet has to be studied longitudinally.

Recovery of Site-Specific Bone Loss in Amenorrheic Runners. M. E. Walcott*[1], K. E. Ackerman[2], N. Glass[1], M. S. LeBoff[1]. [1]Medicine, Brigham and Women's Hospital, Boston, MA, USA, [2]Internal Medicine, Hospital of the University of Pennsylvania, Philadelphia, PA, USA.

While amenorrhea has been shown to have detrimental effects on skeletal health, little is known about whether this process is reversible in amenorrheic athletes who develop normal menstrual function. To examine the skeletal impact of amenorrhea on bone mass, we measured metabolic markers of bone turnover and bone density in elite long distance runners (5k to ultra-marathons.) We enrolled 73 female runners ages 18-40 (mean 26.6±6.5) with and without amenorrhea and with no other secondary causes of low bone mass. Bone density was tested at the left hip, lumbar spine, and whole body by dual x-ray absorptiometry (DXA) and at the bilateral distal radii by peripheral quantitative computed tomography (pQCT). Participants were tested for n-telopeptides, osteocalcin, and 25 (OH) vitamin D and completed dietary intake and training questionnaires. Runners were classified as currently amenhorrheic (Amen, n=18), currently eumenorrheic with a history of amenorrhea during adolescence (AdAmen n=15), or eumenorrheic (Eu n=40). The Eu and Amen groups reported 50% oral contraceptive use, while the AdAmen runners reported 92% oral contraceptive use. While 55-60% of the runners used multivitamin or calcium supplements, data from the dietary intake questionnaire indicated that 79.5% of runners, especially the Amen runners, were unable to meet daily calcium, vitamin D, and B vitamin intakes without supplementation. A significant difference was observed between the Amen and Eu athletes in the pQCT measured Bone Strength Index ($p=0.02$), at the lumbar spine ($p<0.01$), but not at the hip. Specifically, 50% (n=9) of the Amen athletes versus only 12.5% (n=5) of the Eu athletes had a Z-score < -1.0 S.D. at the lumbar spine. BMD at the lumbar spine in the AdAmen runners was significantly higher than the Amen runners, but was not significantly different from the Eu runners. In fact, AdAmen BMD at all locations was comparable to Eu BMD. All three groups showed similar, normal osteocalcin, N-telopeptide, and serum vitamin D levels. The BMD of runners who regain menstrual function after adolescence can recover to levels of eumenorrheic runners. In addition, BMD of the hip was protected from the effects of amenorrhea as a result of the site-specific force from running. Because 60% of the currently amenorrheic runners have had sustained amenorrhea for more than 8 years, these data suggest that the duration of amenorrhea, rather than age of occurrence, is a determining factor in skeletal health.

The Economic Implications of a Policy of Provision of Hip Protectors to Institutionalized Elderly in Ontario, Canada. A. M. Sawka[1], A. Gafni*[2], P. Boulos*[1], K. Beattie*[3], A. Papaioannou[1], A. Cranney[4], D. A. Hanley[5], J. D. Adachi[1], E. A. Papadimitropoulos[6], L. Thabane*[7]. [1]Medicine, McMaster University, Hamilton, ON, Canada, [2]Centre for Health Economics and Policy Analysis, McMaster University, Hamilton, ON, Canada, [3]Faculty of Health Sciences, McMaster University, Hamilton, ON, Canada, [4]Medicine, University of Ottawa, Ottawa, ON, Canada, [5]Medicine, University of Calgary, Calgary, AB, Canada, [6]Eli Lilly and University of Toronto, Toronto, ON, Canada, [7]Clinical Epidemiology and Biostatistics, McMaster University, Hamilton, ON, Canada.

Our objective was to determine whether a policy of provision of hip protectors to Ontario nursing home residents age 65 years and older could result in cost savings, stemming from reductions in initial hospitalizations for hip fracture. We conducted a cost analysis from a Ministry of Health perspective (one year cycle length). The anti-hip fracture efficacy of hip protectors in nursing home residents was based on a Bayesian meta-analysis of randomized controlled trials. We determined that at current prices of hip protectors, a strategy of provision of hip protectors to all elderly nursing home residents in the province could result in an overall mean cost savings of 3.6 million Canadian dollars in one year (95% credibility interval [CRI], -30.3 million, 39.4 million), with a probability of cost savings of 0.57. A strategy of provision of hip protectors to high risk elderly nursing home residents with osteoporosis or dementia would be expected to result in a mean overall cost savings of $12.0 million (95% CRI -18.9 million, 44.8 million), with a probability of cost savings of 0.77. Provision of hip protectors to elderly nursing home residents without either dementia or osteoporosis is unlikely to result in cost savings. Decreasing the price of hip protectors would increase the magnitude and probability of cost savings in each scenario. In conclusion, the largest cost savings in acute hip fracture care are most likely to be achieved if hip protectors are only provided to high risk nursing home residents. Cost savings can be increased by negotiating a lower price for these devices.

SU436

A Meta-Analysis of Hip Protector Trials in Institutionalized Elderly Using a Bayesian Approach. A. M. Sawka[1], P. Boulos*[1], K. Beattie*[2], A. Papaioannou[1], A. Gafni*[3], A. Cranney[4], D. A. Hanley[5], J. D. Adachi[1], E. A. Papadimitropoulos[6], L. Thabane*[3]. [1]Medicine, McMaster University, Hamilton, ON, Canada, [2]Faculty of Health Sciences, McMaster University, Hamilton, ON, Canada, [3]Clinical Epidemiology and Biostatistics, McMaster University, Hamilton, ON, Canada, [4]Medicine, University of Ottawa, Ottawa, ON, Canada, [5]Medicine, University of Calgary, Calgary, AB, Canada, [6]Eli Lilly and University of Toronto, Toronto, ON, Canada.

Objective: Our objective was to design a Bayesian random effects model for pooling hip fracture outcome data from cluster randomized trials (CRTs) and individually randomized trials (IRTs) of hip protectors in institutionalized elderly. Institutionalized elderly included residents of nursing homes, hostels, or residential group homes. A second analysis was conducted in trials of exclusively nursing home residents. **Study Design and Setting:** Eight electronic databases were searched; abstracts and full-text papers were reviewed in duplicate. The pooled mean odds ratio (OR) of a hip fracture in an individual allocated to hip protectors with 95% credibility interval (CRI) was calculated using a Bayesian random effects model. The uncertainty of model parameters (such as cluster size or the intra-cluster correlation coefficient) was modeled. Statistical adjustments were performed to account for the design effect of cluster randomized trials. **Results:** We included six trials of 6213 individuals (2 IRTs and 4 CRTs). The pooled OR of an institutionalized elderly individual (including residents of nursing homes, hostels, or residential group homes) sustaining one or more hip fractures with hip protector allocation was 0.56 (95% CRI 0.17, 1.06); the OR for hip fracture in trials of exclusively nursing home residents was 0.39 (0.06, 0.68). The model was robust in multiple sensitivity analyses in which alternative statistical assumptions were explored. **Conclusion:** Using a Bayesian approach to meta-analysis, we determined that hip protectors decrease the risk of hip fracture in elderly nursing home residents, but not in all institutionalized elderly.

Mechanical vs. Metabolic Component of Self-Reported Physical Activity and Bone Mineral Density in Postmenopausal Scottish Women. A. Mavroeidi*[1], H. M. Macdonald[1], A. D. Stewart*[2], D. M. Reid[1]. [1]School of Medicine, University of Aberdeen, Aberdeen, United Kingdom, [2]School of Health Sciences, The Robert Gordon University, Aberdeen, United Kingdom.

Physical activity (PA) is an important risk factor for osteoporosis and associated fractures, but its assessment in epidemiological studies has always been a challenge. We have developed and validated a new self-administered bone-specific physical activity questionnaire (bsPAQ) using tri-axial accelerometers, which estimates both the metabolic and mechanical component of self-reported PA. Using the Aberdeen bsPAQ we aimed to assess the importance of mechanical vs. metabolic component of PA on BMD. A total of 1847 postmenopausal women from the North of Scotland Osteoporosis Study (NOSOS) who underwent bone densitometry in 2001-3 (mean ± SD age: 69.3 ± 5.5y) were contacted in 2004 and 68.7% (n = 1254) completed the bsPAQ. Median values for self-reported PA

(metabolic component) were 149.4 (IQR: 46.2) MET.h/wk and for peak scores (mechanical component) 4.5 (IQR: 2.0). After excluding women that were taking any medication or suffering from conditions likely to affect bone metabolism (n =148), we found that those in the highest tertile of PA (metabolic component) had a higher BMD at the lumbar spine (LS) (ANOVA p = 0.036), at the total right (RH) (ANOVA p = 0.001) and total left hip (LH) (ANOVA p <0.001) compared to women in the lowest tertile. Differences remained significant for hip BMD (ANCOVA RH p = 0.035 and LH p = 0.013), but not LS BMD (ANCOVA p = 0.164), after adjusting for important confounders (age, weight, height, smoking, HRT use, socio-economic status, energy adjusted calcium and vit D intake, alcohol consumption, family history of osteoporosis, seasonal variations, and time interval between BMD scan and PA assessment). Women in the highest tertile of the mechanical component of PA had a higher BMD at the total RH (ANOVA p = 0.038) and LH (ANOVA p = 0.002) compared to women in the lowest tertile. Differences remained significant after adjustment for confounders at LH (ANCOVA p = 0.017) but not at RH (ANCOVA p = 0.174). There were no differences across tertiles for LS BMD. Multiple regression analysis revealed that the mechanical component of PA explained 1.3% of the LH BMD variation (unstandardized β(SE): 0.007 (0.002)); the metabolic component explained a further 0.2% (β(SE): <0.001 (<0.001)). The corresponding values for RH BMD were 0.6%(β(SE): 0.005 (0.002)) and 0.2% (β(SE): < 0.001 (0.001)). Amongst older Scottish postmenopausal women PA seems to have a small but significant independent effect on current BMD, with the mechanical component explaining more of the BMD variation than the metabolic component, especially at the total hip site.

Radiologic Evidence of Improvement in Thoracic Kyphosis in Osteoporosis and Osteopenia Using a Kypho-Orthosis Program. S. M. Ali*, M. Sinaki. Physical Medicine and Rehabilitation, Mayo Clinic, Rochester, MN, USA.

Kyphosis in osteoporosis has detrimental effects, including a decrease in physical activity and respiratory function, gait and balance dysfunction, and a poor quality of life. In a previous study we reported that kyphosis in osteoporotic subjects can increase the risk of falls. Therefore, measures that improve kyphosis in this population are important in improving physical activity and quality of life and decreasing the risk of falls. The weighted kypho-orthosis is a device used to improve kyphosis by providing a gentle posterior/inferior back-force below the scapulae and by providing proprioceptive feedback. Our objective was to assess radiographic changes in osteopenic/osteoporotic individuals with kyphosis after intervention with a weighted kypho-orthosis. We examined radiographs of the thoracic spine in 22 patients (19 female and 3 male) with either osteopenia or osteoporosis who had been evaluated in an outpatient osteoporosis program at our multispecialty clinic. The study was performed with the approval of the institutional review board. The kypho-orthosis program included the use of a kypho-orthosis for ½ to 1 hour once or twice a day, along with shoulder retraction exercises. Radiographs were obtained at baseline and at follow-up visits with a range of 74 to 878 days (mean 318.4 days) between visits. The angle of thoracic kyphosis was measured using the Lippman-Cobb technique by a physiatry resident (SA). The thoracic curve was measured from the superior edge of T4 to the inferior edge of either T12 or the interference vertebra (the vertebra that comprises the caudal end of the curve). Height and weight were also obtained at baseline and follow up. The results showed subjects' age ranged from 38 to 90 years (mean 66.4 years). Thoracic kyphosis ranged from 42 to 87 degrees at baseline (mean 61.1 degrees) and from 28 to 85 degrees at follow up (mean 57.8 degrees) which was a statistically significant difference (p<0. 0280). This study showed that intervention with a weighted kypho-orthosis showed statistically significant radiologic improvement in thoracic kyphosis. Our study did not take into account the level of patient compliance. More in-depth studies are required with a larger number of subjects to further elucidate radiographic changes in osteoporotic individuals with kyphosis using this kypho-orthosis program.

Effect of Low-Intensity Back Exercise on Quality of Life in Patients with Osteoporosis. M. Hongo[1], E. Itoi[1], N. Miyakoshi[1], Y. Shimada*[1], M. Sinaki[2]. [1]Department of Orthopedic Surgery, Akita University School of Medicine, Akita, Japan, [2]Department of Physical Medicine and Rehabilitation, Mayo Clinic, Rochester, MN, USA.

We have demonstrated that back extensor strength is the most significant contributor to the spinal mobility and spinal mobility has strong effect on quality of life (QOL) in patients with osteoporosis. We also reported back strengthening exercise using a weighted backpack was effective for increasing back extensor strength and decreasing risk of vertebral fractures. However, the weighted back exercise needs to be prescribed on an individual basis according to musculoskeletal fragility in order to be safe. Therefore, an exercise program needs to be safe in intensity but exertional enough to be biomechanically challenging to be effective. The aim of this study was to determine the effects of low-intensity back strengthening exercises on back extensor strength, spinal mobility, and QOL. A total of 80 women with postmenopausal osteoporosis participated in the study. Initial screening excluded women with severe back pain, severe spinal deformity, and history of any known health problems. Average age was 67 years (range, 50-78 years). Participants were randomly assigned to a control group (n=38) or an exercise group (n=42). The study period was 4 months. Each subject in the exercise group was instructed to lie in a prone position with a pillow under the abdomen such that her spine was slightly flexed. Then, she was to lift the chest off the bed toward the neutral position for 5 seconds. Each contraction was repeated 10 times and each exercise was performed 5 times a week. Isometric back extensor strength was measured using the specific dynamometer. Spinal range of motion between upper thoracic spine and sacrum was analyzed with Spinal Mouse®. Scores for the QOL was evaluated by the questionnaires which contained six domains. Back extensor strength significantly increased both in the exercise group (26%; p<0.0001) and in the control group (11%; p=0.01). There was no significant difference in back extensor strength at four month between the groups. Spinal range of motion did not significantly change in both groups. There was no significant difference in spinal range of motion between the groups. Scores for QOL increased in the exercise group (7%; p<0.0001), whereas it remained unchanged in the control group (0%). There was a significant difference in QOL score between the groups (p=0.036). Scores of the domain for the activities of daily living and general health in the exercise group improved significantly and greater than in the control group. In conclusion, low-intensity back strengthening exercise was effective in improving QOL and back extensor strength for patients with osteoporosis.

Nutritional Evaluation and Body Composition in Well-Trained Cyclists. V. S. R. Penteado*[1], M. G. Santana*[2], S. V. Bertolino*[3], M. T. Mello*[3], M. M. Pinheiro*[1], V. L. Szejnfeld[1]. [1]Rheumatology Division, São Paulo Federal University, São Paulo, Brazil, [2]Psicobiology Division, São Paulo Federal University, São Paulo, Brazil, [3]Psicobiology Division, São Paulo Federal University, São Paulo, Brazil.

It is well established that cycling plays an important role on body composition. It increases muscle mass and decreases body fat. This sporting event is characterized by weight bearing with minimal strain and involves prone orientation for long and exhaustive trainings. There is little evidence demonstrating the impact of cycling on bone mass. Moreover, bone health and sporting performance in these athletes could be optimized by suitable nutritional support. Objectives: In this study we aimed to evaluate bone mineral density (BMD), body composition and nutritional aspects in well-trained cyclists. Methods: Thirty-six high performance cyclists (31 road and 5 mountain bike) and 15 health controls, matched for body mass index (BMI), age and race were invited to participate in the study. All the subjects answered a detailed questionnaire about risk factors to osteoporosis and fractures and had the kind and frequency of their physical activities recorded. The nutritional inquiry was performed by four days recording - macronutrients and micronutrients (calcium, phosphorus, magnesium, iron, zinc, vitamin A and C) intake was compared with specific dietary recommendations for each group (FAO/ OMS, 1995; DRI 2002; Williams & Devlin, 1998). Maximal rate of oxygen uptake kinetics test ($VO_{2\,max}$) and bone densitometry at lumbar spine, proximal femur and body total (DXA, GE-Lunar MD +) were performed in all subjects. Results: The athletes had significantly better $VO_{2\,max}$ results as compared to the control group (p<0.05). BMD measurements did not differ significantly between athletes and controls at all sites examined (total body, p = 0.15; lumbar spine, p = 0.71; femoral neck, p = 0.62). Total lean mass and skeletal muscle mass indexes were significantly higher in cyclists as compared to health controls (p = 0.001), while body fat was significantly lower in the athletes (p<0.05). Positive significant correlation was demonstrated between total and lumbar spine BMD measurements and lean mass (r = 0.6029, p <0.001) and body fat (r = 0.5730, p<0.001). Conclusions: Our results demonstrate that cycling has significant beneficial effects on body composition, however no relevant impact on bone mineral density could be demonstrated.

Prevention of Hip Fracture in Aged-Care Facilities with Increased Use of Hip Protectors in Japan. T. Koike[1], Y. Orito*[1], H. Toyoda*[1], M. Tada*[1], R. Sugama*[1], S. Kobayashi*[2], K. Takaoka[1]. [1]Orthopaedic Surgery, Osaka City University Medical School, Osaka, Japan, [2]Orthopaedic Surgery, Shinshu University Medical School, Nagano, Japan.

To assess the effects of an intervention program designed to increase use of hip protectors in frail elderly women in aged-care facilities, we developed a cluster randomization trial in Japan. Two hundred fifty aged-care facilities in seven prefectures in Japan were invited and 76 units agreed to participate. Low adherence rate with protectors is a problem. Adherence will be largely determined by the motivation and competence of staff in nursing homes. To reduce burdens on staff in intervention group, the nursing staff selected 5 residents from each home in protector group and 15 residents in control group according to predefined inclusion criteria: >65 years old, female, not bedridden, with risk factors for falls. Therefore, facilities were randomly allocated in a 1:3 ratio to control and protector group. To keep the motivation of staff in nursing homes, monthly newsletters, posters, illustrated books were provided for all facilities. Furthermore, members of research team visited and conducted staff in all 76 nursing homes every month. We provided three hip protectors per resident (Safehip, Teijin, Japan). Totally 614 residents (308; protector, 306; control) were enrolled and 21 residents (12; protector, 9; control) were excluded from analysis by bedridden, hospitalization and death at 10 months of follow up. At baseline level, there were no important differences between intervention and control groups in age, body height, body weight, arm span, grip strength, %fat, calcaneus SOS (CM-100, Elk, Japan) and cognition level (MMSE). Six hip fractures occurred in the intervention group while 17 occurred in the control group; (RR 0.35; 95% CI 0.14 to 0.86). Adherence with wearing protectors at least daytime was 87.5%. There were 450 falls during follow up with 268 in the intervention group (a mean of 0.91 falls per person) and 182 in the control group (a mean of 0.61 falls per person). Especially among residents who had hip fractures, a mean of falls per person in the intervention group was greater than

control group, 2.83 and 1.94, respectively. We evaluated the hardness of floors in all facilities by measuring the maximum acceleration during the impact of an eight pounds weight and could not find the differences between two groups. Furthermore, there were no differences in the number of staff, rate of hip fractures, rate of falls between the intervention and control facilities recent three years. We conclude the increase in use of hip protectors reduce the number of hip fractures in aged-care facilities.

Resistance Training Using Mechanical Vibration as a New Form of Physical Exercise for Prevention of Osteoporosis. C. Kleinmond*[1], F. E. Thomasius[2], S. Scharla[3], M. Wiseman*[4], E. R. Weissenbacher*[5], M. Hartard[1]. [1]Faculty of Sport Science, AG-MSI, Technische Universitaet Muenchen, Munich, Germany, [2]Osteoporosis Study Society, Frankfurt, Germany, [3]Practice for internal medicine, Bad Reichenhall, Germany, [4]Leibniz Data Processing Center, Bavarian Academy of Sciences, Munich, Germany, [5]Department of Gynecology and Obstetrics, Faculty of Medicine, Klinikum Grosshadern, Ludwig Maximilians Universitaet, Munich, Germany.

High-frequency mechanical strain stimulates bone strength in animals. The effects of mechanical vibrations on the human skeleton however have rarely been examined, especially in postmenopausal women with a higher risk of osteoporosis. Therefore the aim of this randomized controlled 12 month long trial was to prove parameters of safety, bone mass, geometry and metabolism under vibration training (VRT) in comparison to conventional resistance training (CRT) in postmenopausal women. Hip and lumbar spine bone mineral density (BMD) were evaluated by DXA (Norland XR 26 Mark II). Tibial bone mineral content (BMC), bone geometry and volumetric BMD were assessed by pQCT (XCT-2000 of STRATEC) at shank levels of 4, 14 and 38%. 73 post- menopausal (mean age 56.04 ± 3.78) women were randomized to VRT (25 Hz, Galileo 2000®) or CTR. The training was performed twice weekly with an intensity of up to 50-60% (month 1-6) and 60-70% (month 7-12) of 1-RM in 2 sets each over the 12-month intervention time. 50% of each group decided to take a defined HRT (estradiol 2 mg, MPA 10 mg) half of the group did not receive HRT. After intervention there were no significant intergroup differences for parameters of safety, mean spinal or femoral BMD and tibial BMC, BMD and geometric parameters at all shank levels. In both groups we observed a significant increase of torque for the knee extension. Furthermore, the well-known bone spearing properties of HRT were shown in both groups, however, more significant under VRT. At the tibial shaft, HRT user showed higher values for cortical BMC at shank levels of 14% and 38% (14% HRT: 1.31% ± 1.49, Non-HRT: -1.17% ± 2.72, p = 0.016; 38% HRT: 2.21% ± 0.93, Non-HRT: -0.10% ± 1.72, p = 0.002). Smaller medullary areas were seen at 38% under VRT (HRT: -3.30% ± 2.19, Non-HRT: 0.26% ± 2.15, p = 0.003) possibly as a result of an increased endosteal apposition. We conclude that VRT was as safe and at least as effective as CTR. VRT was associated with a significant increase of bone mass in most regions and obviously influenced bone geometry at the distal tibia when in combination with HRT.

The Orthoses Spinomed and Spinomed Active Improve Posture, Trunk Muscle Strength and Quality of Life in Postmenopausal Women with Vertebral Fractures due to Osteoporosis: A Controlled, Randomized, and Prospective Clinical Trial. M. Pfeifer[1], L. Kohlwey*[1], B. Begerow*[1], H. W. Minne[2]. [1]Institute of Clinical Osteology, Bad Pyrmont, Germany, [2]Institute of Clinical Osteology and Clinic "DER FÜRSTENHOF", Bad Pyrmont, Germany.

Spinal orthoses may play an important role in the treatment of spinal fractures due to osteoporosis. So far, however, clinical trials addressing efficacy according to evidence-based medicine are rare. In a first pivotal study, an improvement in posture, trunk muscle strength, and quality of life after wearing the orthosis *Spinomed* has been demonstrated (Pfeifer M et al. 2004). In order to further improve compliance and increase overall acceptance and comfort, a new device has been developed: the initially used system with belts and Velcros has been integrated in a body, whereas the stabilizing back pad is fixed by textile strain elements at the spine. The back pad, which is easily deformable, may be adjusted to individual spinal deformities and is included in a pocket sewed on the back of the body (*Spinomed active*). One hundred and ten patients suffering from vertebral fractures and an angle of kyphosis of 60° and above were recruited via newspaper advertisements and invited to participate in this randomized, prospective clinical trial with the angle of kyphosis being the primary endpoint. Secondary endpoints include body height, trunk muscle strength, body sway, pain and limitations of daily living using standardized questionnaires. **Table 1** presents results after six months of treatment: both orthoses *Spinomed* and *Spinomed active* led to an improvement in posture, trunk muscle strength, and quality of life in patients suffering from osteoporotic vertebral fractures. Especially *Spinomed active*, which is completely invisible below normal clothes is characterized by a very high compliance and acceptance among patients and thus comes very close to an ideal orthosis for the treatment of osteoporosis.

Table 1: Results After Six Months

Parameter	Spinomed active ("Body", N=48)	Spinomed (N=31)	Controls (N=31)
Age (Years)	68.5 +/- 10.6	72.8 +/- 7.1	72.3 +/- 6.7
Baseline Vertebral Fractures (Number)	1.5 +/- 2.4	2.0 +/- 2.7	2.1 +/- 2.8
Angle of Kyphosis (Change in Degrees)	-6.2 +/- 5.3*	-7.9 +/- 4.9*	-1.6 +/- 5.5
Back Extensor Strength (Change in Newton)	+178 +/- 135*	+189 +/- 152*	+7 +/- 55
Body Sway (Change in mm)	-16.2 +/- 31.2*	-20.4 +/- 40.2*	-1.7 +/- 35.6
Vital Capacity (Change in %)	+5.6 +/- 18.9#	+6.1 +/- 20.5#	-9.9 +/- 16.1
Pain (Change in Score-Points)	-1.3 +/- 1.0* *:p<0.01	-1.5 +/- 1.2* #:p<0.05	+0.1 +/- 0.9

Bone Safety Evaluation: Balance Domain Validation. C. Recknor[1], S. Grant*[1], J. Empert*[2], F. Bride*[2], M. Shotwell*[2], B. Schell*[2]. [1]United Osteoporosis Centers, Gainesville, GA, USA, [2]Brenau University, Gainesville, GA, USA.

Patients with osteoporosis present with a unique set of musculoskeletal concerns. The Bone Safety Evaluation© (BSE) is a performance-based assessment tool that is designed to address these unique concerns by assessing spinal compression forces, balance, strength and flexibility. Test properties of the BSE were studied in order to determine the clinical and research utility of this tool. Initial tool validation involved establishing inter-rater reliability. To strengthen this test property, scoring guidelines and standardized instructions were developed. Concurrent criterion-based validity was tested in two stages. First, a convenience sample of 42 patients (age range 63-88) with osteoporosis who were tested with the BSE and a subtest of a computerized assessment of balance: computerized dynamic posturography-sensory organization test (CDP-SOT) was examined retrospectively to determine if a correlation existed between the balance domain on the BSE and CDP-SOT. Then, a prospective study of 37 participants (age range 52-84) with and without osteoporosis was conducted comparing the same instruments and another balance assessment: Modified Clinical Test of Sensory Interaction and Balance (mCTSIB). Among four people scoring the BSE an ICC was found to be ICC=.994. A Pearson Product Moment correlation coefficient of .61 ($p < .001$) was found between the BSE balance domain and CDP-SOT on the retrospective study. In the prospective study, a Pearson Product Moment correlation coefficient of .62 $p < .001$ was found between the BSE balance domain and CDP-SOT when one outlier was removed and .45 $p < .01$ was found between the BSE balance domain and mCTSIB. Additionally, an independent samples t-test was calculated between participants with and without osteoporosis. Results showed no significant difference between these groups on CDP-SOT or mCTSIB, but the BSE detected a difference ($df = 35$), $t = -3.0$, $p < .01$ (two-tailed)). The BSE has good inter-rater reliability and concurrent criterion-related validity with mCTSIB prospectively and CDP-SOT retrospectively and prospectively. Interestingly, the BSE appears to detect a significant difference between balance scores in participants with and without osteoporosis when the other tools did not. This finding is likely related to the BSE characteristic of dynamic motion (i.e. lifting, climbing, squatting) not present in the other instruments. Further validation of the other domains (spinal compression, strength and flexibility) and dynamic balance characteristics is planned. The BSE is a promising tool that addresses the unique musculoskeletal concerns of the osteoporosis population.

Evaluation of Vibration as a Mechanical Stimulation of Bone in Osteoporosis. A. C. A. Souza*[1], E. Dieter*[1], D. Barbieri*[2], R. Schneider*[1]. [1]Institute of Geriatrics, PUCRS University, Porto Alegre, Brazil, [2]Dep of Bio Engeneering, PUCRS University, Porto Alegre, Brazil.

From the premise that low frequency and high amplitude mechanical stimulus provide an osteogenic response in bone, we designed a study to observe this effect in the human skeleton by using a vibrating platform. The study was quantitative, experimental, and in a longitudinal perspective. It was approved by an Ethical Committee of the University as an experimental study for six months in order to evaluate the results in bone and possible side effects by the use of vibration. The subject sample was composed by 20 post menopausal women (59,9 ± 6.2 years) as an experimental group and 8 females (56,3±8,9) as control group. In both groups the diagnosis of osteoporosis were defined by DEXA. All subjects with history of osteoarthritis and osteoarthrosis were excluded. The mechanical platform was developed in order to produce a frequency of 28,8 Hz with an acceleration of 0,2 G. The subjects in experimental group stand in relaxed orthostasis on vibrating platform for 15 minutes, three times a week, during six consecutive months. Bone mass of lumbar spine (L1 to L4), of femur, (neck, throcanter and total)and tibia (ultradistal, mid and 1/3) were measured before(BMD1) and at six months (BMD2) by using a Dual Energy X Ray Absorptiometry - QDR 4500 Acclaim, Hologic Inc USA. Statistical analysis, were performed by using a SPSS® 11,5; Excel 2000; descriptive Statistics; Student t test with $p<0,05$, one-tailed, and paired. At the end of the study, a consistent and significant increase in bone mineral density was seen in the 1/3 region tibia in the experimental group (BMD1 0,985 BMD2 1,005 $p<0,03$). An important and not expected finding was a significant bone loss in ultra-distal region of tibia in the experimental group (BMD1 0,711 ± 0,091 BMD2 0,655 ± 0,085 $p<0,0014$). Femur and lumbar spine showed no significant changes intra group in the period. Comparing experimental and control group, femur showed significant improvement in experimental group. This prospective clinical study disclosed that

mechanical stimulus can have osteogenic effect, however depending of the bone location and intensity of stimulus an opposite effect could happen as it was seen in ultradistal tibia. These results are important findings for future studies on the effect of vibration on bone and also in the study of the impact during exercise when used for the treatment of osteoporosis**.**

The Pharmacokinetics (PK) of AMG 162 following Various Multiple Subcutaneous (SC) Dosing Regimens in Postmenopausal Women with Low Bone Mass. M. C. Peterson, B. J. Stouch*, S. W. Martin*. Amgen Inc., Thousand Oaks, CA, USA.

Receptor Activator of NF-κB Ligand (RANKL) is essential for the differentiation, function, and survival of osteoclasts. The PK of AMG 162, a fully human monoclonal antibody to RANKL, was evaluated in a randomized, double-blind, placebo-controlled, multidose study of AMG 162 in the treatment of postmenopausal women with low bone mass (average T-score -2.2). Eight cohorts of approximately 40 women each received AMG 162 at the following dose levels and frequencies: placebo, 6 mg, 14 mg, or 30 mg every 3 months; or 14 mg, 60 mg, 100 mg, or 210 mg every 6 months. Serum levels of AMG 162 were quantified using a validated ELISA methodology. PK parameters were calculated by noncompartmental methods. Following SC administration, AMG 162 exhibited nonlinear clearance across the dose range investigated; increasing 1.4-fold as dose decreased from 30 to 6 mg every 3 months and increasing 2.6-fold as dose decreased from 210 to 14 mg every 6 months. Absorption was rapid and prolonged with serum levels (~70-80% of maximum) detectable within 72 hours of dosing, and maximum serum concentrations occurring between 3 and 29 days post-dose. Maximum observed concentrations generally increased linearly with dose and dosing frequencies. Following peak concentrations, serum levels generally declined in a linear fashion until reaching a concentration threshold below which concentrations fell more rapidly, producing a biphasic concentration-time curve. Over 12 months, AMG 162 did not accumulate appreciably at any dose or dosing frequencies investigated, and the PK did not change substantially following multiple dosing. Consistent with PK, AMG 162 produced rapid (within 72 hours), profound (>70% reduction), and sustained (up to 6 months) reductions in the levels of the bone resorption marker, serum C-telopeptide, that were dose-dependent and reproducible following multiple dosing. AMG 162 was safe and well tolerated in this study. Two patients exhibited transient non-neutralizing antibody responses to AMG 162 that did not appear to be influential on AMG 162 disposition. In conclusion, the multiple dose disposition and PK of AMG 162 was well characterized in postmenopausal women with low bone mass, and these results support infrequent dosing of AMG 162 in future studies.

Safety, Effects on Markers of Bone Resorption and Pharmacokinetics of Cathepsin-K Inhibitor, AAE581, in Healthy Subjects. S. K. Roy*[1], G. Pillai*[2], T. G. Woodworth*[2], A. Skerjanec*[1], W. C. J. Collins*[2]. [1]Novartis Pharmaceutical Corporation, East Hanover, NJ, USA, [2]Novartis Pharmaceutical Corporation, Basel, Switzerland.

AAE581 is a specific direct inhibitor of the cysteine protease cathepsin-K intended for the prevention and treatment of osteoporosis. A double-blind, placebo-controlled trial was designed to assess the safety, tolerability, effects on markers of bone resorption and pharmacokinetics of single ascending oral doses of AAE581 in healthy male and female subjects. Six dose levels were evaluated sequentially: 10 mg, 25 mg, 50 mg, 100 mg, 200 mg and 400 mg. In total, 44 subjects (25 males and 19 females) ranging in age from 18 to 45 years participated in the study: 32 received AAE581 and 12 placebo. The overall tolerability of AAE581 was good and no serious adverse events occurred. A dose-dependent suppression in biochemical markers of bone resorption (serum CTx and NTx), that is clearly discernible from circadian variation, was noted. At dose levels of ≥25 mg approximately 90% suppression was noted 6-12 hours post-dose. Pre-treatment biomarker concentrations were reached approx. 48 hours after single dose treatment. Experience with bisphosphonates indicates that, after drug administration biomarker concentrations decrease, reaching a nadir of 65 - 83% suppression at 1 month with a gradual recovery of the biomarker response over the next few months. In comparison, AAE581 clearly demonstrated a more rapid onset and offset of effect on the order of hours and days, respectively. AAE581 pharmacokinetics was characterized by rapid absorption across all doses, with t_{max} values ranging from 1.0 h to 2.25 h. The mean C_{max} and AUC values increased proportionally with increasing dose. AAE581 exhibited moderate plasma clearance with mean Cl/F values ranging from 39.4 ± 4.22 L/h (10 mg dose) to 29.6 ± 2.36 L/h (400 mg dose). The AAE581 mean $t_{1/2}$ ranged from 19.9 ± 1.95 (10 mg dose) to 11.7 ± 0.79 h (400 mg dose). Active metabolite, AEE325, mimicked the time course of the parent compound, but accounted for only 8 - 16.6% of the AAE581 systemic exposure across the dose range. The effect of food on AAE581 and AEE325 pharmacokinetics was evaluated in 5 subjects who received a 200 mg dose of AAE581. Prolongation of mean t_{max} from 1.80 h to 3.20 h, 19% decrease in Cmax and 12% increase in AUC of AAE581 was observed in presence of food. These changes are not considered to be clinically relevant. These data show that AAE581, given as a single dose to a non-osteopenic population, is well tolerated and potently decreases serum markers of bone resorption.

The RANKL Inhibitor RANK-Fc Has Potent Antiresorptive Efficacy but Does not Affect Host Immune Responses to Influenza Infection. R. E. Miller*, D. Branstetter*, J. Jones*, L. Cowan*, W. C. Dougall. Amgen Inc., Seattle, WA, USA.

The receptor activator of NF-κB (RANK) and its ligand (RANKL), a tumor necrosis factor (TNF) family cytokine, are essential for osteoclast differentiation and bone resorption. Osteoprotegerin (OPG) is the endogenous soluble receptor inhibitor of RANKL. We investigated whether RANKL inhibition by recombinant mouse RANK-Fc has similar anti-osteoclast efficacy to recombinant OPG-Fc. Since the RANKL pathway is implicated in mouse lymphocytic maturation and activation as well, we also tested if RANK-Fc would affect host immune resistance responses to influenza infection. The relative efficacy of RANK-Fc to OPG-Fc was tested in a Vitamin D hypercalcemia model. C57/BL6 mice received a single dose of 0, 10, 100, 500, or 1000 µg RANK-Fc or 100 g OPG-Fc 2 hours pre-challenge on Day 0. Mice were sacrificed on Days 1, 2, 4, 6, 8, 12, 16, and 20 followed by analysis of serum markers and skeletal parameters. Single doses of ≥100 µg RANK-Fc completely suppressed the elevation of serum calcium at Day 4 and later timepoints, similar to that observed with OPG-Fc. Both RANK-Fc and OPG-Fc suppressed the bone turnover marker, serum pyridinoline, at Day 4 and thereafter. At Day 6, both immature and mature osteoclasts were completely depleted by high doses (500 and 1000 µg) of RANK-Fc or OPG-Fc 100 µg. The effects of RANKL inhibition by RANK-Fc on immune parameters were tested in a mouse respiratory influenza virus host-resistance model. Treatment with dexamethasone, a known immunosuppressant, resulted in enhanced and prolonged virus infection and decreased virus-specific IgG levels. RANK-Fc (100 µg or 500 µg) had no deleterious effect on viral clearance or on the influenza-specific IgG response. In addition, RANK-Fc had no immunotoxicologic effects on the ability to acquire T-cell dependent antigen immunity, as measured by antibody-forming cell induction, or on the innate immune response, as measured by interleukin (IL)-Iβ, TNF-α, or IL-6 induction in the lung. Viral clearance requires an intact immune system that produces cytokines and antibodies and stimulates the activities of natural killer cells, macrophages, and cytotoxic T-cells. Influenza virus is a T-dependent antigen; hence, formation of antibody to influenza virus requires functional T and B cells, and functional antigen presenting cells. Thus, RANKL inhibition by RANK-Fc, at doses shown to have antiresorptive efficacy, did not appear to inhibit host immune responses, suggesting that a RANKL inhibitor may be a safe and effective therapeutic for treating excess bone loss.

Identification of Small Molecule Stimulators of Osteoprotegerin Secretion. S. Kim[1], S. Chang*[2], H. Sung*[2], Y. Kim*[2], S. Cho*[2], S. Ko*[3]. [1]OCT Inc. Dept. of Dental Pharmacology, Dankook University, Cheonan, Republic of Korea, [2]OCT Inc., Cheonan, Republic of Korea, [3]Dept. of Oral Biochemistry, Dankook University, Cheonan, Republic of Korea.

Osteoprotegerin (OPG) is a soluble member of the tumor necrosis factor receptor family, which regulates bone mass by inhibiting osteoclast differentiation and activation. Novel Small Molecule Stimulators of OPG secretion is currently under investigation for osteoporosis treatment. We used high-throughput screening for approximately 16,000 compounds of the Korea Chemical Bank to identify compounds that increase OPG secretion from osteoblastic cell. We found two compounds (O-1, O-2) significantly increased OPG secretion. Secretion of OPG, which was detected from MG63 cell by sandwich ELISA method, showed marked increases after treatment of compounds. Individually, a 1.5 to 2.0 fold increase in the OPG secretion level was observed at the concentration of 1-2 μM compared with the control. Treatment of these compounds resulted in significant decreases in number of TRAP (+) multinucleated cells in total bone marrow cell culture. The inhibitory effect was dose-dependent. These results provide proof of the concept that these compounds can be applied to the treatment of osteoporosis. These hit compounds are under development as a candidate molecule for antiosteoporosis new drugs.

Age-Associated Iron and Free-Radical Accumulation in Bone: Implications for Osteoporosis and a New Ttarget for Prevention and Treatment by Chelation. G. Liu, P. Men*, G. H. Kenner*, S. C. Miller. Radiology/Radiobiology, University of Utah, School of Medicine, Salt Lake City, UT, USA.

Iron is an essential nutrient, but it is also a powerful catalyst for auto-oxidation reactions creating harmful free radicals in cells and tissues. The body has developed numerous mechanisms to sequester iron and thus limit free radical production, but storage iron accumulates with age and is considered a primary catalyst in many free-radical associated diseases. The skeleton is no exception and skeletal disease is reported in iron overload conditions such as hemochromatosis and thalassemias. There is evidence that iron accumulation is inversely related to estrogen levels in women and we hypothesize that this may facilitate the development of osteoporosis in a variety of disease conditions. Using electron paramagnetic resonance spectroscopy (EPR) techniques, we have documented an increase in free iron and long-lived organic free radical accumulation in bone after menopause in women and following ovariectomy (Ovx) in rats. We sought to determine the ability of a novel amphipathic, orally administered transition metal chelator to mitigate changes in bone after ovariectomy in aged rats. The chelator, 1-N-docosyl-

triethylenetetramine-pentaacetic acid (C22TT), was given orally three times per week for 9 weeks beginning the day after Ovx. The free iron content of the bone from the untreated Ovx rats was about 22% greater than the sham-operated controls, as measured by EPR. The free iron in the bones from the C22TT-treated animals was about 60% of the untreated Ovx rats and about 73% of the sham controls. Importantly, the C22TT treatments significantly slowed the loss of bone mineral density (BMD) and cancellous bone volume by about 50% and also mitigated the deterioration of bone microstructure (from pQcT and microCT) after ovariectomy. Histomorphometric analyses show a significant reduction in cancellous bone eroded surface, with a trend ($p > 0.05$ but < 0.1) for greater cancellous bone formation rates. These results add further support to the somewhat controversial theory that age-associated iron accumulation in tissues increases the risk of a variety of diseases, including atherosclerosis, cancer, diabetes, dementia and others. This study suggests that skeletal diseases might now be added to this list. While there is evidence from other studies that free radical reduction does offer some skeletal protection, this study identifies a new target and a potential therapeutic strategy for the treatment of osteoporosis and perhaps other age-related diseases. Our findings may also help raise awareness about iron nutrition, iron supplements and Western diets that may be associated with excess iron intake and accumulation.

RANKL Inhibition Increases Extrinsic Bone Strength and Maintains Intrinsic Bone Strength in Transgenic Rats that Continuously Overexpress a Secreted Osteoprotegerin Transgene. M. S. Ominsky[1], T. J. Corbin*[2], X. Li[1], S. Morony*[1], K. S. Warmington*[1], Z. Geng*[1], M. S. Grisanti*[1], H. L. Tan*[1], V. Shen*[3], B. Bolon*[1], J. McCabe*[1], P. J. Kostenuik[1]. [1]Metabolic Disorders, Amgen Inc., Thousand Oaks, CA, USA, [2]Functional Genomics, Amgen Inc., Thousand Oaks, CA, USA, [3]Skeletech Inc., Bothell, WA, USA.

The optimal level of bone turnover suppression for fracture prevention is unknown. RANKL inhibition provides rapid and sustained reductions in bone turnover. The relationship between these changes and bone strength is unclear. We therefore created a new animal model of continuous turnover suppression to evaluate the relationships between bone turnover and bone strength. Transgenic rats were made to overexpress a soluble rat osteoprotegerin transgene (OPG-Tg) driven by a liver-specific (ApoE) promoter. OPG is the endogenous inhibitor of RANKL, a TNF family member that is critical for osteoclast formation, activation, and survival. Female OPG-Tg rats (n = 10) and age-matched wild-type (WT) controls (n = 5) were analyzed at 16, 20, 24 and 28 weeks of age. Dramatic and continuous suppression of bone turnover was demonstrated in OPG-Tg rats by 80%-90% reductions in serum TRAP-5b at each age ($p<0.01$ vs WT controls). Histomorphometry of the lumbar vertebrae (LV) of 28-week-old OPG-Tg rats showed a 98% reduction in osteoclast surface and a 48% increase in bone volume (BV/TV) ($p<0.01$ vs age-matched WT controls). DXA of the LV revealed significantly greater BMD in OPG-Tg rats at all ages (22%-30% greater than age-matched WT controls, $p<0.01$). These changes were associated improvements in vertebral bone strength. Compression testing showed that the 5th LV of 28-week-old OPG-Tg rats could withstand a 2-fold greater maximum load and had 2.6-fold higher stiffness compared to age-matched WT controls ($p<0.01$). These extrinsic parameters are influenced by bone size and density. Intrinsic parameters, such as ultimate strength, elastic modulus, and toughness, are normalized to bone mass (BV/TV) and are therefore indicative of bone matrix strength and quality. Continuous suppression of RANKL in OPG-Tg rats showed no significant differences in these intrinsic material properties compared to WT controls. These results show that profound and continuous suppression of bone turnover, via RANKL inhibition, results in improvements in vertebral bone mass and strength. No changes were observed in intrinsic bone strength, despite a 98% reduction in osteoclast surface. These data suggest that RANKL inhibition improves rat bone strength by increasing bone mass and maintaining normal bone tissue strength and quality.

RANKL Inhibition Improves Trabecular Architecture in Female Mice. M. S. Ominsky, X. Li, M. S. Grisanti*, K. S. Warmington*, H. L. Tan*, P. J. Kostenuik. Metabolic Disorders, Amgen Inc., Thousand Oaks, CA, USA.

RANKL is the primary physiological mediator of osteoclast formation, function, and survival. RANKL inhibition leads to rapid, profound, and sustained suppression of bone resorption and increased bone mineral density (BMD). While BMD is an important component of strength in cancellous bone, the organization and mineralization of bone mass are important co-factors. Losses of trabecular number, thickness, plate-like structures, and connectivity are hallmarks of osteoporosis and may be associated with increased fracture risk, independent of reduced BMD. We used osteoprotegerin (OPG-Fc) to examine the effects of RANKL inhibition on BMD and trabecular architecture in 2-3 month old intact female mice. OPG-Fc was injected SC twice weekly for 3 weeks at 5 mg/kg (n = 8) while control animals (n = 8) received vehicle. Distal right femurs and lumbar vertebrae (L5) were Micro-CT-scanned ex-vivo (GEHC eXplore Locus SP) and reconstructed at 18µm isotropic voxel resolution. A region of trabecular bone was selected within the distal femur and vertebral body relative to anatomical landmarks and bone length, and analyzed for trabecular parameters. OPG-Fc treatment significantly increased bone mass, mineral density, and mineralization at both sites (Table 1). Trabecular architecture was improved as reflected in significant increases in trabecular thickness, number, connectivity, and decreased spacing. Structural Model Index was decreased 25% ($p<0.01$) in the distal femur with OPG treatment, indicating a preservation of more plate-like structures. No group differences were found in degree of anisotropy, indicating that RANKL inhibition does not alter the normal trabecular orientation. The ability of OPG to increase bone mass and mineralization, while improving aspects of trabecular architecture, suggests that RANKL inhibition results in improved bone quality.

Table 1: % Difference Between OPG- and Vehicle-treated Mice
[Significantly greater than vehicle-treated controls, *$p<0.05$]

MicroCT Parameter	Distal Femur	Lumbar Vertebra
Trabecular BV/TV	+ 162*	+ 56*
Trabecular vBMD [mg/cm^3]	+ 54*	+ 36*
Trabecular Bone Matrix Mineral Density [mg/cm^3]	+ 14*	+ 5*
Trabecular Thickness	+ 13	+ 22*
Trabecular Number	+ 70*	+ 28*
Trabecular Spacing	- 40*	- 42
Trabecular Connectivity	+ 108*	+ 7

AMG 162, a Fully Human RANKL Antibody, Increases Bone Mass and Bone Strength in Cynomolgus Monkeys. J. Atkinson[1], P. Cranmer*[1], T. Saunders*[1], M. Niehaus*[2], S. Y. Smith[3], A. Varela*[3], M. S. Ominsky[1], M. E. Cosenza*[1], P. J. Kostenuik[1]. [1]Amgen Inc., Thousand Oaks, CA, USA, [2]Covance Laboratories GmbH, Munster, Germany, [3]CTBR, Montreal, PQ, Canada.

AMG 162 is a fully human monoclonal antibody that inhibits bone resorption by neutralizing RANK Ligand (RANKL). RANKL inhibition increases BMD in human and non-human primates, but the effects of AMG 162 on bone mass and strength have not been previously described. Male cynomolgus monkeys (4-5 years old) were treated with AMG 162 (50 mg/kg/mo, SC; n = 8) or vehicle (Veh; n= 8) for 1 year. Bone mass, mineral density, and strength were determined at 6 and 12 mos (n=3), and following a 3-mo non-treatment recovery period (n=2). Right femurs were analyzed by pQCT for bone mineral content (BMC) and geometry, and lumbar vertebrae (L3 & L4) were analyzed by DXA for BMC and bone mineral density (BMD). Bone strength was measured by destructive mechanical testing of the femoral diaphysis (3-point bending) and the vertebrae (compression). At the femoral diaphysis, 1 year of AMG 162 treatment resulted in significantly greater cortical area (26%) and cortical BMC (30%) ($p<0.05$ vs Veh). These increases in bone mass were associated with a 40% increase in femur bending load ($p<0.01$ vs Veh). Intrinsic strength parameters, which are normalized to femoral bone mass, were not significantly altered by AMG 162. At the lumbar vertebrae, 1 year of AMG 162 treatment resulted in significantly greater BMC (45%) and BMD (40%) ($p<0.05$ vs Veh). These changes were associated with significant ($p<0.05$ vs Veh) increases in maximum compressive load (101%), apparent strength (97%), and toughness (78%). When bone quality is normal, increases in bone mass should correlate positively with increases in bone strength. We combined all time points within each group to obtain regression analyses that compared bone mass and strength. At the femoral diaphysis, strong positive correlations were shown between maximum load and cortical BMC or cortical area ($r^2 \geq 0.84$ for both treatment groups, $p<0.002$). In the vertebra, strong positive correlations were observed between maximum load and BMC ($r^2 \geq 0.74$ for both treatment groups; $p<0.006$). These results show that AMG 162 increases bone mass at both trabecular and cortical sites in cynomolgus monkeys. Extrinsic bone strength increased in proportion to improvements in cortical area and BMC, while intrinsic bone strength was maintained by AMG 162. The strong positive correlation between cortical area and femur bending load confirms the important contribution of cortical geometry for bone strength. The ability of AMG 162 to improve bone density, cortical geometry, and strength suggests that RANKL inhibition is a promising therapeutic approach for reducing fractures.

Improved Delivery and Retention of Osteoprotegerin to Bone after Conjugation to a Bisphosphonate Drug. M. R. Doschak*[1], C. M. Kucharski*[1], J. E. I. Wright*[1], R. F. Zernicke[2], H. Uludag[1]. [1]Chemical & Materials Engineering, University of Alberta, Edmonton, AB, Canada, [2]Faculties of Kinesiology, Medicine & Engineering, University of Calgary, Calgary, AB, Canada.

The loss of bone mineral density (BMD) through up-regulated osteoclast-mediated resorption is of great clinical concern for many diseases of bone. The peptide factor osteoprotegerin (OPG) is known to block osteoclastogenesis and conserve BMD, however, high quantities of OPG need to be administered to elicit any therapeutic efficacy. The purpose of this study was to improve the specificity of OPG delivery to bone by the chemical conjugation of OPG to a "bone seeking" bisphosphonate (BP) carrier. We chemically conjugated recombinant human OPG monomer (20 kDa) to a bisphosphonate (thioBP) using the heterobifunctional cross-linker N-succinimidyl-3-(2-pyridyldithio) propionate (SPDP). The OPG-thioBP conjugate was characterized using high performance liquid chromatography (HPLC) and polyacrylamide gel electrophoresis (PAGE). The conjugate was then radiolabeled with I-125 and tested with hydroxyapatite (HA) powder *'in vitro'* to assess the affinity for bone mineral. For all experimentation, the OPG-thioBP conjugate was compared against control OPG, that was incubated in the absence of the cross-linker. The conjugates were tested for improved targeting to bone *'in vivo'* after radiolabeling and intravenous injection into rats, followed by pharmacokinetic (PK) evaluation of bones and soft tissues at 24 and 72 hr. Our HPLC results confirmed the chemical modification of the OPG-thioBP conjugate with increased retention on a C4 protein column prior to elution. PAGE also confirmed that the modified OPG-thioBP conjugate was not degraded, and ran as a single protein band at the expected molecular weight for OPG. HA binding experiments showed that the OPG-thioBP conjugate had a 10-fold greater affinity for bone mineral in a phosphate buffer and in the presence of donor serum, as compared to control OPG. PK evaluations *'in vivo'* in the rat confirmed that the

uptake by bone of systemically injected radiolabeled OPG-thioBP conjugate was significantly increased (2-fold) over that of control OPG at the 24 hr time point. Furthermore, the significantly improved retention of the OPG-thioBP conjugate was confirmed at the 72 hr time point, whereas control OPG was barely detectable in bone. In conclusion, the systemic administration of BP-conjugated OPG resulted in the significantly improved targeted delivery, and retention of the peptide factor to bones *'in vivo'* in the rat. Thus, peptide-BP conjugation targeting strategies showed significant therapeutic implication for use in osteopenic bone diseases, including osteoporosis and the arthritidies.

Phase 2 Study of AMG 162 in Postmenopausal Women: Subanalyses and Supplemental Safety. S. B. Cohen[1], E. M. Lewiecki[2], Y. Liu[3], D. J. Zack*[3], L. A. Fitzpatrick[3]. [1]Radiant Research, Dallas, TX, USA, [2]New Mexico Clinical Res and Osteoporosis Cent, Albuquerque, NM, USA, [3]Amgen Inc., Thousand Oaks, CA, USA.

AMG 162 is a fully human monoclonal (IgG_2) antibody that binds to RANK Ligand to inhibit osteoclast formation, function, and survival. We have previously reported that AMG 162 treatment for 1 year rapidly decreased markers of bone turnover and increased bone mineral density (BMD) at the spine (4.6%), total hip (3.6%), and distal 1/3 radius (1.3%; 60 mg 6-monthly dose) compared with placebo in a randomized, dose-ranging, phase 2 study in postmenopausal women with low bone mass. We hereby report BMD and bone turnover data analyzed by subgroups including baseline weight and lumbar spine T-score. Safety, including immune function, was assessed for overall treatment groups. Following 1 year of treatment, greater increases from baseline in lumbar spine BMD were observed in patients treated with AMG 162, 6-monthly, compared with placebo for each baseline weight subgroup (Table). AMG 162 treatment also reduced serum CTX levels regardless of baseline weight. An overall mean reduction in serum CTX of 62.6% ± 7.9% occurred in the AMG 162 60-mg, 6-monthly group compared with a mean change of 0.1% ± 5.9% in the placebo group. When analyzed by baseline T-score, lumbar spine BMD increased by 2.2% to 6.8% with AMG 162 treatment (6-monthly) for patients with T-score <-2.5 compared with changes of -1.1% for placebo and 5.0% for alendronate. The corresponding changes in patients with baseline T-score ≥-2.5 were 3.3% to 5.3% (AMG 162 6-monthly), -0.6% (placebo), and 4.5% (alendronate). Incidence of adverse events, including infections, was not different between AMG 162-treated patients overall and placebo or alendronate. Upper respiratory tract infection was the most common infection (13% placebo, 19% AMG 162, 17% alendronate). No significant differences in white blood cell or lymphocyte counts and no significant changes in T, B, or NK cell (CD3, CD4, CD8, CD19 and CD16/56) numbers occurred across all dose and treatment groups. Therefore, in this study AMG 162 treatment increased bone mass at the lumbar spine regardless of patient weight or bone density at baseline and may be an effective and well-tolerated treatment for osteoporosis.

Table. Percent Change from Baseline in Lumbar Spine BMD at 1 Year by Baseline Weight

	Placebo		AMG 162 (6 monthly dosing)							
			14 mg		60 mg		100 mg		210 mg

Cathepsin K-Deficiency Results in Bone Fragility in Mice. C. Y. Li*[1], B. D. Gelb*[2], K. J. Jepsen[1], M. B. Schaffler[1]. [1]Orthopaedics, Mount Sinai School of Medicine, New York, NY, USA, [2]Pediatrics/Human Genetics, Mount Sinai School of Medicine, New York, NY, USA.

Cathepsin K (CatK)-deficiency has been shown to markedly impair osteoclastic function, leading to osteosclerosis in both humans and in mice. This osteosclerosis (pycnodysostosis) in humans has a significant bone fragility component, the bases of which are not understood. Bone strength in CatK-knockout (KO) mice was reported to be unchanged from normal mouse bone. However, the previous studies did not adequately characterize the overall fracture resistance of bones from CatK-KO mice. In order to address this issue, we examined the bone mechanical properties of CatK-deficient mice. Femoral mid-diaphyses from ten-week-old wild type (wt), heterozygous and homozygous mice were loaded to failure in four point-bending test using a servohydraulic material test system at a displacement rate of 0.05 mm/sec. Maximum load (ultimate force that the specimen sustained), stiffness (the slope of the initial, linear portion of the load-deformation curve), post-yield deflection (deflection at failure minus deflection at yield), and work-to-failure (the area under the load-deformation curve prior to failure) were determined. Cross-sectional architecture was assessed at the mid-diaphyses of contralateral limbs. Despite markedly (30%) increased cortical bone area in CatK-deficient mice, diaphyseal maximum load and stiffness did not differ significantly from wt bone, consistent with previous reports. However, CatK-deficient bones were dramatically impaired in their ability to resist fracture. They were more brittle (60% decrease in post-yield deflection), and work-to-fracture was reduced by nearly 40% compared to wild-type bones. Because CatK-KO morphology was not altered, the increased brittleness of CatK-KO femurs must be a consequence of altered matrix construction. Analysis of femoral cross-sections by polarized light microscopy revealed that the predominantly organized (lamellar-like) matrix architecture of wt was severely altered in CatK-KO (Fig 1). Ongoing studies will test whether there are accompanying alterations in mineralization. These results indicated that the increased fragility associated with impaired osteoclast function results from a failure of modeling and remodeling to establish normal matrix architecture during growth and development.

Treatment of Bone Loss after Renal Transplantation in Children: Alfacalcidol versus Calcitonin Therapy. A. A. M. El-husseini. Nephrology, Mansoura Urology and Nephrology Center, Mansoura, Egypt.

Background. Osteoporosis is a well-known complication of renal transplantation in children. We conducted a randomized trial comparing alfacalcidol with calcitonin for the treatment of bone loss. **Methods.** Among 59 young patients who received live related renal transplant and were subjected to dual energy x-ray absorptiometry (DEXA), 30 patients had low bone mineral density (BMD) (z-score < -1) were enrolled onto the study. Their mean age at time of transplantation was 13.5 ± 3.4 years and the mean duration after transplantation was 46 ± 32 months. Patients with low BMD were randomized into two equal homogeneous groups: group 1 received daily alfacalcidol 0.25 microg by mouth and group 2 received 200 IU /day nasal spray calcitonin. Every patient in both groups received daily 500-mg calcium carbonate supplements. Parameters of bone metabolism (intact parathyroid hormone, serum osteocalcin and urinary deoxypyridinoline) and BMD were assessed before and after the study period. Estimates of bone loss and the incidence of fractures among untreated patients were obtained from a reference group of 15 prospectively recruited patients who received renal transplants within the same period as the intervention groups. **Results**. At one year, the BMD at the lumbar spine had increased from -2.3 to -0.5 in the alfacalcidol group and from -2.3 to -1.0 in the calcitonin group while it was decrease from -2.2 to -2.5 in the reference group. Incidence of vertebral fractures did not differ significantly among the groups (13.3 percent in the calcitriol group, 6.7 percent in the calcitonin and the reference groups). Serum intact parathyroid hormone level decreased significantly in the alfacalcidol group compared with the calcitonin group (P = 0.042). Apart from transient hypercalcemia in 1 patient in the alfacalcidol group, no other significant adverse effects were noted. **Conclusion**. This study suggested the value of alfacalcidol and calcitonin agents in the treatment of osteopenia and osteoporosis in young renal transplant recipients. These therapies were safe, tolerable, simple to administer and potentially applicable to other renal transplant patients.

Comparison of the Effects of Alfacalcidol to Vitamin D Plus Calcium in Spinal BMD in Postmenopausal Osteoporosis. R. Nuti[1], G. Bianchi[2], M. L. Brandi[3], R. Caudarella[4], E. D'Erasmo*[5], C. Fiore[6], G. Isaia[7], G. Luisetto*[8], M. Muratore*[9], P. Oriente*[10], S. Ortolani[11]. [1]University of Siena, Siena, Italy, [2]Ospedale La Colletta, Genoa, Italy, [3]University of Florence, Florence, Italy, [4]University of Bologna, Bologna, Italy, [5]University La Sapienza, Rome, Italy, [6]University of Catania, Catania, Italy, [7]University of Turin, Turin, Italy, [8]University of Padua, Padua, Italy, [9]Presidio Ospedaliero G.Cascione - A.Galateo, Lecce, Italy, [10]University of Naples, Naples, Italy, [11]Istituto Auxologico Italiano, Milan, Italy.

In a randomized multi-center double blind, double dummy parallel group study a comparison of the efficacy and safety of 1µg alfacalcidol to 880 IU vitamin D plus calcium carbonate (1 g calcium) once daily per os was performed on 148 postmenopausal

osteoporotic Caucasian patients with normal vitamin D serum levels for 18 months. BMD was measured at baseline, 12 and 18 months. Safety parameters were followed during the entire study period. Sixty-nine (90.8%) in the alfacalcidol group and 67 (93.1%) in the vitamin D group were included in the ITT analysis. Lumbar BMD in the alfacalcidol group increased by 0.017 (2.33%) and 0.021 g/cm^2 (2.87%) from baseline ($p < 0.001$) at 12 and 18 months, respectively, whereas in the vitamin D plus calcium group the increase was 0.005 g/cm^2 (0.70%) from baseline (N.S.) at both 12 and 18 months. The higher changes from baseline in the alfacalcidol group, as compared to the changes in the vitamin D plus calcium group at both 12 and 18 months, were found to be statistically significant ($P = 0.018$ and $P = 0.005$). A small increase of mean femoral BMD was achieved in both groups (N.S.). Adverse events were similar in both groups. No significant differences were noted between the groups in serum calcium. In conclusion, alfacalcidol was found to be superior in significantly increasing lumbar BMD as compared to vitamin D plus calcium while safety characteristics were found to be similar in both treatments.

SU459

BMD and Bone Markers in Patients with a Recent Low-Energy Fracture: Effect of Treatment with Vitamin D and Calcium. M. F. Hitz[1], P. C. Eskildsen*[2], J. B. Jensen*[1]. [1]Osteoporosis and Bone Metabolic Unit, Copenhagen University Hospital Hvidovre, Hvidovre, Denmark, [2]Medical Department, Roskilde University Hospital in Koge, Koge, Denmark.

The present study evaluate the effect of treatment with calcium and vitamin D for one year on Bone Mineral Density (BMD) and bone-markers in patients with a recent low energy fracture. The trial was double blinded with a prospective design. Patients with a fracture of the hip (LEF) or an upper-extremity-fracture (UEF) were randomly assigned to: 1000 mg $CaCO_3$+1000 IU cholecalciferol or placebo (200 IU cholecalciferol). Baseline visit was performed 14 days post-fracture for the LEF-group and 27 days post-fracture for the UEF-group. We measured BMD of the total hip (HBMD) and lumbar spine (LBMD) by Dual Energy X-ray Absorptiometry (DEXA) and physical performance by Timed Up and Go-test (TUG) at inclusion and after 12 months. Serum levels of vitamin 25-OH-D, parathyroid hormone (PTH), ICTP (crosslinked carboxyterminal telopeptide of type I collagen), osteocalcin and N-propeptides of collagen type I (PINP) were measured at baseline and 1, 3 and 12 months after inclusion. We included 122 patients (84% women) with a mean age of 70 years (SD = 11 years). 79 patients completed the study. For the LEF-group bone turnover increased to a maximum after 1 month and declined there after, osteocalcin levels increased throughout the study. Intervention significantly decreased bone turnover. PTH decreased in the intervention group ($p<0.001$) but increased in the placebo group ($p<0.001$). For the UEF-group bone-markers declined post-fracture and intervention reduced osteocalcin and ICTP levels significantly. No significant change was demonstrated for levels of PTH in either the intervention or the placebo group. LBMD increased significantly by 1.58% for patients below 70 years of age and reduced the BMD loss for patients older than 70 years regardless of fracture type. ICTP and ΔLBMD correlated with the results of TUG-test. We conclude that one-year intervention with 1000 mg $CaCO_3$ and 1000 IU cholecalciferol to patients with a recent low energy fracture reduced bone turnover, increased BMD in patients younger than 70 years of age and decreased the bone loss in older patients. Effects of treatment were related to physical performance.

Disclosures: ***M.F. Hitz****, None.*

Rapid Correction of Vitamin D Inadequacy in Nursing Home Residents. S. Agrawal*, D. Krueger, J. Engelke*, R. Przybelski*, N. Binkley. University of Wisconsin Osteoporosis Clinical Research Program, Madison, WI, USA.

Approximately 1.6 million Americans currently reside in nursing homes (NH); a number expected to triple by 2030. Osteoporosis and vitamin D inadequacy are epidemic in this population. Vitamin D deficiency contributes to bone loss, muscle weakness, and increased falls risk; this deficiency combined with osteoporosis leads to a fracture incidence of approximately 10% annually among NH residents. However, approaches to rapidly correct vitamin D inadequacy among NH residents have received limited attention. This study evaluated the effect of oral high dose vitamin D2 (ergocalciferol) on serum 25-hydroxyvitamin D (25OHD) status, markers of skeletal health and gait speed. This ongoing study examined 23 NH residents. Volunteers were assigned to receive vitamin D based upon serum 25OHD; those individuals with inadequacy (defined as a 25OHD < 25 ng/ml) received vitamin D2 50,000 IU, 3 times weekly for 4 weeks; the others received no change to their routine care. The investigative staff were blinded to treatment group assignment. Serum for 25OHD and other skeletal health measurements (bone specific alkaline phosphatase [BSAP], n-telopeptide of type 1 collagen [NTx], parathyroid hormone [PTH], and calcium) was obtained at baseline and at 4 weeks. Timed 4-meter walk tests were performed at baseline and at 4 weeks. Average subject age was 87.4 (range 75 to 99) years. There were no between group differences in age, gait speed, serum calcium, BSAP or NTx at baseline. Mean (SEM) total 25OHD concentration increased ($p < 0.0001$) from 16.6 (1.9) to 61.6 (5.0) ng/ml in the D2 treated group and remained unchanged in the control group at 32.9 ng/ml. Serum 25OHD3 remained stable in the control group, but declined ($p < 0.0001$) with D2 treatment from 15.8 (2.0) to 9.4 (1.3) ng/ml over the 4 weeks of study. Mean serum calcium was 9.5 (0.1) and 9.6 (0.1) mg/dl at baseline and after 1 month of vitamin D2. Hypercalcemia was not observed. Mean PTH concentration decreased ($p < 0.05$) from 48.7 (10.3) to 37.2 (8.3) pg/ml in the D2 treated group and remained unchanged in the control group. No treatment-induced changes were observed in BSAP, NTx or gait speed. In conclusion, 4 weeks of high-dose oral vitamin D2 supplementation safely increases serum 25OHD and reduces PTH concentrations. The absence of changes in bone turnover markers and gait speed likely reflects short study duration and small sample size. It seems likely that rapid vitamin D repletion of NH residents would reduce fracture risk, however this supposition requires prospective study confirmation. As vitamin D3 has recently been reported to be more potent than D2, the observed reduction in 25OHD3 following D2 treatment is interesting and merits further evaluation.

Long-Term Treatment Of Hypovitaminosis D. Calcidiol Or Cholecalciferol? E. Casado*[1], M. Larrosa*[1], A. Gómez*[1], E. Fernández*[1], E. Berlanga*[2], J. Gratacòs*[1]. [1]Rheumatology, Hospital Sabadell, Sabadell, Spain, [2]Laboratory, UDIAT. Coporació Sanitària Parc Taulí., Sabadell, Spain.

There are different vitamin D metabolites for the treatment of hypovitaminosis D. It is not well known which of them is more efficacious for the long-term treatment. In a previous publication (Rev Esp Reumatol 2003; 30:548-553) we proved that calcidiol 16.000UI/week for 4 weeks is a useful treatment regimen to normalize 25-OHD3 levels in patients with vitamin D deficiency. The aim of the study was to compare the long-term efficacy of calcidiol vs cholecalciferol to maintain normal levels of 25-OHD3 in patients with previously corrected hypovitaminosis D. In a longitudinal study (12 months of follow-up) 99 out-patients visited in our department were included. 88/99 female (89%), mean age 72±9.7 years (43-88). All of them had a hypovitaminosis D previously corrected with calcidiol (16.000UI/week for 4 weeks). The patients were randomised in two-arms of treatment: 63 p with calcidiol 16.000UI every 3 weeks and 36 p. with cholecalciferol 800UI/day. Daily 1-1.2 g of calcium was added in all the patients during the study. The following parameters: 25-OHD3, PTH, Ca, P, ALP and 24-hour calciuria, were determined at baseline, 3, 6 and 12 months. Both groups of patients treated with calcidiol and cholecalciferol had a mean 25-OHD3 serum levels within the normal range at 3, 6 and 12 months, but the calcidiol group achieved higher levels at 6 months (71±31 vs 44±18; p=0.000) and 12 months (75±26 vs 48±23; p=0.001). The percentage of patients with a successful treatment (25-OHD3 within the normal range) was similar in both groups at 3 months, but this rate was higher in the calcidiol group at 6 months (93% calcidiol vs 86% colecalciferol p=0.004) and 12 months (100% cacidiol vs 85% colecalciferol p= 0.02). There were not significant differences in PTH, Ca, P, ALP and 24-hour calciuria between the groups any time during follow-up. The proportion of patients who withdrew the treatment was similar in both groups: 30/63 (47.6%) treated with calcidiol and 15/36 (41.6%) with cholecalciferol. We concluded that both calcidiol (16.000 UI every 3 weeks) and cholecalciferol (800 UI/ day) are efficacious to maintain normal levels of 25-OHD3, but these levels were higher with calcidiol. On long-term treatment (1 year) no patients with calcidiol had hypovitaminosis D. The withdrawal was high in both treatment regimens.

Vitamin D Insufficiency Impairs the Effect of Alendronate for the Treatment of Osteoporosis in Postmenopausal Women. M. Ishijima[1], M. Yamanaka*[1], Y. Sakamoto*[1], K. Kitahara[1], F. Enomoto*[2], M. Sawa*[2], M. Nozawa*[1], A. Tokita[3], H. Kurosawa*[1]. [1]Orthopaedics, Juntendo University, School of Medicine, Tokyo, Japan, [2]Orthopaedics, Juntendo Tokyo Koto Geriatric Medical Center, Tokyo, Japan, [3]Pediatrics, Juntendo Univ. School of Medicine, Tokyo, Japan.

It has been reported that approximately five percents of alendronate (ALD) users for the treatment of osteoporosis did not increase in bone mineral density (BMD) of the spine. There is overwhelming evidence that vitamin D insufficiency (moderate vitamin D deficiency) is common in the elderly, not only in traditional risk groups but also in independent elderly or postmenopausal women with/without osteoporosis. The purpose of this study is to investigate whether ALD used for the treatment for osteoporosis could give full play to increase in BMD in case of the vitamin D insufficiency. A total of twenty-four Japanese postmenopausal women (aged 58 to 78, 65.6 in average) who were diagnosed as a primary osteoporosis were enrolled in this study. All the patients involved in this study took 5mg of ALD daily for one year. Lumbar spine BMD (L-BMD) was measured at first medical examination and every six months thereafter. Serum levels of 25-hydroxy vitaminD (s-25(OH)D), 1α,25-dehydroxy vitamin D_3 and intact-PTH were also measured at the first medical examination and every six months thereafter. Serum levels of bone specific alkaline phosphatase (BAP) and urinary levels of N-telopeptide (u-NTX), calcium and cleatinine were measured at the first medical examination and every three months thereafter. This study was approved by our institutional research committee. We divided the patients for three groups by the s-25(OH)D during twelve months; <15ng/ml: Group A, 15~20ng/ml: Group B, >15ng/ml: Group C. While significant suppression of u-NTX excretion by ALD for one year was observed in Group B and C, such suppression of u-NTX excretion was not observed in Group A. Moreover, while the percent increase in L-BMD by ALD for one year was 5.7% and 8.4% in Group B and C, respectively, that was 1.4% in Group A. These differences of the percent increase in BMD by ALD for one year between Group A and B and Group A and C were statistically significant ($p<0.01$), respectively. These results suggest that vitamin D insufficiency would be a one of the causes for the non-responder of ALD for the treatment of osteoporosis. Therefore, we have to pay more attention to vitamin D status of postmenopausal women in the treatment of osteoporosis. These efforts must be contributed to obtain a more adequate effect of ALD for the treatment of osteoporosis. In conclusion, the effect of ALD for the treatment of osteoporosis was impaired in postmenopausal women with vitamin D insufficiency.

Relationship between Serum 25-hydroxy-Vitamin D Levels and Health-Related Quality of Life in Postmenopausal Women with Osteopenia. A. M. Cheung[1], B. Stewart*[1], G. Tomlinson*[2], H. Hu*[1], J. Scher*[1], R. Vieth*[3]. [1]Osteoporosis Program and Department of Medicine, University Health Network and Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada, [2]Department of Medicine, University Health Network and Mount Sinai Hospital, Universisty of Toronto, Toronto, ON, Canada, [3]Department of Pathology & Laboratory Medicine, Mount Sinai Hospital, Toronto, ON, Canada.

Recent evidence suggests that vitamin D may affect wellbeing and mood. The objective of this study is to examine whether serum levels of 25-hydroxy-vitamin D are associated with health-related quality of life in postmenopausal women with osteopenia. We examined the baseline data obtained from the ECKO trial -- a 2-year single-centre double-blind placebo-controlled randomized trial investigating the effect of vitamin K supplementation on bone mineral density. Four hundred and forty-four postmenopausal women with osteopenia (lowest T-score between -1 and -2 in the lumbar spine (L1-L4), total hip, or femoral neck) completed the screening visit. Serum 25-hydroxyvitamin D levels were measured at the screening visit when each participant also completed a Medical Outcomes Survey 36-item short form questionnaire on health-related quality of life (SF-36). The SF-36 assesses nine health domains: physical functioning, role functioning - physical, bodily pain, general health, vitality, social functioning, role functioning - emotional, mental health, and reported health transition. After adjusting for seasonal variation, we performed regression analyses of serum 25-hydroxyvitamin D levels versus the various domains of the SF36. The mean serum 25-hydroxyvitamin D levels was 76.7 nmol/L (SD 25.2nmol/L). The mean scores for all domains of the SF-36 is approximately 100% of age-adjusted predicted mean scores in the general population. After adjusting for age and seasonal variation, we found that a higher serum 25-hydroxyvitamin D level is associated with higher scores for physical functioning (r^2=0.04, p=0.002), mental health (r^2=0.05, p=0.05) and overall health-related quality of life (r^2=0.05, p=0.003), although the effects are small. For an increase of 10nmol/L of serum 25-hydroxyvitamin D level, there is a 1 point, 0.5 point and 1point increase in score in physical functioning, mental health and overall health-related quality of life, respectively. Our results showed that higher 25-hydroxyvitamin D levels may be beneficial to health-related quality of life in postmenopausal women with osteopenia.

Incidence of Primary Hyperparathyroidism in Rochester, Minnesota, 1993-2001: An Update on the Changing Epidemiology of the Disease. R. A. Wermers, S. Khosla, E. J. Atkinson*, S. J. Achenbach*, A. L. Oberg*, C. S. Grant*, L. J. Melton. Endocrinology, Mayo Clinic, Rochester, MN, USA.

Automated serum calcium measurements were associated with a dramatic rise in primary hyperparathyroidism in the early 1970's, but a progressive decline in incidence thereafter was unexpected and suggested a fundamental change in the epidemiology of the disease. Our objective was to evaluate trends in the incidence of primary hyperparathyroidism since 1992. In this population-based descriptive study, Rochester, Minnesota residents who met defined diagnostic criteria for primary hyperparathyroidism from January 1993 through December 2001 were identified through the medical record linkage system of the Rochester Epidemiology Project and the Mayo Clinic Laboratory Information System. Changes in incidence rates were evaluate by Poisson regression. Altogether, 136 Rochester residents (94 women and 42 men) were newly identified with primary hyperparathyroidism in 1993-2001. Their mean age was 56 years, and 93% had definite disease. The overall age- and sex-adjusted (to 2000 U.S. whites) rate during this period was 21.6 per 100,000 person-years, which was less than the annual rate of 29.2 per 100,000 observed in 1983-1992 and 83 per 100,000 in July 1974-1982. The decline in incidence persisted despite improved case ascertainment through the Laboratory Information System. Although community incidence declined, the number of parathyroidectomies performed at our institution increased during the same period. Serum calcium was deleted from the automated chemistry panel in June 1996, but most subjects remained asymptomatic at diagnosis (95%) with mild hypercalcemia. The majority of subjects were observed (75%), and there was minimal impact on patient management from the 1990 NIH consensus conference on asymptomatic primary hyperparathyroidism. The lower incidence of primary hyperparathyrodism noted through 1992 has persisted in our community from 1993-2001, while parathyroidectomies at our institution remained high. Consequently, perceptions about incidence from referral centers may not reflect the true changing incidence. These data suggest that some underlying etiologic factor in addition to the introduction of automated serum calcium testing may have been responsible for the peak incidence in the 1970s.

Bone Quality Is Markedly Abnormal in Hypoparathyroidism. M. R. Rubin[1], D. W. Dempster[2], S. J. Silverberg[1], E. Shane[1], R. Müller[3], H. Zhou[2], A. L. Boskey[4], J. P. Bilezikian[1]. [1]Columbia University College of P & S, New York, NY, USA, [2]Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [3]ETH, Zurich, Switzerland, [4]Hospital for Special Surgery, New York, NY, USA.

Hypoparathyroidism (HypoPT) is a disorder in which PTH is absent from the circulation. Whereas bone properties have been well described in disorders of PTH excess, virtually nothing is known about the quality of bone that is chronically deprived of PTH. We studied 6 women (52.5 ± 5 yr) with HypoPT (duration 21.2 ± 6 yrs; 4 postsurgery, 2 autoimmune). Bone mineral density was: lumbar spine 1.231 g/cm^2 (T-score, +1.7 ± 1), total hip 0.967 g/cm^2 (T-score +0.1 ± 1) and 1/3 distal radius 0.665 g/cm^2 (T-score, -0.5 ± 1). Iliac crest bone biopsies were performed on all subjects. 2-D histomorphometry was compared with 6 age-matched controls (C). In comparison to C, HypoPT bone was characterized by greater cortical width (1046 ± 236 vs 542 ± 159 µm, p=0.002) and cortical area (32.9 ± 15 vs 15.6 ± 3 %, p=0.02). Osteoid width (Lam#) was reduced in cancellous (2.8 vs 4.6, p=0.02), endocortical (1.5 vs 3.6, p=0.001) and intracortical (2.0 vs 3.7, p=0.03) envelopes. Osteoid perimeter (%) was reduced in cancellous (3.9 vs 9.5, p=0.02) and endocortical (4.6 vs 18.6, p=0.01) envelopes. Mineralized perimeter, mineral apposition rate, and bone formation rate were lower in HypoPT in both cancellous and endocortical envelopes. µCT was used to compare HypoPT biopsies with 52 C biopsies from human cadavers (20 females, 32 males; age: 24-92 yrs). Bone volume was significantly greater in HypoPT (BV/TV; 0.35 ± 0.1 vs 0.16 ± 0.1, p = 0.005). Trabecular number (Tb.N.; 2.1 ± 0.8 vs 1.4 ± 0.3 l/mm) and trabecular thickness (Tb.Th; 0.21 ± 0.1 vs 0.15 ± 0.1 mm) were greater in HypoPT, while trabecular separation (Tb.Sp; 0.53 ± 0.1 vs 0.75 ± 0.2 mm) was lower in HypoPT. Estimation of the plate-rod characteristic (SMI) was significantly reduced in HypoPT (-0.82 ± 2.0 vs 1.15 ± 0.6, p=0.001). Connectivity Density was high (51.0 ± 35 1/mm^3). 2-D (histomorphometry) and 3-D (µCT) parameters were significantly associated: BV/TV:r=+.91; (p=.01); Tb.Th. r=+.94 (p<.01), Tb.N r=+.54 (p>.05), Tb.Sp r=+.82 (p<.05). Fourier Transform Infrared Spectroscopic Imaging showed markedly increased crosslink ratio, consistent with increased mean bone age. These results show, for the first time using highly specific analytical techniques, that bone deficient in PTH is markedly abnormal. Increased bone density in HypoPT is associated with abnormal bone quality. How the administration of PTH can restore these abnormalities towards normal is the subject of ongoing research.

Markedly Elevated Bone Density in a Man with Longstanding Hypoparathyroidism. G. C. Lim*[1], M. Khosla*[1], J. A. Spadaro*[2], A. M. Moses[1]. [1]Department of Medicine- Endocrinology, Diabetes and Metabolism, SUNY Upstate Medical University, Syracuse, NY, USA, [2]Department of Orthopedic Surgery, SUNY Upstate Medical University, Syracuse, NY, USA.

An 85-year-old man was diagnosed with idiopathic hypoparathyroidism in1976 and since then we have maintained his serum calcium and phosphorus levels in the normal range on calcitriol 0.25 mcg bid and calcium carbonate 500 mg tid. No fractures or height loss. Expecting that his BMD might be above age matched controls due to chronic hypoparathyroidism, we obtained a DXA which revealed **remarkably dense bone**. DXA was repeated with a different machine and results were confirmed. Blood work showed low bone turnover markers. See details in Table 1.

Table1 Blood work	**Recent Lab Results**	**Densitometry Sites**	**GE Lunar DPXIQ**	**Hologic QDR 4500**
Calcium (8.4-10.3 mg/dl)	9.3		**L1-L4**	
		BMD(g/cm^2)	2.510	2.154
Phosphorus (2.5- 4.5 mg/dl)	3.7	T-Score	+10.6	+9.7
		Z-Score	+11.5	NA
BSAP (2-24 ng/ml)	10.0		**Total hip**	
		BMD(g/cm^2)	1.641	1.472
Osteocalcin (11.3-35.4 ng/ml)	**9.5**	T-Score	+4.2	+2.9
		Z-Score	+5.5	NA
Serum N-telopeptide (10.7- 22.9 nmol BCE /L)	**9.3**		**Distal 3rd radius**	
		BMD(g/cm^2)	0.852	NA
PTH (11-80 pg/ml)	**<3**	T-Score	-0.2	
		Z-Score	+1.2	
CK-BB* (0%)	0%		**Total Body**	
TartrateResistant		BMD(g/cm^2)	1.577	NA
Acid Phosphatase* (3.0-6.0 U/L)	7.0	T-Score	+4.5	
		Z-Score	+5.5	

*Elevated in osteopetrosis
Other tests including serum lead, copper, fluoride, PSA, H/H, SPEP, creatinine, 25-OHD & 1,25-OHD levels are all normal.

Routine radiographs were unremarkable except for a coarsening of the trabecular pattern in the spine. A peripheral quantitative CT of the ultra-distal radius showed a cortical cross-sectional area about 35% above young adult values and a 50% higher strength index (density adjusted cross-sectional polar moment of inertia). Our patient's radiological bone difference from normal are similar to those caused by teriparatide treatment of osteoporotic patients. However, his bone turnover markers are opposite from those caused by teriparatide. Unfortunatelely bone biopsy could not be obtained for further comparison. Laboratory testing ruled out other sclerosing bone disorders such as osteopetrosis. **In summary**, we report the highest bone density yet reported in

hypoparathyroidism. His low bone turnover markers could be explained by PTH hormone deficiency. Long standing hypoparathyroidism is the only apparent factor causing his marked increase in bone density. Whether or not this increased bone density translates to increase bone quality remains unknown but he has had no fractures by age 86 and the distal radius cortical area and structural strength were at or above young normal values. Since hypoparathyroidism can increase bone density and probably decrease risk of fracture, it is possible that suppression of the parathyroid glands using calcimimetics may in the future be a means of treating osteoporosis.

Low Bone Turnover in Hypoparathyroidism Can Be Restored to Normal by PTH Administration. M. R. Rubin[1], J. Fleischer[1], M. J. Seibel[2], J. de Winter*[2], D. W. Dempster[3], T. F. Lang[4], E. Shane[1], S. J. Silverberg[1], J. P. Bilezikian[1]. [1]Columbia University College of P & S, New York, NY, USA, [2]Bone Research Program, ANZAC Research Institute, University of Sydney, Concord NSW, Australia, [3]Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [4]University of California San Francisco, San Francisco, CA, USA.

Hypoparathyroidism (HypoPT) is a disorder in which PTH is absent from the circulation. In addition to the biochemical manifestations of hypocalcemia and relative hypercalciuria, bone turnover is low. We sought to quantify bone turnover in HypoPT and to determine whether low bone turnover can be enhanced by PTH. We studied 6 women (52.5 ± 5 yr) with HypoPT (duration 21.2 ± 6 yrs; 4 postsurgical, 2 autoimmune). Baseline biochemistries were: serum calcium, 8.6 ± 0.4 mg/dl (nl 8.5-10.4); PTH, 7.6 ± 3 pg/ml (nl 10-65); urinary calcium, 248.7 ± 63 mg/l; serum phosphorus, 4.6 ± 1 mg/dl (nl 2.5-4.5); total alkaline phosphatase, 76.3 ± 10 IU/l (nl 33-96); 25-hydroxyvitamin D, 70.1 ± 25 ng/ml (nl 9-52); 1,25-dihydroxyvitamin D, 28.8 ± 4 pg/ml (nl 15-60). Baseline calcium supplementation ranged from 1-6 g/d (av,3 g/d); baseline calcitriol doses ranged from 0 to 1 ug/d (av, 0.5 ug/d). Baseline bone mineral density was: LS 1.231 g/cm^2 (T score +1.7 ± 1), TH 0.967 g/cm^2 (T score +0.1 ± 1) and 1/3 distal radius 0.665 g/cm^2 (T score -0.5 ± 1). By QCT, volumetric bone density was 53% above normal at the trabecular spine and 150% above normal at the trabecular hip. Biochemical markers of bone turnover, measured twice at baseline, were never elevated and in most cases were below the normal reference ranges: P1NP (-2%), BSAP (+1.5%), osteocalcin (-65%), ß-CTX (-62%) and TRAcP5b (-11%). PTH(1-84) was administered in an open-label, randomized design at 3 dosing regimens: 100 ug daily, 100 ug every other day, or 100 ug every third day. Bone turnover markers increased at 1 month. On the daily dose, P1NP increased 173%, from baseline to almost 2 times above normal; on the every other day dose, it increased 49% to the mid- to high-normal range; on the every third day dose, it increased 38%, to the low-normal range. Serum calcium was maintained at a range of 8.5-10.0 mg/dl, permitting reductions in calcium supplementation by 25 ± 12% and in calcitriol supplementation by 31 ± 16%. We conclude that bone turnover is suppressed in a state of chronic PTH deprivation and that the administration of PTH improves bone turnover in the hypoparathyroid skeleton. The long- term effects of PTH replacement on skeletal dynamics in HypoPT remain to be seen but it is possible that the enhancement of these skeletal dynamics by PTH will be associated with improvements in other qualities of bone.

Disclosures: ***M.R. Rubin****, None.*

Differences in Accuracy of the Sestamibi Scanning between Severe and Mild Forms of Primary Hyperparathyroidism. F. Bandeira, A. T. Coriolano*, L. Griz*, G. Caldas*, C. Bandeira*. Endocrine Unit and Osteoporisis Research Center, Agamenon Magalhães Hospital/ SUS/ University of Pernambuco and Dilab Laboratories, Recife, Brazil.

The preoperative location of the parathyroids using Tc99m-sestamibi scanning is not yet established as a routine diagnostic procedure for primary hyperparathyroidism (PHPT), but the use of the technique is becoming increasingly common. A number of studies have demonstrated a variable degree of accuracy (70-98%) in asymptomatic patients. We evaluated the accuracy of this technique in 64 patients who underwent a scan between January 2000 and January 2005 according to the clinical manifestations of the disease. In 25 asymptomatic patients (Group I) 80% were females, mean age 66.75 ± 0.63 yr, mean serum Ca 10.98 ± 0.02 mg/dL, mean serum P 2.79 ± 0.29 mg/dL, mean PTH 135.45 ± 13.50 pg/mL, mean serum 25OHD 26.97 ± 4.13 ng/mL, urinary Ca 213.21 ± 42.7 mg, t score LS BMD -2.02 ± 0.15 %, t score FN BMD -2.03 ± 0.28 %, t score distal radius BMD -2.23 ± 0.74 %. In 18 nephrolithiasis patients without overt bone disease (Group II) 77.7% were females, mean age 55.8 ± 5.09 yr, mean serum Ca 11.32 ± 0.17 mg/dL, mean serum P 2.56 ± 0.47 mg/dL, mean PTH 165.85 ± 15.06 pg/mL, mean serum 25OHD 20,02 ± 0,56 ng/mL, urinary Ca 303.45 ± 58.9 mg, t score LS BMD -1.83 ± 0.85 %, t score FN BMD -1.81 ± 0.38 %, t score distal radius BMD -1.79 ± 0.04 %. In 21 patients with severe bone involvement / osteitis fibrosa cystica (Group III) 47.6% were females, mean age 38.7 ± 4.38 yr, mean serum Ca 13,35 ± 0.35 mg/dL, mean serum P 1.99 ± 0.29 mg/dL, mean PTH 579.6 ± 628.4 pg/mL, mean serum 25OHD 15.91 ± 1.11 ng/mL, urinary Ca 285.5 ± 67.1 mg, t score LS BMD -4.25 ± 0.24 %, t score FN BMD -5.44 ± 1.37 %, t score distal radius BMD -5.33 ± 0.69 %. Mean urinary NTX in groups I, II and III was 51.3 ± 6.4 nmol/mmol creatinine (9 patients), 154.1 ± 62.9 nmol/mmol creatinine (10 patients) and 501.5 ± 201 nmol/mmol creatinine (16 patients) respectively. Mean serum CTX in groups I, II and III was 752.6 ± 496.3 pg/mL (16 patients), 727.3 ± 220.4 pg/mL (8 patients) and 2210.2 ± 375.4 pg/mL (5 patients) respectively. Sestamibi scan was positive in 64% of patients in Group I, in 83.33 % of those in Group II and in 100% of those in Group III. From patients with severe bone disease, 70% already showed an increased uptake in the initial images, compared with the other groups, in which the increase in uptake was seen only in the later images, as expected. Our data show a high degree of accuracy of Tc99m-sestamibi scanning, as locating procedure, in severe primary hyperparathyroidism.

Can Biochemical Bone Markers, PTH or Ionized Calcium Predict Changes in Bone Mass after Parathyreodectomi in Patients with Primary Hyperparathyreoidism? L. S. Stilgren*, L. Hegedüs*, K. Brixen, B. Abrahamsen. Dept. of Endocrinolgy, Odense University Hospital, Odense C, Denmark.

In the last decade, the diagnosis of primary hyperparathyroidism (PHPT) is diagnosed increasingly early. While PTX is required in many patients, others may be treated conservatively and monitored for disease progression. To make this decision, it would be useful to identify the patients who will obtain the greatest increases in bone mass after surgery We speculated that bone turnover markers could aid in identifying patients with greater disease intensity and thus particular skeletal benefit from PTX. The study comprised 24 patients (females/males=10/2), aged 52 to 75 years (median 60 years), with PHPT confirmed by elevation of plasma PTH (range 8- 44; median 16 pmol/l) and serum ionized calcium levels (range 1.33-1.82; median 1.49 mmol/l). None of the patients had renal disease or other conditions known to affect bone metabolism, or received bisphosphonates, glucocorticoids, or fluoride. Patients were investigated before and one year after successful PTX. Whole body BMC and BMD were measured using a Hologic 2000 DXA-scanner. Serum ionized calcium was normalized in all patients after surgery. During the first year after surgery, total BMC as well as BMD increased significantly by 5% and 2 %, respectively, while biochemical bone markers decreased. A significant, positive correlation was found between pre-operative serum PTH and ionized calcium on the one hand and the change in total BMC on the other hand. Similarly, pre-operative serum phosphate was negatively correlated to the change in total BMC. By contrast, bone turnover markers showed no relationship with the subsequent gain in BMC.

	Parathyroid hormone	Ionized calcium	Phosphate
	Rho	Rho	Rho
Total BMC before PTX	0.23	0.26	-0.23
Change in total BMC	0.67**	0.61**	-0.43*

* p<0.05; **p<0.005

	Alkaline phosphatase	Osteocalcin	P1NP.	P1CP.	Cross-links	U-NTX
	Rho	Rho	Rho	Rho	Rho	Rho
Total BMC before PTX	-0.44*	-0.33	-1.57*	-0.63*	-0.47*	-0.61*
Change in total BMC	-0.02	0.21	-0.15	-0.06	0.02	-0.1

* p<0.05

In this preliminary study we have shown pre-operative serum PTH, ionized calcium, and phosphate predict the change in total body BMC after parathyroidectomy. In contrast, biochemical bone markers had no value as severity markers.

Normal Bone Mineralization Density Distribution (BMDD) in Hypoparathyroidism. M. R. Rubin[1], D. W. Dempster[2], S. J. Silverberg[1], E. Shane[1], P. Roschger[3], K. Klaushofer[3], J. P. Bilezikian[1]. [1]Columbia University College of P & S, New York, NY, USA, [2]Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [3]Hanusch Hospital of WGKK and AUVA Trauma Centre Meidling, Ludwig Boltzmann Institute of Osteology, Vienna, Austria.

In Hypoparathyroidism (HypoPT), bone turnover is markedly reduced and bone mineral density (BMD) is increased. In states of low bone turnover induced by bisphosphonate therapy, along with increased BMD, uniformity of mineralization as reflected by bone mineralization density distribution (BMDD) is also enhanced. We investigated whether prolonged low turnover due to chronically deficient levels of parathyroid hormone in HypoPT would also be associated with a shift of BMDD towards increased mineralization. BMDD was assessed by backscattered electron imaging (qBEI) in iliac crest bone biopsies from 6 women (52.5 ± 5 yr) with HypoPT (duration 21.2 ± 6 yrs). Mean calcium content (CaMean), the variation of calcium content (CaWidth) and the percentage of low mineralized matrix (CaLow), as measured by qBEI, were used to characterize BMDD. The data were compared to 52 normal controls. While variability was present, the mean values for all mineralization parameters, including CaMean (HypoPT 22.3 ± 0.9 vs 22.2 ± 0.45), CaPeak (22.9 ± 0.93 vs 22.9 ± 0.39), CaWidth (3.29 ± 0.16 vs 3.35 ±0.34) and CaLow (4.38 ± 1.72 vs 4.96± 1.57) were all within control values in HypoPT. These results are in marked contrast to the expectation that an increase in mineralization density in HypoPT would be seen because of an association between low bone turnover and increased bone mineralization. However, these findings are consistent with other data indicating that mineralization is remarkably consistent among different skeletal sites, as a function of age, and between men and women and between races (Roschger P et al, *Bone* 32:316-323, 2003). There may well be a maximum, and perhaps optimum, extent of mineralization that is not exceeded even when bone turnover is reduced. Recent data with bisphosphonates also suggest a limit to which the degree of mineralization can be enhanced. These unique results are providing new insights into our understanding of HypoPT and are likely to have direct clinical relevance to prolonged antiresorptive therapy for osteoporosis.

Severe Hypercalcemia due to Thyrotoxicosis. S. Psarelis*[1], G. Trovas[2], S. Gazi*[1], N. Tsakalakos[2], K. Tempos*[1], G. P. Lyritis[2]. [1]Reumatology, KAT Hospital, Athens, Greece, [2]Laboratory for Research of the Musculoskeletal System, Athens, Greece.

Hypercalcemia might be associated with hyperthyroidism rarely.We present a 42 year-old black woman who reffered to our department complaining for myalgias, arthralgias, polydipsia and polyuria. She had no history of previous serious illness and her symptoms began before two months but became severe the last two weeks.The physical examinations show generalized tendonitis,sinus tachycardia (120/min)and blood pressure 110/75 mmHg.Laboratories studies revealed : WBC 5450, (NEU 51%, LYM 38%), HCT 32, Hb10,4, MCV 74, PLT 333.000, RF(-), ANA(-), Anti-ENA (-) CRP<0,325, ESR 25, C_3 170,C_4 41 HBsAg (-),Anti-HCV(-), Anti-HIV(-), GLU 94, BUN 42, CREAT 0,7, SGOT 31, SGPT 23, BIL 0,5, GGT 24, Albumin 4,3, P 4,7, PTH 7,4, 25(OH)D_3 17,1, Anti TG 16, P24h 371,CEA 0,5, CEA 0,5 , CA_{125} 9,1, CA_{19-9} 10,92, CA_{15-3} 6,3, Serum protein electrophoresis was normal.

DPXL L_2-L_4 1,229 g/cm^2 Tscore 0,2, Zscore -0,5.
After excluding primary hyperparathyroidism and other secondary causes of hypercalcemia, we started hydratation with normal saline and administration of Furosemide for hypercalemia and Carbimazol (5mg) 1x3 and Propanolol (40mg) ½ x3 for hyperthyroidism. Her hypercalcemia resolved completely after 11/2 month. Mild hypercalcemia usually can occur in up to 15 to 20 percent of patients with hyperthyroidism. Our case is unusual because the patient demonstrated a significant degree of hypercalcemia secondary to hyperthyroidism alone and we speculate a high bone turnover as reflected by increased bone markers as the putative pathophysiology of this thyroid bone disease and physicians should consider thyrotoxicosis in the differential diagnosis of hypercalcemia.

Mutational Analysis of the PTH 3' Untranslated Region in Primary Hyperparathyroidism. J. Costa-Guda*[1], T. Naveh-Many[2], J. Silver[2], A. Arnold[1]. [1]Molecular Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]Minerva Center for Calcium and Bone Metabolism, Hadassah Hebrew University Medical Center, Jerusalem, Israel.

Sequence alterations in untranslated regions of genes are important contributors to human diseases, including hereditary thrombophilia, hereditary hyperferritinemia cataract and fragile X mental retardation syndromes. Recently, functional studies of the *PTH* gene 3' untranslated region (UTR) have highlighted it as a potential target for pathogenic mutations in patients with primary parathyroid disorders. Specifically, regulation of *PTH* gene expression by calcium and phosphate occurs post-transcriptionally, primarily through alteration of PTH mRNA stability (Naveh-Many, T., *et al,* FEBS Lett., 2002). Calcium and phosphate appear to influence the binding of proteins, including a known regulator of mRNA stability AUF1, in a sequence dependent manner to a specific *cis* element in the 3' untranslated region of PTH mRNA. Decreased serum calcium and increased phosphate lead to increased protein binding to PTH mRNA, resulting in increased stability. AUF1 stabilizes PTH mRNA *in vitro* and decreasing AUF1 decreases PTH secretion from cells transfected with the human *PTH* gene. Thus, the *PTH* 3'UTR has emerged as an important potential contributor to primary parathyroid dysfunction. Consequently, we sought to rigorously examine, by direct DNA sequencing, the *PTH* 3'-UTR in 21 parathyroid glands from 14 patients with primary parathyroid hyperplasia and 40 sporadic parathyroid adenomas from 40 patients. No alterations from the normal sequence were detected in any of the 61 samples examined. Based on the absence of identifiable DNA sequence alterations in these forms of primary hyperparathyroidism, it is unlikely that mutation of the *PTH* 3' UTR frequently contributes to their pathogenesis.

Physical Activity and Nutrition Education Promotes Fitness and Bone Mineral Acquisition in Children with Acute Lymphoblastic Leukemia (ALL). L. J. Moyer-Mileur[1], H. Slater*[1], R. VanOrden*[1], C. Bruggers*[2]. [1]Pediatrics, University of Utah, Salt Lake City, UT, USA, [2]Pediatric Oncology/ Hematology, University of Utah, Salt Lake City, UT, USA.

Background: Young adult survivors of childhood ALL are reported to have higher incidence of obesity and osteoporosis and their related complications. Altered nutrient intake and decreased physical activity in response to cancer therapies and their side effects, particularly corticosteroids, may be key factors for growth, body composition, and bone mineral acquisition alterations in children with ALL. **Purpose**: To compare growth, body composition, bone mineral acquisition, and fitness during 12-mos of maintenance therapy in children with ALL. **Design**: Children age 4-10 y with standard-risk ALL were recruited from the Pediatrics Oncology Program, Primary Children's Medical Center, Salt City, UT at the completion of induction therapy and randomized to a monthly physical activity and nutrition education program (EX, n=6, 3M/3F) or control (C, n=7, 4M/3F). Height, weight, fitness testing (aerobic endurance by PACER test, flexibility, and muscular strength), DEXA measurements of the femoral neck (FN) and lumbar spine (LS), pQCT cross-sections of the tibia, physical activity and dietary intake records, and bone alkaline phosphatase (BAP) and urine pyridinium cross-links (Pyd) samples are obtained at baseline, 6 and 12 months. Statistical analysis included t-test, regression, and MANCOVA. **Results**: Age, weight, height, body mass index (wt/ht^2), body composition, and nutrient intakes were similar at baseline, 6, and 12 mos. EX children had dramatically improved aerobic endurance (201% ± 22% vs. 7% ± 33%, p=0.01) and flexibility (5%±12% EX vs. 1%±13%C, p=0.001) from baseline to12M. FN and LS bone area, FN BMC, and tibia periosteal circumference 12mo gains were greater in C children while greater gains in LS BMC (g), FN and LS BMAD (g/cm^3), and tibia cortical bone area (mm^2), BMC (mg), thickness (mm), and bone strength index (BSI, mm^3) were found in EX children (p≤0.04). Trabecular volumetric BMD (vBMD) values were similar for groups over 12 mos and significantly lower than references values (172 ± 36 mg/cm^3 ALL vs. 235 ± 39 mg/cm^3 REF, p=0.001). BAP values did not change while urine Pyd:creatinine values decreased in EX vs. C children (p=0.006) suggesting increased bone mineralization. **Conclusions**: This pilot work suggests that a monthly physical activity and nutrition education program during maintenance therapy promoted cardiovascular fitness and bone mineral acquisition in children with standard-risk ALL. Further longitudinal work is needed to determine whether lifestyle interventions will lower the risk of obesity and osteoporosis in later life.

Polycystic Ovary Syndrome Is a State of Low Bone Resorption: A Study in Youth. J. G. Warren-Ulanch[1], S. Arslanian*[1], S. L. Greenspan[2]. [1]Endocrinology, Children's Hospital of Pittsburgh, Pittsburgh, PA, USA, [2]Endocrinology, University of Pittsburgh Medical Center, Pittsburgh, PA, USA.

Adults with polycystic ovary syndrome have normal bone turnover. Adolescence, a time of peak growth velocity and bone mineralization, is associated with high bone turnover. No studies have evaluated the bone turnover rates in adolescents with or without PCOS. To determine the impact of age, hormone levels, BMI, and glucose homeostasis on bone turnover, we examined these variables in fifteen obese (BMI>85%ile) females (6 African American) with PCOS and 10 obese females (5 African American) without PCOS. Bone formation was assessed by levels of aminoterminal propeptide of type 1 collagen (P1NP), and bone resorption was assessed by levels of C-telopeptide of collagen cross-links (CTx) measured in plasma. Bone mass was evaluated with dual-energy x-ray absorptiometry (DXA). Those with PCOS had higher BMI (p=.004), and were more mature by Tanner stage (p=.024) than the controls. They had higher levels of estradiol, testosterone, and fasting insulin. No differences were noted in bone mass, but those with PCOS were found to have lower markers of both bone formation and bone resorption. (p<.001).

BMI, Hormone levels, and Bone Turnover. Data are mean (SD).

	PCOS	Controls	*P*
BMI (kg/m^2)	38.1 (5.7)	31.5 (4.1)	.004
Estradiol (pg/mL)	65.6 (51.5)	32.1 (45.6)	.014
Free Testosterone (pg/mL)	12.0 (8.7)	3.4 (3.0)	.001
Fasting Insulin (uU/mL)	52.7 (19.1)	37.8 (32.5)	.002
CTx (ng/mL)	1.39 (.63)	2.67 (.67)	<.001
P1NP (ug/L)	245.5 (227.7)	458.4 (151.1)	.012

Using stepwise linear regression analysis to allow for weight, age, BMI, and Tanner stage, only age had a significant contribution to P1NP (r^2=56.5%, p<.001) and CTx (r^2=32.2%, p=.03). After making this adjustment, PCOS did not significantly affect P1NP, however, it accounted for 30.6% of the variance of CTx (p<.001). These values were not affected after further adjusting for testosterone, estradiol, IGF-1, or fasting insulin. In conclusion, we find that PCOS is a state of low bone resorption in obese adolescents, in the absence of changes in bone formation or bone mass. This is consistent with findings of preserved, if not elevated, bone mass in adults with PCOS. Further studies are needed to determine the etiology of the low bone resorption in this population.

Growth Hormone as an Anabolic Agent in Burned Children. G. L. Klein[1], D. J. Sherrard[2], D. N. Herndon*[3]. [1]Pediatrics, University of Texas Medical Branch, Galveston, TX, USA, [2]Renal Dialysis, VA Medical Center and University of Washington School of Medicine, Seattle, WA, USA, [3]Surgery, University of Texas Medical Branch and Shriners Burns Hospital, Galveston, TX, USA.

Children burned at least 40% total body surface area are catabolic with negative nitrogen balance and loss of muscle mass, lose a mean of 8% lumbar spine bone mineral content(BMC) by 2 mo and 3% total body BMC by 6 mo post-burn. Bone loss is due to glucocorticoid-related reduction in bone formation and excessive urinary Ca loss and results in an increased annual extrapolated age-and sex-related post-burn fracture incidence and a hypothetical reduction in peak bone mass. The aim of our study was to determine if treatment of burned children with an anabolic agent, recombinant human growth hormone (rHGH) or oxandrolone(ox) increases BMC, bone area(BA) and bone mineral density (BMD). We enrolled 28 children, ages 5-19 yr, 22M, 6F with burns of at least 40% body surface area and randomized them to an anabolic agent (rHGH, n=14, ox, n=2) or placebo (n=12) for 1 yr double-blinded. Bone densitometry (DEXA) and iliac crest bone biopsy were obtained at hospital discharge and at 1 yr and analyzed for changes in total body BMC, BA, lean body mass (LBM) and lumbar spine BMD Z scores. Compared to placebo, children receiving anabolics increased total body BMC ($p=0.028$) and BA($p<0.025$) at 1 yr. Changes in BMC correlated with changes in BA, $r=0.96$, $p<0.001$. Changes in BMC per gram LBM did not differ between groups. Changes in lumbar spine BMD Z scores were also not different nor were changes in height. There was a trend toward increased LBM in the anabolic group. 130 +/- 44% vs 110 +/- 11% change from discharge ($p=0.18$). Thus anabolic agents increase BMC and BA in proportion to each other without gain in BMD. If BMD is a risk factor for fractures, anabolic agents are not optimal treatment. Future studies should ascertain whether BA (size) or BMD is more important as a risk factor following bone loss and whether the time needed to improve LBM is a factor in the delayed action of anabolic agents on bone.

The Effect of Oral Cholecalciferol on Serum Concentrations of 25-Hydroxyvitamin D in HIV-Infected Children and Adolescents. S. M. Arpadi*[1], E. Shane[1], D. McMahon*[1], R. Lazell*[2], E. Abrams*[3], M. Bamji*[4], M. Purswani*[5], E. Engelson*[6], M. Horlick[1]. [1]Columbia University, NY, NY, USA, [2]St.Luke's-Roosevelt Hospital, NY, NY, USA, [3]Harlem Hospital, NY, NY, USA, [4]Metropolitan Hospital, NY, NY, USA, [5]Bronx-Lebanon Hospital, Bronx, NY, USA, [6]St. Luke's-Roosevelt Hospital, NY, NY, USA.

We have previously reported that bone mass is decreased in HIV-infected prepubertal children and that vitamin D deficiency and insufficiency are highly prevalent in HIV-infected children and adolescents living in New York City. To determine whether supplementation with vitamin D and calcium results in increased bone mass accrual, we have undertaken a 24 month randomized clinical trial. Here, we report the effect of the intervention (oral cholecalciferol, 100,000 IU every 2 months) on monthly serum 25-hydroxyvitamin D (25OHD) levels and serum and urine calcium during the first year of the trial. Perinatally HIV-infected children and adolescents, aged 6-16 yrs (mean 10.9±2.4), were randomly assigned to receive vitamin D and calcium (VD+; n=18) or placebo (VD-; n=19). Subjects with baseline serum 25OHD < 12 ng/ml were excluded. Dietary vitamin D and calcium were assessed by questionnaire (Block Kids Questionnaire, Berkeley, CA) at baseline and 1 year. Serum albumin-corrected calcium and spot urinary calcium/creatinine ratios (Uca/cr) were measured monthly. Subjects with spot Uca/cr ratios >0.25 were evaluated with 24-hour urinary calcium excretion (Uca). Monthly serum 25OHD levels for each individual were analyzed in batches by radioimmunoassay (Diasorin, Stillwater, MN). VD+ and VD- groups did not differ with respect to age, gender, dietary intake of vitamin D and calcium or baseline serum 25OHD. No episodes of hyper- or hypocalcemia, or hypercalciuria were detected. Mean monthly serum 25OHD levels (Figure 1), were significantly higher in the VD+ group, 32.1 ±8.7 vs. 23.0 ±9.6, $p=0.004$. In addition, mean serum 25OHD area-under-the-curve was higher in the VD+ than the VD- group, $p<0.0001$. We conclude that oral cholecalciferol (100,000 IU every 2 months) is safe and results in significant increases in serum 25OHD levels in HIV-infected children and adolescents. Whether this intervention improves bone mass accrual remains to be determined.

Figure 1. Mean monthly serum 25OHD ± SD in HIV infected children receiving 100,000 IE of VD3 (solid line) and placebo (broken line).

Peak Bone Mass after Childhood Acute Lymphoblastic Leukemia (ALL): Findings in 37 Adult Males. O. Makitie, J. P. Puutio*, K. Jahnukainen*, L. R. Viertomies*, M. Henriksson*, K. Vettenranta*, M. A. Siimes*. Hospital for Children and Adolescents, University of Helsinki, Helsinki, Finland.

Peak bone mass is attained by early adulthood. Controversy exists whether any chronic illness in childhood results in subnormal peak bone mass attainment or whether catch-up in the growth of bone mass takes place after recovery from the illness, ensuring normal bone mass by adult age. We have assessed bone health and its correlates in adult males about 25 years after they have survived childhood ALL. The ALL survivors had been treated at the Hospital for Children and Adolecents, University of Helsinki. Data on their previous medical history were collected from hospital records. The patients were prospectively assessed for bone mineral density (BMD) of the lumbar spine (L1-L4), femoral neck and whole body with dual-energy x-ray absoptiometry (DXA, Hologic Discovery A); the BMDs were transformed into T-scores using age- and sex-specific reference data for the equipment. Lateral spine images were obtained with the same equipment for vertebral morphology assessment. Laboratory investigations included serum Ca, Pi, ALP, PTH, 25-OH-vitamin D, testosterone and IGF-I. The present study comprised 37 males aged 26 - 39 yrs (median 30 yrs) who had been diagnosed with ALL at the median age of 4 yrs (1 - 15 yrs) and treated according to the Nordic treatment protocols. Of the patients, 30 (81%) had received CNS irradiation (18 - 26 Gy) and 11 (30%), testicular irradiation. The median height was 177 cm (-0.3 SDS, range from -2.4 to +2.4 SDS) and BMI 24 kg/m2 (-0.7 SDS, from -2.1 to +2.2 SDS). The median BMD T-scores were for lumbar spine -0.7 (from -3.1 to +3.6), for femoral neck, -0.2 (from -2.2 to +2.1) and for whole body, -1.2 (from -2.4 to +2.2); the lumbar spine T-score was at or below -1.0 in 16 patients (43%). The T-scores for the lumbar spine and total body were significantly lower than normal ($P=0.005$ and $P<0.0001$). Compression fractures were recorded in 9 patients (24%). The median serum testosterone concentration was 14.4 nmol/L; it was below 10 nmol/L in 6 patients (16%). Altogether twelve patients (32%), 10 of whom had received testicular irradiation, had primary hypogonadism; 3 of them were not on replacement therapy. 25-OH-vitamin D concentration was below 38 nmol/L in 11 patients (30%). The results suggest that adult males who have survived childhood ALL have i) significantly reduced peak bone mass and ii) high frequency of spinal compression fractures. The low testosterone and vitamin D concentrations suggest that preventive measures of osteoporosis are often neglected.

Activated T Cells: Regulators of Bone Metabolism in Pediatric Crohn Disease? F. A. Sylvester[1], P. M. Davis*[1], N. Wyzga*[2], J. S. Hyams*[1], T. Lerer*[1]. [1]Pediatric Gastroenterology, Connecticut Children's Medical Center, Hartford, CT, USA, [2]Research, Saint Francis Hospital & Medical Center, Hartford, CT, USA.

Crohn disease, a chronic inflammatory condition of the gastrointestinal tract, is associated with osteopenia and T cell activation. Activated T cells are emerging as regulators of bone mass. We hypothesized that circulating activated T cells of patients with Crohn disease produce cytokines that modulate bone cell function. To examine this hypothesis, newly diagnosed children with Crohn disease (n =23, previously untreated) and healthy age- and sex-matched controls (n = 40) between 7-17 years of age (mean age 12.5 years) were invited to participate. After informed consent, we determined clinical severity and disease location in patients, bone age, bone mineral density of whole body and spine by DXA, laboratory markers of bone turnover, and the serum concentration of RANKL, INF-γ and OPG. We harvested circulating T cells and measured the *in vitro* production of these cytokines after activation. Results were expressed as mean ± SD. Children with Crohn disease had decreased BMD Z scores compared to healthy children (-1.03 ± 0.81 vs. -0.47 ± 0.90, $p < 0.05$, corrected for bone age, lowest Z score at any site). Biochemical markers suggested a state of low bone turnover. Serum OPG (pmol/L) was higher in Crohn patients (mean ± SD 4.24 ± 1.73 vs. 3.3 ± 1.00, $p < 0.05$), whereas serum RANKL (pmol/L) was lower (0.50 ± 0.86 vs. 1.02 ± 1.63, $p < 0.05$). INF-γ (ng/μg protein) released by activated T cells from Crohn patients *in vitro* was two-fold higher than in controls (20.03 ± 26.39 vs. 9.76 ± 14.10, $p < 0.05$). In summary, children with Crohn disease may have reduced BMD at the time of diagnosis, probably due to reduced bone turnover. This may be caused, at least in part, by INF-γ secreted by circulating activated T cells. Since osteoblast function appears to be decreased in children with Crohn disease at diagnosis, elevated serum OPG may be secreted by the inflamed intestine, and may contribute to reduce bone turnover by suppressing osteoclast formation and activity.

The Vitamin D Ratio (P-1,25(OH)$_2$D / P-25OHD) Is Insufficient in Separating Familial Hypocalciuric Hypercalcemia (FHH) from Primary Hyperparathyroidism (PHPT). S. E. Christensen[1], P. H. Nissen*[2], B. Moosgaard*[3], P. Vestergaard[1], L. Heickendorff*[2], L. Mosekilde[1]. [1]Dept. of Endocrinology and Metabolism, Aarhus University Hospital, Aarhus, Denmark, [2]Dept. of Clinical Biochemistry, Aarhus University Hospital, Aarhus, Denmark, [3]GCP Unit, Aarhus University Hospital, Aarhus, Denmark.

Clinically Primary Hyperparathyroidism (PHPT) is usually separated from Familial Hypocalciuric Hypercalcemia (FHH) by the calcium-creatinine clearance ratio (CCCR). Studies have shown reduced P-25OHD and high plasma P-1,25(OH)$_2$D in PHPT, whereas FHH has been characterized by normal P-25OHD and reduced P-1,25(OH)$_2$D. The ratio P-

1,25(OH)$_2$D / P-25OHD (D-ratio), which reflects the renal 1-alphahydroxylase activity, could be a diagnostic tool in separating FHH and PHPT. We wished to compare the D-ratio in FHH and PHPT and to test its discriminative power. Our material consisted of 49 patients with FHH, based on hypercalcemia (mean of 3 measurements) and mutation(s) in the calcium sensing receptor gene (CaSR-gene), who were compared with 160 patients with surgically verified PHPT. The FHH group was separated into two subgroups: subgroup I (n=27) included mutations with obvious effect on the FHH phenotype (R886W, C582F, C582Y, G509R, 1998 insT, S171N, G397R), subgroup II (n=22) included mutations with less effect on the FHH phenotype (R990G, A986S, Q1011E, 1732+16 T>C). All patients had a P-creatinine level < 150 pmol/l. All sequenced DNA fragments were compared to reference sequences. As expected, P-PTH was higher in PHPT than in FHH (2p<0.001). P-25OHD was reduced in the PHPT group compared with the FHH group and subgroups I (2p<0.001) and II (2p<0.001). We found no significant differences between the PHPT group and the FHH groups with regard to P-1,25(OH)$_2$D and P-creatinine. The PHPT group had higher D-ratio (3.42 ± 2.01 (SD) pmol/nmol) than the FHH group (2.10 ± 0.94, 2p<0.001), and the subgroups I (2.12 ± 0.85, 2p=0.001) and II (2.07 ± 1.06, 2p=0.002). ROC curve analysis of the FHH group showed that D-Ratio < 1.60 was the best cut off value for separating FHH from PHPT, diagnostic sensitivity = 0.33, and diagnostic specificity = 0.88. The positive predictive value was 0.44 for D ratio < 1.60 compared with 0.92 for CCCR < 0.01 in the same material. In the FHH group the D-ratio was unrelated to P-PTH (2p=0,38) and P-creatinine (2p=0.75). In the PHPT group the D-ratio was positively correlated to PTH (r= 0.17, 2p<0.04) and inversely correlated to P-creatinine (r= -0.21, 2p<0.01). The D-Ratio is insufficient in discriminating between FHH and PHPT. It is important also to consider calcium-creatinine clearance ratio, pedigree, mutations in the CaSR gene, P-PTH, and eventually ultrasound, and parathyroid scintigraphy.

Causes of Bone Loss in a Clinical Pediatric Population. K. Vandenbulcke*[1], T. Chernova[2]. [1]Katholieke Universiteit, Leuven, Belgium, [2]Russian Academy of Medical Sciences, Moscow, Russian Federation.

Although dual energy x-ray absorptiometry (DXA) is a fast, non-invasive, low-dose and highly reproducible method for the assessment of skeletal status in children, its application in clinical pediatric practice is not widespread. Numerous pathologies (growth hormone (GH) deficiency, AIDS, anorexia nervosa, diabetes) can influence the growth and mineralization of the pediatric skeleton. GE Healthcare provides enhanced pediatric software including spine and total body bone mineral density (BMD) measurements as well as tools to adjust for the child's body size (ratios of height for age, bone mineral content (BMC) for bone area, and bone area for height). In this study we evaluated the clinical value of DXA measurements in pediatric subjects. We reviewed all the pediatric patients who were referred to the clinic over the past four years. A total of 837 boys and girls ranging in age from 5 to 19 years were measured on the Lunar Prodigy (GE Healthcare) in this clinical practice. Of the total, 192 subjects were healthy, while 645 subjects had pathologies known to affect BMD. All children had either a spine scan or a total body scan, or both. Bone density values were compared to the pediatric reference population in the Lunar enCORE software. Follow-up measurements were performed in 176 children with low BMD at baseline.

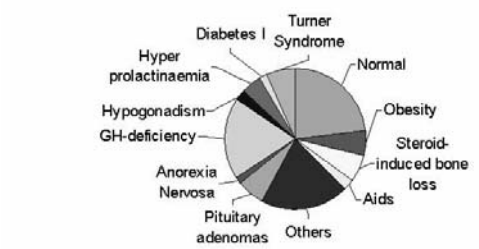

Figure 1: Different pathologies of children having a DXA skeletal assessment

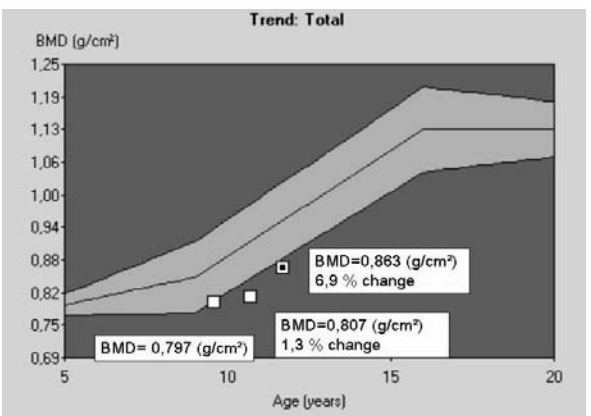

Figure 2: Baseline and follow-up values for a girl with anorexia nervosa

The primary pathologies affecting BMD found in this group were GH deficiency, Turner's syndrome, steroid-induced bone loss, and pituitary adenomas (Figure 1). With most pathologies children had lower bone area, BMC, and BMD when compared to the reference. In 176 of the measured 837 children follow-up scans were performed to check if their bone status improved in function of treatment and/or age. Figure 2 illustrates baseline and follow-up values for a girl with anorexia nervosa. In this study we illustrated that in many diseases occurring in children DXA measurements of the spine and total body allowed baseline and on-going assessment of the bone status of these children.

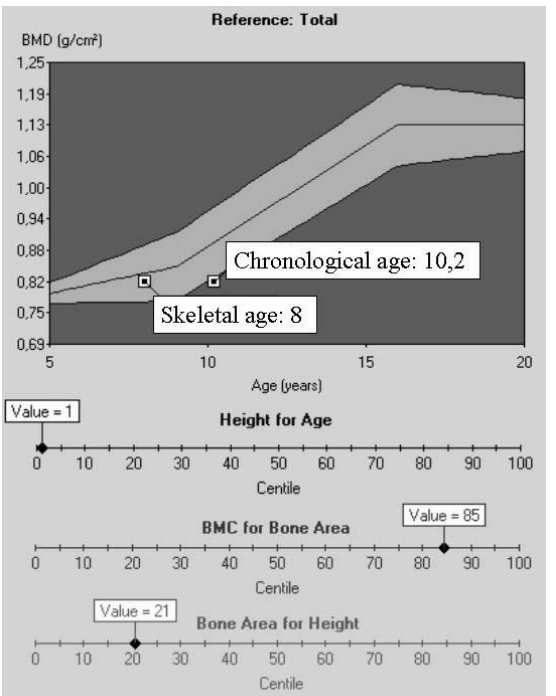
Improved Assessment of Bone Status in Children with the Lunar Pediatric Total Body Software. H. Fors*[1], S. Valdimarsson*[1], K. Albertsson Wikland*[1], K. Vandenbulcke*[2]. [1]GP-GRC, Sahlgrenska Academy of Göteborg University, Göteborg, Sweden, [2]Katholieke Universiteit, Leuven, Belgium.

Measurement of bone mineral density (BMD) in children has become important in clinical endocrinology. Dual-energy X-ray absorptiometry (DXA) is the method of choice to evaluate BMD in children, but the two-dimensional measurement is influenced by body size and can impact the accurate assessment of bone accrual in the growing skeleton. Children with growth abnormalities often show deficient BMD for chronological age, but this low BMD might be a reflection of skeletal size rather than poor mineralization. The Lunar pediatric software provides, in addition to BMD values, a number of tools to adjust for body size. In this study we wished to determine if these body size tools are of clinical value in the assessment of pediatric bone status. Forty-eight children (5-18 yrs, 17 girls), with growth hormone deficiency, had total body scans on the Lunar Prodigy (GE Healthcare). Skeletal age was determined by the Greulich-Pyle method. BMD plots against chronological age (CA) and skeletal age (SA), Z-scores for chronological age (ZCA), the subject's height for age, BMC for bone area (BMC/BA), and bone area for height were obtained with the enCORE software. Z-scores for skeletal age (ZSA) were calculated in the same way as the ZCA. Skeletal age in these subjects was on average 1,5 years (-4 to +0.5 range) younger than chronological age. The children had significantly lower total body BMD (p = 0.0005) when compared to normal children of the same chronological age (average ZCA = -0.2). However, their BMD was not significantly different than normal children of the same skeletal age (average ZSA = 0.5), illustrating that bone mineralisation might be underestimated when only BMD for chronological age is considered. Regression analyses of BMC/BA as a function of CA confirmed that the bone mineralisation of these children is generally normal for their bone area (bone size). Results from this small group of children with growth hormone deficiency demonstrate that adjustment of pediatric densitometry values for body size and skeletal age can be vital for appropriate clinical decisions. Bone mineralisation may be underestimated when only BMD for chronological age is considered.



Lunar total body results for a 10 year old girl with a growth hormone disorder

Children with Osteogenesis Imperfecta Treated with Bisphosphonates Have Site-Specific Bone Responses to Therapy. R. K. Fuchs[1], M. Peacock[2], C. McClintock*[2], L. A. DiMeglio[3]. [1]Department of Anatomy and Cell Biology, Indiana University Medical School, Indianapolis, IN, USA, [2]Department of Medicine, Indiana University Medical School, Indianapolis, IN, USA, [3]Department of Pediatrics, Indiana University Medical School, Indianapolis, IN, USA.

Bisphosphonate therapies improve bone mass, reduce fractures, and improve physical function in children with Osteogenesis Imperfecta (OI). In addition to the primary defect in type I collagen, children with OI also have "disuse osteoporosis" because of fracture- and deformity-induced limitations in their mobility. To test if there were differing responses to bisphosphonate therapy in the arms and legs, we examined site-specific changes in bone mass in ambulatory and non-ambulatory children clinically diagnosed with OI and treated with bisphosphonates. Thirteen children between the ages of 5 and 13 were treated for 24 months with one of two bisphosphonates—intravenous pamidronate (n=7) [3 mg/kg over 3 days every 4 months] or oral alendronate (n=7) [1 mg/kg from a minimum of 10 mg to a maximum of 20 mg daily]. Three children had severe (Type III or IV) OI and 10 children had mild (Type I) OI. Nine children were ambulatory and 4 were non-ambulatory (minimal walking). No children had rods newly implanted during the treatment period. Bone mineral content (BMC; g) of the upper and lower limbs derived from total body DXA scans were evaluated at baseline, and after 24 months of bisphosphonate treatment. Both ambulatory and non-ambulatory children had significant increases in upper and lower limb BMC over 24 months of bisphosphonate treatment (both $p<0.001$ based on repeated measures ANOVA). However, ambulatory children were found to have greater absolute increases in mineral content of the lower limbs compared to non-ambulatory children (absolute Δ over 24 months: 263g vs 103g, respectively; $p<0.02$). In contrast, for the upper limbs there were no differences in mineral content accrual between the ambulatory and non-ambulatory children (absolute Δ over 24 months: 82g vs 53g, respectively). Additionally, the observed site-specific differences between ambulatory and non-ambulatory children were similar between those children receiving IV or oral bisphosphonate treatment. The greater increases in bone mass in the lower limbs may be due to site-specific effects of the bisphosphonates. Alternatively, the greater increases in mechanical loading of the legs in the ambulatory children may have contributed to the greater increases in lower limb bone mass.

Decreased Bone Size and Density in Children with Turner Syndrome (TS) Prior to Growth Hormone Therapy. G. Costin*[1], P. Pitukcheewanont[1], D. Safani*[1], S. Rossmiller*[1], V. Gilsanz[2]. [1]Endocrinology, Childrens Hospital Los Angeles, Los Angeles, CA, USA, [2]Radiology, Childrens Hospital Los Angeles, USC Keck School of Medicine, Los Angeles, CA, USA.

Background: While some studies have reported decreased bone mineral density (BMD) in children with Turner syndrome (TS), others have found normal BMD values when compared to healthy controls. Most studies using dual-energy x-ray absorptiometry (DXA) to evaluate BMD have found that untreated prepubertal girls with TS have normal BMD. The purpose of this study was to compare bone size and density of children with TS to healthy age-, gender-, and ethnicity-matched controls using DXA and quantitative computed tomography (CT). **Subjects and Methods:** 23 prepubertal females, mean age of 11.93 ± 3.28, with karyotype-proven TS had bone measurements obtained prior to growth hormone therapy. Whole body (WB) and spine bone measurements were obtained using DXA while spine and femoral bone measurements were obtained using CT. Subjects were matched with controls based on age, gender and ethnicity. **Statistics:** Paired Student's *t*-test was used to compare bone size and density measurements between children with TS and controls. Pearsons correlation was used to find associations between anthropometric measurements and bone size. **Results:** Children with TS were shorter ($p<0.001$), lighter ($p<0.001$) and had lower BMIs ($p<0.05$) than controls. Accordingly, bone area by CT (CBA of the femur and CSA of the spine and femur) and DXA (spine and whole body area) were lower in children with TS than in controls ($ps\leq0.001$). These areal bone measurements also correlated strongly with height in children with TS ($ps<0.001$). Both DXA- and CT-measured BMD of the spine were lower in children with TS compared to controls ($ps<0.05$). In addition, DXA-measured WB BMD ($p<0.001$) was lower in Turner children than in controls. The mean decreases in CT spine BD and DXA WB BMD were 14% and 13%, respectively. **Conclusion:** Cancellous bone size and density were lower in children with TS compared to controls. While the decreased bone size appears to be secondary to the smaller size of children with TS, the decreased bone density may be due to a chronic lack of estrogen.

Performance of the Lunar Infant Total Body Software in Newborns and Preterm Infants. S. Di Gregorio*[1], L. Del Rio[1], P. Pludowski*[2], J. Czech-Kowalska*[3], A. Dobrzanska*[3], K. Vandenbulcke*[4], R. Lorenc*[2]. [1]Cetir Centre Medic. Densitometry Department., Barcelona, Spain, [2]The children's memorial Health Institute, Warsaw, Poland, [3]Department of Neonatology, The Childrens Memorial Health Institute, Warsaw, Poland, [4]Katholieke Universiteit, Leuven, Belgium.

Different factors like environment, nutrition, hormonal status, diseases affect postnatal skeletal growth and mineralization in preterm infants. Compared to their term counterparts preterms have an increasing incidence of osteopenia and postnatal growth deficiency at the time of hospital discharge. Dual energy x-ray absorptiometry (DXA) is a non-invasive, low dose, fast, accurate and precise method in measuring bone mineralisation and has therefore become the method of choice to measure infants and preterm infants. Recently, GE Healthcare Lunar introduced a total body software dedicated to measure infants. In this study we wished to evaluate the performance of this software both in healthy newborns as well as in preterm infants. 33 healthy Spanish newborns (16 boys, 17 girls), between 8 and 28 days old were scanned with the infant total body software on the Lunar Prodigy (GE Healthcare). Their weight was between 2,4 and 4,3 kgs, their height ranged between 45 and 55cm. 16 Polish preterms (9 boys, 7 girls) were also scanned with the same software. Their weight at birth was between 0,6 and 1,2kg. On acquisition time they weighed between 2 and 4,2 kg and were between 2 and 4 months old. Their body size at acquisition was still rather small ranging from 42 to 50 cm. Acquisition times were around three minutes. The average total body bone mineral density (BMD) of the healthy newborns is 0,157 g/cm² and their average total body bone mineral content (BMC) is 119 g. There was no difference between girls and boys when total body bone mineral density and total body bone mineral content were compared with height and weight. The average total body BMD is 0,154 g/cm² of the polish preterms but their average total body BMC is remarkably low: 42 g. We conclude that the new Lunar infant total body software is a clinically valid, non-invasive, low dose and fast method for measuring bone mineralisation in infants.

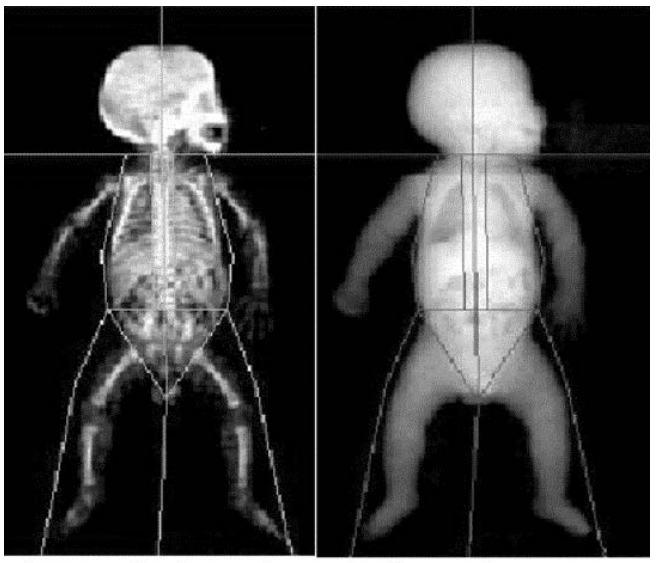

Figure: Total body scan of a 3 month old preterm boy.
His weight was at birth 0,700 kg.
At acquisition time his weightwas 3,3kg and his weight 47 cm.

Femur Densitometry with Adjustment for Body Size in Healthy German Children. K. Minas. Orthopadische Praxis, Papenburg, Germany.

Measurement of pediatric bone mineral density (BMD) of the proximal femur with dual-energy x-ray absorptiometry (DXA) is challenging due to the changing morphometry of the femur during aging. Dimensions of femur regions-of-interest (ROI) should automatically adjust to changes in the child's body size with aging. Pediatric femur software is now available for investigational use that automatically adjusts the neck ROI and total ROI based on the child's stature. Reference data based on this new software is currently being developed. We used the Lunar Prodigy (GE Healthcare) to measure the proximal femur in a sample of healthy, normal German boys (n = 143) and girls (n = 171) age 5 through 15 years. Scans were analyzed with Lunar enCORE software version 9.15, with automatic calculation of BMD values for the size-adjusted ROIs. For comparison, scans were also analyzed without the automatic ROI size adjustment. Results showed that total femur BMD values in boys were somewhat higher (5 to 15%) than girls from age 7 to 11 years, with less difference at younger and older ages. In about 15% of scans, automated analysis of the total femur region was incorrect unless the new software with size-adjusted ROIs was used.Automatic adjustment of the size of femur analysis regions for a child's

stature should allow better evaluation of the pediatric patient. Femur reference data for size-adjusted BMD values are important for appropriate interpretation of BMD in the growing pediatric skeleton.

Reduced Bone Mineral Density in Patients with Early and Active Rheumatoid Arthritis. W. F. Lems[1], J. Bijsterbosch*[2], J. de Vries Bouwstra*[2], Y. Goekoop-Ruiterman*[2], F. Breedveld*[2], R. Allaart*[2], B. Dijkmans[1].
[1]Rheumatology, Free University medical centre, Amsterdam, The Netherlands, [2]Rheumatology, Leiden University medical centre, Leiden, The Netherlands.

Background Generalized osteoporosis is considered as an important extra-articular feature of rheumatoid arthritis (RA). The majority of studies designed to evaluate bone mineral density (BMD) in RA patients is conducted in patients with established RA. **Objective** To identify patients with osteoporosis and to evaluate possible risk factors for osteoporosis in a study population with early, active RA. **Patients and Methods** The BeSt study is a multi-centre randomized controlled trial designed to evaluate the effect of four different treatment strategies for early (symptom duration < 2 years) and active RA. In 342 patients baseline BMD measurements of the lumbar spine L1-L4 and total hip were performed by DXA. Between patients with (T-score <-2,5 at the hips or spine) and those without osteoporosis, clinical, demographic and radiological characteristics were compared using univariate and multivariate analysis. **Results** The population consisted of 240 women and 102 men with a mean age of 54.6 years. Osteoporosis was observed in 10.2% of the patients. Osteoporosis was found more often in rheumatoid factor (RF) positive patients, in patients with higher age, in postmenopausal women and in patients with low body mass index (BMI). No association was found between the presence of osteoporosis and symptom duration or disease activity measured by the DAS_{44}-score (table 1). Stepwise multiple logistic regression analysis showed that postmenopausal status and BMI were independent predictors of osteoporosis. **Conclusions** We found that osteoporosis is already present in a substantial proportion of patients with recent onset of active RA. In this population osteoporosis was predominantly related to classic risk factors as postmenopausal status and low BMI, but not to disease duration or disease activity. Thus, screening for osteoporosis might be also important in early RA, particularly since these patients might be at risk for additional bone loss, because of the disease (RA) and/or antirheumatic drugs (prednisone).

Table 1.

	Odds Ratio	*95% Confidence Interval*
Age	1.03	1.01-1.06
Symptom duration	1.01	1.00-1.01
DAS_{44}-score	0.76	0.52-1.12
Positive Rheumatoid Factor	2.39	1.01-5.66
Postmenopausal status	6.29	1.44-27.47
Body Mass Index	0.86	0.77-0.95

Homocysteine Level, Bone Mineral Density and Fracture Risk in Systemic Lupus Erythematosus Women. E. Y. Rhew[1], C. Lee[1], P. Eksarko*[1], A. R. Dyer*[2], R. M. Pope*[1], S. Spies*[3], R. Ramsey-Goldman[1]. [1]Rheumatology, Northwestern University, Chicago, IL, USA, [2]Preventive Medicine, Northwestern University, Chicago, IL, USA, [3]Nuclear Medicine, Northwestern University, Chicago, IL, USA.

Elevated homocysteine (HCY) is an independent risk factor for fractures (FXs) in the general population. Patients with systemic lupus erythematosus (SLE) are at increased risk for bone loss and FXs, but no data exist in SLE on the relationship between HCY and bone mineral density (BMD) or FXs. We examined the association of baseline HCY with BMD and the incidence of FXs in SLE. We assessed baseline HCY in SLE cases (n=100) and non-SLE controls (n=100) matched on age, race, and menopause status. All women received BMD measurements of at least one anatomic site (lumbar spine, hip or distal forearm) at baseline by dual x-ray absorptiometry. BMD results were expressed as T-scores. Non-fasting serum HCY levels were measured using an enzyme immunoassay (Biorad) (intra-assay CV 5.2-7.3%; inter-assay CV 7.1-9.3%). We collected data on current smoking status; alcohol, caffeine, and total calcium (dietary and supplemental) intake; estrogen and corticosteroid (CS) use; height and weight; FXs at baseline; and new FXs occurring over 2 years of follow-up. Statistical analyses were performed using Student's t-test for paired values, Spearman's correlation and McNemar's test. IRB approval was obtained for this study. Mean HCY ±SD was higher ($p<0.001$) in cases (9.98 ±3.8µmol/L) than controls (7.98 ±2.6µmol/L). Elevated HCY and older age were correlated in cases ($r=0.219$; $p=0.028$), but not in controls. In cases, there were no significant differences in HCY when stratified by race, menopause status, and estrogen or CS use. In controls, pre-menopausal women had notably lower mean HCY than menopausal women (mean 7.63 ±2.49µmol/L vs. 8.59 ±2.65µmol/L, $p=0.016$), but HCY did not differ based on race or estrogen use status. Baseline L-spine BMD T-scores were significantly lower in cases than controls (-0.73 vs. -0.20, $p=0.003$), whereas hip and distal forearm T-scores were comparable between the groups. However, there were no significant correlations between HCY and BMD T-scores at any site for both cases and controls. Cases sustained 14 new FXs, while controls experienced 4 new FXs over the 2 year follow-up period ($p=0.021$). Baseline HCY did not predict new FXs in either cases or controls. In conclusion, cases (women with SLE) have significantly greater baseline HCY, lower L-spine BMD T-scores, and a higher number of new FXs over 2 years as compared with controls. However, in cases and controls, HCY was not significantly associated with BMD T-scores at the L-spine, hip, or distal forearm, and baseline HCY measurement did not predict new FXs.

Autoimmune IFN-Alpha Irreversibly Biases Myelopoiesis Towards Dendritic Cells and Depletes Osteoclast Precursors: A Central Mechanism for Non-Erosive Inflammatory Arthritis. L. Ma*[1], H. Awad[1], C. Ritchlin*[1], R. J. O'Keefe[1], H. Drissi[1], A. Mathian*[2], J. Banchereau*[2], E. M. Schwarz*[1]. [1]Orthopaedics, University of Rochester, Rochester, NY, USA, [2]Baylor Institute for Immunology Research, Dallas, TX, USA.

Introduction: Autoimmune arthropathies present in various forms. While rheumatoid arthritis (RA) is associated with erosive disease there are also non-erosive forms, which are most common in patients that have systemic lupus erythematosus (SLE). Here we investigate the effects of IFNα on myelopoiesis as a potential mechanism. **Methods:** NZBxNZW (lupus) TNF-Tg (arthritis) or Balb/c and B6 (control) mice were untreated, or received recombinant adenovirus containing an empty cassette (Ad-Nul) or IFNα (Ad-IFN). Osteoclast precursor (OCP) and dendritic cell precursor (pDC) populations in blood and spleen were evaluated by FACS using antibodies specific for CD11b and CD11c and by TRAP osteoclastogenesis assays. Tibias were also analyzed by micro-CT and histology. **Results:** IFNα was detected only in the serum of mice treated with Ad-IFNα. Only the NZBxNZW F1 mice (100%) developed lupus. No differences in osteoclast numbers were observed in any of the control groups (Balb/c untreated 70±8; Balb/c empty vector 73±9; NZBxNZW F1 untreated 73±7; NZBxNZW F1 empty vector 73±9). However, Balb/c mice treated with Ad-IFNα had a significant decrease in osteoclasts (26±6; $p<0.002$). The NZBxNZW F1 Ad-IFNα group had significantly lower osteoclast numbers than controls or Balb/c mice (4±2; $p<0.0.05$). Micro-CT analysis revealed that the untreated NZBxNZW F1 mice had a 1.5-fold increase in bone volume vs. Balb/c mice and that IFN significantly increased the bone volume in both strains over 2-fold ($p<0.0.05$). In the TNF-Tg experiments we found that Ad-IFN: 1) decreased $CD11b^+/CD11c^-$ OCP from 53.2% to 30.0% and increased $CD11b^+/CD11c^+$ pDC from 13.7% to 36.1% in PBMC, 2) decreased the osteoclastogenic potential of $CD11b^+/CD11c^-$ OCP down to that observed in untreated $CD11b^+/CD11c^+$ pDC, and 3) completely eliminated the osteoclastogenic potential of $CD11b^+/CD11c^+$ pDC. Discussion: The recent discoveries that: 1) SLE patients suffer from systemic IFN, and 2) IFN dominantly alters myelopoiesis away from osteoclastogenesis, provides a potential mechanism to explain the non-erosive lupus phenotype. The finding here that systemic IFN significantly reduces OCP frequency in the periphery and osteoclast numbers at sites of bone resorption in the absence of lupus documents the dominance of this cytokine. That similar effects are observed in animals that suffer from aggressive-erosive arthritis highlights the role of IFN during myelopoiesis.

Botanical Extracts Isolated from Turmeric or Ginger Prevent Joint Swelling and Associated Joint Destruction in an Animal Model of Rheumatoid Arthritis. J. L. Funk, J. A. Beischel*, J. N. Oyarzo-Somoza*, G. Chen*, R. C. Lantz*, A. M. Solyom*, S. D. Jolad*, B. N. Timmermann*. Arizona Center for Phytomedicine Research, University of Arizona, Tucson, AZ, USA.

PURPOSE: Dried ground rhizomes of turmeric and ginger, related herbs from the Zingiberaceae family that contain structurally similar phenolic compounds (i.e. curcuminoids and gingerols), have been used for centuries in Ayurvedic medicine to treat inflammation and are being viewed with increased interest in the "post-Vioxx era" for the treatment of arthritis. However, scientific data regarding the clinical efficacy of these chemically complex botanicals are lacking. Studies were therefore undertaken to test the effects of well-characterized extracts of turmeric or of ginger on joint inflammation and associated bone destruction in an animal model of rheumatoid arthritis. METHODS: Female Lewis rats were treated with: (1) vehicle alone; (2) botanical extract; (3) streptococcal cell wall (SCW) (25 mg/kg ip); or (4) SCW + botanical extract. Extracts tested include: (i) crude extract of turmeric dosed at 46 mg curcuminoids/kg/D (ii)

essential oil-free, curcuminoid fraction of turmeric dosed at 23-46 mg curcuminoids/kg/D (iii) crude extract of ginger dosed at 26 mg gingerols/kg/D, or (iv) essential oil-free, purified extract of ginger dosed at 26 mg gingerols/kg/D. Extracts were administered via intraperitoneal injection 5-7 days/week beginning 4 days prior to SCW injection and effects of treatment were monitored by clinical evaluation of joint swelling and *in vivo* or *ex vivo* measures of joint destruction. RESULTS: Treatment with crude or purified extracts of turmeric and ginger that contained curcuminoids or gingerols, respectively, profoundly inhibited joint swelling. Joint destruction, as measured by histologic assessment of cartilage destruction, periarticular accumulation of TRAP-positive osteoclasts, and decreases in periarticular BMD, was similarly prevented. Further evaluation of animals treated with the curcuminoid fraction of turmeric revealed an inhibition of NFk-B activation in arthritic joints, as well as inhibition of *ex vivo* osteoclast formation stimulated by M-CSF and RANK-activating antibody. CONCLUSIONS: Extracts of turmeric or ginger containing phenolic compounds prevent inflammation and inflammation-associated joint destruction. At least part of the bone-protective effects of these complex botanical mixtures may be due to inhibition of RANK-mediated bone resorption. These complex botanicals may therefore also be of benefit in the treatment of other bone diseases associated with activation of the RANK pathway, including post-menopausal osteoporosis. (The NIH [P50 AT00474] supported this work).

Baseline Bone Mineral Density (BMD) and Bone Turnover Markers (BTM) to Predict 2-Year Change in BMD in Systemic Lupus Erythematosus (SLE). C. Lee[1], O. Almagor*[2], D. D. Dunlop*[2], C. B. Langman[3], H. Price*[3], S. Spies*[4], A. B. Chadha*[1], R. Ramsey-Goldman[1]. [1]Rheumatology, Northwestern Univ., Chicago, IL, USA, [2]Institute for Healthcare Studies, Northwestern Univ., Chicago, IL, USA, [3]Pediatrics, Childrens Memorial Hospital, Chicago, IL, USA, [4]Radiology, Northwestern Univ., Chicago, IL, USA.

We assessed the utility of baseline bone turnover markers (BTM) and BMD in predicting 2-year change in BMD at the hip, lumbar spine (LS), and distal forearm (DF) in women with SLE (cases) compared with matched controls. Cases (n=97) and controls (n=97) were matched on age, race, and menopause status. All had baseline and 2-year BMD measurements (Hip, LS, and/or DF) and baseline measurements of BTM: 1) osteocalcin (OC), 2) bone alkaline phosphatase (BAP), 3) urine N-telopeptide (U-NTX). Women completed a lifestyle questionnaire and medication survey. We assessed disease features of SLE, including disease duration, renal involvement, and the ACR/SLICC Damage Index (SDI), modified to exclude an osteoporosis/fracture item. Effect of baseline BMD and BTM to predict 2-year change in BMD was determined using multiple regression with generalized estimating equations to account for the matched case/control design. Cases and controls were comparable for age at study visit and body mass index (BMI), but cases were younger at menopause (see Table). Both groups were similar in the proportion using caffeine or alcohol, who currently smoked and used female hormones. Cases had mean SLE duration of 8.4 ±8.2 years, mean SDI of 1.07 ±1.7, 25.8% had SLE renal disease, 76.3% ever used corticosteroids (CS), and 47.4% were currently using CS with a dose equivalent to 8.7 ±10.6 mg/day of prednisone.

TABLE. Comparison of Cases and Controls

Characteristics	Cases (n=97)	Controls (n=97)	P value
Mean age at study visit ±SD	43.3 ±11.4	43.7 ±10.8	0.11
Mean body mass index (BMI) ±SD	26.9 ±7.3	26.1 ±6.0	0.39
Mean age at menopause in years ±SD	41.0 ±7.6	44.5 ±5.9	**0.01**
Mean total daily calcium intake (mg) ±SD	1201.3 ±680.4	959.6 ±603.6	**0.004**
Mean daily vitamin D intake (IU) ±SD	487.8 ±167.6	434.3 ±149.4	0.15
Proportion taken thiazide diuretics (%)	18.6%	5.2%	**0.01**
Baseline Mean BTM			
BAP (U/L)±SD	17.3 ±7.7	18.9 ±7.7	0.09
OC (ng/ml)±SD	8.2 ±7.7	8.5 ±6.6	0.71
U-NTX (nM/mM)±SD	35.3 ±37.9	32.7 ±16.5	0.67
2-year change in BMD (gm/cm^2)			
Anatomical Site			
Hip ±SD	-0.011 ±0.04	-0.002 ±0.03	0.09
Spine ±SD	0.004 ±0.05	0.003 ±0.03	0.91
Distal Forearm ±SD	-0.012 ±0.03	-0.005 ±0.05	0.29

Cases had significantly more BMD loss at the hip (p=0.02) controlling for baseline BMD and BTM. Greater BMD loss at the DF was experienced by cases and increased with higher baseline values of BMD and U-NTX. Cases and control differences were not significant for spine BMD loss controlling for other factors. We conclude that women with SLE (cases) compared to those without SLE (controls) have comparable baseline BTM but greater BMD loss at the hip and DF. Higher baseline hip and DF BMD predicted greater future bone loss at each of these sites. Greater U-NTX predicted larger DF BMD loss controlling for BTM of bone formation.

Disclosures: ***C. Lee****, None.*

RANKL Protein Is Expressed at the Pannus-Bone Interface at Sites of Erosion in Rheumatoid Arthritis. A. R. Pettit[1], N. C. Walsh[2], C. Manning*[2], S. R. Goldring[2], E. M. Gravallese*[2]. [1]Institute for Molecular Bioscience, University of Queensland, Brisbane, QLD, Australia, [2]New England Baptist Bone and Joint Institute, Beth Israel Deaconess Medical Center/Harvard Institutes of Medicine, Boston, MA, USA.

Bone erosion is a characteristic feature of rheumatoid arthritis (RA) and is associated with significant morbidity and with poor prognosis. We previously reported the generation of inflammatory arthritis in the receptor activator of NF-κB ligand (RANKL)-/- mouse. Bone erosion was dramatically reduced in arthritic RANKL-/- mice, and osteoclast-like cells, abundant in erosions in arthritic control mice, were absent in arthritic RANKL-/- mice. These data support the hypothesis that RANKL is required for osteoclast generation in inflammatory arthritis. The expression of RANKL and its decoy receptor osteoprotegerin (OPG) has been reported in RA synovial soft tissues. However, the identification of RANKL, its receptor, receptor activator of NF-κB (RANK), and OPG protein expression in the RA bone microenvironment is essential to fully characterize their contribution to osteoclastogenesis and subsequent bone erosion in RA. Tissues from 20 orthopedic surgeries on RA patients fulfilling American College of Rheumatology criteria were collected as discarded materials, as approved by the Institutional Review Board. Average duration of RA was 16 yrs (range 4 - 31 yrs). Six tissue samples contained only synovium/tenosynovium remote from bone, 7 samples contained bone with adjacent synovium, and 7 samples contained both synovium remote from bone and bone with adjacent synovium. Immunohistochemistry was used to characterize RANKL, RANK, and OPG protein expression. RANKL expression in the bone microenvironment was confined to sites of osteoclast-mediated bone erosion at the pannus-bone interface and at sites of subchondral bone erosion. RANK expressing osteoclast precursor cells were also present in erosion sites and most multinucleated cells on bone expressed RANK. OPG expression was prominent in synovium remote from bone, particularly in cells of the synovial lining layer, but was minimal in the local bone microenvironment, especially at sites of bone erosion and RANKL expression. The results indicate that in the RA bone microenvironment the RANKL/OPG expression balance favors osteoclastogenesis. This is the first demonstration of RANKL, RANK and OPG protein expression at sites of RA focal bone erosion and provides additional strong support for the importance of RANKL and of osteoclasts in the process of bone erosion in inflammatory arthritis.

SU492

Relationship between Baseline Levels of Bone Mineral Density (BMD) and Measures of Calcium Homeostasis (MCH) with 2-Year Change in BMD in Systemic Lupus Erythematosus (SLE). C. Lee[1], O. Almagor*[2], D. D. Dunlop*[2], C. B. Langman[3], H. Price*[3], S. Spies*[4], A. B. Chadha*[1], R. Ramsey-Goldman[1]. [1]Rheumatology, Northwestern Univ., Chicago, IL, USA, [2]Institute for Healthcare Studies, Northwestern Univ., Chicago, IL, USA, [3]Pediatrics, Childrens Memorial Hospital, Chicago, IL, USA, [4]Radiology, Northwestern Univ., Chicago, IL, USA.

We assessed the relationship of baseline measures of calcium homeostasis (MCH) and BMD to 2-year change in BMD at the hip, lumbar spine (LS), and distal forearm (DF) in women with SLE (cases) and matched controls. Cases (n=99) and controls (n=99) were matched on age, race and menopause status. All women had baseline and 2-year BMD (Hip, LS, and/or DF) and baseline measurements of MCH: 1) 25-hydroxyvitamin-D (25-OH-D) and 2) intact parathyroid hormone (PTH). All women completed a lifestyle questionnaire and medication survey. We evaluated SLE features, including disease duration, renal involvement, and the ACR/SLICC Damage Index (SDI), modified to exclude an osteoporosis/fracture item. Effect of baseline BMD and MCH to predict 2-year change in BMD was determined using multiple regression with generalized estimating equations (GEE) to account for the matched case/control design. Cases and controls had similar age at study visit and BMI, but cases were younger at menopause (see Table). Both groups were comparable in the proportion using caffeine or alcohol, who currently smoked and used female hormones. Cases had disease duration of 8.4 ±8.3 years, a mean SDI of 1.06 ±1.7, 26.3% had SLE renal disease, 75.8% ever used corticosteroids (CS), and 48.5% were currently using CS equivalent to 8.7 ±10.5 mg/day of prednisone.

TABLE. Comparison of Cases and Controls

Characteristics	Cases (n=99)	Controls (n=99)	P value
Mean age at study visit ±SD	43.5 ±11.4	44.0 ±10.8	0.08
Mean body mass index (BMI) ±SD	27.0 ±7.2	26.2 ±6.1	0.34
Mean age at menopause in years ±SD	41.3 ±7.8	44.5 ±5.8	**0.02**
Mean total daily calcium intake (mg) ±SD	1219.3 ±674.7	974.8 ±601.2	**0.003**
Mean daily vitamin D intake (IU) ±SD	495.2 ±172.4	443.2 ±157.3	0.15
Proportion taken thiazide diuretics (%)	18.2	5.1	**0.01**
Baseline Mean MCH			
25(OH)D (ng/ml) ±SD*	12.8 ±6.2	13.5 ±8.0	0.42
Intact PTH (pg/ml) ±SD**	28.6 ±21.5	28.0 ±26.7	0.86
2-year change in BMD (gm/cm^2)			
Anatomical Site			
Hip ±SD	-0.013 ±0.04	-0.002 ±0.03	0.06
Lumbar Spine (LS) ±SD	0.002 ±0.05	0.004 ±0.03	0.73
Distal Forearm (DF) ±SD	-0.012 ±0.03	-0.005 ±0.05	0.28

*Reference range for 25(OH)D: (15 - 40 ng/mL)
**Reference range for Intact PTH: (15 - 55 pg/mL)

Cases and controls had similarly low 25(OH)D levels. Cases had more BMD loss at the hip (p=0.04) controlling for baseline BMD and MCH, and greater baseline hip BMD predicted BMD loss. Both groups had similar changes in LS and DF BMD controlling for baseline BMD and MCH. Higher baseline LS and DF BMD were predictive for BMD loss at the LS (p=0.01) and DF (p=0.002) in both groups. We conclude that women with (cases) and without (controls) SLE have low 25(OH)D and similar PTH levels at baseline. 25(OH)D and PTH are not predictive for future change in BMD in SLE. Women with SLE have greater bone loss at the hip, but not at the LS or DF controlling for 25(OH)D and PTH. Higher baseline BMD at any site was predictive for bone loss in both groups.

Bisphosphonate(Alendronate) Decreases Osteoclastogenesis and Changes the Related Cytokine Expression from the Human Peripheral Blood Mononuclear Cells(PBMCs) *In Vitro*: The PBMCs from Patients with Rheumatoid Arthritis (RA) Respond to Bisphosphonates Differently from those of Normal Control. W. Park, S. Kwon*, S. Hong, J. Shin*. Medicine, IN-HA University Hospital, Incheon, Republic of Korea.

There have been many studies regarding the cytokine change and influence on inflammation by the alendronate, but they are conflicting in their results. Although the RA is osteoporosis prone inflammatory disease, there are few studies about the effect of alendronate on osteoclastogenesis from the PBMCs in these patients. Six normal control and 6 patients with definite RA who had not taken the bisphosphonates were selected. The culture of the human PBMC was done with M-CSF (25 ng/ml) containing RPMI-1640 media. After 3 weeks culture with alendronate at the concentration of 50 μM, TRAP stain was done for cytochemical assessment of osteoclast(OC) development and calcium phosphate nano crystal coated culture plate (OAAS^{TM}-04, Oscotec, Korea) was assessed for the osteoclastic resorption activity. After 24 hour incubation of PBMCs in the presence of alendronate 200 μM, real time RT-PCR was done to quantify the expression of the interleukin(IL)-1, tumor necrosis factor(TNF)-α, receptor activator of nuclear factor-kappaB (RANK), RANK-ligand (RANKL), interferon(IFN)-γ, TRAP, and cathepsin-K. At baseline, there was no significant difference of these cytokines mRNA expression in PBMCs between RA patients and normal control. After the incubation with alendronate, the increased mRNA expression of the IL-1, TNF-α, IFN-γ, RANKL, and decreased expression in TRAP mRNA from baseline was seen in control, but it was blunted in PBMC of the RA patients (Mann-Whitney U, 2-tailed significance < 0.05). The cathepsin-K expression was not changed in either group, but the RANK expression was decreased to 27% of the baseline in RA PBMC and to 16% in control group (no significant difference between groups). The TRAP positive adherent giant cell development and calcium phosphate plate resorption were almost completely inhibited throughout the 3 weeks culture in the presence of alendronate in both groups. The bisphosphonate acts on human PBMC to change the osteoclastogenesis related cytokine expression of them, inhibit the development of the osteoclast from them, and finally inhibit the osteoclastic activity of OC. The mechanism of anti-osteoporosis effect of the bisphosphonates in RA may be different from that of the normal population. The anti-absorptive effect of bisphosphonates may be blunted in patients with RA. Further study is needed to define whether the difference in response to bisphosphonate in RA patients is due to the disease itself, glucocorticoid, or other disease modifying drugs

Relationship of Serum Osteoprotegerin (OPG), Receptor Activator of Nuclear Factor Kappa-B Ligand (RANKL), and 2-Year Change in Bone Mineral Density (BMD) in Systemic Lupus Erythematosus (SLE). C. Lee[1], O. Almagor*[2], E. Y. Rhew[1], P. Eksarko*[1], K. McKinney*[3], A. B. Chadha*[1], D. D. Dunlop*[2], S. Spies*[4], R. M. Pope*[1], R. Ramsey-Goldman[1]. [1]Rheumatology, Northwestern Univ., Chicago, IL, USA, [2]Institute for Healthcare Studies, Northwestern Univ., Chicago, IL, USA, [3]Univ. of Pennsylvania, Philadelphia, PA, USA, [4]Radiology, Northwestern Univ., Chicago, IL, USA.

Our aim was to assess the relationship between baseline OPG, RANKL, and 2-year change in BMD at the hip, lumbar spine (LS), and distal forearm (DF) in women with SLE (cases) compared with controls. Cases (n=92) and controls (n=92) were matched on age, race, and menopause status. All had baseline and 2-year BMD (Hip, LS, and/or DF) and baseline serum OPG and RANKL measurements. Women completed a lifestyle questionnaire and medication survey. We assessed SLE features, including disease duration, renal involvement, and the ACR/SLICC Damage Index (SDI), modified to exclude an osteoporosis/fracture item. Effect of baseline BMD, OPG, and RANKL to predict 2-year change in BMD was determined using multiple regression with generalized estimating equations (GEE) to account for the matched case/control design.Cases and controls had similar age at study visit and BMI, but cases were younger at menopause (see Table). Both groups were similar in the proportion using caffeine or alcohol, who currently smoked and used female hormones. Cases had a mean age at SLE diagnosis ±SD of 35.2 ±12.4 years, disease duration of 8.1 ±7.8 years, a mean SDI of 1.03 ±1.7, 22.8% had SLE renal disease, 73.9% ever used corticosteroids (CS), and 42.4% were currently using CS with a current dose equivalent to 8.1 ±9.9 mg/day of prednisone.

TABLE. Comparison of Cases and Controls

Characteristics	Cases (n=92)	Controls (n=92)	P value
Mean age at study visit in years ±SD	43.8 ±11.5	44.0 ±11.1	0.26
Mean body mass index (BMI) ±SD	27.0 ±7.2	25.7 ±6.1	0.13
Mean age at menopause in years ±SD	41.2 ±8.0	44.6 ±5.9	**0.02**
Mean total daily calcium intake (mg) ±SD	1224.4 ±700.3	1003.2 ±609.6	**0.01**
Mean daily vitamin D intake (IU) ±SD	500.0 ±175.4	443.2 ±157.3	0.12
Proportion taken thiazide diuretics (%)	18.5 %	4.4 %	**0.008**
Baseline serum OPG and RANKL			
Mean OPG (pg/ml) ±SD	88.5 ±47.8	81.3 ±38.1	0.24
Mean RANKL (pg/ml) ±SD	10.1 ±19.0	7.3 ±9.7	0.16
2-year change in BMD (gm/cm^2)			
Anatomical Site			
Hip ±SD	-0.008 ±0.04	-0.006 ±0.03	0.75
Spine ±SD	0.003 ±0.05	0.002 ±0.03	0.88
Distal Forearm ±SD	-0.012 ±0.03	-0.006 ±0.05	0.38

Cases had similar 2-year changes in BMD as compared with controls at the hip (p=0.74), LS (p=0.87), and DF (p=0.34) controlling for baseline OPG and RANKL levels. Cases with higher baseline hip and LS BMD and greater baseline RANKL levels had more BMD losses at these sites controlling for OPG levels. Cases with higher baseline DF BMD also had greater BMD loss at this site. OPG was not predictive for bone loss at any site. We conclude that women with SLE (cases) compared with matched controls have similar OPG and RANKL levels and comparable hip, LS, and DF BMD at baseline. Women with SLE having higher baseline BMD experience more BMD loss over 2-years. Higher RANKL level is predictive for BMD loss at the hip and LS in SLE.

Effects of Infliximab on Bone Turnover Markers in Patients with Rheumatoid Arthritis: Improvement of Bone Remodeling Balance and Differential Effects on Cathepsin K and Matrix-Metalloproteases Mediated Bone Resorption. T. Thomas[1], A. le Henanff*[2], F. Debiais[3], A. Daragon[4], C. Roux[5], J. Sany*[6], D. Wendling[7], C. Zarnitsky*[8], P. Ravaux*[2], P. Garnero[9]. [1]Inserm 0366, University Hospital, St-Etienne, France, [2]Hôpital Bichat, Paris, France, [3]University Hospital, Poitiers, France, [4]University Hospital, Rouen, France, [5]Hôpital Cochin, Paris, France, [6]University Hospital, Montpellier, France, [7]University Hospital, Besançon, France, [8]Groupe Hospitalier, Le Havre, France, [9]Molecular Markers, Synarc, Lyon, France.

There is growing evidence that rheumatoid arthritis (RA) is associated with both systemic bone loss and subchondral bone erosion, a major feature of joint destruction, under the control of pro-inflammatory cytokines, including TNFa. Therefore, we tested the hypothesis that administration of infliximab, an anti-TNFa drug in the treatment of RA would modulate both systemic and local bone resorption and improve the balance of bone remodeling. We performed a prospective study of a multicentric cohort of 48 women, mean age 54.2±12.1 years old, with severe RA for 11.4±7.8 years, who started infliximab after failure of other disease-modifying antirheumatic drugs. We measured in the serum type I procollagen N-terminal propeptide (PINP), a marker of bone formation, C-terminal cross-linked telopeptide of type I collagen (CTX), a marker of cathepsin K-mediated bone collagen degradation and carboxyterminal cross-linked telopeptide of type I collagen (ICTP), an index of matrix-metalloprotease (MMP) mediated type I collagen degradation, at 0, 6, 22 and 54 weeks. Total hip and lumbar spine bone mineral density (BMD) was assessed at baseline, and after 6 and 12 months by DXA. No patient received bisphosphonates while 77% were under oral glucocorticoids. BMD remained stable over one year. Serum CTX levels rapidly decreased by 19% and 28% at week 6 and week 22, respectively (p<0.001 vs baseline), values returning to pre-treatment level at week 54. In contrast ICTP levels progressively declined with a maximal 25% decrease at week 54 (p<0.01). On the other hand, PINP levels remained stable over time, which lead to a 30 to 40% improvement in bone remodeling balance as assessed by the ratios of PINP/CTX and PINP/ICTP (p<0.05-0.001). In summary, the improvement in the formation/resorption marker ratio indicates beneficial bone effects of infliximab in patients with RA. The differences in the pattern of changes in CTX and ICTP may correspond to biological difference in response to infliximab, with CTX mainly reflecting effects on systemic cathepsin-K mediated bone resorption while ICTP effects on local MMP-mediated subchondral bone erosion.

PTH(1-34) Improves Spine Fusion Rate and Fusion Mass Volume. S. V. Bukata[1], E. A. Tomin*[2], A. Poynton*[2], J. A. Lane[2]. [1]Orthopaedics, University of Rochester, Rochester, NY, USA, [2]Orthopaedics, Hospital for Special Surgery, New York, NY, USA.

Up to 40% of lumbar fusions fail to heal despite current techniques. In humans and rats, parathyroid hormone (PTH) in low pulsatile doses leads to increased bone formation in fracture and nonfracture conditions. The effect of PTH on spine fusion is unknown. 44male New Zealand white rabbits underwent harvest of iliac crest autograft(1cc/side) and bilateral posterolateral spine fusion (L5-L6). Animals were divided into equal groups and starting post-operative day 4, half received daily subcutaneous injections of PTH(1-34) at 10mcg/kg/dose. Animals were sacrificed at 6 weeks. Animals had an x-ray of the bone grafting site immediately post-op and at the time of sacrifice. The L5-L6 vertebral segments were removed and analyzed by manual bending for fusion in the coronal, sagital and torsional planes. All specimens were analyzed by faxitron radiograph and scored by 3

independent investigators for radiographic fusion and quantity of bone formation. All segments underwent fine cut (0.6mm) CT and volume analysis of the fusion mass. Representative specimens were fixed in parafin and plastic and stained to allow for analysis of new bone formation. Manual bending testing identified fusion in 30% of the control animals while 81% of animals treated with PTH fused (Chi -squared test=10.8, p< .001, Fisher exact test p< .002). Faxitron radiographic analysis of individual fusion sites showed 20% of control animal sites fused and 69% of sites in PTH treated animals fused (p< .001). Using a radiographic scoring system where 0 represented no bone formation and 5 represented full fusion, the average fusion mass score for control animals was 3.36 while the average fusion mass score for PTH treated animals was 4.51 (Chi-squared test= 29.4 , p< .001, Cohen's kappa statistic 0.76 with 83% agreement in interobserver scoring). Fine cut CT analysis and volume measurement demonstrated a 75% increase in bone formation in the PTH treated animals with an average mass of 3.5cc in control animals [range 2.25cc-5.40cc] and 6.1cc with PTH treatment [range 4.34cc-10.58cc] (p< .001). Median bone mass formation was 3.44cc for control and 6.03cc for PTH treatment. Histology showed increased mature bone mass and minimal cartilage in the PTH treated animals and total tissue formation correlated with the radiographic analysis for each group. Intermittent PTH administration increases the rate of spine fusion by 170% and the mass of bone formation by 75%. PTH is a potential treatment to improve the rate of spine fusion and improve the quantity of bone mass formed in the fusion. Histology shows that the maturity of the fusion mass is also improved with more mature bone formation and less cartilage with PTH treatment.

Role of Caveolin-1 and the Cytoskeleton in Extracellular Ca^{2+}-Regulated PTH Release. O. Kifor*[1], I. Kifor*[1], S. J. Quinn*[1], F. D. Moore*[2], R. R. Butters*[1], E. M. Brown[1]. [1]Endocrinology, Diabetes, and Hypertension, Brigham and Women's Hospital, Boston, MA, USA, [2]Medicine and Surgery, Brigham and Women's Hospital, Boston, MA, USA.

Extracellular calcium is the principal physiological regulator of parathyroid hormone secretion. The calcium-sensing receptor mediates the effects of calcium on parathyroid hormone release, such that increasing levels of extracellular calcium inhibit parathyroid hormone secretion. The calcium-sensing receptor, along with various other signaling molecules, resides within caveolin-rich microdomains in parathyroid cells. In this study, we examined the role of caveolin-1 and the cytoskeleton in the regulation of parathyroid hormone secretion. Parathyroid hormone, calcium-sensing receptor, and chromogranin A co-localized with caveolin-1 at the apical secretory pole of parathyroid cells and were also recovered from Triton X-100-insoluble cholesterol/caveolin-1-rich microdomains. Immunocytochemical analysis demonstrated that high calcium caused caveolin-1 and F-actin to aggregate at the apical pole of the cells, and that depolymerization of F-actin with cytochalasin B or disruption of caveolae by depletion of cholesterol with methyl-β-cyclodextrin reduced the actin network and induced redistribution of actin/caveolin-1. Subcellular fractionation of parathyroid cells showed that parathyroid hormone, actin, chromogranin A, and caveolin-1 were present within the secretory granule fraction, and methyl-β-cyclodextrin treatment reduced the amounts of these proteins in secretory granules. Moreover, methyl-β-cyclodextrin and both of the two F-actin-severing compounds, latrunculin and cytochalasin B, significantly increased parathyroid hormone secretion, while the actin polymerizing agent, jasplakinolide, substantially inhibited parathyroid hormone secretion. Thus, we have demonstrated that in polarized parathyroid cells, caveolin-1-containing microdomains are required for secretory granule formation and for entry of parathyroid hormone into the regulated secretory pathway, and that assembly of a caveolin-1/actin network is required for inhibition of parathyroid hormone secretion by high calcium.

A Structure-Activity Relationship Study of PTH Analogs Modified in Position 5. I. Woznica*[1], N. Tsomaia*[2], P. Ruchala*[1], B. E. Thomas*[1], D. F. Mierke*[2], M. Chorev*[3], R. V. Alexander*[4], J. Sueiras-Diaz*[4], C. Schteingart*[4], K. O. Akinsanya*[4], P. J. Riviere*[4], M. Rosenblatt[1], A. Wittelsberger[1]. [1]Department of Physiology, Tufts University School of Medicine, Boston, MA, USA, [2]Departments of Chemistry and Molecular Pharmacology, Brown University, Providence, RI, USA, [3]Laboratory for Translational Research, Harvard Medical School, Cambridge, MA, USA, [4]Ferring Research Institute, San Diego, CA, USA.

Parathyroid hormone 1-34 (PTH) activates both PTH receptors 1 (PTHR1) and 2 (PTHR2), whereas PTH-related peptide 1-36 (PTHrP) only interacts with PTHR1. The residue in position 5 of PTH (Ile) and PTHrP (His) was found to be the major structural determinant of receptor specificity. Namely, it was shown that Ile^5-containing PTHrP activates both PTHR1 and PTHR2 and that His^5-containing PTH activates only PTHR1 [1]. To investigate the role of position 5 in receptor selectivity, we designed eight new PTH analogs containing phenylalanine, alicyclic, and aromatic, non-natural amino acids in position 5 with side-chains varying in hydrophobicity, ring size, and the presence of heteroatoms. Activities and binding affinities were determined for both PTHR1 and PTHR2, expressed stably on HEK293 cells (see Table). Two analogs, [Cpa^5]PTH and [2''-$PyAla^5$]PTH, were fully selective for PTHR1.

Analog	PTHR1 EC50 (nM)	PTHR2 EC50 (nM)	Ratio EC50 PTHR2/ PTHR1	Binding (IC50 PTHR1 [nM])
PTH*	0.33	13.6	41.2	6.1
[**Chg^5**]PTH	0.73	87.7	120.2	41.0
[**Cha^5**]PTH	6.87	21.1	3.1	440
[**Cpa^5**]PTH	5.03	no fit	selective	170
[**Phe^5**]PTH	7.15	28.5	4.0	410
[**2''-$PyAla^5$**]PTH	8.7	no fit	selective	230
[**3''-$PyAla^5$**]PTH	140.18	145.6	1.0	360
[**4''-$PyAla^5$**]PTH	212.97	no fit		530
[**2-Nal^5**]PTH	260.76	90.8	0.3	400

* based on sequence [$Nle^{8,18}$, 2-Nal^{23}, Tyr^{34}] hPTH (1-34)-NH_2.

Chg: cylcohexylglycine. Cha: cyclohexylalanine. Cpa: cyclopentylalanine. PyAla: pyridylalanine. Nal: naphthylalanine.

Molecular dynamics simulations of the ligand-receptor complex were carried out for each analog for both PTHR1 and PTHR2. The resulting models give insight into interactions occurring between the side-chain of residue 5 and receptor residues in its binding pocket. These atomic details help to more rationally explain certain differences in activities and receptor specificities: 1) the position 5 binding pocket of PTHR2 is smaller and less tolerant to substitutions than the one of PTHR1; 2) a coulombic interaction (such as with His) becomes advantageous in the PTHR1 binding pocket when residues larger than Ile^5 are introduced. This is rationalized by the negative charge of receptor residue D421 at the entrance of the binding cavity.

Intermittent vs. Continuous PTH Differentially Regulate Primary Response Gene Expression in a Gene, Dose and Time Dependent Manner. C. E. Magyar*, O. Bezouglaia*, S. Tetradis. School of Dentistry, UCLA, Los Angeles, CA, USA.

Intermittent and continuous PTH treatments have important and diverse effects on bone metabolism. Because the molecular mechanisms mediating PTH's effect are largely unknown, we examined how PTH pretreatment regulates induction of select primary response genes (PRG) in osteoblasts. Expression levels of Nurr1, Nurr77, c-fos, cox-2, IL-6 and RANKL were evaluated by real-time PCR of RNA isolated from primary mouse osteoblasts (POB). To compare the effect of intermittent vs continuous PTH exposure on PRG induction, POB were treated with 10 nM PTH for 0-4h. PTH was removed at 0.5, 1 or 2h and replaced by fresh media for the remainder of 4h. 0.5-1h PTH exposure was sufficient to induce maximal and transient expression, similar to continuous PTH, for all genes except RANKL. Continuous PTH exposure was necessary for sustained induction of RANKL mRNA levels. Given that both continuous and 1h PTH exposure resulted in similar PRG expression patterns, we investigated the effect of these PTH regimens on subsequent PTH-induced PRG expression. Continuous pretreatment with 10 nM PTH for 24h prevented subsequent PTH induced PRGs, but upregulated basal RANKL levels. POB pretreatment with 10 nM PTH for 1h followed by 23h in PTH-free media attenuated, but did not block, maximal PTH-induced Nurr1 and cox-2 and had no significant effect on c-fos, IL-6 and RANKL induction. The inhibition of PTH induced PRG by continuous PTH pretreatment was dose dependent. 50% inhibition was attained at approximately 0.1 nM and 95-100% inhibition by 1-10 nM PTH for all PRGs, except RANKL, where increased continuous PTH concentrations upregulated expression. PTH binding to its receptor activates cAMP-PKA, PKC and calcium signaling cascades. To elucidate the effect of PKA or PKC signaling in continuous PTH regulation of PRGs, POB were pretreated with 10 nM PTH, 10 μM forskolin (FSK), or 1 μM PMA for 24h and then treated with the same doses of PTH, FSK or PMA. FSK pretreatment completely blocked PTH induction of all PRGs except RANKL. However, PMA pretreatment attenuated PTH induction of c-fos and IL-6, but not of the other PRG. PTH pretreatment partially blunted FSK induced PRG expression. In conclusion, 0.5-1h PTH treatment is sufficient to elicit maximal and transient induction of all PRGs tested except RANKL. The duration and concentration of PTH pretreatment differentially regulated the ability of subsequent PTH to induce PRGs. This inhibition is primarily cAMP-PKA mediated. We hypothesize that the differences on PRG regulation might reflect the diverse effects of intermittent vs continuous PTH on osteoblastic function.

Rapid *In Vivo* Integrated Hormonal Responses to Alterations in Dietary Phosphate Intake. S. Sommer*, T. Berndt*, R. Singh, R. Kumar. Nephrology Research, Department of Medicine, Biochemistry and Molecular Biology, Mayo Clinic College of Medicine, Rochester, MN, USA.

The temporal and quantitative changes in serum/tissue concentrations of various peptide and sterol hormones in response to changes in dietary phosphorus intake are unknown. Male Sprague Dawley rats (n=45) were fed a normal phosphate diet (NPD) for 2 weeks. Rats were divided into 3 groups and fed either a low phosphate diet (LPD) (0.02%; n=15), NPD (0.6%; n=15) or high phosphate diet (HPD) (1.65%; n=15) for another 2 weeks. We measured plasma or blood ionized and total calcium (Ca), inorganic phosphorus (Pi), intact immunoreactive parathyroid hormone (iPTH), intact full-length fibroblast growth factor-23 (iFGF-23), and urinary Pi and creatinine on day 0 and again on days 1, 3, 7 and 14. Plasma 1,25-dihydroxyvitamin D concentrations were measured on days 1 and 14. On days 1 and 14, the rats were killed and renal tissue was harvested for assessment of

messenger RNA levels and protein expression of 25-hydroxyvitamin D 1α-hydroxylase cytochrome P450 and secreted frizzled related protein 4 (sFRP 4). In the rats fed the LPD, there was a reduction in plasma Pi (NPD=2.27 mm/L; LPD=0.86 mm/L; p<0.0001) and an increase in ionized calcium concentrations (NPD=2.23 mEq/L; LPD=2.53 mEq/L; p=0.002) within 1 day. The excretion of urinary Pi (NPD=0.17 mm/24hr; LPD=0.006 mm/24hr; p<0.0001) showed a marked decrease on day 1 that was associated with a reduction in iPTH (NPD=52.7 pg/ml; LPD=5.36 pg/ml; p=0.0002) and iFGF-23 (NPD=292.7 pg/ml; LPD=106.4 pg/ml; p<0.0001) plasma concentrations. Similar changes in UVPi, iPTH and iFGF23 were observed at days 3, 7 and 14. There were no changes in sFRP4 in the renal tissue at day 14. In contrast, in rats fed a HPD, an increase in plasma Pi concentrations was not observed on days 1 through 14. There was a marked increase in the excretion of Pi in the urine (NPD=0.17 mm/24hr; HPD=2.22 mm/24hr; p<0.0001) within 1 day that remained elevated on days 3 to 14. Modest changes were observed in iPTH concentrations from day 1 to day 14 (HPD day 0=57.6 pg/ml; day 1=30.8 pg/ml, p=0.09; day 3=72.8 pg/ml, p=0.014; day 7=92.3 pg/ml, p=0.62; day 14=47.2 pg/ml, p=0.32; all values compared to NPD). There was a 2-fold increase in FGF-23 concentrations on day 1 (NPD=292.7 pg/ml; HPD=526.3 pg/ml; p<0.0001) and day 3 (NPD=190.1 pg/ml; HPD=361.9 pg/ml; p=0.0009). However, by day 7, iFGF23 concentrations were approximately 1.5-fold higher (NPD=253.8 pg/ml; HPD=395.8 pg/ml; p=0.0096) and only slightly elevated on day 14 (NPD=358.3 pg/ml; HPD=454.4 pg/ml; p=0.17). sFRP-4 in renal tissue assessed by Western blot analysis was increased at day 14. We conclude that iPTH, iFGF-23, and sFRP-4 are involved in the adaptation of low and high phosphate diets.

Estimate of Misdiagnosis of ABD and Potential Overdosing of Suppressive Therapy Resulting from the Use of the Intact PTH Assay Compared to the Specific 1-84 PTH Assay for ESRD Patients. T. L. Cantor[1], A. Tokumoto*[2]. [1]President, Scantibodies Laboratory, Inc., Santee, CA, USA, [2]Nephrology, Sanin Rosai Hospital, Tottori, Japan.

The intact PTH assay is a measurement of both 1-84 PTH and 7-84 PTH. 7-84 PTH is secreted by the parathyroid gland and binds to PTH target cells and has been demonstrated to be a counter regulatory hormone compared to 1-84 PTH in that it is hypocalcemic, inhibitory of osteoblast & osteoclast formation, inhibitory of bone resorption, lowering of bone turnover, inhibitory of 1-84 PTH secretion, down regulating the PTH type 1 receptor (when NHERF1 is absent). The specific measurement of 1-84 PTH does not include the measurement of 7-84 PTH. It has been shown with bone biopsies and ROC curves by both Malluche et al and Tokumoto et al that the 1-84 PTH assay is more accurate than the intact PTH assay in predicting bone turnover in ESRD patients. Using bone biopsies it was also possible to determine the optimal range for bone turnover in these patients at 90-170 pgm/ml. 150-300 pgm/ml has been the range used for the intact PTH assay for normal bone turnover in ESRD patients. Using these 2 ranges and the 1-84 PTH assay range as the evaluation standard it was possible to estimate the number of adynamic bone disease ESRD patients misdiagnosed with the intact PTH assay and the number of patients that might be overdosed with PTH suppressive therapy for approximately 1000 ESRD patient specimens.

Changes in the Nichols Advantage iPTH Assay. T. L. Cantor[1], S. Schibel*[2], Z. Yang*[3]. [1]President, Scantibodies Laboratory, Inc., Santee, CA, USA, [2]Reserch and Development, Scantibodies Laboratory, Inc., Santee, CA, USA, [3]Research and Development, Scantibodies Laboratory, Inc., Santee, CA, USA.

The Nichols IRMA intact PTH assay has been the standard used for research studies that have formed the basis for clinical practice guidelines. In particular the National Kidney Foundation's Kidney Disease Outcome Quality Initiative Clinical Practice Guidelines for Bone Metabolism and Disease in Chronic Kidney Disease (K/DOQI) have relied on 73 articles that used the Nichols IRMA iPTH assay. It is important to note that Nichols manufactures two types of intact PTH assays, the manual overnight, radioactive IRMA iPTH assay and a 37 minute, chemiluminescent automated version called the Advantage intact PTH assay. Not one of the 73 articles used by K/DOQI referenced the Advantage intact PTH assay. ESRD patient lab testing is centralized in the US. Virtually all ESRD patient lab specimens are tested at one of seven centralized laboratories. All of these 7 centralized laboratories use the Nichols Advantage PTH tests. These labs do not use the Nichols IRMA iPTH test on which K/DOQI is based. When the Advantage iPTH assay was launched in 1992 patient specimen values matched those obtained using the Nichols IRMA iPTH assay. However, in 1999 there was an upward shift of approximately 52% for ESRD plasma specimens with some specimens measuring 2 or 3 times higher on the Advantage compared to the Nichols IRMA iPTH assay. In 2004 this upward shift observed in ESRD plasma specimens was reduced to approximately half and in 2005 this upward shift was eliminated. Also in 1999 there was a similar upward shift in Japan in a Nichols chemiluminescent iPTH assay, but in that case that upward shift was eliminated in Japan in the year 2000.

PTH 1-84 More Effectively Induces Jagged-1 mRNA than Does PTH 1-34 in UMR 106-01 Osteoblastic Cells. A. T. Pearman, B. L. Baker, N. E. Lloyd*, J. Fox. Pharmacology, NPS Pharmaceuticals, Salt Lake City, UT, USA.

Microarray and immunohistochemistry have shown that parathyroid hormone (PTH) 1-34 increases expression of the Notch receptor ligand, jagged-1 (jag-1) (Qin *et al*. and Calvi *et al*., 2003). However, the effects of full length PTH (1-84) on relative jag-1 expression are unknown. Therefore, we determined the levels of jag-1 expression in UMR106-01 rat osteosarcoma cells treated with either PTH 1-84 or PTH 1-34 (1 nM) for 30 min to 24 hr. Northern blot analysis revealed that PTH 1-84 induction of jag-1 peaked at 16 hr while PTH 1-34 maximally induced jag-1 mRNA by 2-4 hr. Concentration-dependence experiments were then conducted for each peptide at their peak time points. Both PTH 1-84 and PTH 1-34 maximally induced jag-1 expression at 1 nM with peak jag-1 induction in response to PTH 1-84 significantly exceeding that of PTH 1-34. Both PTH peptides induced jag-1 independent of *de novo* protein synthesis as indicated by cycloheximide addition. Analysis of the jag-1 5'-UTR revealed a region similar to the enhancer A element. Enhancer A interacts with the Mod-1 protein complex consisting of fos related antigen 2 (fra-2) and the NF-κB p50 subunit. A time course showed identical fra-2 induction in response to the peptides. However, concentration-response studies revealed that PTH 1-34 is significantly more potent than PTH 1-84 with regard to fra-2 mRNA induction. Specifically, 0.1 nM PTH 1-34 induced fra-2 while 1 nM PTH 1-84 was required for similar induction. Given that the relative efficacy of PTH 1-84 and PTH 1-34 is reversed for jag-1 and fra-2 expression and the presence of an enhancer-A-like region in the jag-1 5'-UTR, fra-2 may regulate PTH1R-mediated jag-1 expression as a subunit of the Mod-1 complex. Forskolin induced both fra-2 and jag-1 suggesting a cAMP-mediated mechanism. However, there was no difference in cAMP accumulation in response to the two PTH peptides. Alternatively, PTH 1-34 was a slightly more potent activator of protein kinase C (PKC) than was PTH 1-84. This suggests that PTH 1-84 and PTH 1-34 differentially modulate cAMP-mediated gene expression through differences in PKC activation. In summary, PTH 1-84 is a more efficacious inducer of jag-1 gene expression than PTH 1-34 although both events are independent of protein synthesis. Additionally, PTH 1-84 induces jag-1 at a later time point than does PTH 1-34. Furthermore, PTH 1-84 and PTH 1-34 induce fra-2 and PKC activation with reverse relative efficacy compared to jag-1 expression patterns. Based on these data, differential responses of fra-2 and PKC may participate in the mechanisms through which the PTH peptides induce jag-1 expression. These observations demonstrate unique differences between the effects of PTH 1-84 and PTH 1-34.

Changes in the Nichols Bio-Intact PTH Assay. T. L. Cantor[1], S. Scheibel*[2], Z. Yang*[2]. [1]President, Scantibodies Laboratory, Inc., Santee, CA, USA, [2]Research and Development, Scantibodies Laboratory, Inc., Santee, CA, USA.

The Nichols Bio-Intact PTH assay was launched in 2001 and has been demonstrated to not measure 7-84 PTH which is a counter regulatory hormone compared to 1-84 PTH. Several studies (including those of our own) from 2001 to early 2003 used ESRD plasma specimens to demonstrate that the Bio-Intact PTH assay gave equivalent results compared to the Scantibodies 1-84 PTH or whole PTH (CAP) assay. However, in late 2003 we observed a 29% increase in the Bio-Intact PTH assay values compared to the Scantibodies whole PTH assay using ESRD plasma specimens. This same (28%) increase was also observed in 2005 for the same type of patient specimens.

Chondrosarcoma of the Right Hip in Association with Teriparatide. M. C. Spady*, A. M. Macasa*, J. Zakem*, R. Quinet. Rheumatology, Ochsner Clinic Foundation, New Orleans, LA, USA.

We describe a 74-year old female with pre-existing polymalgia rheumatica requiring low dose prednisone with a history of severe osteoporosis. Between 1996 to 2003 she sustained 17 osteoporotic fractures (including hip, lumbar spine, thoracic spine, and ribs) while on FDA approved treatment for osteoporosis. She was tried on and failed all FDA available antiresorptive agents to treat osteoporosis. She was then treated with teriparatide (Forteo) for 9.5-months. While on treatment she was found to have a grade III chondrosarcoma of the right femur. To date there is no other reported incident of chondrosarcoma or osteosarcoma and teriparatide use.

Changes in Intact PTH, 1-84 PTH/7-84 PTH and the Calcium x Phosphate Product following 5 Months of Cinacalcet Therapy in 13 ESRD Patients. T. L. Cantor[1], R. Amerling*[2]. [1]President, Scantibodies Laboratory, Inc., Santee, CA, USA, [2]Division of Nephrology and Hypertension, Beth Israel Medical Center, New York, NY, USA.

Cinacalcet HCL (Sensipar) is a calcium sensing receptor stimulating agent (calcimimetic) that has been demonstrated to be effective in suppressing the level of both calcium and PTH in ESRD patients. The new pharmaceutical has been proposed as an alternative or adjunct therapy compared to the use of calcium supplements and vitamin D sterols with the advantage of eliminating hypercalcemia associated in some patients with the use of vitamin D sterols or calcium. Increased calcium and calcium x phosphate product have been demonstrated to be associated with increased mortality among ESRD patients. As with any PTH suppressant an accurate marker of parathyroid function and bone status is essential in order to guide therapy. The intact PTH assay has been demonstrated to be a measurement of 2 counter regulatory hormones, 1-84 PTH and 7-84 PTH with opposite biological actions. Both the intact PTH assay and the measurement of the 1-84 PTH/7-84 PTH ratio were assessed with bone biopsies for accuracy in predicting bone turnover in ESRD patients. It was found that the iPTH assay was 72% accurate whereas the 1-84 PTH/7-84 PTH assay was 94% accurate in predicting bone turnover in ESRD patients. 13 ESRD patients were placed on Cinacalcet (one 30 mg tablet per day) and their intact PTH, calcium x phosphate products and 1-84 PTH/7-84 PTH ratios were studied over 5 months. An overall lowering in the intact PTH value was not observed over the 5 months of study. However after the first 2 months of therapy the 1-84 PTH/7-84 PTH ratio decreased indicating a significant lowering of bone turnover. During the first 4 months there was a decrease in the calcium x phosphate product. However, following the 4th month there was a rise in the calcium x phosphate product. The changes in calcium x phosphate suggest that the bones may have entered into an adynamic bone disease status and were, therefore, unable to buffer calcium and phosphate, thus causing a rise in the serum calcium x phosphate product.

Parathyroid Hormone Is also Mediating Osteoporosis in Hypersensitive Patients? M. R. G. Mascarenhas[1], J. Ferreira*[1], D. S. Pinto*[2], D. J. Duarte*[2], M. Bicho*[1]. [1]Metabolism e Endocrinology Center (Genetics Lab), Lisbon´s Faculty of Medicine, Lisboa, Portugal, [2]Endocrinology, Diabetes and Metabolism Lisbon´s Clinic, Lisboa, Portugal.

Aim Prospective and cross-sectional study in order to evaluate the bone mineral density (BMD) in hypertensive patients, females and males, and the intact parathyroid hormone (PTHi) blood levels and BMD relationships. **Methods** Bone mineral density (BMD, g/cm2) at the lumbar spine (L1-L4), at the proximal femur (femoral neck, trochanter and total) and at the distal forearm (total) and at the whole body were studied by using the radiological densitometer QDR Discovery W (Hologic, Inc.) in a group of 524 hypertensive patients. BMI (kg/m2) was also estimated. In this group 369 were women (mean age: 62 years, post-menopausal since 13.4 years9 and 155 males (56.7 years) The PTHi blood levels were measured in a subset of patients (n = 309). The T-scores of the BMD have also divided the patients in three subgroups: normal BMD (T-score > -1.0 SD), osteopenia and osteoporosis (T-score ≤-2.5 SD), as compared with reference populations. The One-Way Anova test was used to differentiate the data, after descriptive analysis, with statistical difference for $P < 0.05$. **Results** In these **hypertensive patients**, **osteoporosis** was detected in 38,8% of the women and 19,0% of the males. **Hypertensive and osteoporotic patients**, both sexs, were **the oldest** ($P < 0,05$), **the leanest** ($P < 0,05$) **and those with shortest stature**($P < 0.05$). However, PTHi was higher just in hypertensive and osteoporotic patients sub-groups, both women and men ($P < 0.05$). **Conclusions** The data of our study show that prevalence of osteoporosis is higher in the oldest, lowest weight and shortest stature hypertensive patients, as described for osteoporotic individuals with normal blood pressure. Finally, in hypertensive osteoporotic patients, the PTHi blood levels were higher, suggesting a potential role for PTHi in osteoporosis development and in high blood pressure mediation.

Impact of Aromatic Versus Branched-Chain Amino Acids on Calcium Excretion, Absorption, and Bone Turnover - Potential Role of the Calcium Sensor Receptor. B. Dawson-Hughes, H. Rasmussen*, S. S. Harris*, G. Dallal*. USDA Human Nutrition Research Center on Aging at Tufts University, Boston, MA, USA.

Aromatic amino acids (AAAs), but not branched-chain amino acids (B-CAAs), bind to the calcium sensor receptor (CaSR) in renal tissue and thus AAAs may have a greater calciuric action than B-CAAs (1). This study was done to determine and compare the effects of increasing intake of these two types of amino acids on urine calcium excretion (UCa), calcium absorption (CaAbs), serum parathyroid hormone (PTH), and biochemical markers of bone turnover in humans. Thirty men and women, age 51+, were placed on low-protein metabolic diets containing 0.5 g/kg/d of protein and including 0.027 moles of phenylalanine (phe), 0.023 moles of histidine (his), 0.070 moles of leucine (leu), and 0.046 moles of isoleucine (ileu) per 100 g of protein, for 24 days. On days 13-24, 15 subjects, selected randomly, received a 5-fold increase in gm-molar content of the two AAAs (phe and his) and the other 15 received a similar increase in B-CAAs (leu and ileu), mixed into their food. Bloods and 24-hr urines were collected on days 1, 13, and 24 and CaAbs (estimated from 4-hr increase in Ca excretion after a 600 mg Ca load) was assessed on days 13 and 24. Mean values on the low amino acid intakes (day 13) and changes (day 24-13) in UCa, CaAbs, urinary N-telopeptide (NTX), and serum osteocalcin were compared in the two groups. The groups did not differ significantly in mean age, BMI, or day 13 biochemical measures. The change (day 24-13) in UCa on AAAs differed from that on B-CAAs (0.252 ± 0.931 mmol/d vs -0.457 ± 0.808, respectively, $P = 0.034$). There was a trend toward a greater change in CaAbs in the AAA than the B-CAA group (0.172 ± 0.351 mmol vs -0.003 ± 0.173, respectively, $P = 0.098$). Although the difference in correlation coefficients did not achieve statistical significance ($P=0.103$) in this small sample, on day 24, UCa was significantly correlated with CaAbs in the AAA group ($r =0.715$, $P = 0.003$) but not in the B-CAA group ($r = 0.227$, $P = 0.416$). Changes in serum PTH, serum osteocalcin, and urinary NTX did not differ significantly in the two groups. In conclusion,

AAAs promote UCa excretion more than B-RAAs, perhaps because they bind to renal CaSRs. The higher UCa excretion in the AAA group appears to result from increased calcium absorption rather than increased bone resorption.

Cinacalcet in a Case of Hypocalciuric Hypercalcemia with Recurrent Pancreatitis. P. Filipponi[1], S. Cristallini*[1], A. Nicasi*[1], G. Pioda*[2]. [1]ASL1 Umbria, Centro Regionale Osteoporosi e Malattie Metaboliche dello Scheletro, Umbertide - Perugia, Italy, [2]Perugia, Polizia di Stato, Perugia, Italy.

Introduction. Inactivating mutations in CaSR gene has been reported as the cause of hypocalciuric hypercalcemia (HH) with inappropriate PTH serum levels. Calcimimetic agents, allosterical activators of CaSR, have been successfully tested in the treatment of primary, as well of secondary, hyperprathyroidism. We report the effect of the calcimimetic Cinacalcet on mineral metabolism in a patient affected with hypocalciuric hypercalcemia and recurrent acute pancreatitis. **Case report and methods**. A16 year-old male presented with mild hypercalcemia and acute pancreatitis at Perugia Regional Hospital. The patient had a cholecistectomy and initiated a treatment with ursodesossicolic acid, which is still in use. After a second pancreatitis episode the patient was referred to our Centre. The patient's basal mineral metabolism parameters were assessed over 4 months using 4 different determinations. After basal investigations, cinacalcet 30 mg/day was started and administered for 15 days. On day 16, the dosage of cinacalcet was doubled to 30 mg twice daily (60 mg/day). **Results**. The Table shows the patient's mineral metabolism parameters before and during treatment with cinacalcet. sCa decreased from a mean value of 11.5 to 10.0 and to 9.2 mg/dL respectively with 30 and 60 mg/day cinacalcet admnistration. sCa++ decreased from 1.43 to 1.29 and 1.28 mmol/L respectively with 30 and 60 mg/day cinacalcet dosing. There was a parallel decrease in tubular reabsorption of Calcium (TmCa) and a decrease in urinary Ca/Cr ratio. Serum phosphate levels increased from a mean basal value of 2.8 to 4.2 and 3.9 mg/dL respectively with 30 and 60 mg/day cinacalcet dose, with a parallel increase in tubular reabsorption of phosphate (TmPO4). Cinacalcet was well tolerated and no changes were observed in pancreatic enzymes and other laboratory parameters except for the indices of mineral metabolism. **Conclusions**.The results of this case report shows that the calcimimetic cinacalcet, 30 mg twice daily, normalizes serum calcium in a patient affected with HH. This encouraging case shows the need to evaluate cinacalcet as a potential therapy for HH.

Expression and Functional Assessment of an Alternatively Spliced Extracellular Ca2+-Sensing Receptor in Growth Plate Chondrocytes. L. Rodriguez*, C. Tu*, T. Chen*, Z. Cheng, D. Bikle, D. Shoback, W. Chang. Endocrine Research Unit, VAMC, Department of Medicine, University of California San Francisco, San Francisco, CA, USA.

Previous studies on extracellular Ca^{2+}-sensing receptor (CaR)-knockout (CaR-/-) mice indicate that insertion of a neomycin cassette into exon 5 of the mouse CaR gene blocks the expression of full-length CaRs, but it allows the expression of alternatively spliced CaRs [$^{Exon5(-)}$CaRs] missing exon 5. This shift in expression of the full-length CaR to the alternatively spliced CaR occurs in a number of tissues including growth plate chondrocytes (GPCs). We characterized the signaling and expression properties of the $^{Exon5(-)}$CaRs and addressed whether CaR-/- GPCs, that express $^{Exon5(-)}$CaRs, remain responsive to changes in extracellular [Ca^{2+}] ([Ca^{2+}]$_e$). Expression of $^{Exon5(-)}$CaR transcripts and protein in growth plates from CaR-/- mice and cultured CaR-/- GPCs was confirmed by RT-PCR and immunocytochemistry. In stably or transiently transfected CHO and HEK-293 cells, recombinant human $^{Exon5(-)}$CaRs [$^{Exon5(-)}$hCaRs] failed to reach the cell-surface as determined by intact-cell ELISA and immunocytochemistry and was therefore unable to activate the PLC pathway in response to high [Ca^{2+}]$_e$. Western analysis confirmed the expression of ample amounts of $^{Exon5(-)}$hCaR protein in these cells. In contrast, $^{Exon5(-)}$hCaRs trafficked normally to the cell surface when expressed in GPCs from either wild-type or CaR-/- mice. Immunocytochemistry of growth plate sections and cultured GPCs from CaR-/- mice showed cell-surface expression of endogenous CaR protein (judged to be $^{Exon5(-)}$CaRs in CaR-/- cells), suggesting that stable expression of $^{Exon5(-)}$CaRs to the membrane requires a specific cellular context. In GPCs from CaR-/- mice, raising [Ca^{2+}]$_e$ increased total InsP production with a potency comparable to that in GPCs from wild-type mice. Raising [Ca^{2+}]$_e$ also promoted the differentiation of CaR-/- GPCs as indicated by decreased proteoglycan accumulation, increased mineral deposition, and altered gene expression indicative of advanced cell differentiation. Taken together, our data suggest that $^{Exon5(-)}$CaRs may compensate for the loss of full-length CaRs in GPCs in CaR-/- mice and perhaps in other tissues in a cell context that permits stable cell-surface expression of $^{Exon5(-)}$CaRs.

The Effects of Strontium Ranelate on Osteoclasts Are Calcium-Sensing Receptor Dependant. R. Mentaverri*[1], R. Mentaverri*[2], N. Chattopadhyay*[1], A. S. Lemaire-Hurtel*[1], S. Kamel*[1], M. Brazier*[1], E. M. Brown[2]. [1]Université de Picardie Jules-Vernes, 80037 Amiens, France, [2]Brigham and Women's Hospital, Boston MA 02115, MA, USA.

Strontium ranelate is a new compound available for the treatment of osteoporosis to reduce vertebral and hip fracture risk in postmenopausal women. Strontium ranelate stimulates bone formation and decreases bone resorption resulting in a rebalance of bone turnover in favor of bone formation. As with Ca, extracellular strontium, is a full agonist of the calcium sensing receptor (CaR). To date, there has been no direct proof of the role of the CaR in mediating the effects of strontium ranelate on osteoclasts (OC). The present study firstly used bone cells isolated from wild-type or CaR knock-out mice (as a negative control) to confirm CaR expression on OC, by immunohistochemistry and confocal microscopy. Secondly, we demonstrated the role of the CaR in strontium ranelate effects using mature rabbit OC: 1) Increasing strontium ranelate concentrations, up to 25 mM, stimulated OC apoptosis by 40% (Hoechst staining). Western blots analysis using antibodies to caspases 3 and 9 as well as specific caspases inhibitory peptides (Z-VAD-fmk, Z-LEHD-fmk), clearly demonstrated that the caspases cascade is involved in strontium ranelate-induced OC apoptosis. 2) For the first time, we have established with the immunocytochemical method[1], that increasing concentrations of strontium ranelate directly trigger a transient translocation of NFkB into OC nuclei. Temporal control of NFkB activity regulates the expression of numerous genes involved in cell survival as well as in cellular responses to inflammation and stress. This effect is maximal at 30 min, when 50% of OC showed a nuclear localization of NFkB. 3) Both strontium ranelate-induced NFkB nuclear translocation and OC apoptosis, were blocked by a phospholipase C inhibitor (U73122, 10µM), indicating that a G protein coupled receptor could mediate the effect of strontium ranelate on OC. 4) Moreover, in mature rabbit OC infected with a dominant negative form of CaR (rAAV technology), the strontium ranelate-induced NFkB nuclear translocation was abolished and the strontium ranelate-induced OC apoptosis was significantly reduced by 50% compared to β-galactosidase transfected cells (i.e. control infected cells). This approach unequivocally demonstrates that strontium ranelate acts at least in part through the CaR to enhance OC apoptosis, confirming several converging lines of evidence. Further studies are needed to further clarify the role played by NFkB signaling in these cellular events and whether this pathway is involved in mediating the effects of strontium ranelate on bone resorption.

Efficient Expression of the Extracellular Domain of the Calcium-Sensing Receptor in Insect Cells. T. Craig*[1], Z. Ryan*[2], J. Thompson*[2], R. Kumar[1]. [1]Nephrology Research, Department of Medicine, Biochemistry and Molecular Biology, Mayo Clinic College of Medicine, Rochester, MN, USA, [2]Department of Physiology and Biomedical Engineering, Mayo Clinic College of Medicine, Rochester, MN, USA.

The human Calcium-Sensing Receptor (CaSR) is a 1078-amino acid cell-surface G protein-coupled receptor involved in the fine sensing of serum calcium concentrations and is localized in tissues involved in calcium homeostasis including parathyroid gland, kidneys, thyroid C-cells, bones (osteoclasts, osteoblasts), intestines and in several tissues such as nerve terminals and oligodendrocytes without obvious roles in maintenance of extracellular calcium. The CaSR is composed of three domains: a large extracellular domain (ECD, amino acids (aa) 20-612), a seven-transmembrane-spanning segment (aa 613-867), and an cytoplasmic tail (aa 868-1078). The exact amino acid residues and molecular orientations which are responsible for Ca^{2+} binding, Ca^{2+} sensing, and signal transduction in response to changes in the serum Ca^{2+} concentrations are unknown. In order to examine the biophysical properties of the CaSR, we devised an efficient system for the expression of the CaSR in quantities sufficient for functional studies and x-ray crystallography. The c-DNAs coding for amino acids 20-610 (extracellular domain)(ECD), 536-610 (cysteine rich domain)(CRD) and 20-535 (extracellular domain without the cysteine rich domain)(ECD w/o CRD) were inserted into the pIB/V5-His insect vector. In place of the native secretory signal a melittin secretory signal was used, and was inserted 5' to the CaSR coding sequences. The orientation of the inserts and the DNA sequences thereof were verified by DNA sequencing. *Trichoplusia ni* (High Five) insect cells were stably transformed with pIB/V5-His-CaSR constructs. After Blasticidin S selection of adherent cells, the stably transformed cells were adapted to grow in suspension cultures. Shake cultures in 2L flask were grown for protein production. Secreted CaSR proteins were isolated from the conditioned media by ion exchange chromatography and Ni^{2+} chelate chromatography and analyzed by SDS-PAGE, Western blots, PNGase F deglycosylation and amino-terminal protein sequencing. CaSR constructs were readily expressed in low milligram amounts. The results demonstrate the utility of the insect expression system for production of properly folded, glycosylated CaSR protein constructs that contain disulfide bonds.

Experimental Hypercalcemia in Horses Results in Hypomagnesemia, Hypkalemia, and Hyperphosphatemia with Increased Uninary Excretion of Electrolytes. R. E. Toribio, K. M. Rourke*, A. L. Levine*, C. W. Kohn*, T. J. Rosol. Veterinary Biosciences, The Ohio State University, Columbus, OH, USA.

Electrolyte disturbances are common in critically ill humans and animals. In critically ill horses, low serum ionized calcium (Ca2+) and ionized magnesium (Mg2+) concentrations are frequent. High serum Ca2+ is common in horses with chronic renal failure, hypercalcemia of malignancy, hyperparathyroidism, and vitamin D intoxication. There is evidence that the renal reabsorption of Ca2+ is also regulated by parathyroid hormone (PTH)-independent mechanisms, primarily by the calcium-sensing receptor (CaR) that affects the transepithelial transport of Ca2+ and Mg2+. Because extracellular Ca2+ can affect other electrolytes, the goals of this study were to evaluate the effects of experimental hypercalcemia on the serum concentrations of electrolytes and their urinary excretion in healthy horses. By the direct effects of Ca2+ on CaR, we speculated that hypercalcemia will result in hypomagnesemia and increase the urinary excretion of electrolytes. Hypercalcemia was induced in twelve healthy mares; six were infused with 23% calcium gluconate (G) for 120 min and six mares were infused with 10% calcium chloride (CaCl2) for 120 min. Blood was collected to measure serum electrolytes, PTH, and insulin concentrations, and urine was collected to determine the fractional excretions of Ca2+ (FCa), Mg2+ (FMg), Na+ (FNa), Pi (FP), K+ (FK), and Cl- (FCl). In hypercalcemic mares, serum Ca2+ increased 6.6±0.1 to 9.7±0.3 (G) and 6.4±0.1 to 10.2±0.10 mg/dL (CaCl2); Mg2+ decreased 0.52±0.02 to 0.33±0.02 (G) and 0.51±0.02 to 0.32±0.02 mmol/L (CaCl2); K+ decreased from 4.3±0.1 to 3.4±0.1 (G) and 4.2±0.2 to 3.6±0.2 mEq/L (CaCl2), and Pi increased from 3.4±0.2 to 4.8±0.3 (G) and 2.9±0.2 to 4.1±0.4 mg/dL (CaCl2). PTH decreased to very low concentrations. No changes in insulin concentrations were detected. FCa increased from 5.4±1.0 to 56.2±6.9% (G) and 5.4±1.1 to 47.7±6.4 % (CaCl2); FMg from 23.5±2.4 to 55.0±4.5 (G) and 28.5±4.3 to 54.4±7.3 % (CaCl2); FNa from 0.09±0.04 to 4.3±0.8 (G) and 0.03±0.003 to 4.8±0.8 % (CaCl2); FK from 45.4±7.6 to 116.6±19 (G) and 38.4±1.5 to 89±8.3% (CaCl2); FCl from 0.65±0.1 to 5.6±1.5% (G) and 0.7±0.1 to 9.3±1.6% (CaCl2), and FP from 0.04±0.02 to 0.5±0.2 (G) and 0.14±0.06 to 0.81±0.3 % (CaCl2). Urine specific gravity and osmolality decreased and urine output increased. In conclusion, hypercalcemia results in hypomagnesemia, hypokalemia, and hyperphosphatemia, increases the urinary excretion of Ca2+, Mg2+, K+, Na+, Pi, and Cl-, and has diuretic effects. This study has clinical implications as excessive administration of Ca2+ salts can further increase the waste of electrolytes, in particular of Mg2+.

Interleukin-6 Upregulates Transcription of the Calcium-Sensing Receptor Gene via Elements in both P1 and P2 Promoters. L. Canaff, G. N. Hendy. Medicine, McGill University, Montreal, PQ, Canada.

The calcium-sensing receptor (CASR), expressed in parathyroid gland, thyroid C-cells and kidney tubule critically regulates the blood calcium concentration. Increases in expression of the CASR in these tissues leads to hypocalcemia. Hypocalcemia is common in critically ill patients (such as those with burn injury or sepsis) in whom circulating levels of cytokines, such as interleukin-6 (IL-6) are markedly increased. We hypothesized that IL-6 upregulates expression of the CASR thereby reducing parathyroid hormone (PTH) secretion and renal calcium reabsorption and increasing calcitonin secretion. We first demonstrated by immunoblot analysis that the CASR protein was increased (~3 fold) in human thyroid C-cells (TT) stimulated with IL-6 (8ng/ml) for 16, 24 and 36 hours. The human CASR gene has two promoters (P1 and P2) yielding transcripts having alternative 5' untranslated regions (1A and 1B), but encoding the same receptor (exons 2-7). By run on assay of nuclear extracts of human proximal tubule kidney (HKC) and TT cells, it was shown that IL-6 stimulated CASR exon 1A, exon 1B and exon 2 transcripts >2 fold at 8 and 12 hours. The transcriptional activities of human CASR P1 and P2 promoter constructs driving a luciferase reporter gene were stimulated ~2-3 fold by IL-6 (relative to basal activity) after transient transfection into HKC and TT cells. The P1 construct contained 1439 bp of the promoter upstream of the transcription start site (+1), the 638 bp exon 1A and 242 bp of exon 2 before the ATG translation start site. Transfection of a series of P1 deletion constructs (-1439, -938, -701, -382 and -194) into HKC cells revealed that specific regions from -382 to -194 bp in the promoter and +197 to +206 bp of exon 1A (both of which have canonical STAT elements) mediated the induction of P1 by IL-6. The P2 construct contained 460 bp of the promoter upstream of the transcription start site (+1), the 259 bp exon 1B and 242 bp of exon 2 before the ATG translation start site. Transfection of a series of deletion constructs (-460, -341, +220) into HKC cells showed that the -341 to +220 region is required for IL-6 responsiveness. There are no STAT elements in the P2 promoter or exon 1B but potential AP-1 and SP1 elements (that have been implicated in IL-6 responsiveness of other genes) are present. In conclusion, elements in the CASR gene promoters mediate transcriptional upregulation by the proinflammatory cytokine, IL-6. This is likely to be important in contributing to the hypocalcemia of critically ill patients with burn injury or sepsis.

Extracellular Ca2+ Concentration Directly Regulates 1,25-Dihydroxyvitamin D Receptor (VDR) Level in Human Kidney, HK-2, Proximal Cells. A. Maiti*[1], A. Bajwa[2], M. J. Beckman[2]. [1]Orthopaedic Surgery, Virginia Commonwealth University, Richmond, VA, USA, [2]Biochemistry, Virginia Commonwealth University, Richmond, VA, USA.

The primary role of biologically active form of vitamin D, 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$), is to regulate calcium (Ca) homeostasis, proliferation, differentiation and other cellular physiological processes. Many of the actions of $1,25(OH)_2D_3$ are mediated by interaction with vitamin D receptor (VDR) a member of steroid/thyroid receptor superfamily of ligand regulated transcription factors. In renal proximal tubules, VDR is transiently decreased by parathyroid hormone (PTH) during times of hypocalcemia and returns to normal levels commensurate with the rise in serum Ca^{2+}. These in vivo effects were mimicked in vitro using the human proximal kidney HK-2 cell line that expresses extracellular Ca sensing receptor (CaSR) endogenously. In these cells, PTH significantly decreased ($p<0.05$) VDR mRNA in a low Ca^{2+} (0.2 mM) medium, which led to a decrease in VDR protein. However, high extracellular calcium (3.2 mM) treatment triggered an increase in HK-2 cell VDR mRNA following 6 hrs of incubation and an increase in protein at 12 hrs in a manner consistent with CaSR activation. To better understand the hypothesis that transition from low to high serum calcium concentration is marked by an upward directional regulation of VDR by a mechanism that utilizes CaSR activation, HK-2 cells were treated with different doses of calcium for different time periods to study phosphorylated-ERK (pERK) activation and VDR by Western blot analysis. An increase in extra cellular calcium from 0.2 mM to a maximum of 4.2 mM increased the percentage of pERK/total ERK in HK-2 cells. A treatment of 3.2 mM Ca^{2+} in the medium caused rapid activation of pERK at 5 min, which remained elevated at 15 min and declined at 30 min. In addition, extracellular Ca^{2+} treatment dose-dependently activates VDR increases compared to low 0.2 mM Ca^{2+} in HK-2 cells. Past studies by our laboratory have explored the PTH-dependent down-regulation of VDR in renal proximal cells and demonstrated a possible counter regulatory role of Ca^{2+}. The present study supports the concept of opposing regulation by Ca and PTH in effecting changes in renal proximal cell VDR. In conclusion, in renal proximal HK-2 cells, a normal level of VDR protein is partially dependent upon adequate extracellular Ca^{2+} in a range of 1.0-2.0 mM, and high extracellular Ca^{2+}, ~3.2 mM, plays a modulating role to increase VDR protein, that is independent of PTH.

Identification of a Novel G-Protein Coupled Receptor with Calcium and Osteocalcin Sensing Properties. M. Pi[1], G. Ekema*[2], P. Faber*[2], P. D. Jackson*[2], K. Brunden*[2], J. J. Harrington*[2], L. D. Quarles[1]. [1]Kidney Institute, Department of Medicine, KUMC, Kansas City, KS, USA, [2]Athersys, Inc., Cleveland, OH, USA.

The extracellular calcium sensing receptor (CASR) plays an important role in the regulation of calcium homeostasis. CASR, which belongs to the C family of G-protein coupled receptors, is characterized by a long extracellular segment containing calcium binding domains and a 7-transmembrane (7-TM) region typical of GPCRs. Calcium sensing responses are also observed in tissues, such as bone, where the physiological role of CASR is not certain. There is evidence that bone expresses a distinct calcium sensing receptor in osteoblasts, called Ob.CASR, which has not yet been isolated and cloned. To identify if other Family C receptors are present in bone and sense extracellular calcium, we investigated a recently described orphan receptor belonging to this family. Alignment of this receptor with CASR revealed that two of the putative calcium binding residues in CASR (Ser-147 and Ser-169) are conserved in this receptor (Ser-149 and Ser-171). To test the response to extracellular cations, we transfected the full-length of this receptor into HEK-293 cells and evaluated the effects of a panel of cations to stimulate a co-transfected serum response element/reporter construct (SRE-luciferase), ERK activation and increments in intercellular calcium. Calcium, magnesium, strontium, aluminum, and gadolinium resulted in a dose-dependent stimulation of activity in HEK-293 cells, requiring concentrations that exceeded those needed to activate CASR. To examine the effects of calcium binding proteins in the bone milieu to modify the response of this receptor to extracellular calcium, we investigated the effects of osteocalcin, the most abundant calcium binding protein in bone, on the ability of calcium to activate this receptor in HEK-293 cells. Osteocalcin resulted in a dose-dependent stimulation of this receptor in the presence of calcium, but inhibited the calcium-dependent activation of CASR transfected into HEK-293 cells. Coexpression of either beta-arrestins 1 and 2, regulators of G protein signaling, RGS2 or RGS4, the RhoA inhibitor C3 toxin, and the dominant negative Galphaq(305-359) minigene, all inhibited cation-mediated activation of this receptor. Results from RT-PCR analyses showed that this receptor is expressed in mouse heart, brain, lung, liver, spleen, skeletal muscle, kidney, testis, epididymis, fat, bone, calvaria and the osteoblastic cell line MC3T3-E1. These data suggest that this is a novel calcium sensing receptor with unique properties that make it a strong candidate for Ob.CASR.

DMPA-SC 104 Is Associated with Significantly Smaller Effects on Bone than Leuprolide Acetate in the Treatment of Endometriosis. J. Jain*[1], S. Kipersztok*[2]. [1]Department of Obstetrics and Gynecology, Keck School of Medicine, University of Southern California, Los Angeles, CA, USA, [2]Department of OB/GYN, University of Florida College of Medicine, Gainesville, FL, USA.

A clinical trial compared depot medroxyprogesterone acetate subcutaneous injection 104 mg/0.65 mL (DMPA-SC 104) with leuprolide acetate in patients with endometriosis. The primary safety endpoint was percent change in bone mineral density (BMD). This 18-month, evaluator-blinded, comparator-controlled trial was conducted in the United States and Canada. Premenopausal women aged 18 to 49 years with recently diagnosed, persistent, or recurrent endometriosis were randomized to 6 months' treatment with DMPA-SC 104 or leuprolide acetate 11.25 mg every 3 months and followed for an additional 12 months post-treatment. BMD assessment included percent change from baseline to months 6, 12, and 18. BMD data were available for 77 DMPA-SC 104 subjects and 98 leuprolide subjects at month 6; approximately 50 and 63 subjects, respectively, at month 12; and approximately 31 and 42 subjects, respectively, at month 18. As previously reported, DMPA-SC 104 was associated with significantly (P<.001) smaller median percent changes from baseline in total hip and lumbar spine BMD at month 6 compared with leuprolide. At month 12, the leuprolide group continued to show significant (P<.001) decreases in median percent change from baseline in both total hip and lumbar spine BMD, while the DMPA-SC 104 group did not. The median percent change from baseline was -0.25 in the DMPA-SC 104 group compared with -1.60 in the leuprolide group for total hip BMD (P=.002), and 0.00 versus -3.20, respectively, for lumbar spine BMD (P<.001) at month 12. For total hip BMD, most DMPA-SC 104 users had only small decreases from baseline to month 12 (48% of subjects had 0%-2.4% decreases; 10% of subjects had 2.5%-4.9% decreases; none had ≥5% decreases), while more leuprolide users had larger decreases (34% of subjects had 0%-2.4% decreases; 25% of subjects had 2.5%-4.9% decreases; 14% of subjects had ≥5% decreases). For lumbar spine BMD, more DMPA-SC 104 users had smaller decreases from baseline to month 12 (26% of subjects had 0%-2.4% decreases; 24% of subjects had 2.5%-4.9% decreases; 2% of subjects had ≥5% decreases) while leuprolide users had larger decreases (27% of subjects had 0%-2.4% decreases; 37% of subjects had 2.5%-4.9% decreases; 22% of subjects had ≥5% decreases). Results were similar at month 18. In this study, 6-month treatment with DMPA-SC 104 resulted in significantly less reduction in BMD compared with leuprolide. At month 12, BMD values were at or near baseline levels in the DMPA-SC 104 group but not in the leuprolide group.

Expression and Subcellular Localization of 17β-Estradiol Binding Proteins in C2C12 Cell Line. L. Milanesi*, A. Russo de Boland*, R. Boland*. Biologia, Bioquimica & Farmacia, Universidad Nacional del Sur, Bahia Blanca, Argentina.

The classical cellular mechanism of 17β-estradiol actions involves the steroid diffusion through the plasma membrane; its binding to a cytoplasmic/nuclear receptor (ER), and subsequent transcription and protein synthesis regulation. In addition to this mechanism, increasing evidence for non-genomic estrogen short-term effects in different cells types has been accumulated and led to hypothesize the existence of cell-surface resident receptor forms triggering membrane events. These cell- surface protein receptors have been detected in different cell lines (MCF-7, SHM, HT-29) and the expression of an estrogen binding protein and its effects on the development and function of human and bovine skeletal muscle was reported. The present study was focused to analyze the subcellular localization of ER binding proteins in C2C12 cells (a murine skeletal muscle cell line). By competition assays we have detected binding sites for [^{3}H]17β-estradiol in total homogenates. The subcellular localization of these binding sites was predominantly mitochondrial-microsomal. The sites were specific for the steroid hormone 17β-estradiol, as progesterone was no effective to compete with the radioactive ligand. The nonsteroidal estrogenic and antiestrogenic compounds diethylstilbestrol, tamoxifen and ICI 182, 780 were as effective as 17β-estradiol in competition studies. The protein nature of the estrogen binding sites was clearly indicated by their sensitivity to trypsin degradation. Specific antibodies against different domains of the classical ER (ERα) could reduce the specific radioligand binding. Immunochemical studies employing the same monoclonal antibodies detected the 67 kDa immunoreactive band expected for the ERα in nuclear and cytosolic fractions and, additionally, low molecular weight bands present in the mitochondrial and microsomal fractions. These reactive bands were able to bind the steroid hormone in Ligand blot assays. Also these studies showed a clear surface labeling of the macromolecular complexes E_2-BSA-FITC in non-permeabilized living cells. The characterization of these estrogen binding proteins and the signaling cascades activated thereby by the steroid hormone in skeletal muscle cells may provide information about molecular events implicated in alterations in muscle contractility and development which occur in menopause.

Regulation of Mouse Osteoprotegerin Gene Expression by Glucocorticoids. T. Kondo[1], R. Kitazawa[1], A. Yamaguchi[2], S. Kitazawa[1]. [1]Division of Molecular Pathology, Kobe University Graduate School of Medicine, Kobe, Japan, [2]Department of Oral Restitution, Oral Pathology, Graduate School of Tokyo Medical and Dental University, Tokyo, Japan.

Increased bone fragility attributed to osteopenia is a serious side effect of glucocorticoid (GC) treatment. It is known that GC-induced bone loss is caused primarily by hypofunction and apoptosis of osteoblasts; an increase in bone resorption markers is concurrently observed during GC therapy, indicating that accelerated bone resorption also contributes to this loss. The mechanism whereby dexamethasone (Dex) stimulates osteoclastogenesis was explored by analyzing the effect of Dex on cis-acting elements of mouse osteoprotegerin (OPG) and on the c-Jun signaling pathway. Realtime RT-PCR analysis revealed that the steady-state transcription of the OPG gene in C6 cells, established from calvariae of *runx2*-deficient mice, was 7 times that in ST2 cells, suggesting that Runx2 itself may suppress steady-state OPG gene expression. Dex, however, reduced OPG expression to the same extent in both cells, indicating that the inhibitory effect of Dex on OPG expression is independent of Runx2; nevertheless Dex reduced the Runx2 expression in ST2. On the other hand, the amount of OPG protein secreted by ST2 was significantly decreased by Dex treatment. We have reported that mainly the c-Jun homodimer binds to the AP-1 binding site (-293/-287) in the mouse OPG promoter and maintains steady-state transcription of the OPG gene. Since the mutation of the AP-1 site negated Dex-driven OPG suppression, we focused on the mitogen-activated protein (MAP) kinase signaling cascade. Western blot analysis revealed that the amount of phospho-c-Jun protein (p-c-Jun) decreased 1hr after treatment of ST2 with Dex; correspondingly, the amount of the phosphorylated p46 isoform of Jun N-terminal kinase (JNK) decreased significantly after 30 min, whereas that of the p54 isoform decreased after 12 hr. The amount of phospho-SEK1 also decreased significantly after 30 min, whereas the amounts of phospho-ERK and p38 were constant. Among MAP kinase inhibitors (JNK inhibitor SP600125, ERK inhibitor PD98059 and p38 inhibitor SB203580), only the JNK inhibitor mimicked the inhibitory effect of Dex on the OPG promoter activity. These data suggest that Dex negatively regulates OPG by transrepressing the OPG gene through the AP-1 site via a reduction in the proportion of the p-c-Jun in a JNK-dependent manner; also the reduction is mediated mainly by the decrease in the p46 isoform of JNK. We speculate therefore that GCs per se promote osteoclastogenesis mostly by inhibiting OPG as the main target and partly by concurrently stimulating RANKL reciprocally, thereby enhancing bone resorption.

Osteoblast Targeted Overexpression of Hydroxysteroid Dehydrogenase Type 2 Induces Delayed Calvarial Development in Transgenic Mice. C. R. Dunstan, H. Zhou, K. Brennan*, Y. Zheng*, M. J. Seibel. Bone Research Program, ANZAC Research Institute, Sydney, Australia.

The effects of glucocorticoids on bone are still obscure. Transgenic (tg) expression of 11 beta hydroxysteroid dehydrogenase type 2 (HSD2), a glucocorticoid inactivating enzyme, under the control of a 2.3Kb collagen type I promotor abrogates intracellular glucocorticoid signalling in mature osteoblasts, as demonstrated by Sher et al. (1). We evaluated morphological changes in the calvaria and tibiae of wild-type (WT) and tg mice aged 1 day, 7 days and 6 weeks. Tg and WT littermates were assessed concurrently to avoid litter-to-litter variation. HSD2 mRNA and protein expression was present in the calvaria and the long bones of tg mice at these time points, but absent in WT mice. Skeletal expression of HSD1 was similar in WT and tg mice. Histomorphometry of 1 day old HSD2 tg mice revealed a distinct phenotype with incompletely formed calvaria. The amount and extent of bone was reduced by 33% relative to WT mice. Cartilage was present in all tg mice but almost completely absent in WT mice. In 7-day old mice, increased amounts of cartilage were present in the calvaria of tg animals, but the extent of bone was similar to WT mice, indicating a degree of recovery. Calvaria appeared normal at 6 weeks of age. The tibiae and femurs were similar in transgenic and wild type mice at all ages evaluated. These results indicate that in mice, glucocorticoid signalling in osteoblasts is required for normal development of the calvarial bone structures, but not of the long bones. Calvarial bones form by intramembranous bone formation above a cartilaginous template that is then removed after adjacent bone is formed without undergoing hypertrophy or mineralisation as occurs during endochondral bone formation of the long bones. Blocking of glucocorticoid signalling through the overexpression of HSD2 in mature osteoblasts results in a delay in bone formation and in cartilage removal in the calvaria. This may reflect a specific requirement for glucocorticoid signalling in the formation of intramembranous bone structures or may be specific for the calvaria.
(1) Endocrinology 145:922-9, 2004). The authors would like to thanks Prof B Kream for kindly providing the transgenic animals.

Determinants of Aromatase Expression and Serum Estradiol Levels in Males. C. Swanson, M. Lorentzon, S. Movérare Skrtic, J. Brandberg*, L. Lonn*, C. Ohlsson. Center for Bone Research at the Sahlgrenska Academy, Dept. of Internal Medicine, Göteborg University, Göteborg, Sweden.

Serum levels of estradiol are of importance for the regulation of bone mass in males. Cyp 19 (aromatase) is responsible for the synthesis of estradiol, using testosterone as a precursor. Inactivation of the aromatase gene results in reduced bone mass in males. Thus, the aromatase activity is of importance for serum estradiol levels and bone mass in males. The major part of serum estradiol in males is believed to be fat-derived. The aims of the present study were (i) to elucidate the major determinants of serum estradiol in a large male clinical cohort (19-year-old men participating in *the GOOD study*, n=1068) and (ii) to investigate the hormonal regulation of the aromatase expression in white adipose tissue in male mice. In the clinical study, total body lean mass and fat mass were measured by DXA and fat distribution was analysed by cross sectional CT scans of the abdomen. In the mouse study, orchidectomized male mice were treated with vehicle, estradiol or DHT (not aromatizable, specifically activating the androgen receptor). Aromatase levels were analysed by qRT-PCR. Regression models including age, BMI, smoking, physical activity and serum testosterone levels as covariates demonstrated that BMI (β= 0.129, $p < 0.001$) and serum testosterone (β= 0.37, $p < 0.001$) are strong independent positive predictors of serum estradiol levels in men. Individuals in the highest quartile of serum estradiol levels had increased total fat mass (+46%, $p < 0.001$), serum levels of leptin (+55%, $p < 0.001$) and subcutaneous fat mass (+41%, $p < 0.05$) while the total lean mass and the intra abdominal visceral fat mass were unaltered compared with individuals in the lowest quartile of serum estradiol. These findings indicate that it is the subcutaneous and not the visceral fat mass that is responsible for the major part of the aromatase activity in fat mass in men. As serum testosterone levels were the strongest predictor of serum estradiol levels in men, we next wanted to investigate if the aromatase expression in white adipose tissue is regulated by androgen receptor stimulation in male mice. Orchidectomy resulted in a dramatic reduction of aromatase mRNA levels. DHT treatment clearly increased the aromatase expression compared with vehicle treated orchidectomized mice ($p < 0.001$). Estradiol treatment did not affect the aromatase levels. In conclusion, subcutaneous but not visceral fat mass is a strong determinant of serum estradiol levels and this might be due to higher aromatase activity in subcutaneous fat than in visceral fat. Furthermore, the aromatase mRNA levels in fat are strongly up-regulated by androgen receptor but not estrogen receptor stimulation.

5α-Androstane-3β,7β-diol in Urine Is an Independent Positive Predictor of Trabecular and Cortical Bone Mineral Density in Young Adult Swedish Men -*The GOOD Study*. L. Vandenput[1], M. Lorentzon[1], D. Mellström[1], J. Jakobsson*[2], A. Rane*[2], C. Ohlsson[1]. [1]Center for Bone Research at the Sahlgrenska Academy, Departments of Internal Medicine and Geriatrics, Gothenburg University, Gothenburg, Sweden, [2]Department of Laboratory Medicine, Karolinska Institute, Huddinge, Sweden.

Androgens and estrogens regulate skeletal growth and maturation in both males and females, but there is limited information on the relevance of (locally produced) sex steroid precursors and metabolites for bone mass and structure. Urinary levels of conjugated sex steroid metabolites are believed to be reliable markers of the total androgen and estrogen pool. Recently, the dihydrotestosterone metabolite 5α-androstane-3β,17β-diol (3βAdiol) was reported to act as an estrogen receptor-β agonist in the prostate, while its role in bone is still unknown. To address this, we investigated the predictive role of urinary 3βAdiol for bone density and size in young adult Swedish males (age 18.9 ± 0.6 years) at peak bone mass, included in the *G*othenburg *O*steoporosis and *O*besity *D*eterminants (*GOOD*) study. 3βAdiol in urine was quantitated by GC-MS in 124 men. Serum levels of testosterone and estradiol were measured by RIA and corresponding serum free levels were calculated. Bone parameters were assessed using both DXA (total body, lumbar spine) and pQCT (tibia, radius). Regression models including age, height, weight, smoking, calcium intake and physical activity as covariates demonstrated that 3βAdiol in urine is an independent positive predictor of areal BMD of the total body ($\beta = 0.18$, $p < 0.05$) and lumbar spine ($\beta = 0.25$, $p = 0.002$), as measured by DXA. pQCT analysis, separating cortical (diaphyseal) and trabecular (metaphyseal) bone, showed that urinary 3βAdiol is significantly correlated with cortical volumetric BMD (vBMD) at both the tibia ($\beta = 0.28$, $p < 0.001$) and radius ($\beta = 0.33$, $p < 0.001$). In addition, trabecular vBMD of the tibia ($\beta = 0.29$, $p = 0.001$) and radius ($\beta = 0.17$, $p < 0.05$) were also positively associated with levels of 3βAdiol in urine. Including serum free estradiol and free testosterone in the regression model did not change the predictive value of 3βAdiol for any of these bone parameters.These findings demonstrate that urinary 3βAdiol is a strong independent predictor of cortical and trabecular vBMD in young adult men and support the notion that local sex steroid metabolism is an important determinant of skeletal homeostasis. Therefore, 3βAdiol in urine may be an interesting novel diagnostic marker for osteoporosis.

Estradiol Regulates Gene Expressions of Osteoclast Cytoskeleton: A Microarray Study. D. Saintier*[1], N. Sevenet*[2], P. Manivet*[2], M. de Vernejoul[1], M. E. Cohen-Solal[1]. [1]Hospital lariboisiere, INSERM 606, Paris, France, [2]Hospital lariboisiere, IFR 139, Paris, France.

Estrogen deficiency in postmenopausal women is followed by enhanced bone resorption and bone loss. Estradiol is a potent inhibitor of bone number and activity. However the mechanisms by which estradiol inhibits osteoclastic resorption is not clearly known. To identify gene regulatory mechanisms that drive osteoclast differentiation and function in response to estradiol, we performed gene expression by microarray analysis of about 15 000 genes (CEA, Evry, France). We used RAW 264.7 monocyte cell line differentiated into osteoclasts in order to analyze changes in gene expression that occur after estradiol exposure. Total RNA was isolated from RAW cells cultured for 5 days with RANKL (30 ng/ml) and in the presence or absence of 17β-estradiol (10^{-8}M). Hybridization were performed with the inverted labeling (flip/flop method). The RNA samples from each condition were subjected to oligonucleotide gene chips. The experiment was performed three times on two sets of RNA. Analysis was assessed using Image software (Biodiscovery, USA). Overall, in three experiments we found that estradiol consistently changed the expression of several genes with different levels of significance : 7 genes with p value <0.001, 38 with p value <0.005 and 77 with p value <0.01. Thirteen genes were continually up-regulated and 25 were continually down-regulated. Estradiol increases the expression of plakoglobin, a protein implicated to cell-cell adhesion in adherent junctions. We also observed changes in mRNA expression of genes involved in cytoskeleton reorganization. Genes of myosin 1D, an actin-based motor and Ckap1, a cytoskeletal-associated protein for microtubule folding, were significantly down-regulated. These latter suggest that estradiol might have a potential inhibitory role on actin contractility and microtubule polymerisation and therefore might result in a decreased cell migration and motility. In agreement with this result, we found that estradiol decreased actin polymerisation by phalloidin staining. Furthermore, estradiol inhibited the mRNA expression of Rps3a, a ribosomal protein involved in the inhibition of cell apoptosis. These data indicated a potential role of estradiol on cell-cell adhesion, cytoskeletal dynamics and apoptosis. In conclusion, the analysis using microarray showed that estradiol might regulate the expression of several genes implicated in osteoclast fusion, motility and survival. Moreover, the microarray may provide tools for further investigations in order to improve the understanding of the regulation of osteoclast function with estradiol.

SHBG Is an Independent Negative Predictors of Bone Mineral Density in Elderly Swedish Men- *MrOS Sweden*. M. Lindberg[1], A. Eriksson[1], E. Orwoll[2], Ö. Ljunggren[3], O. Johnell[4], D. Mellström[1], C. Ohlsson[1]. [1]Center for Bone Research at the Sahlgrenska Academy, Department of Internal Medicine, Gothenburg University, Gothenburg, Sweden, [2]Bone and Mineral Unit, Oregon Health and Sciences University, Portland, OR, USA, [3]Department of Medical Sciences, University of Uppsala, Uppsala, Sweden, [4]Department of Orthopaedics, Malmö General Hospital, Malmö, Sweden.

SHBG is an important determinant of bioavailable and free estradiol and testosterone. However, some studies have indicated that it also is an independent regulator of serum bone markers and bone mineral density (BMD). It has been suggested that SHBG exerts direct cellular functions by acting through a specific membrane receptor, and that this effect may be independent of estradiol and testosterone. The aim of the present study was to investigate if SHBG is an independent predictor of BMD in a large cohort of elderly Swedish men. In the Swedish part of the MrOS study (n= 3000, average age 75.4 years) bone parameters were measured using DXA. Serum levels of testosterone, estradiol and SHBG were measured and free testosterone and free estradiol were derived from the mass action equations. The independent role of SHBG as a predictor of skeletal parameters was evaluated in regression models including age, height, weight, physical activity, smoking habits, calcium intake, free testosterone, free estradiol and SHBG. SHBG was an independent negative predictor of total body (β= -0.041, p= 0.02), lumbar spine (β= -0.045, p=0.02), trochanter (β= -0.040, p=0.03) and femur neck (β= - 0.053, p=0.005) BMD. We next compared the subjects with high SHBG levels (h-SHBG, the 10% with highest SHBG levels) with those with low SHBG levels (l-SHBG, the 10 % with the lowest SHBG levels). Subjects with l-SHBG had increased BMD in the lumbar spine (12.2 % over h-SHBG, $p < 0.001$), trochanter (8.9 % over h-SHBG, $p<0.001$) and femur neck (8.8% over h-SHBG, $p<0.001$) compared with subjects with h-SHBG. In conclusion, SHBG is an independent predictor of BMD in elderly Swedish men, supporting the notion that SHBG exerts effects on bone independent of estradiol and testosterone. The mechanism(s) of action for the estradiol/testosterone independent effects of SHBG remains to be elucidated.

Longitudinal Follow-Up of Androgen Action on the Skeleton of the Growing SAMP6 Mouse Model: No Evidence for Blunting of Androgen Action. J. Ophoff*, K. Venken*, S. Boonen, E. Van Herck*, R. Bouillon, D. Vanderschueren. KULeuven, Leuven, Belgium.

The SAMP6 mouse model (P6) is a well-characterized animal model of deficient peak bone mass acquisition and osteoporosis. Previous studies suggested that the P6 skeleton is also resistant to orchidectomy. However, bone effects of androgen replacement have never been evaluated in P6 and their respective SAMR1 (R1) controls. In this study, the non-

aromatisable androgen 5α-dihydrotestosterone (DHT) was administered (45µg/day via subcutaneous implants) to orchidectomized male P6 and R1 mice at week 4 (start of puberty). Both bone resorption and formation markers (urinary deoxypyridinoline [DPD] and serum osteocalcin [oc]) and tibial bone mass (by *in vivo* pQCT) were measured every 4 weeks between 4-20 weeks of age. At baseline and endpoint serum osteoprotegerin (OPG) was evaluated. At the tibial diaphysis, DHT had similar bone anabolic effects in P6 and R1. DHT increased periosteal expansion more than endocortical expansion, resulting in thickening of the cortex (+7% in P6 and +4% in R1, respectively; P<0.001). At the tibial metaphysis, DHT also induced a sustained increase of trabecular bone mineral density during the entire experimental period; this increase was significantly greater in P6 (+150% in P6 versus +68% in R1, P<0.001), despite similar action of DHT on seminal vesicles in P6 and R1. In accordance with its bone sparing action on cancellous bone, DHT lowered oc and DPD in P6 (-47% and -59%, respectively, P<0.001) and R1 (-53% and -60%, respectively, P<0.001) during the entire experimental period. Moreover, DHT increased serum OPG (which was already higher in P6 than R1) in P6 (+63%, P<0.05) but not in R1. In conclusion, DHT action on the skeleton is not impaired in growing P6. DHT has similar anabolic action on cortical bone in P6 compared to controls. In cancellous bone, on the other hand, DHT shows a stronger bone sparing effect in P6; this effect is consistent with an increase of OPG in this animal model of senile osteoporosis. The longitudinal follow-up of bone markers in combination with *in vivo* pQCT appears an interesting tool for the combined evaluation of cortical and cancellous bone acquisition during growth in animal models.

Aromatase Inhibition Causes Lower Bone Density Than Ovariectomy in Mice, an Effect Prevented by Bisphosphonates. W. Kozlow[1], K. Mohammad[1], R. McKenna*[1], N. Niewolna*[1], L. Suva[2], C. Rosen[3], T. A. Guise[1]. [1]Internal Medicine, University of Virginia, Charlottesville, VA, USA, [2]Orthopaedic Surgery, University of Arkansas, Little Rock, AR, USA, [3]Jackson Laboratory, Bar Harbor, ME, USA.

Aromatase inhibitors (AIs), effective treatment for breast cancer, block estrogen synthesis by inhibiting the conversion of testosterone and androstenedione to estradiol and estrone. Increased bone resorption and decreased bone mineral density (BMD) are predicted consequences. We hypothesized that bisphosphonates (BPs) may prevent bone loss from AI therapy. We studied the effect of estrogen deficiency on bone remodeling in 4-week-old female nude mice that underwent ovariectomy (ovx) or sham surgery. Ovx and sham mice did not differ in BMD (assessed by DXA) or in histomorphometric assessment of trabecular bone volume. Next, to study the effect of AIs +/- BPs on bone remodeling, 4-week-old female nude mice were treated with letrozole (10 mcg/d), zoledronic acid (ZA) (5 mcg/kg twice weekly), letrozole (10 mcg/d) + ZA (5 mcg/kg twice weekly) or control. Mice treated with letrozole alone had lower BMD compared to control mice (p<0.0001; total body, spine, femur and tibia). Mice treated with ZA alone had higher BMD compared to control mice (p<0.0001; total body, spine, femur and tibia). Mice treated with letrozole plus ZA achieved the same BMD as mice treated with ZA alone at the spine and tibia, but had greater BMD than mice treated with ZA alone at the femur (p<0.0001) and total body (p<0.0023). MicroCT analysis of the proximal tibia showed no difference in bone volume (BV/TV), structural model index, or trabecular number, thickness or spacing in mice treated with letrozole alone compared to control. Treatment with ZA (+/- letrozole) resulted in a significant increase in BV/TV and trabecular number and thickness, and the structural model index indicated that the bone structure was unusually solid. Dynamic bone histomorphometry of the lumbar spine demonstrated decreased bone formation and mineral apposition rates in mice treated with letrozole, ZA or the combination compared to control. Serum testosterone concentrations were increased in mice treated with letrozole compared to control. Serum IGF-1 concentrations were similar in all groups. These data indicate that aromatase inhibition with letrozole caused lower BMD in female nude mice than that observed with ovx. The greater effect of AIs compared to ovx may be due to reduced adrenal androgen conversion to estrogen. ZA prevented AI-induced bone loss, but microCT and dynamic bone histomorphometry suggest reduced bone remodeling. BPs may be useful to prevent AI-induced bone loss, but further studies are needed to assess the effects of these treatments on bone quality.

Estradiol Therapy in Murine Congenital Aromatase Deficiency Normalizes Serum IGF-I and Femoral Width but not Length. O. K. Oz[1], A. M. Thomas*[1], G. Hirasawa*[1], C. Rosen[2], E. R. Simpson*[3]. [1]Radiology, UT Southwestern Medical Center at Dallas, Dallas, TX, USA, [2]Maine Center for Osteoporosis Research, St. Joseph's Hospital, Bangor, ME, USA, [3]3Victorian Breast Cancer Consortium, Prince Henry's Institute of Medical Research, Clayton, Victoria, Australia.

Aromatase catalyzes the biosynthesis of estrogens from androgen precursors. We have shown previously that adult aromatase deficient male mice (ArKO) have significantly lower trabecular bone volume, low turnover, low serum IGF-I and significantly decreased femur length compared with Wt males. In the present study we sought to determine if estradiol therapy during puberty could normalize IGF-I levels and axial and appendicular skeletal growth. We followed and compared the growth of male ArKO mice, or ArKO mice treated with 20ug E2 3x/week subcutaneously in sesame oil, to their Wt littermates from age 3 weeks to 7 weeks. Nasal anal length (NAL) was used as an index of axial skeletal growth. Femur length and transverse mid-shaft diameter at the time of sacrifice were used as a measures of appendicular skeletal growth during puberty. Serum IGF-I levels were measured by RIA. Compared to Wt littermates ArKO males showed shorter NAL beginning at 5 weeks (p<0.05) of age and lower body weight. Placebo treated ArKO mice had shorter (p<0.05) and narrower femurs (p<0.05). Estradiol therapy normalized the mid-shaft diameter but worsened the femur length deficit. IGF-I serum levels in placebo treated male ArKO mice were lower than Wt males (p<0.001). Estradiol treatment normalized serum IGF-I levels. Since hepatic IGF-I production is regulated by growth hormone signaling through the JAK/Stat pathway and inhibited by SOCS-2, we measured SOCS-2 levels in hepatic proteins of 7 week old animals. The placebo treated ArKO animals had lower SOCS-2 levels compared to Wt. Estradiol therapy raised the SOCS-2 expression to Wt levels. Despite this, serum IGF-I was normalized. These data show that the dose regimen of estradiol used was not sufficient to normalize appendicular skeletal growth despite normalization of IGF-I but was sufficient to normalize transverse mid-shaft diameter. Estradiol may regulate radial bone growth through IGF-I action. In previous work we have shown that femur length in ArKO males can be restored by treatment with rhIGF-I. Taken together, the data raise the question of whether estradiol and IGF-I might have opposing effects at the growth plate of animals in the age range of this study.

A Cross Sectional Survey of Age-Dependent Changes in Mineral Metabolism and Bone Turn-Over Markers in 461 Chinese Subjects Age 2 Month to 100 Years. B. H. Sun[1], W. J. Chu*[2], H. Y. Zhang*[2], K. L. Insogna[1]. [1]Internal Medicine/Endocrinology, Yale University School of Medicine, New Haven, CT, USA, [2]Laboratory Medicine, Beijing Ji Shui Tan Hospital, Beijing City, China.

Several studies have reported that the ratio of dietary calcium to dietary phosphorus is an independent predictor of bone mineral content (BMC) and bone mineral density (BMD). Effects on circulating levels of PTH, and a vitamin D-independent effect on intestinal calcium absorption have been suggested as possible mechanisms for this relationship. Although alterations in dietary calcium and phosphorus can effect circulating levels of these ions, little is known about the relationship of the serum calcium/phosphorus ratio (Ca/P) or the serum calcium-phosphorus product (CaxP) to age-dependent changes in mineral metabolism and bone turnover. To address this issue BMD and BMC as well as serum iPTH, calcitonin and Alk.Phos were measured, and their relationship to Ca/P and CaxP analyzed in 461 healthy Chinese subjects from age 2 months to 100 years. Subjects were divided into 13 age groups with 30-40 individuals in each group and equal proportions of each sex in each group. The data are summarized graphically below. We found that Ca/P was positively correlated with BMD before age of 40 (i.e. before attainment of peak bone mass) and negatively correlated with BMD after age of 40. Sex-dependent differences were found only for iPTH and only in the 41 to 50 and 71 to 80 age groups (data not shown). Alk. Phos. declined and iPTH rose in parallel with the change in Ca/P ratio. We conclude that the Ca/P ratio tracks with changes in bone anabolism, such as Alk Phos and with bone accretion in childhood and young adulthood. The divergence between Ca/P and bone mass in later adult life may reflect changing needs in these two minerals for optimal skeletal health or simply age-dependent changes in mineral homeostasis. These two possibilities are currently under investigation.

Flagellin Stimulate Osteoclast Formation by Increasing RANKL Expression in Osteoblasts. Z. Lee, H. Ha*, H. Kwak*, H. Kim*, J. Lee*, M. Kang*, H. Kim*. Cell and Developmental Biology, College of Dentistry, Seoul National University, Seoul, Republic of Korea.

Stimulation of several Toll-like receptors (TLRs) has been shown to increase osteoclast formation in the co-cultures of osteoblasts and bone marrow cells. We investigated whether activation of TLR5 could modulate osteoclastogenesis. Flagellin, which act as a ligand of TLR5 stimulated osteoclast formation in co-cultures, and significantly increased the number of osteoclasts and the resorbed area in the calvarial bone of mice. Flagellin also stimulated the expressions of RANKL, TNF-α, IL-1, and M-CSF, known to stimulate osteoclastogenesis. Flagellin-induced osteoclastogenesis was blocked by addition of OPG, but not IL-1ra and anti-TNF Ab. In addition, flagellin had no effect on PGE_2 production in co-cultures. We also found that the activation of Erk pathway was involved in flagellin-induced RANKL expression in osteoblasts. However, treatment with flagellin from the beginning of the BMM cultures significantly inhibited RANKL-induced osteoclast formation by inhibiting expression level of c-Fos protein. Taken together, these results suggest that flagellin stimulate osteoclastogenesis via osteoblasts which overcome the inhibitory effect of flagellin on osteoclast precursors, as well as increasing RANKL induction.

Bone Mineral and Predictors of Whole Body, Total Hip, and Lumbar Spine for 740 Early Pubertal White, Hispanic, and Asian Girls. C. M. Weaver[1], L. D. McCabe*[1], G. M. McCabe*[1], R. Novotny*[2], M. D. Van Loan[3], S. B. Going[4], C. Boushey*[1], D. A. Savaiano*[1], V. Matkovic[5]. [1]Purdue University, West Lafayette, IN, USA, [2]University of Hawaii, Honolulu, HI, USA, [3]University of California - Davis, Davis, CA, USA, [4]University of Arizona, Tucson, AZ, USA, [5]Ohio State University, Columbus, OH, USA.

To determine ethnic differences and predictors of bone mass in early pubertal girls, we recruited White, Hispanic, and Asian 6th grade girls across six states for a school-based educational intervention. Here we report baseline bone mineral content data (Figs 1-3) and developed models for predicting bone mineral content (BMC) for the whole body, 33% radius, total hip, and lumbar spine for 740 subjects. Multivariate analysis of variance indicated that there are differences in BMC among ethnic groups (Wilks' Lambda=0.926, p<0.0001). For each of the bone sites, the corresponding area was a strong predictor of BMC with correlations ranging from 0.78 to 0.98, confirming that larger subjects have more BMC. Detailed results for total body BMC, and radius 33% BMC were qualitatively similar. Ethnicity was not a significant predictor when added to the models that predict BMC with area. Models using anthropometric variables (height, weight, bitrochanteric width, waist depth, waist circumference, trunk length, forearm length) plus ethnic group to predict total body area, and radius 33% area explained 88%, and 32%, of the variability respectively. Final models included ethnic group, the anthropometric predictors of area, Tanner score, age, physical activity, and dairy calcium intake explained 85% and 64% of BMC respectiviely. Ethnic group was not a significant statistical predictor of BMC in these models. Significant positive associations of BMC were found with Tanner score and physical activity for both bone sites; and with age for total body BMC. For lumbar spine and total hip, 76% and 79% of the variability in area was explained by anthropometric variables. Final models predicted 79% and 77% of the variability in BMC. These models included statistically significant interactions of ethnicity with anthropometry variables. Significant positive associations of BMC were found with Tanner score, age, and dairy calcium for lumbar spine; Tanner score and physical activity for total hip. All analyses were controlled for study site.

Responses of Human Bone Marrow Stromal Cells to PTH Decrease with Age. S. Zhou, I. Amato*, J. Glowacki. Orthopedic Surgery, Brigham and Women's Hospital, Boston, MA, USA.

Studies with human and animal culture systems indicate that a sub-population of bone marrow stromal cells (hMSCs) has the potential to differentiate into osteoblasts. We and others showed that there is an age-related decline in the osteoblast potential of hMSCs. Parathyroid hormone (PTH), when applied intermittently, has osteoanabolic effects in a variety of systems. The ability of PTH to regulate gene expression in target cells is dependent upon activation of transcription factors involved in cascades stemming from PKA, such as cAMP response element binding protein (CREB), or β-catenin. In this study, we tested the hypothesis that the response of human marrow stromal cells to PTH decreases with age. Early passage hMSCs obtained from young (*Y*; 34, 42 yr) and elderly (*E*; 68-90) women were treated with PTH in MEM-α with 1% heat-inactivated FBS, 1% P/S supplemented with 10^{-8}M dexamethasone, 50 μg/ml ascorbate phosphate, 5mM β-glyceraldehyde. Growth of cells, abundance of Senecence Associated β-galactosidase (SAβ), and effects of PTH on alkaline phosphatase (ALK) activity, and Western immunoblots for activation of CREB and β-catenin were assessed. An additional 6 days was required for *E* cells to expand to the numbers reached by *Y* cells. There were 10-fold (± 2) more SAβ-positive cells in *E* cultures than in *Y*. Osteoblast differentiation, measured by ALK activity, in *E* cultures was half that in *Y*. After 7 d, alkaline phosphatase (ALP) activity in a *Y* culture was stimulated by 10^{-8}M PTH to a magnitude twice that in *E* (Figure, Left). PTH activation of p-CREB and β-catenin was dimished in *E* (Figure, Center and Right). In sum, there are age-related decreases in human marrow stromal cell proliferation, differentiation into osteoblasts, and magnitude of stimulation of osteoblastogenesis by PTH. PTH signaling of p-CREB and β-catenin are diminished with age. Intrinsic alterations in signaling pathways may explain cellular and tissue aging.

Effects of Local Administration of Recombinant Human IGF-I (hIGF-I) on New Bone Formation in an Aged-Mouse Model Using Distraction Osteogenesis. J. L. Fowlkes[1], L. Liu*[2], E. C. Wahl*[1], R. C. Bunn*[1], K. M. Thrailkill[1], C. K. Lumpkin[1]. [1]Pediatrics, UAMS, Little Rock, AR, USA, [2]Orthopeadics, UAMS, Little Rock, AR, USA.

Human and rodent research supports a primary role for insulin-like growth factor-I (IGF-I) in bone formation. IGF-I is involved in stimulating longitudinal bone growth and in enhancing bone formation. In mice, elimination of hepatic IGF-I affects bone formation only minimally, suggesting that paracrine/autocrine actions of IGF-I may play an essential role in bone homeostasis. To test this hypothesis, we designed a study using surgical distraction osteogenesis (DO) in aged mice (12-month CB57BL/6 male mice) who were distracted one day after surgery at 0.075 mm bid for 13 days. At the time of surgery, Alzet® Model 2002 mini-osmotic pumps were filled with either 1) PBS (vehicle; n = 10); 2) human IGF-I (hIGF-I; n = 11; delivery rate: 1ug/7ul/day); or 3) methylene blue (n = 2). Alzet pumps were inserted subcutaneously and infusion tubing was routed subcutaneously from the pump to the distraction site with the catheter outlet placed adjacent to the osteotomy. Continuous infusion of vehicle, hIGF-I or methylene blue occurred for the full 14 days. After DO, the mice were anesthetized, decapitated for blood collection, and the distracted tibiae were removed and fixed. DO gaps were assessed by X-ray analyses for new bone formation and blood was sampled to determine hIGF-I concentrations using a human-specific IGF-I ELISA. No hIGF-I was detected in the serum of hIGF-I treated or vehicle treated animals, attesting to the concept that local delivery of this growth factor can be achieved with little to no systemic spread. Methylene blue as tracer confirmed that the delivery modality was precise and efficient. Comparison of radiographs from vehicle versus hIGF-I treated animals showed that more calcified bone was present within the distraction gaps of hIGF-I treated versus vehicle-treated mice. Radiologic quantification of aligned distraction gaps revealed that vehicle-treated mice demonstrated 16.532 +/-6.425 % new bone formation compared to the hIGF-I treated mice which displayed 45.178 +/-8.152 % new bone formation (p = 0.02). These studies demonstrate that local hIGF-I can be effectively and successfully applied to the distraction gap using a subcutaneous osmotic minipump. Furthermore, local infusion of hIGF-I to the distraction gap was successful in producing a ~2-3 fold increase in new bone when compared to no hIGF-I, making it highly feasible to detect a local IGF-affect in this new bone formation model, without altering peripheral IGF-I concentrations.

Lean Mass, but not Fat Mass, Is a Significant Predictor of Peak BMC and BMD in Mice Fed a High-Fat Diet. M. Hamrick, C. Pennington*, C. Webb*, C. M. Isales. Medical College of Georgia, Augusta, GA, USA.

Body mass is known to be a significant predictor of bone strength, although it is unclear whether lean mass or fat mass is a more important determinant of peak bone mass (BMC) and density (BMD). We examined the effects of lean mass and fat mass on peak BMC and BMD by feeding normal (wild-type CD-1/ICR) mice and myostatin-deficient mice a high-fat (45 kcal %fat) diet for 8 weeks starting at two months of age. Mice lacking myostatin (GDF-8) have increased muscle mass compared to normal mice, and are also known to have less body fat than normal mice. Control mice of each genotype were fed standard chow (4 kcal %fat). Lean and fat mass, percent body fat, BMC, and BMD were analyzed using DEXA (PIXImus system). Serum insulin, leptin, and resistin levels were measured using a Luminex assay kit (Linco Research). Fat mass, percent body fat, and serum resistin levels increased significantly in normal and myostatin-deficient mice fed a high fat diet, whereas serum leptin increased significantly in normal mice but not in myostatin-deficient mice. Whole-body BMC decreased by approximately 10% in normal mice fed a high fat diet compared to mice on the control diet, whereas the high fat diet yielded a slight but non-significant increase in skeletal BMC and BMD in the myostatin-deficient mice. Coefficients of determination calculated from regression analyses within mice of each genotype (pooled control and high fat diet animals) indicate that lean body mass is a significant ($P<.05$) determinant of BMD and BMC in mice of each genotype whereas fat mass, serum leptin, serum insulin, and serum resistin were not significant predictors of BMD or BMC in either group. These data suggest that increasing lean mass early in life may be an effective strategy for increasing peak BMD and BMC, whereas fat mass and total body weight may be more important for maintaining bone mass and density after skeletal maturity.

Vitamin D Status and Calcium Absorption in Black and White Boys and Girls on a Range of Controlled Calcium Intakes. M. Braun[1], B. R. Martin[1], G. P. McCabe*[2], L. A. DiMeglio*[3], M. Peacock[3], C. M. Weaver[1]. [1]Foods & Nutrition, Purdue University, West Lafayette, IN, USA, [2]Statistics, Purdue University, West Lafayette, IN, USA, [3]Indiana University School of Medicine, Indianapolis, IN, USA.

The relationships among serum 25 and 1,25 vitamin D, serum levels of calcium regulating hormones and calcium absorption have been established in adults but not in children. These relationships were investigated in 236 adolescents during their pubertal growth spurt to determine whether similar relationships exist in children and whether they are affected by race and sex. Calcium balance studies were conducted in American white and black girls and boys, aged 11-15 years, on calcium intakes ranging from 760 to 2195 mg Ca/day for 3-week controlled feeding periods. In addition, dual stable isotope calcium tracer studies were conducted in a subset of individuals. All procedures were approved by the Purdue University and Indiana University School of Medicine Institutional Review Boards. Serum 1,25 D increased in response to a low calcium intake and apparent calcium absorption increased as 1,25 D increased. Serum parathyroid hormone (PTH) levels and 1,25 D were positively related. Serum 1,25 D was different between American whites and blacks ($p<0.05$). Serum 25 D was different between racial groups ($p<.0001$) and between boys and girls ($p=0.0010$). Serum 25 D was inversely related to PTH, however, the relationship varied with race (Figure 1). Relationships among serum 25 and 1,25 vitamin D, serum levels of calcium-regulating hormones and calcium absorption are similar in children as in adults, but in addition to racial differences known in adults, sex differences were found.

Defining the Serum Vitamin D Concentration Required for Maintenance and Buildup of Bone in Young Japanese Women. H. Ohta[1], Y. Onoe[1], Y. Miyabara*[1], A. Harada*[2], R. Yoshikata*[1], T. Kuroda*[1], H. Okano[1], N. Tsugawa*[3], T. Okano[3], M. Kume*[4], S. Sasaki*[5]. [1]Obstetrics and Gynecology, Tokyo Wemen's University, Tokyo, Japan, [2]Biostatistics, Tokyo University, Tokyo, Japan, [3]Hygienic Science, Kobe Pharmaceutical University, Kobe, Japan, [4]Nursing, Tokyo Wemen's University, Tokyo, Japan, [5]National Institute of Health and Nutrition, Tokyo, Japan.

Vitamin D is known to play as a important role in bone mineralization, and Vitamin D insufficiency is known to cause hyperparathyroidism, bone reduction and fracture in elderly people. In recent years, it is suggested that serum vitamin D levels are reduced in the elderly, and vitamin D supplementation is called for in these people. To develop a methodology for the prevention of osteoporosis, we examined serum 25OH-VD and PTH levels in young Japanese females, to elucidate the relationship between these variables and bone mineral density (BMD) in these subjects. Between October 2003 and April 2004, healthy female volunteers aged between 19 to 25 years who gave prior informed consent were recruited into the study. Those receiving treatment for any disease affecting bone mass, as well as pregnant or breast-feeding women, were excluded from the study. The subjects were asked about their age, current menstrual status, height, body weight, weight at birth, and as well as their gestational age. Biochemical variables examined in these subjects included the levels of serum calcium (Ca), phosphorus (P), intact-PTH, cross-linked N-telopeptide of type I collagen (NTX), and bone-alkaline phosphatase (BAP). The BMD of the lumbar vertebrae 2 to 4 (L 2-4), as well as the total BMD of the proximal femur (BMD of the hip) was also measured in the subjects using QDR 4500. A total of 293 subjects (mean age, 20.6 ± 1.5) were enrolled in the study. The BMD of the L2-4 (mean, 1.00 ± 0.11 g/cm^2) and of the total hip (mean, 0.90 ± 0.10 g/cm^2) were confirmed to remain at a certain level between the ages of 19 to 25. The mean serum Ca and P levels were 9.50 ± 0.33 mg/dl and 3.75 ± 0.43 mg/dl, respectively. The mean serum 25OH-D and intact-PTH levels were 18.8 ± 4.9 ng/ml and 22.0 ± 7.4 pg/ ml, respectively. During the entire observation period, serum Ca and P levels remained stable, while 25OH-VD levels were shown to significantly negatively correlate with intact-PTH levels. Furthermore, the subjects who had higher vitamin D levels (over 25 ng/ml) showed no increase in intact-PTH levels; however, they showed significantly higher BMD values than those with lower vitamin D values. Our study results indicate that reduced vitamin D levels lead to an increase in intact-PTH levels resulting in reduced BMD values even in young females; in contrast, higher vitamin D levels contribute toward higher BMD levels in these subjects.

Impact of Nutrition and Exercise on Acquisition of Bone Mineral Density in Young Japanese Women. Y. Miyabara*[1], A. Harada*[2], Y. Onoe[1], R. Yoshikata*[1], M. Yoshida*[1], T. Kuroda*[1], H. Okano[1], M. Kume*[3], S. Sasaki*[4], H. Ohta[1]. [1]Obstetrics and Gynecology, Tokyo Wemen's University, Tokyo, Japan, [2]Biostatistics, Tokyo University, Tokyo, Japan, [3]Nursing, Tokyo Wemen's University, Tokyo, Japan, [4]National Institute of Health and Nutrition, Tokyo, Japan.

Acquisition of bone mineral density (BMD) in women in their early years is assumed to be crucial to the prevention of osteoporosis. Furthermore, observance of appropriate physical exercise and intake of necessary nutrients are assumed to play a key role in their early acquisition of BMD. A cross-sectional study was therefore conducted to identify which lifestyle habits might be definitive factors affecting the status of BMD in young Japanese women based on their background factors, nutritional intake, physical exercise, and BMD.Female volunteers aged 19 to 25 years of age were enrolled in this study and the subjects were asked about their age, weight at birth, and age at menarche; height, weight, serum Ca, P, ALB, intact-OC, NTX, BAP were also measured in these subjects. Furthermore, BMD of the lumbar vertebrae 2-4 (L2-4 BMD), as well as BMD of the proximal femur (hip BMD), was also measured in these subjects by using QDR4500. Additionally, all subjects were asked about their physical activity and nutritional intake using the Questionnaire on the Amount of Physical Activity developed by the JALS Physical Activity Working Group, Japan Atherosclerosis Society, and the self-administered Diet History Questionnaire (DHQ). The present study accrued 254 subjects over time between October 2003 and April 2004, and the data collected from these subjects were analyzed. The mean age of the subjects was 20.7 ± 1.5 years old; the mean age at menarche, 11.9 ± 1.2 years old; and the mean L2-4 and hip BMD, 1.00 ± 0.11 and 0.90 ± 0.10 ng/cm^2, respectively. Of the variables examined, height, weight, BMI, weight at birth, and intact-OC were found to be significantly correlated with the mean L2-4 and hip BMD values; total physical energy, prior exercise habits, of all physical activity-related variables examined, as well as cholesterol and phosphorus, of all DHQ variables examined, were significantly correlated with the L2-4 and hip BMD. Furthermore, multiple regression analysis of the data showed BMI, prior exercise habits, total physical energy, and total cholesterol intake to be definitive factors affecting the status of the L2-4 and hip BMD. Our study results suggest that self-control of BMI, regular physical activity, and cholesterol intake play a pivotal role in promoting the acquisition of BMD in women in their early years.

Weight at the Age of Peak Bone Growth Affects Bone Mass in Japanese Adolescents but Birth Weight Does not. M. Iki[1], J. Tamaki*[1], Y. Ikeda*[1], A. Morita*[1], Y. Sato*[2], H. Naka*[3]. [1]Department of Public Health, Kinki University School of Medicine, Osaka-Sayama, Japan, [2]Department of Nutrition, Tenshi College, Sapporo, Japan, [3]Department of Physical Education, Kyoto University of Education, Kyoto, Japan.

The birth weight has been suggested to affect adult bone mass in Caucasian women. Neonatal bone growth retardation may increase the risk of osteoporosis later in life. We tested whether this was the case in for Japanese persons or not, and investigated which weight measured during childhood had the greatest effect on bone mass. We examined 263 healthy Japanese boys and girls from the 4th to 6th grade of the elementary schools (11.2±0.9 years old) for height, weight and bone mineral density (BMD) at the spine and hip by DXA, and measured the same items for the same subjects 3 years after the baseline. The height and weight values for the subjects at birth and at health checkups for children of age 1.5 and 3 years were obtained from their Maternal and Child Health Handbook and values for those at the entry into elementary school (6 years old) and junior high school (12 years) were obtained from the medical records at the schools. The correlation coefficient between the weight at birth or at age 1.5 years and BMD at baseline or follow-up was not significant, regardless of sex and skeletal site. The correlations between weight at age 3 years and BMD at both skeletal sites and on both occasions were all significantly positive only in boys. The weight after age 3 years showed a significantly positive correlation with BMD. The correlation between the weight and BMD at follow-up was the strongest in boys, while the correlation between those at baseline was the strongest in girls. When the results were adjusted for age and weight at the time of bone measurement, all the correlations turned out to be insignificant in boys, but the correlations between weight at the entry into junior high school and BMD at follow-up were still significant in girls. We performed a multiple regression analysis for BMD at follow-up in girls using the age and weight at follow-up and weight at the entry into junior high school, in order to evaluate the relative importance of the weights at these 2 time points for BMD. A significant regression coefficient was given to the weight at the entry into junior high school but not for the weight at follow-up. The weight at birth or in infancy did not affect the BMD in the Japanese pupils and junior high-school students. The greatest effect on BMD in girls was observed for the weight at the upper grades of elementary school or at the entry into junior high school, which was around the age at peak bone growth. This finding suggests that weight around the age at peak bone growth may have a critical effect on the peak bone mass in women.

Correlations among Age, Sex and Growth Variables for Bone Mineral Content and Bone Mineral Density Acquisition in Healthy Children from Central Italy . P. Caradonna[1], E. Ausili*[2], D. Rigante*[2]. [1]Department of Internal Medicine, Università Cattolica Sacro Cuore, Rome, Italy, [2]Department of Pediatric Sciences, Università Cattolica Sacro Cuore, Rome, Italy.

Aim: To evaluate cross-sectionally bone mineral content (BMC) and bone mineral density (BMD) in healthy Italian children and to find correlations with age, sex and growth variables.*Methods:* We have examined a cohort of 359 healthy children (187 males and 172 females, aged 3-14 years) recruited from the same Italian region in 1 year: demographic, anthropometric data and informations about physical activity and pubertal development were obtained. Total body (TB), lumbar spine (LS), femoral neck (FN) and body composition were assessed with dual-energy X-ray absorptiometry (Hologic QDR 2000). *Results:* No significant difference of TB-BMC annual increments was found for both sexes (b value: 107.5 in females, 113.5 in males). LS-BMD increased at the same rate in males and females until the age of 9 years (23 g/cm^2/year); then females showed a significant greater annual increment (95 g/cm^2) differently from males (24 g/cm^2). When compared by gender, LS-BMD was higher in females older than 9 years. FN-BMD showed until the age of 9 years a mean annual increment of 26 g/cm^2 in males and 30 g/cm^2 in females; then the increment was 50 g/cm^2 in both sexes. When compared by gender, FN-BMD appeared higher in males than in females for all age groups. Stepwise multiple linear regression analysis (multivariate model) was performed using BMD as dependent variable. This model revealed that pubertal stage was the stronger predictor of LS-BMD increase in females rather than in males (respectively R = 0.837 and 0.738); if physical activity was considered, R improved only in the female sex (0.885). When other variables (BMI, father BMI, mother BMI, lean/fat mass, puberal stages according Tanner) were introduced, the interaction of lean mass and pubic hair stage gave the best fit for females (R = 0.939), while the exclusive lean mass fitted in the model for males (R = 0.833). When FN-BMD was considered as dependent variable, only age was the stronger predictor of BMD increase both for males and females (respectively R = 0.663 and 0.810). If BMI and lean/fat mass were analyzed, the stronger predictor of FN-BMD increase was lean mass both in males and females (respectively R 0.817 and 0.900). *Conclusions:* Before puberty LS-BMD was equally distributed in both sexes; after puberty LS-BMD resulted significantly higher in females, due to minor dimensional development of female vertebrae. FN-BMD was higher in males at whatever age. In both sexes the stronger predictors for bone mass acquisition were pubic hair stage and lean mass at LS and only lean mass at FN.

Effect of Physical Activity in Elementary School on Bone Mineral Density in Japanese Children and Adolescents: A 3-Year Longitudinal Study. J. TAMAKI[1], M. Iki[1], A. Morita*[1], Y. Ikeda*[1], Y. Sato*[2], H. Naka*[3]. [1]Public Health, Kinki University School of Medicine, Osaka-Sayama, Japan, [2]Nutrition, Tenshi College, Sapporo, Japan, [3]Physical Education, Kyoto University of Education, Kyoto, Japan.

It is recognized that physical activity during childhood plays an important role in determining peak bone mass. However, how the frequency and the duration of physical activity affect bone growth is not well known. We examined the effects on bone mineral density (BMD) at the baseline and 3-year later among Japanese children and adolescents. We studied 579 healthy children aged 10-16 y (283 boys, 296 girls) from a town in Japan in 2001, and conducted a follow-up (follow-up rate; 75.8%). At both surveys, we investigated the following. We measured their heights and weights, and BMDs at the spine and hip using dual-energy X-ray absorptiometry. A history of each child's physical activity in sport clubs from the elementary school (from age 6 y) was estimated, using a questionnaire administered by interviewers who were trained public health nurses in the town. The questionnaire asked the average active duration (hours) per each activity, the frequency per week, and the period taken participate in each sport club. The total time spent in sport clubs was calculated as the sum of each active duration multiplied by the frequency, and by the period. The Ethics Committee of Kinki University School of Medicine approved the studies. With multivariate analysis predicting BMDs at baseline among 579 children, the total time spent during elementary school (ages 6-12 y) was significantly and positively related with hip and lumbar BMD among pre-pubertal boys, and with hip BMD among post-pubertal boys and girls, respectively. The total time spent during junior high school (ages 13-15 y) was significantly and positively related with only lumbar BMD among pre-pubertal boys. Multivariate analysis adjusted for years after the onset of puberty, height, and weight to predict BMDs at 3-year follow-up showed that the total time spent during elementary school was significantly and positively related with hip and lumbar BMD among boys, and with lumbar BMD among girls. Similar analysis showed that the total time spent during junior high school was significantly and positively related with hip lumbar BMD among boys. Similar analysis predicting percent change of BMDs during 3 years showed that the time spent at elementary school during follow-up period was still significantly and positively related with lumbar and hip percent change of BMD among boys, and the time spent at high school was similarly related with hip and lumbar BMD among girls. Thus, the physical activity before age 13 may be especially important for child and adolescent bone growth.

Eating Disorders and Amenorrhea Are Strong Predictors of Change in Bone Mass in Physically Active Young Females. J. W. Nieves, M. Zion*, J. Ruffing*, P. Garrett*, R. Lindsay, F. Cosman. Clinical Research Center, Helen Hayes Hospital, West Haverstraw, NY, USA.

Data concerning prospective changes in bone mass in a college-aged physically active population, as a function of diet, menstrual function and oral contraceptives use are limited. In a cohort of 91 females entering the US Military Academy (average age=19; 75 Caucasian, 9 Asian, 7 African American), we prospectively evaluated the relative importance of menstrual function, use of oral contraceptives (OC) or depot medroxyprogesterone acetate (DMPA), eating disorders and calcium intake on bone mass accrual over 4 years. Menstrual function and use of OC or DMPA were assessed annually by questionnaire. Menstrual function was assessed as number of cycles per year. Calcium intake was determined by annual food frequency questionnaires. Eating disorders were assessed by using 3 subscales of the Eating Disorder Inventory: EDI-A (anorexia); EDI-B (bulimic tendencies) and EDI-D (body dissatisfaction) and the final score was divided into quartiles. A Lunar Dual x-ray absorptiometry (DPX-IQ) was used to assess bone mineral density (BMD) at the lumbar spine and total hip at baseline and annually. Slopes of change in spine and hip BMD were determined in each cadet over 4 years. The average daily calcium intake was 1073± 420 mg. The highest quartile of EDI for the 3 scales had a mean of 38.5 with a range of 25-57, a value equivalent to that representing sub-clinical eating disorders. The average change in BMD over the 4 years was +0.3±3.9% in the spine and -1.0±4.5% in the hip; gains in BMD occurred at the spine in 50% and at the hip in 36% of cadets . In univariate analyses, bone gain in the spine, but not hip, was significantly and positively related to number of menstrual cycles (p=0.037). Both spine and hip BMD change were inversely related to EDI score (p<0.03) and DMPA use (p=0.007). There was no significant relationship between change in BMD at the spine or hip and OC use or calcium intake, although the average calcium intake was high in these women. Those women with EDI scores in the highest quartile had average change in spine BMD of -0.99% and hip BMD of -2.59%, as compared to the rest of the cohort that had a change of +0.74% in the spine and no change in the hip, after controlling for number of menstrual cycles, use of DMPA or OC, BMI and race. Females with an average of 0-9 menstrual cycles/year, over the four years, had spine BMD loss of -1.19%, compared to women with normal cycles (≥ 10/year) who gained 0.87%, after controlling for EDI, BMI and race. There was the same trend at the hip (-2.26 vs -0.52 respectively; p=0.09). Both sub clinical eating disorders and infrequent menstrual function can have significant detrimental effects on bone gain in young athletic women.

Bone Accretion Elongation and Metabolic Activity during Skeletal Growth in the Rat. J. A. Horton*, J. T. Bariteau*, R. M. Loomis*, T. A. Damron*. Orthopedic Surgery, SUNY Upstate Medical University, Syracuse, NY, USA.

Introduction: Due largely to advances in cancer treatment, a population of long term survivors of pediatric solid tumors has been identified who present with osteopenia and signs of precocious osteoporosis as young adults. While the etiology for this morbidity is multifactorial, age at which therapy was begun relative to the stage of skeletal maturity has been implicated as one of several factors of this late effect. Developing prophylactic strategies requires use of animal models to evaluate the efficacy of such methods. The purpose of this study was to identify periods of high skeletal metabolic activity, growth and mineral accretion in the growing rat to serve as a foundation for further study of this clinical morbidity. Methods: With institutional approval, 6 male and 6 female 21 day old Sprague Dawley rats were obtained. The rats were subjected to weekly *in vivo* bone densitometry, radiography, blood collections, and body weight measurement. DXA derived bone mineral content and density was determined for both femurs and lumbar vertebra using the Piximus2 densitometer. Tibial lengths were measured from digitized plain film radiographs. Serum levels of osteocalcin were measured by IRMA as an indicator of osteoblastic bone formation. Serum levels of tartrate resistant acid phosphatase 5b were measured by ELISA, as an indicator of osteoclastic resorption. Results: An early phase of exponential bone mineral accretion, elongation and body weight gain was identified through 10 weeks of age (R^2>0.96). An inflection toward less aggressive tibial elongation was seen from 10 to 20 weeks of age where decay in the exponential growth rate was evident. A similar decay pattern was seen for both femoral and lumbar mineral accrual, though the plateau in bone density was reached 3 weeks later than the asymptote of elongation. Serum analysis indicated that osteoclastic activity remained relatively constant throughout the time observed, while osteoblast activity declined 3 fold from high levels of formation during exponential growth to a static level upon plateau. Temporal patterns of growth were not different between sexes though males tended to be larger in tibial length and body weight beyond 5 weeks of age (t test, $p<0.04$). Discussion: The plotted curves of these femoral and lumbar BMD, tibial length over time were found to conform to the Gompertzian model of growth (R^2>0.93). Body weight also followed a similar decay pattern, though the failure to reach an asymptotic plateau is likely due to extraskeletal gain rather than maturative skeletal growth. Metabolic activity in the young rat favored bone formation, with the decline in osteoblast activity corresponding to the plateau in femoral and lumbar BMD.

Determinants of Consolidation of Peak Bone Mass in Young Women - Bath Cohort Study. S. Venkatachalam[1], D. Elvins*[2], I. Reading*[3], A. K. Bhalla[2], C. Cooper[3]. [1]Rheumatology, Cannock Chase Hospital, Cannock, United Kingdom, [2]Royal National Hospital for Rheumatic Diseases, Bath, United Kingdom, [3]MRC Environmental Epidemiology Resource Centre, Southampton, United Kingdom.

We had earlier identified that infant growth and physical activity in childhood are important determinants of peak bone mass in women at the age of 21 years, in a cohort of young women from Bath, UK born in 1968-69. We aimed to identify the determinants of consolidation of peak bone mass in these young women at the age of 31 years. We traced 90 of 153 women from the intial cohort and assessed bone mineral density (BMD) at 31 years of age by DXA (Hologic QDR4500A). We ascertained lifestyle factors like calcium intake, physical activity, smoking and alcohol consumption by questionnaire. Data were analysed by multiple regression with changes in BMD as the dependent variable. The mean percentage gain in lumbar spine BMD between 21 and 31 years of age was 1.7(4.4) and in the total hip BMD was 1.1(4.6). Current weight and weight at 21 years of age were significantly associated with lumbar spine (r = 0.28, r = 0.28) and total hip (r = 0.31, r = 0.32) BMD. Only the lumbar spine BMD correlated with height at 21 and 31 years of age (r = 0.26, r = 0.27).Weight of the women at 21 years of age was associated with increase in BMD at both lumbar spine (r =0.30) and total hip (r = 0.42). It also significantly predicted gain in BMD at 31 years at both the spine (beta = 0.179, p = 0.022) and the hip (beta = 0.263, p =0.001). However, weight at birth and conditional weights at 1 year, 5 or 10 years did not predict gain in BMD. Weight at 1 year conditional on birth weight negatively predicted total hip BMD and BMAD (bone mineral apparent density) at 31 years (p = 0.006, p = 0.007). Walking was significantly associated with only the total hip BMD at 31 years but did not predict consolidation. Calcium intake, smoking or alcohol consumption failed to determine consolidation in the women. Parity was negatively associated with the change in BMD and BMAD only at the lumbar spine over the decade. Our longitudinal study shows continuing gain in BMD in the third decade at both the lumbar spine and the total hip in young women. Their weight at the age of 21 years was the only significant determinant of consolidation of peak bone mass.

Genetic and Maternal Determinants of Bone Mass at the Humerus in Newborns. V. De Paola[1], D. Merlotti[1], L. Gennari[1], A. Cadirni*[1], A. Calabrò*[1], G. Martini[1], E. Cervo*[2], G. Buonocore*[2], S. Gonnelli[1], N. Dal Canto*[1], A. Montagnani*[1], R. Nuti[1]. [1]Internal Medicine, Endocrine-Metabolic Sciences and Biochemistry, University of Siena, SIENA, Italy, [2]Department of Pediatrics, Obstetrics and Reproductive Medicine, University of Siena, SIENA, Italy.

Bone metabolism is strongly influenced by heredity and environmental factors. Although some studies have reported a relationship between several candidate polymorphic genes and bone mineral density in adults, little is known concerning the genetic factors influencing bone mass in children. Moreover the role of environmental and genetic factors during intrauterine or early postnatal life is actually unknown. The aim of this study was to evaluate the role of maternal environmental factors and of the translation initiation site (FokI) polymorphism in the vitamin D receptor gene (VDR) in 200 newborns and their mothers. Quantitative ultrasound (QUS) parameters at distal diaphysis of humerus were assessed within three days of birth by using a Bone Profiler (IGEA, Italy), after an appropriate modification of the calliper and software. Newborn's anthropometric data, such as weight, length, head circumference and APGAR score at 3rd and 5th minute after birth were also collected. Phalangeal QUS measurements were performed in all mothers. In all subjects the amplitude-dependent speed of sound (AD-SOS) and the bone transmission time (BTT) QUS parameters were evaluated. Maternal AD-SOS at phalanxes significantly correlated with newborn QUS parameters at the humerus. Interestingly, the correlation was higher in mother-daugther pairs than in mother-son pairs. No gender specific differences in body heigh or weight were observed. In contrast, head circunference and BTT (but not AD-SOS) were significantly higher in male than female newborns. Moreover head circunference, birth weight and height and BTT were significantly and positively related to gestational age. None of the newborn QUS parameters was influenced by maternal smoking or calcium intake. In newborns, BTT showed a significant positive correlation with birth weight and head circunference. A trend approaching statistical significance was observed between maternal Fok I genotype and BTT at birth. By contrast, Fok I genotype in newborns did not significantly correlate with neonatal QUS or anthropometric measurements at birth. In conclusion, results from this study suggest that newborn bone mass is, at least in part, genetically determined and that gender related differences in QUS parameters may exist at birth. Fok I polymorphism at the VDR gene does not seem to play a major contribution in the determination of body weight and ultrasound bone parameters at birth.

Is my Arm Broken? The Likelihood of Forearm Fracture According to Age, Gender and Race among Children Undergoing Conventional Radiologic Evaluation. H. J. Kalkwarf, T. Laor*, L. Tague*, A. Roy-Chaudhury*, D. Bianchi*, J. Bean*. Cincinnati Children's Hospital Medical Center, Cincinnati, OH, USA.

Forearm fractures are common among children and adolescents. However not all children who are injured and are evaluated for a suspected fracture have a radiographically evident bone fracture. Little information is available regarding the probability of fracture among the children referred for radiographic diagnosis. The objective of this study was to determine the probability of a radiologically evident fracture among children undergoing radiography based on the child's age, gender and race. To collect our sample, we performed weekly queries of the Radiology Information System at a large regional pediatric hospital to identify all consecutive children who underwent a radiograph of the forearm or wrist during initial evaluation. Over 29 months, we identified 2994 patients ages 6-16 years. We excluded radiographs obtained for follow-up of fracture, identification of foreign bodies, motor vehicle related-injuries, injury at multiple skeletal sites, genetic disorders and identified chronic diseases. Fracture cases were those in which a fracture was identified in the radiology report. Controls included those in which no fracture was clearly evident. The sample was 54.5% boys, 45.5% girls, 71.6% white, 25.5% black and 2.9% other races. The largest number of radiographic evaluations occurred at ages 12-13 years among boys and at ages 9-10 years among girls. Boys were more likely than girls to have a fracture identified in the radiology report (64.7% vs. 52.0%, $p<0.0001$), and whites and other races were more likely than blacks to have had a fracture identified (62.2% and 61.4% vs. 49.5%, $p<0.0001$). The likelihood of fracture decreased with age. Among boys the proportion fractured decreased from 83% (207/250) at ages 6-7 years to 42% (83/196) at ages 15-16 years ($p<0.0001$), and a plateau was evident between 10-14 years of age. Among girls, the respective decrease in the proportion fractured was from 77% (190/246) to 21% (20/95) ($p<0.0001$), with less evidence of a plateau at interim ages. The absolute number of fractures was greatest among boys 6, 12 and 13 years of age and among girls between 6-11 years of age. We conclude that: 1) the probability of a radiologically evident fracture among children evaluated decreases with age, is lower in girls than boys, and is lower in blacks than whites; 2) peaks in fracture occurrence at the onset of adolescence is apparent in boys but not girls. These data may underestimate fracture rates in the community, because as children age we speculate that they are more likely to seek injury-related orthopedic care at adult facilities.

Accretion of Bone Quantity and Quality in the Developing Murine Skeleton. S. Judex[1], W. Little*[1], C. Rubin[1], L. Donahue[2], L. Miller[3]. [1]SBU, Stony Brook, NY, USA, [2]Jackson Labs, Bar Harbor, ME, USA, [3]BNL, Upton, NY, USA.

To meet the mechanical challenges during early development, the skeleton requires the rapid accretion of bone quantity as well as bone quality. Here, we describe early bone development in the murine skeleton and tested the hypothesis that changes in a number of morphological, chemical, and mechanical bone properties are controlled interdependently. Tibiae of female BALB mice were harvested at 8 time points (n=4 each) distributed between birth and 40d of age. Tibiae of 15mo old mice served as fully mineralized control specimens. High-resolution microCT determined bone area and volumetric material density of the tibial mid-diaphysis. Chemical and mechanical properties of the same region were analyzed by high-resolution in situ synchrotron infrared spectroscopy and nano-indentation, including phosphate/protein content, carbonate/protein content, collagen cross-linking, and Young's modulus. Relations between morphological, chemical, and mechanical properties across different time points were tested by non-parametric rank correlations. Cortical bone area increased linearly (tau=0.87) by 30-fold over the first 40d of post-natal growth, reaching 60% of its adult (15mo) areal properties. Concomitantly, material density increased linearly (tau=0.88) by 46%. The phosphate/protein ratio in 40d old mice was 90% greater than in 1d old mice (tau = 0.70 for linearity) and 30% smaller than in 15mo old mice. In contrast, the carbonate/protein ratio showed a smaller (28%) and highly non-linear increase over the first 40d of life. Collagen cross-linking was not altered over time. Spatial variability in chemical properties across the mid-diaphysis was very high for the early time points and declined over time. Similarly to changes in bone area, Young's modulus increased dramatically with age and reached 87% of its adult value at 40d of age. Cortical bone area, volumetric mineral density, phosphate/protein ratio, and carbonate/protein ratio all showed significant correlations with the reduced elastic modulus (tau = 0.4-0.6). These data indicate that the mineralization of new bone during early skeletal development is at least one order of magnitude slower than during the later adolescent stages of growth. Considering that murine long bone development covers at least three distinct morphological stages during the first 40d of life, the linearity by which many of the morphological, chemical, and mechanical matrix properties are acquired is remarkable. Future more detailed analyses with these high-resolution in situ measurement techniques may provide insight into the chemical, cellular, and molecular factors by which bone modulates its quality and quantity.

Total Body Bone Mineral Content in Young Children: Influence of Head Bone Mineral Content. J. M. Eichenberger Gilmore*[1], S. M. Levy[1], T. A. Marshall*[1], E. M. Letuchy*[2], T. L. Burns*[3], K. F. Janz*[4], M. C. Willing[5], J. C. Torner*[2]. [1]Preventive and Community Dentistry, University of Iowa, Iowa City, IA, USA, [2]Epidemiology, University of Iowa, Iowa City, IA, USA, [3]Program in Public Health Genetics, University of Iowa, Iowa City, IA, USA, [4]Health and Sports Studies, University of Iowa, Iowa City, IA, USA, [5]Pediatrics, University of Iowa, Iowa City, IA, USA.

Assessment of bone health in children requires acknowledgement of the contributions of bone mineral content (BMC) from various body compartments. Reference values are typically presented as age or body size adjusted values. An important consideration when evaluating these measures is the contribution of the head BMC during childhood growth. Our objective was to describe the contribution of head BMC relative to whole body BMC (WB BMC) and determine the change in contribution of head BMC over time among participants of the Iowa Fluoride Study. Analysis included 981 whole body scans (466 M, 515 F) of children age 4.5 - 10.5 years. Four hundred twelve children (192 M, 220 F) had baseline and 3 year follow-up scans. BMC was measured by DXA using a Hologic QDR-2000 (Waltham, MA) in the array-beam scanning mode (software version 5.60A). SAS MIXED procedure was used to compare WB BMC, head BMC, subtotal BMC (WB BMC - head BMC), and % head BMC for each age group (4.5-5.5 years, 5.5-6.5 years, 7.5-8.5 years, 8.5-9.5 years, and 9.5-10.5 years) incorporating correlations for observations on the same person. The contribution of head BMC decreased from 51% to 32% WB BMC from youngest to oldest (Table 1). Repeat scans revealed an increase in all body size parameters (height, weight, WB BMC, head BMC and subtotal BMC) with a 4.4% decrease in the contribution of head BMC per year (Table 2). The results suggest care must used when comparing individual bone scan data to reference values. Further statistical interpretation of body compartment contributions to WB BMC is warranted.

Table 1. Least Square Means by Age Group.

Age group, years	n	WB BMC, gm		Head BMC, gm		Subtotal BMC, gm		% Head BMC

A Prospective Analysis of Geometric Changes in the Proximal Femur in Young Female Gymnasts. E. M. Laing[1], C. M. Modlesky[2], A. R. Wilson*[1], D. B. Hall*[3], T. J. Beck[4], R. D. Lewis[1]. [1]Foods and Nutrition, The University of Georgia, Athens, GA, USA, [2]Health, Nutrition and Exercise Science, University of Delaware, Newark, DE, USA, [3]Statistics, The University of Georgia, Athens, GA, USA, [4]Radiology, Johns Hopkins Medical Institute, Baltimore, MD, USA.

Assessment of bone mineral accrual with exercise is limited because important changes in the geometric properties of bone may occur and go undetected. Changes in the strength indices of the intertrochanteric (IT) and shaft (S) regions of the proximal femur (PF) were examined in prepubertal females, 4-8 yrs of age, who selected to perform recreational gymnastics (GYM; n=65), nongymnastic activities, or no organized activity (CON; n=78). High-level gymnasts advancing to competition (HLG; n=9), low-level nonadvancing gymnasts (LLG; n=56) and CON were compared. Participants had essentially no lifetime history of organized athletic participation (<12 wks). Pubertal maturation was assessed annually by a physician. Non-dominant PF scans were obtained every 6-mo using DXA (Hologic QDR-1000W). BMD (g/cm^2) and bone strength indices [cross sectional area (CSA; cm^2) and section modulus (Z; cm^3)] were calculated using the hip structural analysis program. Baseline differences between groups were determined using independent samples t-tests. Repeated measures ANCOVA (covariates: race, age, socio-economic status, initial strength value, calcium intake, height, weight and final breast stage) was used to assess changes over 4 consecutive 6-mo time periods. At baseline, GYM were shorter, lighter, and had lower IT Z compared with CON ($p<.05$), whereas HLG did not differ from LLG in any measure. Group x time interactions were found for S BMD ($p=.098$) and CSA ($p=.035$). Interactions between group and final breast stage were found for IT ($p=.036$) and S ($p=.001$) BMD, IT ($p=.003$) and S ($p=.003$) CSA and IT ($p=.009$) and S ($p=.038$) Z. In these cases significant differences between groups where GYM>CON were found in high maturational status subjects for IT BMD ($p=.099$), IT CSA ($p=.010$), IT Z ($p=.019$), S BMD ($p<.025$ at each measurement occasion), S CSA ($p<.074$ at each measurement occasion), and S Z ($p=.032$). HLG remained prepubertal throughout the study and showed no geometric differences in the PF compared to LLG or CON. These results indicate that recreational artistic gymnastics initiated in prepubertal females conferred moderate geometric structural benefits at the PF. GYM who advanced in pubertal stage at the conclusion of the study demonstrated the greatest strength benefits over time compared to CON.

Body Fatness and Bone Properties in Prepubertal Females: A Two Year Study. N. K. Pollock[1], E. M. Laing[1], A. R. Wilson*[1], C. M. Modlesky[2], T. J. Beck[3], R. D. Lewis[1]. [1]Foods and Nutrition, University of Georgia, Athens, GA, USA, [2]Health, Nutrition and Exercise Science, University of Delaware, Newark, DE, USA, [3]Radiology, Johns Hopkins Medical Institute, Baltimore, MD, USA.

Overweight and obese children are thought to be at high risk for skeletal fractures. Whether this is the result of poor bone mineral acquisition is equivocal. The purpose of this prospective study was to explore the effects of body fatness on changes in bone area (BA), BMC and femur geometry in prepubertal females. Fat mass (FM, kg), percent fat (%FAT), fat-free mass (FFM, kg), bone area (BA) and BMC of the total body (TB), lumbar spine (LS), total proximal femur (TPF) and forearm were determined using DXA (Hologic, QDR 1000-W). Structural properties of bone including BMD (g/cm^2), cross sectional area (CSA, cm^2) and section modulus (Z, cm^3) of the narrow neck, intertrochanteric (IT) and shaft (S) regions of the TPF were assessed every 6-mo using the hip structural analysis program. Baseline differences between groups and 24-month change data were determined using one-way ANOVA and repeated measures ANCOVA, respectively. At baseline, groups were classified by %FAT: non-obese (%FAT<25, n=32) and obese (%FAT≥30, n=27). Although similar in maturation, obese females had significantly higher values for age (6.9 vs. 5.7 yrs), weight (32.1 vs. 21.3 kg), height (125.9 vs. 116.2 cm), FM (4.1 vs. 12.2 kg) and FFM (18.2 vs. 15.7 kg) compared to non-obese at baseline ($p<0.05$; $\eta^2>0.09$). Over 24-mo, the obese gained more weight and FFM ($p<0.01$; $\eta^2>0.25$) compared to non-obese. Baseline BMC, CSA and Z of all measured sites was significantly higher in the obese ($p<0.05$; $\eta^2>0.10$) but after adjusting for age and height, differences between groups were only observed for TB BA and BMC ($p<0.01$; $\eta^2>0.11$). 24-mo changes in TB BA and BMC, as well as forearm BA and S CSA were significantly greater in the obese ($p<0.04$; $\eta^2>0.06$), however once corrected for FFM, these differences no longer remained, except for forearm BA ($p=0.03$; $\eta^2=0.05$). Whether the changes in bone properties observed in obese vs. non-obese prepubertal females are sufficient to accommodate the observed weight gain is unknown. Future studies with site-specific estimates of bone material and structural properties in obese vs. non-obese children are warranted.

Primary Human Osteoblasts Show Enhanced Differentiation upon Treatment with BMPs. W. A. Grasser, K. A. Riccardi*, V. M. Paralkar. CVMD Osteoporosis, Pfizer Global Research and Development, Groton, CT, USA.

Bone morphogenetic proteins (BMPs) are members of the transforming growth factor-beta (TGF-β) superfamily. They were initially identified by their ability to induce endochondral bone formation at ectopic sites which suggested an important role for these proteins in skeletogenesis. The differentiation of osteoblasts is regulated by various local factors in an autocrine and/or paracrine fashion, and a number of studies have shown that BMPs can have an effect on the recruitment, proliferation and differentiation of osteoblast progenitors. In addition, it has been demonstrated that BMPs can enhance the expression of markers of the mature osteoblast phenotype such as, alkaline phosphatase (AP), collagen synthesis, osteocalcin expression and the ability of the cells to form mineralized matrix. Studies with murine pluipotent stem cells have demonstrated an increased expression of osteoblastic phenotype upon treatment with BMPs. However, surprisingly little work has been done on the effects of BMPs on human cell systems. The clinical doses of BMP required to show bone healing are an order of magnitude greater than the doses observed in animal studies. Although various hypotheses for this discrepancy have been proposed our scientific understanding of this dose response remains poor. In this study, we wanted to develop a human cell culture system using primary human osteoblasts (HOB), characterize known markers of osteoblast expression and examine the effect of BMPs and in particular BMP-6 on these cell cultures. Treatment with rhBMP-6 accelerates cell differentiation as indicated by the formation of mineralized nodules by day 18 of culture versus 28 to 30 days in vehicle treated cultures In addition, AP activity is dramatically increased beginning at Day 10 and is paralleled by a similar increase in the expression AP message as measured by qRT-PCR. The expression of BMP-6 message is down regulated in cultures that were treated with BMP-6 indicating the ability of BMP-6 to auto-regulate its own expression.

***In Vivo* Imaging of Adenoviral vs. Lentiviral Gene Therapy in Two Bone Formation Models.** B. T. Feeley[1], A. H. Conduah*[1], O. Sugiyama[1], N. Liu*[1], M. J. Jo*[1], I. S. Y. Chen*[2], J. R. Lieberman[1]. [1]Orthopaedic Surgery, University of California, Los Angeles, Los Angeles, CA, USA, [2]Dept of Microbiology, Immunology, Molecular Genetics and Medicine, UCLA AIDS Institute, University of California, Los Angeles, Los Angeles, CA, USA.

The clinical use of recombinant proteins and regional gene therapy are promising techniques to enhance bone formation in large bone defects that would be difficult to treat with allograft or autograft bone stock. The selection of the appropriate gene therapy strategy depends on the clinical scenario. We have previously demonstrated that lentiviral mediated delivery of BMP-2 produced robust bone formation *in vivo*. In this study, we compared the temporal expression patterns of adenoviral and lentiviral mediated gene therapy in two bone formation models using *in vivo* molecular imaging techniques. Rat bone marrow cells (RBMC) were co-transduced either lentiviral or adenoviral vectors containing the cDNAs for BMP-2 or luciferase, driven by the murine leukemia virus (MLV) promoter. *In vitro*, adenoviral expression of BMP-2 and luciferase in RBMCs peaked at 1 week, and was able to be detected by ELISA or luciferase assay, respectively, for 4 weeks after initial transduction. In contrast, lentiviral mediated expression of BMP-2 and luciferase was sustained in culture for 3 months. Luciferase activity correlated with BMP-2 expression *in* vitro (R^2=0.83) Using a cooled charged coupled device (CCD) camera, we were able to demonstrate prolonged *in vivo* gene expression in both a murine hindlimb muscle pouch and radial defect model. Adenoviral vectors expressed target gene (luciferase) expression for up to 21 days in both models, but lentiviral vectors expressed target gene expression for 3 months *in vivo* in both the hindlimb muscle pouch and radial defect model. Co-transduction with both the luciferase reporter gene and BMP-2 target gene did not affect BMP-2 production *in vitro*, or bone formation *in vivo*. In the radial defect model, 9/10 animals treated with Ad-BMP-2+Luc healed, and 9/10 animals treated with Lenti-BMP-2+Luc healed.There was no detectable difference in the amount of bone formed between the adenoviral and lentiviral groups with either histologic or radiographic analysis. These results suggest that lentiviral mediated delivery of BMP-2 can induce long term *in vitro* and *in vivo* gene expression, which may be beneficial when developing tissue engineering strategies to heal large segmental or cavitary bone defects. Our data also suggests that CCD imaging is a successful technique to follow *in vivo* gene therapy in bone formation models.

C/EBP Homologous Protein (CHOP) Interacts with Cyclic AMP Responsive Element Modulator (CREM) and Enhances Bone Morphogenetic Protein (BMP)/Smad Signaling. R. C. Pereira, V. Deregowski, S. Rydziel, E. Canalis. Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA.

CCAAT/enhancer binding proteins (C/EBPs) regulate cell fate and gene regulation. C/EBP homologous protein (CHOP) forms heterodimers with classic C/EBPs and additional transcription factors, preventing their binding to target DNA sequences. In ST-2 cells, CHOP suppresses adipogenesis and induces osteoblastogenesis by sensitizing these cells to the effect of BMP-2 on Smad, but not on MAP kinase signaling. CHOP overexpression sensitizes a transiently transfected 12xSBE-Oc-pGL3 construct, containing 12 repeats of a Smad binding site, to the effect of BMP-2, without modifying the phosphorylation of Smad 1/5/8. This suggests that indirect mechanisms are involved in the sensitization of the BMP-2 effect on transactivation. Accordingly, co-immunoprecipitation experiments and confocal microscopy failed to reveal direct interactions or co-localization of CHOP and Smad 1 after BMP-2 treatment. The effect of CHOP on BMP-2/Smad signaling did not require prolonged cellular exposure to CHOP, since acute co-transfection of a vector where CHOP was expressed under the control of the cytomegalovirus promoter enhanced the BMP-2 induced transactivation of the 12xSBE-Oc-pGL3 construct. However, the dimerization domain of CHOP was required since a CHOP dimerization mutant had no effect, also suggesting that CHOP acts indirectly, possibly by binding an inhibitor of transactivation. To test this possibility, we analyzed interactions and possible heterodimerization of CHOP with members of the cyclic AMP responsive element (CRE) binding protein (CREB)/activator of transcription (ATF) family of transcription factors, known to interact with CHOP and regulate transcription. Electrophoretic mobility shift assays of nuclei from CHOP overexpressing and vector transduced ST-2 cells, revealed that binding to a labeled CRE consensus sequence was decreased in CHOP overexpressing cells and supershift assays revealed that CRE modulator (CREM), but not ATF-1, ATF-3 or ATF-4 antibodies shifted the complex. To explore mechanisms involved, the expression and actions of CREM α, ß, and γ were determined. Control and CHOP overexpressing cells expressed CREM α, ß, and γ, and the level of expression increased as CHOP overexpressing cells differentiated in culture. In an initial co-transfection experiment with CREM α, ß, and γ expression constructs, CREM ß reduced the stimulatory effect of CHOP on the transactivation of 12xSBE-Oc-pGL3. In conclusion, CHOP enhances osteoblastic differentiation by sensitizing the BMP/Smad signaling pathway, and interactions with the transcriptional repressor CREM appear central to this effect.

Similarity of Chondroinduction by Combined rhBMP-2/TGFb or Demineralized Bone *In Vitro*. J. Glowacki, S. Mizuno, S. Zhou. Orthopedic Surgery, Brigham and Women's Hospital, Boston, MA, USA.

Demineralized bone implants are widely used for skeletal repair and reconstruction. Demineralized bone powder (DBP) in a 3D porous collagen sponge chondro/osteoinduces target human dermal fibroblasts (hDFs) *in vitro*. Multiple pathways are signaled by DBP and they differ from those elicited by BMP-2. In this study, we tested the hypothesis that a combination of BMP-2 and TGFβ1 would approximate effects of DBP. Sponges were used either plain or with 3 mg DBP with 10^6 hDFs per sponge and cultured in DMEM with 1% heat-inactivated FBS. In one set of experiments, factors were added to the medium: 10 ng/ml TGF-β1 and/or 100 ng/ml rhBMP-2. DBP, TGFβ1, and the combination of TGFβ1/BMP2 upregulated TGFβ/Smad target genes (*TGFBI*, *PAI-1, IGFBP3)* between 100 and 500%; as expected, BMP2 had little effect on those targets that are mediated through TGFβ type I receptor (ALK-5). On the other hand, DBP and BMP2 upregulated the BMP/Smad target gene *ID3.* Cotreatment with a specific inhibitor of ALK-5 (SB431542, 10 μM) antagonized the stimulation by DBP and TGF-β1 on *TGFBI*, *IGFBP3*, but not of BMP-2 on *ID3* gene expression. Thus, some of DBP's effects are mediated through TGFβ/Smad signaling and some are mediated through BMP/Smad signaling. In another set of experiments, BMP-2 (6 ug) and/or TGFβ1 (40 ng) were delivered in a square of absorable collagen felt (identical to that used clinically) that was inserted into a collagen sponge for comparison with DBP-containing sponges. Sponges were cultured for 7 days for histological and biochemical analysis of chondroitin sulfate by fluorophore-assisted carbohydrate electrophoresis (FACE). Histological analysis showed metachromatic extracellular matrix (ECM) around cells in proximity to DBP and around cells within felt that contained the combination of rhBMP-2 and TGFβ1, and, to a lesser degree, that with only TGFβ1. FACE showed that sponges treated with DBP had the greatest content of Chondroitin 4- and 6-sulfate (Ch-4S and Ch-6S, 113 ± 18 ng, p=0.023). Cells treated with TGF produced more unsulfated (Ch-0S) than did the other groups. The cartilage-like distribution of Ch-0S, 4S, and 6S was similar for cells treated with DBP or the combination of BMP/TGFβ (Figure). These data indicate that, although neither TGFβ1 nor BMP induced production of cartilage-specific ECM, a combination of TGFβ1 and BMP elicited effects in hDFs similar to those by DBP.

BMP3 Signals through SMAD2 in MC3T3 Cells. B. Sun*[1], J. Pretorius*[2], E. Valente*[2], D. L. Lacey[1], W. S. Simonet[1], W. G. Richards*[1]. [1]Metabolic Disorders, Amgen, Thousand Oaks, CA, USA, [2]Pathology, Amgen, Thousand Oaks, CA, USA.

BMP3 was first characterized as a protein with osteogenic activity isolated from bovine bone. However, this activity was called into question when BMP3 null mice were found to have increased bone mass. The cause of this apparent discrepancy is uncertain, but may be related to the complex biology of this molecule. In fact, even though BMP3 is a member of the TGFβ family, analysis of a phylogenetic tree of this superfamily reveals that BMP3 does not group to the clade containing the osteogenic BMPs, but appears to constitute its own distantly related group along with BMP3b. To develop our understanding of this molecule and its involvement in bone biology, we studied the expression of BMP3 and the signaling pathways BMP3 utilizes in MC3T3.E1/C4 cells. BMP3 expression was studied by in situ hybridization in embryonic and adult mice. In embryonic bone, BMP3 was detected in perichondrium and mesenchymal condensations around developing bones, and in areas of ossification. In adult bone, BMP3 expression was detected in osteoblasts throughout bone including areas around the growth plate, in endosteal lining of cortical bone and in trabeculae of the epiphysis and diaphysis. To explore the signaling pathways used by BMP3 we first set out to replicate published data, which demonstrated that BMP3 could inhibit BMP2 induced osteogenic differentiation of W20 cells. We demonstrated a similar response in MC3T3.E1/C4 cells with conditioned medium containing BMP3 and with recombinant BMP3. This inhibitory response was only evident in the presence of BMP2, as inclusion of BMP3 alone in cultures of differentiating MC3T3 cells had no effect on the ability of these cells to produce the differentiation markers alkaline phosphatase and osteocalcin. We next addressed how BMP3 might engender this anti-osteogenic response. K. Lyons proposed several mechanisms to explain the observed anti-osteogenic effects of BMP3, including the involvement of SMAD signaling. We used phospo-SMAD specific antibodies to study SMAD signaling in MC3T3 cells treated with BMP3. In MC3T3 cells treated with BMP3 we were not able to detect phosphorylation of SMAD1, a BMP SMAD, but did detect phosphorylation of SMAD2, a TGFβ SMAD. In addition, we demonstrated that BMP3 was capable of binding human activin receptor IIB and that BMP3 activated a TGFβ reporter construct in C2C12 cells, but did not activate a BMP reporter construct in the same cell line. These data provide support for the hypothesis put forth by Lyons that the anti-osteogenic activity of BMP3 may result from the use of the TGFβ/activin signaling pathway and potential sequestration of SMAD4 from, and potential inhibition of, the BMP osteogenic pathway.

LMP-1 Interacts with Smurf1 and Potentiates Cellular Responsiveness to BMP-2. S. Sangadala, Y. Liu, M. Viggeswarapu, S. D. Boden, L. Titus. Orthopaedics, Emory University, Decatur, GA, USA.

BMPs initiate osteogenic differentiation and maintenance of cell lineage while inhibiting myogenic and adipogenic differentiation pathways. The activity of BMPs is regulated through alteration in steady state levels of various key intracellular signaling proteins. LMP-1, an intracellular osteogenic factor, was observed to significantly increase the responsiveness of mesenchymal stem cells (MSCs) to BMP-2 by inducing bone nodule mineralization. Additional evidence of LMP-1/BMP-2 synergy was seen by induction of Dlx5 mRNA by overexpression of LMP-1 in BMP-2-treated MSCs. To determine the mode of action of LMP-1 we designed biochemical pull-down assays to identify key intracellular proteins that interact with LMP-1. Recombinant LMP-1 was labeled with SBED-biotin transfer agent and incubated with nuclear proteins. Biotin transfer to target interacting proteins was initiated by photo-activation. The linked proteins were de-coupled by reduction. Biotinylated target proteins were enriched, detected by western blots and identified by MALDI-TOF of in-gel tryptic digests of target proteins. Smad Ubiquitin Regulatory Factor 1 (Smurf1), was identified as key binding protein along with some cytoskeletal proteins. The identity of Smurf1 as binding protein, was verified based on molecular size (85 kDa), immunoreactivity with Smurf1 antibody and tryptic peptide mass profile.To determine if the interaction of Smurf1 occurs with endogenous LMP-1 we performed immunoprecipitations on nuclear extracts of mesenchymal stem cells using LMP-1-specific antibodies. The immunoprecipitates contained both Smurf1 and LMP-1 confirming that they co-associate in physiological conditions. To test our working hypothesis that LMP-1 potentiates BMP-2 response by protecting Smad1 from Smurf1-directed proteosomal degradation, we performed overexpression of LMP-1 in the presence or absence of BMP-2 treatment and determined the levels of phospho-Smad1. The level of phospho-Smad1 showed dramatic increase in cells overexpressing LMP-1 upon BMP-2 treatment. Further studies are underway to determine which domains of LMP-1 and Smurf1 are involved in binding interaction as well as the effect of their interaction on steady-state levels of other Smads targeted by Smurf1.

Desmoid Tumor with Ossification in Chest Wall: Possible Involvement of BAMBI Promoter Hypermethylation in Metaplastic Bone Formation. S. Kitazawa[1], R. Kitazawa[1], T. Kondo[1], K. Mori*[1], C. Obayashi*[2], T. Yamamoto*[3]. [1]Division of Molecular Pathology, Kobe University Graduate School of Medicine, Kobe, Japan, [2]Division of Diagnostic Pathology, Kobe University Graduate School of Medicine, Kobe, Japan, [3]Department of Orthopaedic Surgery, Kobe University Graduate School of Medicine, Kobe, Japan.

Since the osteoporosis-pseudoglioma syndrome attributed to inactivating mutations in the Wnt receptor, LRP5, shows reduced bone mass, and conversely, since autosomal-dominant high bone mass traits attributed to activating mutations in LRP5 show increased bone mass, the classical Wnt/beta-catenin/LEF1 signaling pathway must play important roles in regulating bone density by modulating postnatal osteoblast proliferation. On the other hand, somatic mutations of the beta-catenin gene that result in the stabilization and accumulation of beta-catenin by escaping from ubiquitination, have been demonstrated as causative genetic alterations in desmoid-type fibromatosis (DF). DF, therefore, provides an in vivo constitutive active model for the classical Wnt/beta-catenin/LEF1 signaling pathway in mesenchymal cells. Here, we describe a sporadic case of DF with metaplastic ossification in the left anterolateral chest wall occurred in a 43-year-old man. Histopathological specimens were used for immunohistochemical, genetic and methylation studies. To explain the mechanism of metaplastic bone formation, we hypothesized that in the presence of active wnt signaling, mesenchymal cells transdifferentiate into an osteoblastic phenotype when additional events leading to the activation of BMP signaling occur either through the increased expression of BMPs, their receptors and intercellular signal transducers or the decreased expression of the inhibitors of BMP signaling. Immunohistochemically, the expression of BMP and activin membrane-bound inhibitor (BAMBI) was selectively diminished at the site of the ossifying focus, whereas that of BMP-2 and its receptor remained unchanged. We examined the methylation status of the BAMBI promoter by methylation-specific PCR, and observed CpG island hypermethylation in the promoter specifically in the microdissected samples taken from the ossifying focus, indicating that selective reduction of BAMBI expression is probably due to the selective hypermethylation of the BAMBI promoter region in the ossifying focus. Since both BMP and classical Wnt/beta-catenin/LEF1 signaling cooperatively and mutually induce differentiation of mesenchymal cells into osteoblastic cells and promote bone formation, the epigenetic event leading to the enhanced responsiveness to BMP signaling may play a crucial role in the formation of metaplastic bone.

HSPGs Mediated BMP4 Signaling Is Disrupted in Fibrodysplasia Ossificans Progressiva Lymphoblastiod Cells. M. P. O'Connell*[1], P. C. Billings*[1], J. L. Fiori*[1], H. I. Roach*[2], E. M. Shore[1], F. S. Kaplan[1]. [1]Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, USA, [2]University Orthopaedics, University of Southampton, Southampton, United Kingdom.

Fibrodysplasia ossificans progressiva (FOP), a rare autosomal dominant genetic disorder characterized by congenital malformations of the great toes and progressive heterotopic ossification of soft connective tissues, is associated with dysregulation of the bone morphogenetic protein (BMP) signaling pathway. Cell surface heparan sulfate proteoglycans (HSPGs), known as syndecans and glypicans, are ubiquitously expressed in almost every cell type and are capable of binding or affecting a range of molecules through interactions with their heparan sulfate side chains (HSSCs). BMP and their secreted antagonists have HSSC binding domains. We hypothesize that HSPGs play a role in modulating BMP4 signaling in FOP and control cells via interactions with BMP ligands and antagonists. Control and FOP lymphoblastoid cells (LCLs) were treated with heparinase III to specifically remove HSSCs, and with phosphatidylinositol-specific phospholipase C (PI-PLC), to remove GPI-linked core proteins (glypicans). Cells were subsequently treated with BMP4 and BMP signaling was monitored by following expression of the BMP early response genes ID1 and ID3 (inhibitors of DNA binding and differentiation) by real-time PCR. Treatment with PI-PLC had little if any effect on BMP signaling in control or FOP cells. In contrast, heparinase treatment resulted in a statistically significant reduction in expression of both ID1 and ID3 in BMP treated control LCLs but surprisingly not in BMP treated FOP cells. The HSSC binding domain on the BMP4 molecule resides in an independent region to the receptor binding site. Therefore, BMP4 could simultaneously bind to the BMP receptor type IA (BMPRIA) and cell surface HSPGs. We suggest that HSPGs act as ligand reservoirs for BMP4 that promote BMP signaling under normal conditions. Under conditions of receptor over-abundance, as in FOP cells, there is little or no contribution of HSPGs to BMP signaling. At present it is unknown if this effect is specific to one type of HSPG, to subtypes of HSPGs, or generalized to the entire population of HSSC containing molecules. Our data demonstrates that HSPG play an important role in BMP4 signaling but that role can be negated if a dysregulation exists in the signaling pathway, as in FOP.

Matrix Vesicles Are Carriers of Bone Morphogenetic Proteins (BMPs) and Non-Collagenous Matrix Proteins. N. N. Nahar*[1], L. R. Missana*[2], R. Garimella[1], S. E. Tague*[1], H. Clarke Anderson[1]. [1]Department of Pathology, University of Kansas Medical Center, Kansas City, KS, USA, [2]Oral Pathology, Tucuman University Dental School, Tucuman, Argentina.

A study was undertaken to confirm the presence of bone morphogenetic proteins (BMPs) 1 through 7 and non-collagenous matrix proteins, bone sialoprotein (BSP), osteopontin (OPN), osteocalcin (OC) and osteonectin (ON) in isolated matrix vesicles (MVs) of rat growth plate. Besides the well-defined role of MVs in the initiation of biomineralization in growth plate, developing bone, tendon and predentin, MVs of the growth plate could serve as carriers of morphogenetic information, such as BMPs. MVs thus could be involved in signaling uncommitted osteoprogenitor cells subjacent to the growth plate to undergo osseous differentiation. It is likely that MVs receive BMP proteins from the BMP-enriched cytoplasm of maturing chondrocytes of the growth plate during budding of the MVs into the matrix. BMPs carried in MVs would be released from the matrix at the base of the growth plate during cartilage resorption and vascularization. BMPs carried in MVs and released from the base of the growth plate could stimulate not only osteoblastic activity, but also osteoclastic resorption. MVs were isolated by differential ultracentrifugation from collagenase-digested rachitic rat tibial and femoral growth plate cartilage. The presence of BMPs 1-7, BSP, OPN, OC and ON was evaluated in the isolated MVs by western blot analysis. BMP-2 and BMP-4 were detected at the expected 18 KD as a monomeric molecular weight and BMP-6 appeared as two bands at an expected 15 and 18 KD level. BMP-3 was detected as single band at approximately 66 KD, which corresponds to a similar band of rhBMP-3. BMP-5 was identified as a dimer at 36 KD, a homodimer at 52 KD and another higher KD band that could be a homodimer with the mature protein at 70 KD. BMP-7 was detected at the expected 54 KD molecular weight with other bands that could represent a dimer at 36 KD, a pro-domain at 40 KD and a hemidimeric form at 70 KD, the latter consists of a mature dimer with a pro-domain. Immunoblots of BMP-1 showed the unprocessed precursor at approximately 111 KD and two splice variants were seen approximately at 79 KD and 34 KD. Non-collagenous proteins, BSP, OPN, OC and ON were detected at approximately 81 KD, 80 KD, 65 KD and 40 KD respectively. Thus our data confirmed the presence of BMP-1 through 7 and non-collagenous proteins, BSP, OPN, and OC and ON in isolated rat matrix vesicle. It is suggested that MVs may carry morphogenetic information, thus promoting differentiation of the lower growth plate and subjacent, newly forming bone. The non-collagenous matrix proteins in MVs could function to promote or regulate mineral-initiation by MVs.

Prostaglandin E2 EP4 agonist (ONO-4819) Accelerates BMP-Induced Osteoblastic Differentiation via PKA Signaling. K. Nakagawa*, Y. Ohta*, Y. Imai, C. Nomura-Furuwatari*, K. Takaoka. Department of Orthopaedic Surgery, Osaka City University Graduate School of Medicine, Osaka, Japan.

The anabolic effects of EP4 agonist(ONO-4819)on bone formation have been reported. In our previous *in vivo* study, we reported that ONO-4819 also accelerated BMP-induced ectopic new bone mass without changing systemic bone mass or density. However, the mechanism of ONO-4819 associated with BMP signaling is unknown. In this study, we attempted to clarify how ONO-4819 accelerates the BMP signaling in osteogenic cells in an *in vitro* system. **Materials and Methods:** Bone marrow derived stroma cells (ST2) with the capacity to differentiate into the osteoblastic lineage in response to exogenous BMP-2(100ug/ml) stimulation were used. First, we examined the specificity of the EP4 agonist action towards BMP action by measuring the rate of change of differentiation markers, the change in Osterix expression by real-time RT-PCR analysis and alkaline phosphatase (ALP) activity in the presence or absence of BMP-2.Total RNA was extracted from the cells treated with BMP-2 and/or ONO-4819 for various periods of time and the expression levels of Osterix were assessed by real time RT-PCR. ALP activity was measured two days after the drugs were applied. To estimate the interaction between BMP signaling and PKA, we used the PKA inhibitor (H89) pre-treatment. Next, whether ONO-4819 accelerates or maintains the phosphorylation of regulatory Smads (Smad1/5/8) or not, we performed the western blot analysis using anti-phosphorylated Smad1/5/8 for the lysates from the cells treated with or without BMP-2 and/or ONO-4819. **Results:** Both ALP activity and Orterix expression in the ST2 cells were elevated significantly following BMP-2 treatment for a period of 48 hours. This elevation was further elevated by the addition of the EP4 agonist (10^{-9}-10^{-5}M range). However, treatment of the cells with EP4 agonist alone for 48 hours did not alter the markers. The accelerated BMP action by the ONO-4819 was abolished by pre-treatment with PKA inhibitor, H89. Since levels of phosphorylated regulatory Smads (Smad1/5/8) were not changed by ONO-4819 in Western blot analysis using anti-phosphorylated Smad1/5/8, the accelerated BMP action by the EP4 agonist may be a result of cross-talk between the BMP (Smads) and PKA signaling pathways on the target genes of BMP at the transcriptional level. **Conclusion:** This study suggests that ONO-4819 accelerates BMP-induced osteoblastic differentiation of ST2 cells by enhancing the transcriptional activity of phosphorylated regulatory Smads in association with transcriptional factor(s) involved in the PKA signaling pathway on the target genes of BMP.

Combination Treatment of rhBMP-2 and Bisphosphonate Stimulate Bone Formation and Inhibit Bone Resorption in the Transplanted Bone Allograft. Y. Kaji*, S. Mori, T. Mashiba, T. Manabe*, T. Akiyama*. Orthpedic Surgery, Kagawa University, Kita-gun, Japan.

Recently, bone allografts have become very common in the field of orthopedic surgery. But the size of the graft is still limited if the blood supply is not preserved. To succeed bigger non vascularized bone allograft, stimulation of bone formation and inhibition of bone resorption in the grafted bone are needed. In this study we evaluated whether combination treatment of bone morphogenetic protein (BMP) and bisphosphonate effectively stimulates bone formation and inhibits bone resorption in bone allograft. Forty female Sprague-Dawley rats at 7 weeks of age were used as donors of bone allograft. Five mm thick bone discs were collected from mid-shaft of femora of donor rats and they were preserved in freezer (-80°C). At the time of bone graft surgery, saline (control), 5 microgram of rhBMP-2 (BM), 10^{-4} M of alendronate (AL), and mixture of rhBMP-2 and alendronate (BM+AL) were added on the bone discs. Fifteen microgram of heparin, which was recently found to stimulate the action of BMP, was also added on the bone discs in addition to BMP and alendronate (BM+AL+Hp). The discs were transplanted into the paravertebral muscles of forty male Wister rats at 7 weeks of age. Following bone labeling with calcein the bone discs were collected from recipients at 4 weeks after the transplantation surgery. Decalcified and undecalcified specimens were prepared for histomorphometry to evaluate the effect of BMP and alendornate on bone formation and bone resorption in the grafted bones. In the bone discs of control and AL group no remarkable bone formation and bone resorption were observed. On the other hand, significantly increased bone formation (increased labeled bone surface and volume of newly formed bone) was observed in the bone discs of BM group. However, in these discs bone resorption (the number of osteoclast and bone surface covered with osteoclasts) was also increased. In the bone discs of BM+AL group significantly increased bone formation and decreased bone resorption were observed. Heparin effectively stimulate the effect of BMP and the largest volume of newly formed bone was observed in the bone discs of BM+AL+Hp group. Our results suggests that combination treatment of BMP and bisphosphonate is very effective to preserve larger size of bone allograft. Addition of heparin effectively stimulate the effect of this treatment.

BMP-2 and Osteoporosis Associated Traits in 2,109 Young Adult and Elderly Women. E. Larzenius[1], M. Callreus[1], P. Gerdhem[1], K. Obrant[1], H. Luthman*[2], K. Åkesson[1]. [1]Department of Clinical Sciences, Malmö, Clinical and Molecular Osteoporosis Research Unit, Malmö, Sweden, [2]Medical and Genetics Unit, Malmö, Sweden.

Osteoporosis is a multifactorial disease with a strong genetic component. A candidate locus for regulation of osteoporosis has been identified on chromosome 20p12 by linkage analysis; a locus containing the gene for bone morphogenetic protein-2 (BMP-2). This multi-functional growth factor belongs to the transforming growth factor β superfamily and stimulates osteoblast differentiation and induces bone formation. Genetic variation at the BMP-2 locus has been reported linked and associated with osteoporosis and fracture before and after menopause in a recent report. The aim of this study was to investigate if allelic variation in the BMP-2 gene contributes to regulation of peak bone mass or postmenopausal bone mass in Swedish women. Material and methods: Four different single nucleotide polymorphism (SNP) in the BMP-2 gene region were genotyped in two randomly selected population-based cohorts; the PEAK-25 cohort of 1059 young adult women (age 25.5±0.2 yrs, BMI 23.0±3.8 kg/m^2) and the Osteoporosis Prospective Risk Assessment study (OPRA) of elderly women (age 75.2±0.1 yrs, BMI 26.2±4.2 kg/m^2). The primary phenotypes were bone mineral density (BMD) and quantitative calcaneus ultrasound (QUS). Previous fractures and lifestyles factors were also registered. The four SNPs were chosen in and around the BMP-2 gene; rs2373073 (SNP-2) is a rare missense S37A variant located in exon 2 and identified in the Icelandic and Danish populations, rs235767 (SNP-3) is located in intron 2, rs235710 (SNP-1) and rs235754 (SNP-4) are located 10 kb up-stream and 8 kb down-stream of the gene. Result: In the young women, QUS was the only phenotype consistently associated with the SNPs. SNP-1 and SNP-4 was nominally associated with two out of three calcaneus QUS parameters (p=0.017-0.032), using a multivariate regression model including body weight, height, smoking and years since menarche, the associations remained significant in SNP-1. These genotypes accounted for up to 1.6% of the population variance. Non of the SNPs were associated to QUS in elderly women. We could not confirm significant association with BMD of the S37A variant or of the allelic variation in any of the other SNPs in the BMP-2 region at the hip or spine in either population. Among elderly women 42% reported previous fracture, within this group, those homozygous for C in SNP-4 had significantly lower QUS values (p0.015-0.042).In summary, this study indicates that allelic variation of the BMP-2 gene may contribute to the genetic regulation of qualitative properties of bone and in particular of peak bone mass as measured with calcaneus QUS.

BMP Signaling in Bone Stimulates Osteoclastic Bone Resorption and Remodeling during Endochondral Bone Formation and Fracture Repair. M. Okamoto*, J. Murai*, H. Yoshikawa, N. Tsumaki. Department of Orthopaedic Surgery, Osaka University Graduate School of Medicine, Suita, Japan.

Extensive studies have showed that bone morphogenetic proteins (BMPs) play important roles in skeletal patterning and postnatal bone maintenance. But it still remains obscure how BMPs are involved in endochondral bone development, which is the process residing between skeletal patterning and postnatal bone maintenance. This process is recapitulated during fracture healing after birth. BMP signals are regulated by a balance between BMPs and their antagonists including noggin. To clarify roles of BMP signaling in bone development, we here generated and analyzed transgenic mice expressing noggin or BMP4 in developing bone under the control of the 2.3-kb *Col1a1* promoter sequence which direct expression to immature osteoblasts. Overexpression of noggin in developing bone significantly inhibited osteclastic bone resorption and caused increase in bone volume from 17.5 days postcoitus to 3 weeks after birth. Osteoblast numbers increased, but bone formation rates significantly decreased in noggin transgenic mice compared with the wild-type. Cortical bones of noggin transgenic tibiae were woven and frequently undergo fractures in spite of increased bone volume, suggesting mechanical weakness probably due to reduced remodeling. *Rankl* expression was not decreased. Co-culture experiments showed that osteoclastogenesis was reduced in co-cultures containing transgenic osteoblasts compared with those containing wild-type osteoblasts. This reduction in osteoclastgenesis *in vitro* was recovered by addition of recombinant BMP2, suggesting overexpressed noggin exerted its effects *via* down-regulating BMP signals. In parallel, overexpression of BMP4 in bone increased osteoclast number, causing severe bone loss at 16.5 and 18.5 days postcoitus. BMPs seemed to stimulate osteoclastogenesis directly. We also found that overexpression of BMP4 in cartilage expanded cartilage anlagen, leading to formation of thick bone. These phenomena were recapitulated in the process of fracture repair. After tibial fracture in mice, application of recombinant BMP2 at fracture sites 2 days after fracture produced a large callus, whereas application at 16 days after fracture caused transient callus resorption associated with an increase in the osteoclast number. Our results suggest that secreted BMPs in bone stimulate osteclastic bone resorption and remodeling during endochondral bone development and fracture repair. BMP application to cartilage caused expansion of cartilage anlagen, resulting in increased volume of bone or callus. The present findings are useful for planning strategies for treating fractures using BMPs.

Micro-CT Analysis of Trabecular Bone in a Rat Model of High-Turnover Renal Osteodystrophy: The Effects of Systemic Administration of BMP-7. R. A. Dodds, D. Xu, X. Cui*, A. Hughes, J. Tullai*, P. Patel, F. X. Farrell. Growth Factors, Johnson&Johnson PRD, Raritan, NJ, USA.

BMP-7 (OP-1) is expressed highly in kidney during fetal development and in adult life. If the kidney experiences an acute injury, e.g., ischemia, BMP-7 mRNA levels decline in parallel with loss of renal.function. Chronic renal failure (CKF) is a progressive disorder leading to end stage renal disease. Present treatments (ACE inhibitors) do not impact the deleterious effects of CKF, including renal osteodystrophy (RO). Skeletal abnormalities in patients, rats and mice with CKF include excessively increased bone turnover (2^0 hyperparathyroidism), abnormal mineralization, and marrow fibrosis. In patients, this leads to fracture and extreme pain. This study evaluated the efficacy of BMP-7 in preventing RO in the rat CKF 5/6 nephrectomy model. Rats (400g) were nephrectomized (NPX): a left contra-lateral NPX was followed in two weeks by right total NPX. The upper and lower poles of the left kidney were removed in the first operation and the whole right kidney was then removed two weeks later. Sham surgery was the same procedure minus NPX. The rats received BMP-7 (100 ug/kg), or vehicle i.v, weekly, 5 weeks after the 2nd surgery, for 6 weeks, at which time the tibia were removed for micro-CT analysis. Briefly, BMP7 groups showed positive effects in inhibiting renal fibrosis, reducing mesangial area, tubular lumen dilation and interstitial edema. Furtherore, BMP-7 maintained normal blood pressure. The following structural parameters were assessed in the tibiae metaphyseal trabeculae: BV/TV, Tb.N, Tb.Th, Tb.Sp, trabecular connectivity and BMD. CKF resulted in a significant decrease in trabecular bone volume versus sham (50% decrease, $p< 0.05$), attributed to a decrease in TB.N, but not Tb.Th. Tb.Sp was increased and BMD decreased (40% versus sham, $p< 0.05$) in the CKF tibia. Trabecular connectivity was dramatically decreased in the CKF rats bones (50% lower versus sham, $p< 0.05$). In the BMP-7 treated rats BV/TV and BMD were maintained at sham levels or dramatically increased ($p< 0.05$ versus CKF). As such, Tb.N and Tb.Sp were also equivalent to sham tibia. Trabecular connectivity was higher in the BMP-7 treated group (20% higher than CKF). In conclusion, BMP-7 prevented the disruption in bone integrity caused by renal failure.

The Effects of Growth/Differentiation Factors-5, 6, and 7 on Mesenchymal Cell Condensation and Chondrogenesis. A. T. Boyce*, R. S. Tuan. NIAMS, NIH, Bethesda, MD, USA.

Growth/Differentiation Factor-5 (GDF-5), a member of the TGF-beta superfamily of bone morphogenic proteins, is required for limb mesenchymal cell condensation, joint formation, and chondrocyte maturation during skeletogenesis. In post-natal development, GDF-5 is expressed during the chondrogenic phase of endochondral fracture repair, recapitulating early developmental events. Brachypod (BP) mice have a functionally null mutation of the GDF-5 gene, causing an acromesomelic chondrodysplasia of the appendicular skeleton. GDF-5 is closely related to two additional GDFs: 6 and 7. While both GDF-6 and GDF-7 transcripts have been located in the developing bone, their functions have not been closely examined. Using limb bud micromass cultures from wild-type animals, we aim to determine whether GDF-5, 6, and 7 can accelerate mesenchymal cell condensation and chondrogenesis. Using limb bud micromass cultures from BP animals, we aim to determine whether GDF-5, 6, and 7 can rescue mesenchymal cell condensation and chondrogenesis. To quantify acceleration and rescue, we will use peanut agglutinin staining for condensation, alcian blue staining for chondrogenesis, and PCR for markers of maturation and differentiation. In addition, we are interested in the signaling cascade of the three GDFs in early limb bud development. While studies have identified the receptors GDF-5 can bind, none have examined the endogenous receptors and intracellular signaling components (SMADs) used in mesenchymal cell condensation and chondrogenesis. Using the limb bud micromass system, we will perform PCR and Western blotting to determine which receptors and SMADs are expressed and how their expressions and phosphorylation status are changed with time and addition of GDFs. We propose that GDF-5, 6, and 7 rescue the BP phenotype and accelerate wild-type condensation and differentiation, though the three GDFs may not use the same signaling cascade.

Regulation of Differentiation and BMP Signaling by Twisted Gastrulation and Chordin in MC3T3-E1 Osteoblast-like Cells. R. Gopalakrishnan[1], O. Shimmi*[2], X. Jia*[3], A. E. Carlson*[1], L. Tervonen*[1], M. Jarcho*[4], M. B. O'Connor*[2], A. Petryk*[4]. [1]Oral Sciences, University of Minnesota, Minneapolis, MN, USA, [2]Genetics, Cell biology and Development, Howard Hughes Medical Insitute University of Minnesota, Minneapolis, MN, USA, [3]R&D Systems, Minneapolis, MN, USA, [4]Pediatrics, University of Minnesota, Minneapolis, MN, USA.

Bone morphogenetic proteins (BMPs) are necessary for inducing osteoblast differentiation as well as for regulating and maintaining the differentiated state of committed osteoblasts. Twisted gastrulation (Tsg) and Chordin (Chd) are secreted proteins that regulate accessibility of BMP ligands to their receptors. Tsg has both anti-BMP and pro-BMP activity. Tsg antagonizes BMP signaling by forming ternary complexes with Chd and BMPs, thereby preventing BMPs from binding to their receptors. The pro-BMP activity is partly mediated by cleavage and degradation of Chd, which releases BMPs from ternary complexes. The roles of Tsg and Chd in osteoblast differentiation are not known. Therefore, using a well-characterized subclone of MC3T3-E1 cells, we investigated the roles of Tsg and Chd in osteoblast differentiation and mineralization. Our results show that Tsg and Chd are expressed in MC3T3-E1 osteoblast-like cells. While Tsg mRNA levels decrease during osteoblast differentiation, Chd levels are found to increase. Tsg and Chd proteins accumulate in the cell culture media as the osteoblasts differentiate. Further, Tsg and Chd treatment inhibits osteoblast mineralization in a dose-dependent manner. Evaluation of osteoblast differentiation markers revealed a dose-dependent reduction in alkaline phosphatase (ALP) activity following Tsg and Chd treatment. Osteocalcin (OCN) mRNA levels decreased following both Tsg and Chd treatment. To determine if the effects of Tsg and Chd on osteoblast differentiation are mediated by regulation of BMP signaling, we investigated the levels of phosphorylated Smad1 in MC3T3-E1 cells following treatment with Tsg and Chd. Both Tsg and Chd independently and in combination reduced pSmad1 levels in MC3T3-E1 cells treated with BMP4. Further, BMP2 partially reversed the inhibitory effects of Tsg and Chd on ALP activity. In summary, our results show that exogenous treatment with Tsg and Chd inhibits osteoblast differentiation and mineralization, and suggest that these effects could be partially mediated by regulation of BMP signaling.

Regulated BMP2 Gene Therapy for Bone Regeneration. J. Koh*[1], C. Ge*[1], Z. Wang*[2], P. Krebsbach*[2], R. T. Franceschi[1]. [1]Periodontics, Prevention and Geriatrics, University of Michigan School of Dentistry, Ann Arbor, MI, USA, [2]Biologic and Materials Sciences, University of Michigan School of Dentistry, Ann Arbor, MI, USA.

Adenoviruses expressing bone morphogenetic proteins (BMPs) have been extensively used as a gene therapy vectors for bone regeneration. These viruses induce bone formation and can partially heal calvarial and long bone critical size defects. However, because these vectors use a constitutively active viral promoter to drive BMP expression, they provide little control over the timing or level of BMP induction. Nevertheless, such control may be critical for successful bone regeneration. To begin exploring this issue, we developed and evaluated an inducible system for regulated synthesis of BMP2. Inducible BMP2 expression was achieved using a rapamycin (Rap)-inducible expression system (ARIAD

Pharmaceuticals). Rat BMP2 cDNA was cloned into a retrovirus containing a Rap-sensitive artificial promoter. BLK fibroblasts were transduced with this virus and a second vector encoding a 2-component Rap-binding factor to induce BMP2 expression. Stable cell lines were developed and tested for inducible BMP expression by ELISA. One clone (BLK-RapBMP2/23) was examined in vitro and in vivo. In the absence of rapamycin, cultured BLK-RapBMP2/23 cells produced undetectable BMP2. Rap treatment induced BMP2 expression in a dose-dependent manner (0.1-10 nM), and the expression was rapid (within 3-6 h) and readily reversible. To evaluate in vivo biological activity, BLK-RapBMP2/23 cells were suspended in a type I collagen hydrogel and implanted into subcutaneous sites or calvarial critical sized defect of syngeneic C57BL6 mice. In subcutaneous implants, a single i.p. injection of Rap induced BMP2 dose-dependently (0.1-3 mg/kg). The induction occurred within 24h and decayed to basal levels after 1 week. Alternate day Rap injections (1 mg/kg) induced subcutaneous ectopic bone formation and orthotopic bone regeneration from calvarial defects in mice containing BLK-RapBMP2/23 cell implants after 4-6 wks. In summary, we successfully developed a system for controlled expression of BMP2 using a rapamycin-inducible promoter. This system induces ectopic and orthotopic bone formation and should be extremely useful for identifying stages of bone healing that are most sensitive to BMP stimulation.

Osteoactivin Expression Is Regulated by BMP-2 through Smad-1 Signaling Pathway during Osteoblast Differentiation. S. Abdelmagid*[1], T. A. Owen[2], S. N. Popoff[1], F. F. Safadi[1]. [1]Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, USA, [2]Cardiovascular and Metabolic Diseases, Pfizer Global Research and Development, Groton, CT, USA.

Our laboratory previously showed that osteoactivin (OA) is a secreted osteoblast-related glycoprotein and plays a distinct role in their differentiation and function. In this study, we examined whether the effect of BMP-2, a potent osteotrophic factor, can regulate OA expression using primary osteoblast cultures. Cultured osteoblasts were treated with different concentrations of BMP-2 and examined for OA expression. BMP-2 treatment caused a does-dependent increase in OA expression with a maximum response at 50 ng/ml. In order to examine the regulatory effect of BMP-2 on OA expression during osteoblast development, osteoblast cultures treated with BMP-2 (50 ng/ml) caused an up-regulation of OA expression at all stages during oateoblast differentiation. We next examined whether OA is a downstream mediator of BMP-2 effect on osteoblast differentiation. OA anti-sense oligo-transfection was used to down regulate OA expression. Cells transfected with OA anti-sense oligonucleotide shows a reduction in OA expression associated with a decrease in alkaline phosphatase staining, nodule formation and mineralization compared to control, sense, transfected cultures. OA anti-sense oligo-transfected culture treated with BMP-2 shows re-induction of OA expression associated with a restoration of alkaline phosphatase staining, nodule formation and matrix mineralization. To examine whether the up-regulation of OA by BMP-2 is Samd-1 mediated, cultures were transfected with Smad-1 siRNA and treated with BMP-2. OA expression level was inhibited in Smad-1 siRNA transfected compared to non-silencing siRNA, transfected, control, cultures. Collectively, these data suggest a significant role for OA as a downstream mediator of BMP-2 effect in osteoblasts differentiation and BMP-2 regulates OA protein expression through Smad-1 signaling pathway.

Effects of Pulsed Electromagnetic Field (PEMF) and BMP-2 on Rat Primary Osteoblastic Cell Proliferation and Gene Expression. N. Selvamurugan, S. Kwok*, N. Partridge. Physiology and Biophysics, UMDNJ-Robert Wood Johnson Medical School, Piscataway, NJ, USA.

Transforming growth factor-β (TGF-β) family members, including TGF-βs and bone morphogenetic proteins (BMPs), play important roles in directing fate decisions for mesenchymal stem cells. BMPs inhibit adipogenesis and myogenesis, but they strongly promote osteoblast differentiation. BMPs along with other growth factors or cytokines act synergistically to induce osteoblastic differentiation. The beneficial therapeutic effects of selected low energy, time varying pulsed electromagnetic fields (PEMFs) have been documented with increasing frequency to treat therapeutically resistant problems of the musculoskeletal system. PEMF promotes fracture healing in non-unions. Since PEMF has effects on bone formation *in vivo* and BMPs, in co-operation with other factors, have synergistic effects on bone formation, we hypothesized that a combined BMP-2 and PEMF stimulation would augment osteoblast proliferation and differentiation to a greater degree than treatment with either single stimulus. Hence, the objectives of this work were to determine the effect of BMP-2 and PEMF (Spinal-Stim) together or separately on osteoblastic cell proliferation, differentiation, and mineralization. We used normal rat osteoblastic cultures derived from postnatal day 1 rat calvariae. Every alternate day cells were treated with BMP-2 at different concentrations. The proliferative activity of cells was maximally increased at 25 ng/ml BMP-2 concentration at 7 days culture. Analysis of gene expression by real time RT-PCR from the cells in differentiation and mineralization phases showed that BMP-2 stimulated mRNA levels of alkaline phosphatase, type I collagen and osteocalcin. The effect of PEMF (1.5 Hz burst; 99 pulses per burst; 9/3 teslas/second amplitude; 6 h treatment, daily) on its own, or together with BMP-2 on rat osteoblastic cell proliferation, differentiation, and mineralization was determined. BMP-2 and PEMF had effects on proliferation of rat osteoblastic cells which were additive when both agents were combined. PEMF itself or together with BMP-2 increased only alkaline phosphatase mRNA expression and only during the differentiation phase. This effect was additive when both agents were combined. Hence, we suggest that a combined treatment of BMP-2 and PEMF has additive effects on osteoblastic cell proliferation and early osteoblastic differentiation, and this additive effect is possibly mediated by different intracellular signaling pathways. Thus, a combined effect of BMP-2 and PEMF *in vitro* could be considered as groundwork for *in vivo* bone development that may support skeletal therapy.

Fourier Transform Infrared Microscopic Analysis of Subchondral Sclerotic Lesion in Knee Osteoarthritis. M. Sato*[1], N. Miyoshi*[2], H. Baba*[1]. [1]Orthopaedics and Rehabilatation Medicine, University of Fukui, Fukui, Japan, [2]Pathology, University of Fukui, Fukui, Japan.

Introduction The subchondral bone has long been known to be sclerotic in osteoarthritis. Recently the turnover of bone mineral and collagen metabolism is increased several fold and further suggests that the subchondral bone plays a significant role in osteoarthritis. The biochemical and biomechanical properties of the subchondral bone are therefore of particular interest to elucidate the pathogenesis of osteoarthritis. Study design In the present study, we analyze the mineralization of subchondral sclerotic lesion in knee osteoarthritis by Fourier Transform infrared microspectroscopy (FTIRM). Marerials and methods 10 OA knee joints were collected from elderly patients immediately after knee arthroplasty. Subchondral bone samples were isolated using a punch from distal medial femoral (MF) , distal lateral femoral (LF) , proximal medial tibial (MT) and proximal lateral tibial (LT) region. All samples were fixed and dehydrated and then, each of them were snap-frozen in liquid nitrogen and milled to a powder using a stainless steel mill. For IR micro-spectroscopic analysis, KBr pellets were prepared by mixing 10mg of bone powder with 500 mg of KBr in a mortar and pestle and pressing the pellet in a 13mm KBr pellet die. The spectra were recorded with FTIRM (model IRT-30 ; JASCO, Tokyo, Japan) coupled to a spectrometer (model 410M ; JASCO, Tokyo, Japan) at a resolution of 4cm-1, 200 scans. The mineral:matrix ratio was determined by integrating the area under the peak at phosphate vibration (900-1200 cm-1) and Amide1Â (1725-1585 cm-1) vibration in the FTIR spectrum. Results The mean mineral:matrix ratio of the medial sclerotic lesion(MF, 1.95Â±0.002, MT, 1.85Â±0.002) was significantly lower than the lateral region (LF, 2.45Â±0.002, LT, 2.50Â±0.017) of the subchondral bone. Discussion In this study, infrared data suggested the hypomineralization in the subchondral sclerotic lesion. The nucleation of mineralization requires the gap region within the precise organization of the collagen fiber. These structures are essential for the stability and strength of bone. In osteoarthritis, normal bone mineralization process might to be inhibited and the biochemical and biomechanical properties of subchondral bone might to be weakened.

Increase of Erythrocyte Ca and Mg with Age and Effect of Ca Supplementation. T. Fujita[1], S. Ohgitani*[2], M. Ohue*[1], Y. Fujii*[3], A. Miyauchi*[4], Y. Takagi*[4]. [1]Medicine, Katsuragi Hospital, Kishiwada, Japan, [2]Medicine, Imai Hospital, Osaka, Japan, [3]Medicine, Calcium Research Institute, Kishiwada, Japan, [4]Medicine, National Hospital System Hyogo Chuo Hospital, Hyogo, Japan.

Calcium (Ca) deficiency increases secretion of parathyroid hormone (PTH) Which paradoxically raises intracellular Ca interfering with signal transduction. Nevertheless, intracellular Ca has not been measured as frequently as its extracellular counterpart because of a sampling problem. Since erythrocytes are readily sampled as a representative cell mass, Ca in erythrocytes was measured along with magnesium (Mg), a commonly coexisting divalent cation, to assess its significance in systemic mineral metabolism. From 135 healthy male and female volunteers 2 ml blood samples were obtained with EDTA-2K anticoagulant and Ca content of the washed erythrocytes measured by atomic absorption spectroscopy. Both Ca (5~10 ppm, r= 0.195, p=0.0232) and Mg (30~75 ppm, r= 0.287, p=0.007) in erythrocytes significantly increased with advance in age. Neither erythrocyte Ca nor Mg showed significant gender difference. In 41, 12 and 13 of these subjects, 900mg, 300mg and 0mg /day active absorbable algal calcium (AAACa, Fujix) was supplemented respectively for 4 months. Erythrocyte Ca contents decreased by 1.13 (SE 0.22) ppm in A and by 0.24(SE 0.39) in B, but not in C with a highly significant difference between A and C (p<0.0001) and significant difference between A and B (p=0.0447). Ratio of erythrocyte Ca contents after/before supplementation in Group A was 75.1 (SE 2.3) % of that in the non-supplemented Group C (p= 0.0001), and that in Group B 86.6 (SE 4.4) %.(p=0.0208). No significant changes occurred in erythrocyte Mg contents. The progressive increase in erythrocyte Ca content with age and its doseÂ|related decrease on supplementation with readily absorbable AAACa is compatible with a hypothesis of Ca deficiency and secondary hyperparathyroidism associated with aging and its reversal by effective Ca supplementation. Erythrocyte Ca measurement appears to be useful to evaluate the degree of Ca deficiency and efficacy of Ca supplementation.

BrdU Tracking of Preosteoblasts in Formalin Fixed, Decalcified Regenerating Bone. E. C. Wahl*[1], J. Aronson*[2], R. A. Skinner*[2], C. K. Lumpkin[2]. [1]Arkansas Children's Hospital Research Institute, Little Rock, AR, USA, [2]Departments of Orthopedics and Pediatrics, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Distraction osteogenesis (DO) is a limb lengthening procedure that induces rapid bone formation by slowly stretching a surgically introduced fracture at a prescribed rate and rhythm. In order to track the pre-osteoblasts in the distraction gaps of rats, we utilized two types of immunohistochemical markers. The first was an injection of bromodeoxyuridine (BrdU), a thymidine analog, followed by immunohistochemical staining for BrdU positive nuclei. The second was the antibody against proliferating cell nuclear antigen (PCNA). Four male Sprague Dawley rats (350g) underwent standard DO surgery. External fixators were placed on the left tibiae and mid-diaphyseal tibial osteotomies were performed immediately following fixator placement. Distraction began one day after surgery at 0.2mm b.i.d. (0.4mm/day) for 12 days. On the twelfth day of distraction the rats were given an intraperitoneal injection of BrdU labeling reagent (1ml/100g). A rat was sacrificed 2, 24, 48, and 72 hours after the injection. At the time of sacrifice, the distracted tibiae were harvested and stored in neutral buffered formalin (NBF) until processed for histology. A small section of intestine from each rat was also collected as a positive BrdU control. After fixation in NBF, the tibiae were decalcified in 5% formic acid, dehydrated, and embedded in paraffin. Serial sections were then stained with either a mouse monoclonal antibody against PCNA (PC-10), a monoclonal antibody against BrdU, or a normal mouse IgG for negative control. A comparison of PCNA+ cells and H&E stained cells in serial sections at each time point demonstrated that the PCNA+ cells were located in the zone outlining the new osteoid columns and in the sinusoids between the columns. No PCNA+ cells were noted in the new microcolumns. A comparison of BrdU+ cells and H&E stained cells in serial sections at the 2 and 24 hour time points demonstrated that BrdU+ cells were also located outside the microcolumns. At the 48 hour time point, BrdU+ cells first appeared scattered throughout periosteal new bone, microcolumns, and cartilage. This same pattern was observed at the 72 hour time point, except that a greater majority of cells in the new columns were labeled. The results demonstrate for the first time that during DO at least a subset of the proliferating cells, juxtaposed to the newly developing osteoid column tips, can be “tracked” over a 48 -72 hour period, into the osteoid columns, confirming their identification as preosteoblasts.

Comparative Analysis of Confocal and Light Microscopy for Detecting *In Vivo* Microdamage in Wild and Domesticated Animals. W. E. Anderson*[1], J. G. Skedros[2]. [1]Univ. Utah Dept. Orthop. Surg., Salt Lake, UT, USA, [2]UofU, SLC, UT, USA.

Microdamage (mdx) accumulation is believed to be important in the etiology of stress and fragility fractures. But detecting in vivo bone mdx is difficult. Confocal microscopy appears to be gaining popularity as the “gold standard” for detecting mdx because it is considered more sensitive than light microscopy. We tested this hypothesis using one calcaneus from each of 11 wild deer, 11 wild elk, 11 domesticated sheep, and 11 non-racing horses. In addition to examining entire bone sections, we also examined prevalent/ predominant medial/lateral “shear” regions and caudal “tension” regions to see if these relatively more deleterious loading environments are associated with increased in vivo mdx when compared to cranial “compression” regions.14mm-thick mid-diaphyseal segments were bulk stained in 1% basic fuchsin [Burr & Stafford 1990 Clin. Orthop.]. Two investigators, blinded to the hypotheses, rigorously examined three 100micron-thick slices/ bone at 10-40X using transmitted light and confocal microscopy for various forms of in vivo (fuchsin stained) mdx (linear microcracks, diffuse mdx, wispy mdx, and osteonal debonding). Confocal microscopy was conducted using a Nikon PCM-2000 with a green HeNe LASER (543nm wavelength excitation; 565 LP filter). Evaluation in light microscopy revealed 15 linear microcracks in 132 sections: nine in deer (4 bones), two in elk (1 bone), and four in horses (3 bones). In addition to confirming the presence of the 15 linear microcracks with light microscopy in the deer, elk, and horses, evaluation using confocal revealed 83 additional mdx entities (debonded, wispy, and diffuse), none of which could be detected with light microscopy. Frequencies of additional mdx entities included: deer (n=45; all bones), elk (n = 24; all bones), and horses (n=14; 9 bones). No mdx was detected in sheep calcanei using light or confocal microscopy. These results confirm the greater sensitivity of confocal microscopy. Higher levels of physical activity may explain why the wild animals exhibited significantly more mdx. Approximately 60% of mdx was concentrated in the caudal cortices where tensile strains are prevalent/predominant, possibly accounting for the high remodeling activity in this region. Confocal microscopy may help determine if bones subject to habitual bending incur similar regional variations in mdx prevalence and/or if these regional variations are minimized by regional adaptations (e.g., osteon densities, collagen orientation) that serve to "toughen" the bone. In turn, confocal microscopy may help determine how strain distributions might increase fracture propensity in some bones, especially with aging (e.g., proximal human femur).

Assessment of Neovascularization in Fracture Healing of COX-2 -/- Mice Using Micro-Computed Tomography. C. Xie*[1], A. S. P. Lin*[2], E. M. Schwarz[1], R. E. Guldberg*[2], R. J. O'Keefe[1], X. Zhang[1]. [1]Orthopaedics, University of Rochester Medical Center, Rochester, NY, USA, [2]George W. Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, USA.

Angiogenesis has been shown to play a key role in bone regeneration and fracture repair. We previously demonstrated that COX-2-/- mice exhibited impaired fracture healing, as evidenced by significant delay in mesenchyme differentiation and cartilage mineralization. To further determine whether delayed mineralization in COX-2-/- mice was associated with the deficiency in neovascularization, we used micro-computed tomography (Micro-CT) to examine the quantity and quality of vasculature in the fracture callus of COX-2-/- mice and their wild type control mice. A mid-diaphyseal fracture was created via 3 point bending in mouse femur and subsequently stabilized by a metal pin placed in the intramedulllary canal. MicroCT vascular imaging was obtained via perfusion of a lead chromate based contrast agent Microfil followed by complete decalcification. Segmentation was performed using software provided by Scanco to contour out the periosteal external callus and endosteal internal callus, excluding the cortex of the fractured femur. The three-dimensional reconstruction of microvasculature within fracture callus demonstrated a dramatic reduction of neovascularization in COX-2-/- mice compared to the wild type control at day 14 post-fracture (Figure). Clusters of highly connected, closely spaced, and isotropically oriented small vessels were observed in wild type mice, but were almost absent in COX-2 -/- mice. Quantitative analyses demonstrated that the volume fraction of mineralization within fracture callus was reduced by 2.5 fold , whereas the total vessel volume fraction was reduced by 3.75 folds in Cox-2-/- mice ($p<0.05$, n=3). Accordingly, vessel separation was increased by 1.5 fold and the average thickness of the vessels was decreased by 25% in the knockouts ($p<0.05$). The dramatic difference seen between COX-2 knockout and wild type mice was the connectivity of the vessels. Wild type mice demonstrated about 25 fold higher connectivity than COX-2-/- mice. Taken together, our data suggests that deficiency in angiogenesis may play a key role in delayed fracture healing in COX-2-/- mice.

Automated Volumetric Imaging of *In Vivo* Bone Formation Labels. G. J. Kazakia*[1], M. Singh*[2], W. Yao[3], N. E. Lane[4], T. M. Keaveny[2]. [1]UC, San Francisco, CA, USA, [2]UC, Berkeley, CA, USA, [3]Stanford, Stanford, CA, USA, [4]UC Davis, Sacramento, CA, USA.

In vivo administered fluorescent labels are indispensable in the study of bone metabolism. Standard histomorphometry - particularly in mineralized tissues - is technically challenging and labor intensive. Moreover, histomorphometric measures based on thin sections allow only 2D measures of the 3D structures of interest. With renewed interest in the role of bone quality in osteoporosis, the distinction between 2D and 3D measures of histological structures such as remodeling spaces and microdamage may be important. The goal of this work was to apply a novel technique for visualizing 3D distribution of fluorochrome labeled components within large biological specimens to the reconstruction of an *in vivo* administered bone formation label. This method is based on computer controlled milling technology and combines an arrayed imaging technique with fluorescence capabilities, thus enabling 3D fluorescence imaging of bone specimens of any size at high resolution (on the order of a few microns). Biological specimens containing fluorescent labels are embedded in an opaque resin and mounted onto the system for serial milling and imaging. After each milling pass, an imaging station excites the exposed fluorochromes and captures the emitted fluorescence through a series of filters. As an example, an *in vivo* calcein-labeled femur from a six month old female Sprague-Dawley rat was harvested and imaged. The proximal femur was fixed in 10% NBF, dehydrated, and embedded in opaque MMA. Autofluorescence was exploited to capture bone morphology using a UV excitation filter and a DAPI emission filter. Calcein fluorescence was imaged using a FITC filter set. Two 2x3 image arrays (one per filter set) were captured for each exposed surface. A 5 mm length was imaged using 680 slices at an in-plane resolution of 3 microns/pixel and an out-of-plane resolution of 8 microns. Two superimposed volumetric data sets were rendered for visualization - one representing bone morphology and a second representing bone formation zones. Spatial distribution of bone forming zones and their relation to local bone architecture were clearly distinguished and substructures such as an entire osteon (length 1.36 mm; mean diameter 129 microns) were isolated. Imaging time

was approximately 20 h. However, the automated nature of the system greatly reduced operator time, requiring a total of 2 h (independent of total imaged volume). Use of this system is expected to provide unique *three-dimensional* data on structures such as osteons, remodeling cavities, mineralization distributions, remodeling surfaces, and microdamage, all having substantial relevance to studies in bone quality and osteoporosis.

How Long Does Secondary Mineralization of Osteonal Bone Take? R. K. Fuchs[1], M. R. Allen[1], M. E. Ruppel[2], L. M. Miller[2], D. B. Burr[1]. [1]Anatomy and Cell Biology, Indiana University Medical School, Indianapolis, IN, USA, [2]Brookhaven National Laboratory, National Synchrotron Light Source, Upton, NY, USA.

The time-course required for newly formed bone to achieve "complete" mineralization is unclear yet may be important to help understand how common anti-resorptive therapies for osteoporosis alter tissue mineralization. Our aim was to determine the time-course of secondary mineralization in normal cortical bone using synchrotron infrared (IR) microspectroscopy. Twelve 4-month old female New Zealand white rabbits were administered four different fluorochrome labels at various time points to identify sites of newly formed bone. Rabbits were sacrificed after 8, 18, 35, 70, 105, and 210 days of formation to determine the level of mineralization at labelled sites. Phosphate, carbonate, and collagen content of labeled osteons were measured from 4 μm thick sections of tibial diaphysis using synchrotron Fourier transformed IR microspectroscopy (FTIRM). IR spectra were recorded using a Continuum IR microscope coupled to a Nicolet Magna 860 FTIR. Curve-fiting and area integrations were carried out on protein (Amide I: 1700-1600 cm^{-1}), carbonate (CO_3^{2-}: 905-825 cm^{-1}), and phosphate (PO_4^{3-}: 650-500 cm^{-1}) IR bands. Collagen cross-linking was studied as a ratio of 1660/1690 cm^{-1}. Because PO_4^{3-} is the most abundant anion in bone, overall mineralization was estimated by the ratio of PO_4^{3-} to protein. Results showed that the rate of increase of mineralization slowed to nearly zero by day 210, and did not change significantly between days 105 and 210, thus we assumed that mineralization was nearly complete by 210 days. After only 8 days, the level of mineralization was 76% of the value observed at day 210. Between days 8 and 105 the level of mineralization increased significantly, reaching 95% of its estimated final value by day 105 ($p<0.001$, Fig. 1). Changes in CO_3^{2-} over time were similar to those seen for PO_4^{3-}. Mineral crystallinity and collagen cross-linking did not change significantly from days 8 to 210. Thus, changes in crystallinity and cross-linking either occur rapidly (<8 days) or very slowly (longer than 210 days). Our findings demonstrate that newly formed osteonal bone continues to mineralize for approximately 3 months, by which time it has achieved 95% of its final value. The rate of mineralization slows asymptoptically between 3 and 7 months of formation.

Real Time Skeletal Metabolism Differences during and after Lactation Using Dynamic Micro-Postitron Emission Tomography (MicroPET) Imaging. B. L. Anderson*[1], B. M. Bowman[1], J. Slater*[2], S. C. Miller[1]. [1]Radiobiology, University of Utah, Salt Lake City, UT, USA, [2]Loma Linda University, Loma Linda, CA, USA.

Lactation is a period of altered skeletal metabolism to provide the mineral requirements of milk production. During lactation, skeletal turnover is increased but dominated by bone resorption. After lactation there is a rapid transition or "reversal" to a profoundly anabolic period that reconstitutes the maternal skeleton. The purpose of this study was to determine the dynamic uptake of the bone-seeking ion [^{18}F] fluoride in different skeletal regions and to compare these results with histomorphometric indices of bone formation and resorption. ^{18}F is a bone seeking ion that either binds to bone tissue on the surface or as an ionic exchange with the hydroxyl groups of hydroxylapatite to form fluorapatite. Tomographic images with anatomic resolution can be obtained from the ^{18}F positron emission. Three groups of rats were studied: 1) Female rats at mid-lactation; 2) females rats at 18 hrs after weaning; and 3) non-mated, age-matched controls. ^{18}F at a (700 μCi) was injected into the tail vein at the beginning of image acquisition by microPET. Blood samples were taken 1 min after the ^{18}F injection and then every 5 minutes during the 70 minute scan. Fluoride activity was measured (gamma counter) in blood samples and individual bones. Dynamic images of the proximal tibia and lumbar vertebra (4-6) were reconstructed with 10 frames at 30 sec, 10 frames at 120 sec and 12 frames at 300 sec. From this, time-activity curves were generated. The slowest rate of ^{18}F uptake was observed during mid-lactation; a period of excess bone resorption and bone loss. The fastest uptake of ^{18}F occurred in the early post-weaning period; a period of osteoclast apoptosis and commencement of mineral accumulation in the skeleton. The uptake of ^{18}F in the non-mated controls was intermediate with the other groups. As expected, relatively greater metabolic activity was observed in cancellous bone regions, particularly the metaphyseal spongiosa. This study first demonstrates the utility of using microPET to assess skeletal metabolism in a living animal. In this case, the changes in the rates of ^{18}F uptake can be correlated with the histomorphometric observations. This study also further demonstrates the profound differences in maternal mineral metabolism that occur during and immediately after lactation.

Diesel Motor Oil Is an Effective Contrast Agent for Micro-CT Visualisation of Pre-Ossification Cartilage in the Mouse Fetal Limb. P. L. Salmon[1], M. Kmita*[2], D. Duboule*[3]. [1]Skyscan, Aartselaar, Belgium, [2]Frontiers in Genetics, University of Geneva, Geneva, Switzerland, [3]Frontiers of Genetics, University of Geneva, Geneva, Switzerland.

The development of bones in the vertebrate fetus is an integral part of the development of segmented and articulated limbs. An important part of this development is the acquisition of proximal-to-distal patterning, and mutant mice have been employed to study the genetics of development of limb patterning (Duboule 2002). Development of pattern, sequence and symmetry are controlled by the highly conserved Hox genes. Two naturally occurring mutations, Ulnaless (Ul) and Hypodactyly (Hd), have proved useful in clarifying the respective roles of the HoxD and HoxA complex genes. To study developmental phenotypes of mice it is necessary to image the structure of bone at its first appearance in the fetus, both at the onset of calcification, and also importantly just before calcification. Such imaging should ideally be in 3 dimensions. Calcified bone can be imaged clearly in 3D by micro-CT since even low level calcification confers significantly higher x-ray absorption in bone compared to nonmineralised soft tissue. So newly calcifying bone is readily imaged by micro-CT. However pre-ossification cartilage in the developing mouse limb shows no x-ray contrast against surrounding soft tissue. Mineral oils were evaluated as contrast agent to facilitate micro-CT imaging of pre-ossification cartilage by conferring increased x-ray absorption selectively to pre-ossification cartilage. Of the oils evaluated diesel motor oil was found to be the most successful, providing sufficient contrast to allow spatial imaging of pre-ossification cartilage (see figure 1). It is possible that metals within the motor oil were sequestered by sulphur bridges within the glycosaminoglycans of cartilage.

Duboule D (2002) Making progress with limb models. Nature 418: 492-493.

Figure 1. Micro-CT crossection images of a fetal mouse limb (ex-vivo) before (left) and after (right) immersion of the limb in diesel motor oil for one month. The oil immersion resulted in visualisation of pre-ossification cartilage rings representing the developing radius and ulna.

LRP5 Regulation of Intrinsic Material Properties of Cortical Bone. G. E. Lopez Franco[1], R. Blank[1], B. L. McGuckin*[2], M. L. Johnson[2], D. M. Cullen[2], R. R. Recker[2], M. P. Akhter[2]. [1]Endocrinology, University of Wisconsin Medical School, Madison, WI, USA, [2]Medicine, Creighton University, Omaha, NE, USA.

The $LRP5^{G171V}$ mutation (high bone mass [HBM]) is autosomal dominant and is responsible for high bone mass in human. Transgenic HBM mice harboring an expressing human $LRP5^{G171V}$ construct show a similar phenotype with greater bone mass and strength than wild type mice as determined by whole bone testing. Whole bone quality, however, depend jointly on bone mass, architecture, and intrinsic bone tissue properties. To find if the HBM mutation affects tissue-level properties, we performed nanoindentation testing of fresh cortical bone from HBM mice and their nontransgenic (NTG) littermates. Femora from 17-week old (female, 8mice/genotype) mice were polished with multiple grain diamond cloths and subjected to nanoindentation using a Triboscope (Hysitron, Minneapolis, MN) and a diamond Berkovich tip. A series of indentations in fused quartz were used to calibrate the area function and machine compliance. Approximately 10 indentations were made on the femoral mid-shaft anterior surface with a target force of either 3 or 9 mN at a constant loading rate of 400 mN/s, including a preliminary thermal drift rate correction limited to a maximum of 0.05 nm/s. The 50% to 95% of the unloading curves was used for calculation of elastic properties. The load-displacement data from each test were used to calculate reduced indentation modulus and hardness for bone tissue. The bone modulus was 48% greater in the HBM than the NTG mice (Table). The greater

modulus in the HBM agrees with the previously reported greater bone mass/density, strength, and bone ash content, but go beyond the prior findings in that nanoindentation allows modulus to be determined independent of specimen size and geometry. Our data show that the G171V mutation increases the cortical bone modulus in adult female mice, in addition to the mutation's effect on bone mass. However, the impact of G171V mutation on trabecular bone intrinsic properties remains unknown in both genders. Moreover, mechanical performance includes many aspects in addition to modulus and hardness, including ductility, viscoelasticity, and fatigue behavior. Therefore, additional work is needed to explore these additional biomechanical properties in HBM mice and fully explain the role of WNT signaling in regulating bone mass and strength.

Intrinsic material properties of cortical bone in mice

	NTG	HBM
Modulus bone (GPa)	20.4 ± 5	30.2 ± 9.3 [a]
Hardness (GPa)	1.0 ± 0.4	1.1 ± 0.2

[a] P <0.05 as compared to NTG by Student's t test (mean ± SD)

Effect of Image Noise and Partial Volume Averaging on QCT-Derived Femoral Neck Strength Indices. M. Sode[1], J. Keyak*[2], T. Lang[1]. [1]Radiology, University of California, San Francisco, San Francisco, CA, USA, [2]Orthopaedic Surgery, University of California, Irvine, Irvine, CA, USA.

The cortical thickness (CTh) can be as low as 0.5mm at some portions of the femoral neck, which is below the spatial resolution available for in vivo CT imaging. The resulting partial volume averaging (PVA) errors cause underestimation of cortical BMD and overestimation of CTh, but the effects of PVA errors on femoral neck strength estimates are not well understood. We carried out a computer simulation to understand the effect of PVA errors on the accuracy of strength estimates and the variation of these errors over the range of bone size and density values typical of postmenopausal women. In these simulations, a computer program generated femoral neck cross-sections consisting of 2 nearly concentric ellipses that were shifted slightly off-center along their common major axis. Our computer model allowed us to vary the CTh, trabecular BMD, and cross-sectional area (CSA). We varied superior CTh from 0.2-1.0 mm, inferior CTh from 3.0-5.0 mm, trabecular BMD from 50-150 mg/cm^3 and CSA from 6-9 cm^2. To simulate CT imaging, the structures were blurred a spatial resolution of 2.0 mm FTWM, and Gaussian noise similar to noise of typical hip CT images was added to the images. We compared estimates of moments of inertia (Izz, Iyy, and Iyz), compressive and tensile stresses, and mean factor of safety (FOS) derived from the raw images (noBN) and the blurred, noisy images (BN). A bending moment 5.0 N was applied and FOS was calculated for each pixel as the strength/stress. The mean FOS calculated for the BN images consistently underestimated the true values. A similar trend was observed for the other parameters. This simulation provides an estimate of the magnitude and variability of accuracy errors introduced by PVA into CT-derived strength indices. Although they are lower, the calculated values are highly correlated with the true values. Further investigations will require use of realistic loading forces and cross-sectional shape models.

	Superior CTh [mm]	Inferior CTh [mm]	Trab BMD [mg/cm^3]	CSA [cm^2]	NoBN FOS	BN FOS	%ΔFOS = (NoBNFOS - BNFOS)/NoBNFOS
Osteoporotic	0.5	3.0	50	6.0	60.84	45.73	24.8%
Osteopenic	0.6	4.0	100	7.0	91.86	74.85	18.5%
Healthy	0.75	5.0	150	8.0	132.8	113.7	14.4%

Systematic Approach for Gene Screening within Discrete Compartments in the Growth Plate Using DNA Microarrays. S. Nishimori, J. Paruch*, H. M. Kronenberg. Endocrine Unit and Harvard Medical School, Massachusetts General Hospital, Boston, MA, USA.

DNA microarrays are powerful tools for gene screening, but the murine growth plates are too small for straightforward microarray that requires high yield and high quality of total RNA. Here we report a systematic approach using the Affymetrix® GeneChip®, which can examine 45,000 putative genes on one chip. To investigate the molecular underpinnings of the conversion of round chondrocytes to flat columnar and then to hypertrophic chondrocytes, we attempted to dissect cells from the three distinct chondrocyte layers in the proximal tibiae from new born mice. We chose manual microdissection of fresh-frozen tissues under an inverted microscope rather than Laser Capture Microdissection, to obtain as much total RNA as possible, to minimize the needed rounds of RNA amplification. After collecting all the samples from the pups belonging to one litter, total RNA was isolated using an RNeasy Mini® column (Qiagen) with DNase I treatment. Using 20 tibiae, we dissected 200-260 sections for each layer, and could extract 2.7-4.8 μg of total RNA from each layer. Analysis of RNA by capillary electrophoresis using the Bioanalyzer® (Agilent Technologies) showed total RNAs with little degradation. We repeated these procedures with two other litters to prepare independent triplicate samples. After one round of amplification using T7dT primer in the Affymetrix® protocol, we could obtain sufficient complementary RNA probes (more than 15 μg for one chip). 9 Mouse Genome 430 2.0 Arrays showed us the similar average signal intensities, very low backgrounds, and consistency between parameters for normalizing intensities on each chip. Using the Rosetta Resolver® Gene Expression Data Analysis System (Rosetta Biosoftware), we screened differentially expressed genes in each layer as follows, 793 genes for Round(R)/Flat (F)>2.0, 646 genes for F/R>2.0, 1005 genes for Hyper (H)/R>2.0, 1247 genes for R/H>2.0, 532 genes for F/H>2.0, and 586 genes for H/F>2.0. To narrow the list of candidate genes expressed preferentially in one layer or another, we performed real time (RT)-PCR for the second step of validation and *in situ* hybridization for the final step of validation. We found that signal intensities are as important as fold ratios, because genes with low signal intensities led to predictions sometimes not verified by RT-PCR. We are now picking up interesting genes which showed similar fold ratios in microarray and RT-PCR, for example, Nephroblastoma overexpressed gene (R/F/H=100/27/4), Carbonic anhydrase 3 (100/300/150), protease nexin I (R/F/H=100/200/400), etc. In summary, these procedures should prove useful for studying chondrocyte differentiation.

Osteoprotegerin Treatment Inhibits the Growth of Lytic Prostate Cancer Lesions in Bone. J. M. Blair[1], L. A. Perryman*[2], H. Y. Pwint*[2], J. Leliott*[2], J. De Winter*[1], P. Russell*[2], C. R. Dunstan[1], M. J. Seibel[1]. [1]Bone Research Program, ANZAC Research Institute, Sydney, Australia, [2]Oncology Research Centre, UNSW Clinical Medicine, Prince of Wales Hospital, Randwick NSW 2031, Sydney, Australia.

Prostate cancer (CaP) bone metastases, whilst typically osteoblastic, have a strong resorptive component. Therefore, we investigated whether osteoprotegerin (OPG) treatment inhibits tumour growth in a lytic CaP bone metastasis model. Male NOD-SCID mice aged 6-8 wks were injected with 4 x 105 PC-3-EGFP cells into the right tibia. Serum samples and radiographs were taken at the start, middle and end of each study. Sera were analysed for mouseTRAP 5b levels. Harvested tibias were analysed by immunohistochemistry to detect human cytokeratins. Controls were age-matched non-injected and sham-injected mice. In study 1, mice were randomised for x3/wk treatment with vehicle or 1 mg/kg OPG starting at wk 0 (prophylaxis) or wk 2 (delayed treatment). In study 2, vehicle or 3 mg/kg OPG treatment x3/wk began at wks 1 (early), 0 (late) or 2 (delayed) (n=6-7 mice/ group): endpoint sera in study 2 were also analysed for osteocalcin levels. Osteolytic tumours were radiographically apparent in all vehicle-treated mice at wk 6. In study 1, OPG-treated mice had smaller osteolytic tumours and decreased serum mouseTRAP 5b levels in the prophylaxis group versus the vehicle-treated mice. In the delayed treatment arm, OPG treatment partially inhibited tumour growth and reduced serum mouseTRAP 5b levels when compared with vehicle control at wk 6. In study 2, early OPG mice had little evidence of tumor and had extended calcified growth plates; late OPG mice displayed little tumor growth; and, delayed OPG mice had small discrete tumors that did not breach the cortex. When compared with their respective vehicle controls, bone resorption was inhibited in early OPG mice (wk 1, $p<0.0001$; wk 2, $p=0.0137$; wk 6, $p<0.0001$), late OPG mice (wk 2, $p<0.0001$; wk 6, $p=0.0002$) and delayed OPG mice (wk 2, $p=0.0210$; wk 6, $p<0.0001$). Serum osteocalcin was significantly decreased in late and delayed OPG mice ($p<0.0001$ and $p=0.0017$, respectively) when compared with respective vehicle controls. All tumors were positive for anti-human pan-cytokeratin antibody. In conclusion, OPG treatment reduced bone resorption from the time treatment was initiated. Study 1 results suggested that low resorption levels were sufficient for PC-3-EGFP cells to establish and grow in bone, and that a higher OPG dose was required to inhibit PC-3-EGFP tumor growth in bone. Although low levels of bone resorption were still detected in study 2, 3 mg/kg OPG effectively inhibited prostate cancer induced osteolysis and tumor growth.

Functional and Anatomical Imaging Allows for More Sensitive Monitoring of Tumor Burden and Osteolysis in a Mouse Model of Breast Cancer Metastasis to Bone . J. A. Sterling, B. Goins*, B. Grubbs*, M. Amurao*, C. Zavaleta*, A. Soundararajan*, Z. Wang*, W. Phillips*, B. Oyajobi, G. Mundy, S. S. Padalecki. UT Health Science Center, San Antonio, TX, USA.

The skeleton is the most common site of metastasis in breast cancer patients. We have hypothesized that once established in the skeleton, breast tumors induce a vicious cycle in which tumor produced factors stimulate bone resorption resulting in release of growth factors from bone further stimulating tumor growth and osteolysis. We have utilized a well-established mouse model of breast cancer metastasis to bone to identify molecular targets for the development of therapeutics. We have previously tested this hypothesis, monitoring bone metastases using standard radiography and bone histomorphometry. Osteolytic lesions are visible by radiography approximately 14-21 days after tumor cell inoculation via the left cardiac ventricle. Although tumors are well established at this time point, there are skeletal sites which cannot be visualized by radiography. Furthermore, it is not possible to monitor tumor burden in bone in living animals throughout the course of the experiment with these techniques. To better understand the relationship between tumor burden and osteolysis, we have used more sensitive techniques. In breast cancer patients, ^{18}FDG PET scans and ^{99m}Tc-MDP SPECT are used to track tumor growth, bone metastases and response to therapy. We hypothesized that ^{18}FDG MicroPET scans and ^{99m}Tc-MDP MicroSPECT with MicroCT anatomical co-registration would allow us to detect tumors at earlier time points, detect smaller bone metastases than by radiography alone, and more thoroughly test the vicious cycle hypothesis. Here, we present the first use of MicroPET, MicroSPECT/CT to track tumor burden and bone metastases in this model. Using this model, tumor in bone was detected as early as 7 days post tumor cell inoculation using ^{18}FDG MicroPET, 7-days earlier than by radiography. In addition, ^{99m}Tc-MDP uptake was decreased in mice with more severe osteolytic lesions. Furthermore, we were able to detect osteolytic lesions by MicroCT that would otherwise have been undetectable by radiography because of their size and by histological methods because of their site. For example, multiple lesions in the scapula can be seen that were not visible by faxitron. These techniques are a better measure of tumor burden than traditional histologyallowing for monitoring of tumor burden throughout the course of metastasis. This approach will

enhance the utility of this model of as it will allow monitoring of changes in and correlations between tumor burden and osteolysis in mice bearing breast tumors with various manipulations.

^{41}Ca Non-Invasively Identifies at High Sensitivity Skeletal Perturbations from Bisphosphonate Therapy and Metastatic Bone Disease. D. J. Hillegonds*[1], D. W. Burton*[2], R. L. Fitzgerald*[2], E. Denk*[3], T. R. Walczyk*[3], L. J. Deftos*[2], J. S. Vogel*[1]. [1]Lawrence Livermore National Laboratory, Livermore, CA, USA, [2]San Diego Veterans Administration Healthcare System and University of California, San Diego, CA, USA, [3]Swiss Federal Research Institute (ETH), Zurich, Switzerland.

The goal of this project is to develop ^{41}Ca as a clinical tool for staging and monitoring skeletal tumor growth, assessing response to therapy, and detection of bone metastasis. We hypothesize that high precision assessment of bone turnover will enable improved clinical management in disorders affecting calcium metabolism. Following administration of a radiologically benign ^{41}Ca dose, body-wide ^{41}Ca/Ca quickly decreases as the tracer is cleared from small and fast calcium pools, concentrating in the skeleton, from which it is slowly re-released. Due to low natural abundance (<10^-15), ^{41}Ca remains above quantitation limits of accelerator mass spectrometry (AMS) for many years following a single <1ug dose. Low natural ^{41}Ca/Ca variability (<10%) facilitates detection of small perturbations in bone turnover. We measured urinary ^{41}Ca/Ca in 6 osteopenic postmenopausal women on weekly risedronate in a study conducted at ETH. Results show a consistent ^{41}Ca/Ca decrease (53±9)% (mean±SD) from baseline that is significant at each post-intervention measurement, making ^{41}Ca more sensitive than available biomarkers. We have also completed a preclinical study in 50 immunocompromised mice injected intra-tibially with a green fluorescent protein-expressing human prostate cancer cells (PC3-GFP) two weeks after an IP ^{41}Ca dose. Five groups were treated monthly with vehicle or one of four bisphosphonates; six weeks later lesions were assessed via fluorometry and X-rays. AMS analysis showed high correlation of ^{41}Ca/Ca and serum PTHrP, [Ca^{2+}], and fluorimetry; animals with low bone destruction (via X-ray) had significantly lower serum ^{41}Ca/Ca. We have demonstrated that urinary ^{41}Ca/Ca is consistently and significantly depressed from baseline with weekly risedronate in individual research subjects, making the ^{41}Ca assay the most sensitive available marker of bone turnover. We have also shown that serum ^{41}Ca/Ca identifies bone destruction and cancer proliferation in a preclinical model of metastatic prostate cancer.

Skeletal Effect of Exemestane in Patients with Breast Cancer. L. Banks[1], S. Girgis[1], R. Coleman*[2], L. Porter*[3], G. Baffoe*[1], D. Price*[3], E. Hall*[3], J. Bliss*[3], C. Coombes*[1]. [1]Imperial College, London, United Kingdom, [2]Weston Park Hospital, Sheffield, United Kingdom, [3]Institute of Cancer Research, Sutton, United Kingdom.

Tamoxifen (T) preserves bone in post menopausal women with primary breast cancer but use of non-steroidal aromatase inhibitors (AI) can accelerate bone loss & increase fracture risk. Pre-treatment with T, coupled with possible anabolic effects of the steroidal AI exemestane (E) may lead to fewer adverse effects than up-front non-steroidal AI. In the IES, 4724 postmenopausal women with primary breast cancer, disease-free following 2-3 yrs T, were randomised to further T or E to complete a total of 5 yrs adjuvant endocrine therapy. We report results, up to 12 months, of the bone sub-protocol aimed to assess changes in bone density (BMD) & bone turnover during & after 2 yrs of stopping randomised treatment. 206 randomised IES patients (100E, 106T) with no evidence of osteoporosis or osteoporotic fracture, evaluable BMD measurements & not taking medication known to affect BMD participated in the bone sub-protocol. Lumbar spine & hip BMD measurements were assessed by dual-energy x-ray absorptiometry at pre-randomisation, 6 & 12 months. Serum & urine samples were collected pre & at randomisation, 3, 6, 9 & 12 months, for analysis of biochemical markers of bone turnover: urinary NTX & DPD, serum CTX, bone ALP, OC & PICP. At randomisation, the T & E groups were comparable with respect to patient demographics, BMD & bone markers. At 12 months a significant difference in the mean BMD percent change from randomisation was seen between the E & T groups (lumbar spine: -3.05% (95%CI: -4.09 to -2.01) p<0.0001; total hip: -1.56% (95% CI: -2.32 to -0.79) p=0.0001). Within the E group, a reduction was seen in lumbar spine & total hip BMD's [3.2 % (95% CI: 2.5 to 4.0) & 2.1% (1.6 to 2.7) respectively]. Significantly less change was seen within the T group [spine= -0.2% (-0.9 to 0.5), hip= -0.6% (-1.1 to -0.03)]. Difference in median % change of all bone markers from randomisation to each follow-up assessment was statistically significant between the E & T groups (p<0.0001, except for PICP p=0.002 at 3 months). At 12 months, there was a significant negative correlation between % change in lumbar spine BMD & % change in each of the bone markers (p<0.0001, except for CTX p=0.0002). Similar negative correlations were seen with total hip BMD (p<0.0001 for OC, p=0.0003 for CTX, p=0.001 for DPD, NTX & bone ALP, p=0.03 for PICP). In contrast to T, E has a significant effect on bone with BMD loss consistent with other AI's. Observed changes could be due to dual effects of T withdrawal & E treatment. Comparison of post treatment data will help elucidate this relationship.

Mevalonate Inhibition by Lipophilic Statin Induces Apoptosis in Human Prostatic Cancer Cells. V. Thoreau*[1], A. Kitzis*[1], P. J. Marie[2], F. Debiais[3]. [1]LGCM CHU Poitiers and UMR 6187 CNRS, Poitiers, France, [2]Inserm U 606, Lariboisiere Hospital, Paris, France, [3]Department of Rheumatology, CHU, Poitiers, France.

Prostate cancer is the most common malignancy and a leading cause of male cancer deaths. Additionally, prostate cancer cells frequently metastasize to the bone marrow, resulting in significant mortality. Among possible mechanisms, dysregulation of apoptosis may play a role in the development of prostate cancer and metastatic process. Agents that promote malignant cell apoptosis may therefore help to develop new therapeutic strategies for prostate cancer. Inhibitors of 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase were found to trigger apoptosis in soft tumor cells in vitro. In this study, we analysed the effects of a lipophilic statin (atorvastatin) and hydrophilic statin (pravastatin) (kindly provided by Bristol-Myers Squibb, USA) on apoptosis in androgen-independent human prostate cancer cells (PC3) and less-malignant, androgen-dependent LNCaP cells. Prostate cancer cells were treated with atorvastatin or pravastatin, at concentrations ranging from 0.1 to 100 µM. Apoptosis was determined by terminal deoxynucleotidyl transferase-mediated nick-end labeling (TUNEL) analysis, and annexin V binding and propidium iodide incorporation were analyzed with flow cytometry. Treatment with atorvastatin (10 µM) significantly increased by 50 % the number of TUNEL-positive prostatic cells (p <0.01) and the number of annexin V-positive apoptotic cells at 48 hours. Similar results were obtained with LNCaP cells. This pro-apoptotic effect occured through stimulation of caspase-3 activity, as atorvastatin increased caspase-3 activity by about 50 % (p <0.001) at 48 hours. In contrast, no pro-apoptotic effect was observed with pravastatin on these cell lines. Pre-treatment with mevalonate prevented the effects of atorvastatin on apoptosis. Pre-treatment with geranylgeranylpyrophosphate (GGPP), but not farnesylpyrophosphate (FPP), also significantly decreased atorvastatin-induced apoptosis in PC3 cells. These results show that inhibition of mevalonate pathway by the lipophilic statin atorvastatin induces human prostatic cancer cell apoptosis by a mechanism involving caspase-3 activity. This suggests that some statins may be used for controlling prostate cancer cell growth and reduce progression to bone metastasis.

Msx2 Antagonizes Runx2 Regulation of Osteolytic Activity in Breast Cancer Cells. G. L. Barnes[1], D. Buczak*[1], J. Renz*[1], A. Javed[2], J. B. Lian[2], G. S. Stein[2], L. C. Gerstenfeld[1]. [1]Orthopaedic Surgery, Boston University Medical Center, Boston, MA, USA, [2]Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA.

Recent studies from our laboratory have demonstrated that human breast cancer cells express the transcription factor Runx2, a central regulator of skeletal cell differentiation. We further showed that Runx2 regulated the ability of breast cancer cells to disrupt the normal balance of bone cell differentiation and the generation of osteolytic lesions in bone. One of the known co-regulatory proteins of Runx2 activity in osteoblasts is the Msx2 homeodomain factor. We have reported that in breast cancer cells Msx2 acts as a negative regulator of the expression of bone sialoprotein, a Runx2 regulated extracellular matrix molecule whose expression is highly correlated with skeletal metastasis in a number of cancers including breast, prostate and lung. The current studies examined the functional relationship between Runx2 and Msx2 in metastatic breast cancer cells. Highly aggressive MDA-MB-231 and LCC15-MB breast cancer cells express low to undetectable levels of Msx2 while low aggressive MCF-7 cells express high levels. This expression pattern is inversely correlated with both the aggressiveness of the individual cell lines and endogenous level of Runx2 expression. In addition, we found that when Runx2 function in MDA-MB-231 cells is disrupted by over-expression of a dominant negative mutant of Runx2 (C-terminal deletion of Runx2) Msx2 expression was markedly increased. In order to further analyze the function of Msx2 in breast cancer mediated osteolysis we have generated MDA-MB-231 based cell lines that over-express Msx2. Co-culture of these cells with bone derived marrow stromal cells (MSCs) demonstrated that over-expression of Msx2 partially rescues the imbalanced bone cell differentiation generated by breast cancer cells. Unlike control MDA-MB-231 cells, Msx2 over-expressing MDA-MB-231 cells do not inhibit osteoblast differentiation as determined by osteoblast associated mineralized nodule formation and the expression of the osteoblast marker genes. However, MSC co-cultured with Msx2 over-expressing MDA-MB-231 cells do express increased levels of the pro-osteoclastogenic cytokines RANKL, M-CSF and TNFα similar to control breast cancer cells. Taken together these data demonstrate a functional relationship between Runx2 and Msx2 in breast cancer cells and support the conclusion that Msx2 acts as a negative regulator of Runx2 functions involved in the generation of osteolytic lesions in bone.

The Runx2 Transcription Factor Supports Expression of Genes Coupled to the Invasive and Osteolytic Properties of Breast Cancer Cells. J. Pratap[1], A. Javed[1], G. L. Barnes[2], L. C. Gerstenfeld[2], M. Breen*[1], A. J. van Wijnen[1], J. L. Stein*[1], L. R. Languino*[3], G. S. Stein[1], J. B. Lian[1]. [1]Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA, [2]Department of Orthopaedic Surgery, Boston University Medical Center, Boston, MA, USA, [3]Department of Cancer Biology, University of Massachusetts Medical School and Cancer Center, Worcester, MA, USA.

Breast cancer (BC) cells metastasize to bone resulting in its destruction. Secreted factors from BC cells are known to disturb the balance between osteoblast and osteoclast activities, but the transcriptional mechanisms responsible for induction of factors that cause osteolytic lesions are poorly understood. We and others have demonstrated that Runx2 is upregulated in bone metastatic cancer cells compared to primary tumor cells. Here we addressed the role of Runx2 in the cancer cell by generating MDA-MB-231 BC cells stably expressing a Runx2 mutant (mRunx2) protein. Because mRunx2 protein blocks in vivo osteolytic activity of the parental MDA-MB-231 expressing wild type Runx2, we hypothesized that Runx2 contributes to cancer cell metastasis through expression of Runx target genes. Gene profiles of BC cells expressing wild type and mRunx2 revealed VEGF and several MMPs (matrix metalloproteinases) including MMP9, a key metastatic marker, are downregulated in the mRunx2 cells. We show here MMP9 is a novel Runx2 target gene by chromatin immunoprecipitation and EMSA studies and by loss of Runx2 mediated transcription after induction of a point mutation of a Runx site in the MMP promoter. Forced expression of Runx2 upregulates MMP9 promoter activity, indicating that Runx2 is a potent activator of the MMP9 gene. In addition, microarray data identified changes in expression of cytokines and integrins in the mRunx2 cells that suggests a less invasive and less osteolytic phenotype. To establish that Runx2 levels are related to metastasis, we performed Matrigel invasion assays. Cell invasion of the non-metastatic MCF-7 line was induced 3-fold upon Runx2 adenovirus mediated expression which also induced VEGF and MMP9. Depletion of Runx2 in metastatic MDA-MB-231 cells with siRNA results in significant decrease in endogenous MMP9 and other Runx2 target genes and decreases cell invasion by 65%. In conclusion, we identified MMP9 as a novel Runx2 target gene and demonstrated that Runx2 expression is directly correlated with invasive properties of bone metastatic breast cancer cells. These findings indicate that Runx2 plays an important role in modulating cancer cell invasion by regulating the expression of target genes implicated in bone metastases.

The Effect of Bisphosphonates on Gene Expression: The GAPDH as a Housekeeping or a New Target Gene? F. Bertoldo*[1], M. Valenti*[1], L. Dalle Carbonare*[1], M. Zanatta*[1], S. Zenari*[1], Z. Carandante*[1], O. Vinante*[2], V. Lo Cascio[1]. [1]Biomedical and Surgical Sciences, University of Verona, Verona, Italy, [2]Oncologia Medica, Ospedale di Noale, Noale, Italy.

The employment of the RT-PCR method has been widely used for the analysis of gene expression in many systems, including tumor samples. The GAPDH (Glyceraldehyde-3-phosphate dehydrogenase) has been commonly considered as a constitutive housekeeping gene to normalize the specif gene expression. However the GAPDH has been shown to be upregulated in cancer. Bisphosphonates (BPs), synthetic analogs of pyrophosphate, are potent inhibitors of bone resorption and recently an antitumor effect has been shown in vitro and in animal models by inhibition of the mevalonate pathway. Furthermore BPs has been shown to modulate many gene expression not only in osteoclasts but also in cancer cells. The aim of this study was to evaluate GAPDH gene expression by real time RT PCR (Applied Biosystems) in different breast (MCF-7 and T-47D) and prostate cancer cell lines (PC-3 and DU-145) lines (purchased from ATTC Rockville, MD, USA). treated with amino and non-amino bisphosphonates (clodronate, pamidronate, alendronate and zoleronate) to exclude, if any, effects of BPs on GAPD mRNA expression, and to explore the suitable of GAPDH as housekeeping gene in gene expression studies. Cells were treated for 48 h with BPs with doses of 10, 50 and 100 μM . For each concentration three experiments were performed. The housekeeping gene B2M was used to normalized GAPDH mRNA expression. Our results show a significant dose-dependent downregulation of GAPDH gene expression after treatment of different cancer cells line with different amino-BPS. Zoledronate resulted the most powerfull bisphosphonate, whereas Clodronate, a non-amino BP, exerted significant effect on GAPDH expression only with the highest concentration tested. In conclusion, the use of GAPDH as a control gene, in particular in studies investigating the effects of BPs on bone or cancer cells, should be inappropriate and RT PCR data on the effects of BPs in cancer cell should be reviewed, utilizing a different house keeping gene, i.e. B2M.On the other hand, this gene could be considered as a novel target gene for BPs on cancer cells.

p65 Subunit Is Essential for Osteoclastogenic Factors Expression in Breast Cancer Cells. C. Menaa, A. Abdouelaziz*, S. Sprague. Medicine, Evanston Northwestern Healthcare, Evanston, IL, USA.

Bone metastases are a frequent complication in patients with advanced breast cancer (BC). This is related to the process by which tumor cells metastasize; that involves adhesion, migration, and induction of osteoclast (OC) formation. How tumor cells acquire these capacities and the mechanisms involved are not yet identified. However, it is known that tumor cells are the source of factors involved in bone metastasis, bone resorbing factors (BF). Previous studies have highlighted the role of NF-κB as potential signaling pathway critical for BC cell viability. Specifically, NF-κB has been reported to be responsible for cell transformation, death resistance, and motility. In addition, constitutive activity of NF-kB has been recorded in BC. During last year meeting we reported that NF-κB activity is the key pathway involved in BC cells' capacity to secrete osteoclastogenic factors, a key element for bone metastasis. We also showed that IkB kinase complex is involved in this process. Now, which subunits are involved in such activity and what triggers the Ikks complex activity is yet to be analyzed. Five members of NF-κB family have been described: p50/p105, p52/p100, Rel A (p65), Rel B and c-Rel. The classical complex involved into transcription activity is p65/p50 complex where only Rel bears transcription activity. Furthermore, previous studies demonstrated the abnormal nuclear translocation of RelA in cancer cells. Thus, the role of p65 in BF in BC cells was examined. Stable cell lines, MCF7 and MDA-MB-231, over-expressing p65 dominant negative where transctivation domain (c-terminal) was deleted (p65RHD) were developed. We found the absence of p65 activity blocks basal and activated NF-κB as reported by luciferase reporter gene assay following TNF-α stimulation. Condition media harvested from these lines do not support OC formation compared to the WT type cells. The absence of BF factors was not related to a reduction into cell proliferation but rather a specific blockage BF expression. Further analysis in the upstream signaling pathway demonstrate that Ikks complex is required for p65 translocation and transcription activity and more importantly the TAK/TAB complex is the module that regulates this complex and is involved into BF production by BC cells. In summary, we found that p65 subunit plays a key role into NF-κB activity controlling BF production by BC cells. In conclusion, these data establish the role p65 subunit of the NF-κB in bone metastasis in BC. Thus, RelA could be a suitable therapeutic target for bone destruction in BC.

Estren Is Devoid of Proliferative Effects on Hormone-Dependent Human Breast and Prostate Cancer Cells and Counteracts the Mitogenic Effects of 17β-Estradiol (E_2) or Dihydrotestosterone (DHT). P. Yang, S. Kousteni, S. C. Manolagas. Div. of Endocrinol., Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Affairs Healthcare System, Univ. Arkansas Med. Sci., Little Rock, AR, USA.

It was reported earlier that, unlike E_2, 4-estren-3α,17β-diol (estren) does not stimulate breast cancer cell proliferation. However, the potency of estren on a variety of kinase-mediated (nongenotropic) *in vitro* actions on bone cells is either similar or far greater than that of E_2 or DHT at equimolar concentrations. This is in spite of the fact that estren has 300-fold lower affinity for the estrogen receptor (ER) in conventional equilibrium binding assays, compared to E_2; and estren also binds to the androgen receptor (AR) with an affinity that is approximately 1/40 that of R1881 or 1/25 that of DHT. Because of reports suggesting that the effects of estren may result from its ability to activate classical genotropic actions of the ER and/or the AR, we have compared the effects of estren to those of E_2 or DHT on human breast and prostate cancer cell lines, respectively. Estren (10^{-12} to 10^{-8} M), unlike E_2, had no effect on the proliferation of two ER positive breast cancer cell lines, MCF-7 and T47D. Moreover, when added to the cultures in the presence of the maximal mitogenic dose of E_2 (10^{-8} M), estren dose-dependently attenuated the proliferative effect of E_2. Consistent with the distinct biologic effect, whereas E_2 had a transient stimulatory effect, estren induced sustained ERK phosphorylation. Furthermore, whereas E_2 (10^{-8} M) induced the association of the p85 subunit of PI3K with the ER as well as the phosphorylation of the epidermal growth factor receptor (EGFR) and Akt, estren not only lacked these activities, but it opposed the E_2-induced changes. In difference to estren, DHT could not reverse the effect of E_2 on EGFR or PI3K/Akt phosphorylation. Likewise, in sharp difference from DHT or the androgenic metabolite 19-nortestotsterone, estren (10^{-12} to 10^{-8} M) not only did not affect the proliferation of the LNCaP prostate cancer cell line, but it antagonized the effects of DHT. We conclude that at least some of the effects of estren cannot be accounted for by classical genotropic actions through the ER or the AR. In addition, we propose that the distinct biologic profile of estren on hormone-dependent breast and prostate cancer cells may result from the activation of distinct signaling cascades that perhaps counteract those activated by classical ER or AR ligands, probably by recruiting distinct partners to the ER/kinase signalsomes.

Short- and Long-Term Precision of GE Lunar Prodigy and Hologic Delphi Scanners. T. N. Hangartner. BioMedical Imaging Laboratory, Wright State University, Dayton, OH, USA.

Whereas short-term precision is important in setting a lower bound on accuracy of a dual-energy absorptiometry instrument, long-term precision is particularly relevant in the assessment of follow-up scans done years later. The goal of this study was to determine the short- and long-term precision of GE Lunar Prodigy and Hologic Delphi scanners. As part of the daily quality assurance, a phantom containing four blocks of bone-like material, embedded in water-equivalent plastic and covering a density range from 0.45 to 2.9 g/cm^2 (Hologic units) was measured over a 3.5 year period. These BMD values span the range seen in images of common spine and hip scans. The plane areas of the blocks were evaluated by sub-region analysis on two GE Lunar Prodigy and two Hologic Delphi scanners. All scanners were stable over time periods between service events, and the data collected during these periods were used to calculate the short-term precision. For both Delphi scanners, the short-term precision was better than 0.6% for densities larger than 1 g/cm^2; for the Prodigy scanners it was better than 0.7% for the two mid-sized blocks and 0.8% for the largest block. The precision error of the thinnest block was about 1.2% for all scanners. The long-term performance of all scanners was influenced by necessary recalibrations, as all scanners were moved to new locations during the observation period,

as well as regular scanner maintenance. The Delphi scanners showed no break points in the phantom data, only a very small but significant drift of 0.08% per year change in BMD. One of the Prodigy scanners showed changes between service events of -2.1%, -1.6%, -0.4%, -0.4% and 0.0%, resulting in a cumulative change of -4.5% compared to baseline. The other Prodigy scanner showed a +0.5% and a +1.0% change due to service events, resulting in a cumulative 1.5% change. Based on this small sample of scanners, the short-term precision is similar between Prodigy and Delphi scanners; however, the long-term precision is considerably worse for the Prodigy scanners.

Imprecision of Whole Body DXA Measurements: Implications for Interpretation of within Person Changes in Fat, Lean and Bone Mass in Obese and Non-Obese Children. K. S. Wosje, B. Knipstein*, H. J. Kalkwarf. Division of Gen & Comm Peds, Children's Hospital Med Ctr, Cincinnati, OH, USA.

Supervision of children undergoing intervention to combat obesity requires clinicians to appropriately interpret within person data on changes in fat, lean and bone mass. Assumptions inherent to DXA measurement of body composition might lead to greater within person variance (imprecision due to instrument error) in obese than nonobese because of increased tissue thickness. We determined imprecision of whole body (WB) fat, lean and bone mass measurements in obese (n=32) and nonobese (n=34) children (6-19 y) using Hologic QDR 4500. We used the imprecision data to calculate the within person changes in fat, lean and bone mass that are necessary to ensure that those changes are unlikely to be a consequence of instrument error; these are termed least significant changes (LSC) and are expressed in absolute (kg) or relative (%) terms. Subjects received 2 WB DXA scans, with repositioning, and ht, wt, and abdominal thickness (abd thk) measurements. Imprecision was calculated as kg and % for fat, lean and bone mass by finding the root mean square average of within person SD (SD_w) for obese and nonobese. We calculated absolute and relative LSC values as 1.96*1.414*imprecision. We used linear regression to examine the association between SD_w (fat, lean or bone) and wt, fat mass, % fat, and abd thk. Obese and nonobese did not differ in age (12.7±3.2 y), ht (155±15 cm), or bone mass (2.0±0.6 kg). BMI %ile for age and sex was ≥96% for obese and 22-84% for nonobese. Expressed in kg, the LSC for fat and lean were 3.3 and 2.8 times higher, respectively, for obese [1.39 kg (fat), 1.30 kg (lean)] than nonobese [0.42 kg (fat), 0.47 kg (lean)]. Expressed as %, the LSC for fat was 1.5 times lower for obese (3.6%) than nonobese (5.2%), but the LSC for lean was 2.0 times higher for obese (2.6%) than nonobese (1.3%). Bone mass LSC values for obese and nonobese were 61 and 49 g, and 2.9% and 2.9%, respectively. There was a positive relationship between SD_w for fat mass and wt (R^2=0.24), fat mass (R^2=0.24), % fat (R^2=0.13), and abd thk (R^2=0.23) (all p<0.01). There was also a positive association between SD_w for lean mass and wt (R^2=0.26), fat mass (R^2=0.26), % fat (R^2=0.17), and abd thk (R^2=0.27) (all p<0.001). The positive association between SD_w for bone mass was significant for wt (R^2=0.08), fat mass (R^2=0.26), and abd thk (R^2=0.08) (all p<0.05), but not % fat (R^2=0.04, p=0.12). This study suggests that imprecision of DXA fat, lean and bone mass measurements increases with adiposity, but LSCs are low for both obese and nonobese. It is important to view imprecision in both absolute and relative terms. We speculate that body size of obese persons inhibits ideal positioning for WB DXA.

Correlation of Plain Radiographic Indices of the Hip with Bone Mineral Density. J. Glowacki[1], A. P. Sah*[1], T. S. Thornhill*[1], M. S. LeBoff[2]. [1]Orthopedic Surgery, Brigham and Women's Hospital, Boston, MA, USA, [2]Medicine, Brigham and Women's Hospital, Boston, MA, USA.

The plain hip radiograph is one of the most widely used diagnostic tools in the orthopedic evaluation of hip pathology. T-scores by dual energy x-ray absorptiometry (DXA) and serum 25-hydroxyvitamin D levels were available from a previous study with postmenopausal osteoarthritic women presenting for total hip arthroplasty. We had previously reported that 25% of those subjects had occult osteoporosis by DXA and that 22% were vitamin D-deficient. The purpose of this study was to test the hypothesis that radiographic interpretation of osteoporosis by routine hip x-rays is correlated with bone mineral density. It was our aim to determine the relationships of T-score and serum level of 25-hydroxyvitamin D with radiographic parameters that assess bone geometry and structure at the hip. Pre-operative radiographs of postmenopausal women undergoing total hip arthroplasty for advanced osteoarthritis were studied. Radiographic parameters including Singh index, Dorr classification, canal-to-calcar ratio, and cortical thickness indices were measured and compared with T-score at the femoral neck and with serum vitamin D status. Pre-operative radiographs were available for 37 subjects and included 17 Dorr type A (funnel-shape canal), 14 type B, and 6 type C (stovepipe-shape canal) femurs. These three types showed significantly different canal-to-calcar ratios and cortical thickness indices (p<0.007). The median T-score at the femoral neck for type A bone (-0.415, p<0.02) was significantly higher than that of types B (-1.935) and C (-2.370) (Figure). Cortical thickness indices were correlated positively with T-score (p<0.005). Neither Singh grading nor canal-to-calcar ratios were correlated with T-score. With the numbers available, there was no relationship between vitamin D-deficiency and the radiographic parameters. DXA is not routinely performed prior to total hip arthroplasty, but was available for our study group of osteoarthritic women. Analysis of radiographic parameters of the hip and T-score at the femoral neck revealed several significant correlations. These radiographic measurements are easily obtainable from routine hip radiographs and provide information useful for diagnosis, treatment, pre-operative planning, and referral for DXA and osteoporosis management.

Estimated Volumetric Bone Mineral Density in a Rural Thai Men and Women: Khon Kaen Osteoporosis Study (KKOS). C. Pongchaiyakul*[1], T. V. Nguyen*[2], C. Foocharoen*[3], R. Rajatanavin*[4]. [1]Division of Endocrinology, Department of Medicine, Faculty of Medicine, KKU, Thailand, [2]Garvan Institute of Medical Research, Sydney, Australia, [3]Division of Rheumatology, Department of Medicine, Faculty of Medicine, KKU, Thailand, [4]Division of Endocrinology, Department of Medicine, Faculty of Medicine, MU, Thailand.

We examined the areal bone mineral density (aFNBMD) and volumetric bone mineral density at the femoral neck (vFNBMD) in rural Thai men and women. A total of 181 men and 255 women, between 20 and 84 years of age, living in rural areas of Khon Kaen province, were randomly selected. Areal FNBMD and estimated vFNBMD were determined using dual energy X-ray absorptiometry (DPX-IQ, GE Lunar Corp, Madison, WI). Men had a significantly higher aFNBMD than women, whereas the vFNBMD was similar regardless of sex. The peak for the aFNBMD *vs*. vFNBMD was observed between 20 and 29 *vs.* 30 and 39 years of age in men and women, respectively. The prevalence of osteoporosis in men and women using estimated vFNBMD *vs*. aFNBMD cut-offs was 19 and 14.2 *vs.* 11.8 and 26 percent, respectively. Prevalence increased with age. Volumetric BMD shows only small sex-correlated differences in bone density. Estimated volumetric BMD was more sensitive than areal BMD, when used to define the osteoporotic cut-offs in men, while it was less sensitive than areal BMD in women.

Fat Mass Measured by DXA and Risk of Cardiovascular Disease: Preliminary Results. S. R. Eis[1], S. A. Barros*[2], R. R. Machado*[1], B. Albergaria*[1], E. J. Moana*[1], J. C. Borges[3]. [1]CEDOES, Vitoria - ES, Brazil, [2]LABIOM, UFES - Vitória (ES), Brazil, [3]Universidade Católica de Brasília, Brasília, Brazil.

Cardiovascular disease (CVD) is one of the most important cause of death and morbidity around the world. In particular, body fat distribution has been shown to be an important predictor of risk of CVD. The details and the exact mechanism of how intra-abdominal obesity leads to these conditions is not completely known. Several studies have used DXA technology to provide a more direct measure of fat distribution than that provided by other methods such as anthropometric measurements. The purpose of the study was to evaluate the applicability of fat mass measured by DXA at the total body as well as the ratio between two standardized areas (Android and Ginoid) measured at the waist and the hip, respectively, as predictors of CVD. We evaluated 63 over weighted postmenopausal women with Body Mass Index (BMI) between 25 and 29.9, and divided into two groups as follows: (A)Disease group: 28 women (mean age 62,3 ± 2 and mean BMI 26.9 ±1.2) with recent diagnosis of coronary heart disease (CHD), established not more than 90 days before the evaluation date and (B)Control Group: 35 women (mean age 63,1 ±2 and mean BMI 26.0 ± 1.0) without such diagnosis. The study was approved by the local Ethics Committee and all subjects gave their written informed consent prior to their participation in this study. All women were submitted to a Total Body Densitometry scan, using a Prodigy (GE-Lunar, Madison USA) densitometer, and the scans were analyzed using the Encore® software version 9.15, 2005. A blood sample was collected and a biochemical panel was obtained from all subjects to evaluate other parameters related to the risk of cardiovascular disease.
Table 1 summarizes the results for some of the measured parameters.

Group	Cholesterol(95%CI)	%Fat Mass Total Body (95%CI)	%Fat Mass Android Region (95%CI)	% Fat Mass Gynoid Region (95%CI)	A/G Ratio
A	223 (182-267)	44.1% (40.3-46.2)	45.9 (42.8-47.3)	40.2 (38.7-42.8)	1.14*
B	192 (176-215)**	40.2% (38.2-42.1)	39.5 (36.2-42.1)	42.1 (39.8-43.4)	0.93

**(p<0.05) *(p<0.02)
Cholesterol values were significantly higher in the CVD group vs. controls (p<0.05). There was no significant difference between the CVD and control groups for %fat at the total body, android, or gynoid regions. However, the Android/Gynoid Ratio as defined by DXA analysis was a significant predictor of CVD (p<0.02) in this group of overweight postmenopausal women. Further study is needed to confirm these results in larger groups and in different populations, as well as to determine the cutoff level that could perhaps identify increased risk of CVD.

Recent Calcium Tablet Ingestion: Impact on Lumbar Spine Bone Mineral Density Measurement. D. Krueger[1], M. Checovich[1], D. Gemar[1], X. Wei*[2], N. Binkley[1]. [1]University of Wisconsin Osteoporosis Clinical Research Program, Madison, WI, USA, [2]Biostatistics and Medical Informatics, University of Wisconsin, Madison, WI, USA.

It is common for densitometry centers to require that patients abstain from ingesting calcium supplements prior to DXA examination to avoid interference with BMD measurement. However, it is not clear that this practice is important or necessary. This study assessed the impact of recent calcium supplement intake on lumbar spine BMD measurement and evaluated the frequency with which tablets are visualized on a DXA image. In this study, 36 subjects (3 male/33 female), mean age 66 years, received baseline and two subsequent spine scans using a GE-Lunar Prodigy densitometer. Subjects were randomly assigned to ingest one calcium tablet: Citracal (315 mg), OsCal (500 mg) or People's Choice (600 mg). Follow-up scans were performed 15 and 30 minutes after tablet ingestion. The three study groups were not different in age or BMI, however the L1-4 BMD was lower ($p < 0.05$) in the People's Choice group compared to the Citracal group. Specifically, the mean L1-4 T-score was -1.6, -1.1 and -0.1 in the Citracal, Oscal and People's Choice supplement groups respectively. The change in L1-4 BMD on repeat scans in this study was compared to the changes observed in a clinical precision dataset consisting of 30 patients scanned twice with repositioning between scans. In the clinical precision study, the least significant change (LSC) was 0.044 g/cm^2. In that set of 30 patients, the BMD change between scans differed from baseline by more than 0.044 g/cm^2 in 3 individuals. Similarly, in 3/36 subjects who ingested calcium tablets, L1-4 BMD changes greater than 0.044 g/cm^2 occurred at 15 minutes, only one of which persisted at 30 minutes. In an additional subject, the BMD differed by more than the LSC only at 30 minutes. Tablets were visualized on one or more scans in 47% (17/36) of subjects; in 38% at 15 minutes and 25% at 30 minutes. People's Choice calcium and OsCal were visualized in 66% of scans while Citracal did not appear in any scan. Visualization of calcium tablets was rarely associated with significant changes in BMD; in only a single instance was a significant BMD change demonstrated when a tablet was visualized. In conclusion, although calcium supplements are often visualized when DXA scans are performed soon after ingestion, they rarely affect measured BMD. It does not appear necessary to require abstinence from calcium supplement ingestion prior to DXA examination.

Quantitative Assessment of Bone Tissue Mineralization with Polychromatic Micro-Computed Tomography. A. Burghardt*[1], G. Kazakia*[1], A. Laib*[2], K. Saldanha*[1], S. Majumdar[1]. [1]Radiology, University of California, San Francisco, San Francisco, CA, USA, [2]Scanco Medical AG, Bassersdorf, Switzerland.

To date there is no consensus on the validity of calibrating polychromatic µCT linear attenuation values to the degree of bone mineralization. The present study investigates short term reproducibility of phantom measurements, hydroxyapatite (HA) phantom sampling limitations, and the accuracy of calibrated mineral density measurements. Phantom and specimen measurements were made on a commercial µCT system (µCT-40, Scanco Medical). Custom beam hardening correction factors were determined using a 200 mg/cc HA wedge phantom imaged at 45, 55 and 70 kV. Density calibration of the reconstructed grayscale attenuation values was performed at each voltage setting using a phantom composed of 5 cylinders of HA-resin mixtures with mineral densities ranging from 0 to 800 mg/cc. Short term reproducibility was assessed by acquiring 5 sets of calibration data at each voltage. CV % was calculated for each cylinder at each energy level. To characterize sampling limitations due to phantom heterogeneity, the full length of the phantom was imaged at 70kV. Mean attenuation values were determined for the 800 mg/cc cylinder in 10 randomly placed regions with 6 different lengths ranging from 0.9 to 13 mm along the cylinder. RMS error was calculated for each length against the mean density of the full cylinder. The accuracy of mean mineral density measurements of bone tissue was assessed by comparison to ash density. Eight 8mm cylindrical cores of human vertebral bone were imaged at 70kV with a pixel size of 16µm. Mean mineral density was calculated from the grayscale of the bone phase. Tissue volume was determined for each sample using Archimedes' Principle prior to ashing at 600C for 48 hours. Ash density was correlated to mineral density determined by µCT. The variation for repeat phantom scans ranged from 0.03% to 0.21%. In general, CV was highest at 70kV and lowest at 45kV. RMS error was found to decrease as the sampled length along the phantom increased. RMS error was generally higher in the low density cylinders (0.20-0.40% for 100, 200 mg/cc) and lower in the background and high density cylinders (0.04-0.20% for 0, 800 mg/cc). Mineral density in the vertebral cores ranged from 1.01 to 1.08 g/cc and was well correlated to ash density ($R = 0.85$). The proposed calibration technique was found to have a high level of precision over the short term, little error due to HA phantom granularity, and to accurately depict mean tissue mineralization. In the future, correlations will be extended to cover a wider range of tissue densities, anatomical sites, and species. Regular calibration measurements will be necessary to assess long term stability.

The Effect of Dual Femur Scanning on Osteoporosis Diagnosis and Treatment Decision Making in Postmenopausal Women. R. E. Cole. Internal Medicine, Michigan State University College of Osteopathic Medicine, East Lansing, MI, USA.

The aim of this study was to determine: To what extent does a dual femur Bone Mineral Density (BMD) scan change osteoporosis diagnosis and treatment decision making over a single femur scan? Dual femur results from 313 postmenopausal women were evaluated for right/left T-score discordance at the femoral neck, trochanter, and total hip. Analysis determined the change in diagnosis and treatment classification for the spine measurement and dual femur measurements, as opposed to the spine and single femur measurement. Our results demonstrate when a dual femur scan is performed as opposed to a single femur scan, T-score differences between the contralateral hips result in a change to a more severe diagnosis or treatment category in 14.35% of subjects. We conclude that the dual femur BMD scan results in a change in diagnosis or treatment classification over a single femur scan in 1 in 7 subjects. This discrepancy is large enough to warrant consideration for performing a dual femur BMD scan on all postmenopausal women.

Development and Testing of a BMD Reporting Tool in a Tertiary Academic Centre. A. M. Cheung[1], H. McDonald-Blumer[1], L. Tile*[1], M. Kapral*[1], J. Pokovic*[2], H. Hu*[1], R. Ridout[1]. [1]Osteoporosis Program and Department of Medicine, University Health Network and Mount Sinai Hospital, University of Toronto, Toronto, ON, Canada, [2]Osteoporosis Program, University Health Network and Mount Sinai Hospital, Toronto, ON, Canada.

Despite recent ISCD guidelines for BMD reporting, the quality and usefulness of BMD reports are highly variable. The objective of our study is to develop and test a software model for BMD reporting based on ISCD guidelines and what referring physicians find useful. We reviewed the medical literature on risk factors for fractures in different populations and on the usefulness of various components in a BMD report. We then devised and tested an evidence-based software tool for BMD reporting. This software incorporates a simple clinical assessment that patients can complete by themselves, routine information obtained by the BMD technologist, validated fracture risk assessments based on a combination of risk factors and BMD where possible, and expert opinion of the reporting clinical densitometrist. The software tool was tested on a Hologic densitometer and the procedure was refined. The resulting MS Word document report gives the referring physician the information recommended by ISCD as well as quantitative estimations of 5-year, 10-year and lifetime fracture risks. Using this software tool as part of the reporting process does not require more time than routine review and reporting by the clinical densitometrist. This evidence-based software tool is useful for BMD reporting. It can be easily updated to incorporate new evidence on the relationship between BMD, risk factors and fracture risk as they emerge. Further testing and validation of this reporting software should be conducted at other academic centres.

Age-Related Regional Changes in Body Composition and Bone Mass in Healthy Men. B. Oliveri, S. R. Mastaglia*, C. Fernández*, J. M. Deferrari*, M. Seijo*, A. Bagur*. Sección Osteopatías Médicas, Hospital de Clínicas, Universidad de Buenos Aires, Buenos Aires, Argentina.

DXA methodology allows performing a precise assessment of bone mineral density (BMD) and the three compartments of body composition (BC): bone mineral content (BMC), fat and lean mass. These parameters are measured in a total body (TB) scan, and body subregions can be distinguished. This evaluation may have implications in clinical practice. Normal reference values are necessary to correctly evaluate changes in different diseases. The purposes of this study were to 1- Establish BMD reference values in healthy men at different decades of life (from the age of 20 to 79 years) 2- Analyze BMD and BC changes throughout the decades of life 3- Evaluate changes in the different subregions. The study population comprised 103 normal Caucasian male volunteers aged 20 to 79 years with a body mass index (BMI) between 20-30 g/m^2. BMD and BC (BMC, fat, %fat and lean mass) of TB and subregions (legs, arms, trunk, total spine and pelvis) were determined by DXA (LUNAR-DPX-L). The changes from 20-29 to 70-79 years were analyzed by ANOVA. Comparative data from 20-29 years and 70-79 years are shown. From 20-29 to 70-79 years there was a small decline of ≅ 4% in TB BMD and subregions (arms, legs, trunk) (NS) and only pelvis and total spine BMD showed a significant diminution (10% and 6%; $p<0.002$ and $p<0.006$ respectively). TB BMC showed a 15% diminution ($p<0.02$), with all subregion BMCs decreasing significantly from 13 to 23% ($p<0.05$). TB lean mass also showed an 8% decline (56.5 vs 51.5 kg) ($0.1<p>0.05$) with only lean mass of the legs exhibiting a significant diminution (-15%) ($p< 0.001$). A progressive increase in BMI (24± 2.1 to 27± 2.0 g/cm2) ($p<0.02$), percentage of fat (18.8± 5.6 % to 29.5± 4.9%) ($p<0.001$) and total fat mass (14.3± 5.7 to 21.6± 3.8) ($p < 0.003$), mainly due to a 5 kg (+73%)($p< 0.0001$) increase in trunk fat mass, was observed throughout the decades of life. To conclude: 1-Reference values for TB and BMD of subregions and BC in healthy men were obtained for each decade of life. 2-Non significant changes in TB BMD, with a diminution in TB BMC, were observed with aging. 3- TB lean mass tended to decrease with aging, while BMI, TB fat mass and its percentage were found to increase. 3- Analysis of subregional BMD showed a diminution in total spine and pelvis and in all BMC subregions.4.Evaluation of BC subregions showed a central increase in fat mass

(predominantly trunk) with peripheral lean mass (predominantly legs) tending to decrease. These changes in BC may have implications in the risk of cardiovascular and metabolic syndromes.

Bone Density and Geometry in Women With Osteopenia, Osteoporosis and Hip Fractures. A. Bagur, M. Seijo*, F. Solis*, C. Mautalen*, B. Oliveri*. Sección Osteopatías Médicas, Hospital de Clínicas, Universidad de Buenos Aires, Buenos Aires, Argentina.

Bone mineral density (BMD) and femur geometry are predictors of osteoporotic hip fractures (HF) (Osteoporos Int 5:167,1995). The aim of this study was to evaluate BMD and femur geometry of control women (C), patients with osteopenia (O), osteoporosis (OP) and HF. The study population comprised 75 C (age: 69.8 ± 5.2 years), 132 O (age: 70 ± 6.3 years), 48 OP (age 74.1 ± 6.3 years) and 13 with recent FC (age: 75.2 ± 8.8 years); BMD of the hip contralateral to HF was determined in the latter. BMD and femoral geometry were evaluated by DXA (Lunar Prodigy). BMD of femoral neck (FN), Ward triangle (W), trochanter (T), total femur (TF), upper FN (UFN) and lower FN (LFN) was determined. As regards geometry, hip axis length (HAL), cross sectional moment of inertia (CSMI), and cross sectional areas (CSA) of the femoral neck were evaluated. The following results were obtained (X ± 1SD):

	Controls	Osteopenia	Osteoporosis	Hip Fractures
Height	153.4 ± 0.06	152.9 ± 0.06	151.6 ± 0.06	156.1 ± 0.1***
Weight	71 ± 11.0	67.2 ± 10.1*	59.8 ± 10.1****	61 ± 11.15****
BMD FN	0.988 ± 0.09	0.771 ± 0.05****	0.642 ± 0.031****	0.688 ± 0.11****
BMD UFN	0.814 ± 0.11	0.614 ± 0.06****	0.497 ± 0.042****	0.507 ± 0.06****
BMD LFN	1.153 ± 0.10	0.924 ± 0.07****	0.781± 0.05****	0.865 ± 0.2****
BMD T	0.858 ± 0.09	0.687 ± 0.09****	0.669 ± 0.06****	0.55 ± 0.13****
BMD TF	1.046 ± 0.09	0.831 ± 0.09****	0.669 ± 0.06****	0.693 ± 0.14****
HAL	102.9 ± 6.15	102.07 ± 5.62	103.6 ± 4.92	110.2 ± 7.01***

p<0.01 ;***p<0.001; ****p<0.0001 versus control group

A greatest decrease ranging from 25 to 39% was observed in the upper femoral neck region. OP women presented decreased Height (151 ± 0.06 vs 156 ± 0.10 m, p<0.05) and HAL (103.6 ± 4.9 vs 110.2 ± 7.0 mm, p< 0.003) compared with HF. Our results show that: 1- Femur BMD decreased progressively in patients with O, OP and HF, compared with C. 2- The decrease was greatest at the level of the upper femoral neck, which is where the fracture may start. 3- Hip geometry allowed differentiating the fractured population from the osteoporotic population. 4- An index combining BMD and geometry may prove to be a useful predictor of hip fracture.

Application of the National Osteoporosis Society Guidelines for Peripheral X-ray Absorptiometry Bone Densitometry Scanners (UK). E. J. Harrison*, H. Prow*, J. E. Adams. Clinical Radiology, ISBE, The University of Manchester, Manchester, United Kingdom.

In December 2004 the National Osteoporosis Society UK released guidelines for the use of peripheral dual energy X-ray absorptiometry (pDXA) scanners. These guidelines suggest a triage approach to classify patients into one of three groups: i) treatment recommended especially if accompanied with other risk factors ii) refer for axial DXA iii) no further action required if no low trauma fracture evident. To determine the thresholds for classification the document states that the upper triage threshold should be the peripheral T score below which 90% of osteoporotic subjects lie, and the lower triage threshold should be that above which 90% of non-osteoporotic subjects lie. The aim of this study was to determine threshold values for three peripheral devices (one pDXA and two quantitative ultrasound scanners (QUS)) and examine the degree of agreement in classification in the same group of subjects. The scanners used were the Pixi (GE Lunar) the CubaClinical (McCue) and the Achilles Insight (GE Lunar). One hundred and ninety seven female patients aged 55 to 70yrs had DXA of spine and hip and pDXA and QUS of the non-dominant calcaneum. Of these 63 patients were osteoporotic and 134 were normal using WHO criteria. The lower threshold T score value beneath which subjects should be treated (classification i) were -2.97 for Achilles, -2.28 for Cuba, -1.7 Pixi. The upper threshold T score value above which subjects required no more treatment (classification iii) were -1.64 Achilles, -1.25 Cuba, -0.4 Pixi. The classification of patients by the three devices was identical in 60% of patients. Using these thresholds on the Pixi 1.5% of osteoporotics would be missed and of the 23.4% treated 34.8% (8.1% of population) would be normal; on the Achilles 3.0% of osteoporotics would be missed and of 18.3% treated 36% (6.6% of population) would be normal; on the Cuba 3.0% of osteoporotics would be missed and of 17.3% treated 38.2% (6.6% of population) would be normal. In this study we have applied the NOS guidelines to three peripheral devices all of which scan the calcaneum. The agreement in classification between the three peripheral devices was only moderate and was at best 79% between the two QUS scanners. However the percentage of osteorporotic and normal patients placed in each classification by each peripheral scanner was similar. Using the threshold values determined for each scanner very few osteoporotics would be missed, however between 34.8 to 38.2% of those classed as requiring treatment were normal using the WHO criteria.

Fracture Risk Assessment Model: Do Values Derived from Western Populations Apply to other Caucasians? A. Arabi[1], H. Awada*[2], R. Baddoura[2], S. Haddad*[3], N. J. Khoury*[4], G. Ayoub*[2], G. El-hajj Fuleihan[1]. [1]Internal Medicine, American University of Beirut, Beirut, Lebanon, [2]Rheumatology, Saint Joseph University, Beirut, Lebanon, [3]Radiology, Saint Joseph University, Beirut, Lebanon, [4]Diagnostic Radiology, American University of Beirut, Beirut, Lebanon.

Bone mineral density (BMD) using Dual-energy X-ray absorptiometry (DXA) is a powerful predictor of fractures. Estimates relating BMD to fracture risk have been expressed as RR/SD decrease in BMD, and most estimates were derived from large Western databases. The applicability of such estimates has not been validated in non-Western Caucasian populations. The aim of this study was to assess the ability of BMD measurements, to identify subjects with prevalent vertebral fractures, based on measurements at the hip or forearm in a local non-Western Caucasian population, and compare these estimates to those derived from Western counterparts[1-3]. 460 subjects (301 women and 159 men), aged 65-85 years, were randomly recruited from a large metropolitan area. BMD at the hip and forearm were measured by DXA, using Hologic device. Lateral radiographs of the thoraco-lumbar spine were assessed using the semi-quantitative method of Genant (JBMR, 1993). Mild fractures were excluded. Age-adjusted Odds Ratio (OR) for vertebral fracture/SD decrease in BMD (hip or forearm) was derived by a logistic regression model using STATA version 7. 56 women (19%) and 18 men (12%) had at least one vertebral fracture.

Table. Age-Adjusted OR [95% CI] for vertebral fracture per SD decrease in non-Western Caucasian population using hip or forearm BMD, and comparison to estimates derived in Caucasians from Western countries.

Site	Local N=301women N=159 men	Western[1] Metaanalyses women only	Western[2] N=2067women N=317 men	Western[3] N=351women N=348 men
Total Hip (Women)	1.5 [1.1; 1.9]	1.8 [1.1; 2.7]	1.7 [1.5; 1.8]	2.4 [1.4; 2.1]
Distal Radius (Women)	1.5 [1.2; 1.8]	1.7 [1.4; 2.1]	----------	----------
Total Hip (Men)	1.7 [0.9; 3.1]	----------	1.4 [1.08; 1.7]	1.2 [0.9; 1.7]

[1-] Marshall et al B Med J 1996 (based on 90.000 person years)
[2-] Cauley et al, Osteoporos Int, 2004
[3-] Melton et al, JBMR, 1998

Our study suggests that the ability of BMD to predict prevalent vertebral fractures is the same in Caucasians whether from Western or non-Western countries, especially when using hip BMD. This has important implications regarding the applicability of using fracture risk assessment estimates in local populations using estimates derived from populations from Western countries.

***In Vivo* and *Ex Vivo* Measurement of Skeletal Development in Non-Clinical Pediatric Studies in Rats.** I. A. Moreau*, A. Varela, M. Sabourin*, C. Chevrier*, S. Barbeau*, K. Robinson*, J. Jolette*, L. Chouinard, S. Y. Smith. Charles River Laboratories Preclinical Services•CTBR, Senneville, PQ, Canada.

The aim of this study was to establish procedures for the evaluation of the effects of drugs in non-clinical pediatric studies on skeletal development in rats, the primary rodent species used in post-natal and juvenile studies. The techniques evaluated included radiography, DXA, pQCT, histology and histomorphometry. Litters of Sprague-Dawley CD (CD®[SD]IGS BR) rat pups were used ranging in age from 7 to 35 days. *In vivo* procedures were performed under isoflurane gas anesthesia. Medio-lateral and ventro-lateral radiographs were taken to measure the lengths of the femur, tibia and lumbar spine (L1-L6). The anatomical landmarks selected were reliable with coefficient of variation (CV%) on repeat measurements of the same animal up to 1.7% for males and females at 14 days of age. CV% between age groups ranged from 0.7% to 4.7% across all sites evaluated and were similar for males and females 14, 21, 28 and 35 days old. As expected, increases in bone length at each site with age were consistent with growth. In addition, radiographs allowed evaluation of morphological abnormalities. Peripheral QCT scanning was feasible and performed *in vivo* on pups as young as 7 days of age at the tibial proximal metaphysis and diaphysis, and provided information on the trabecular and cortical bone compartments and bone geometry. DXA scanning of the tibia of weanling rats 29 and 35 days of age was also feasible although manual bone mapping was necessary. Double staining of rat skeletal specimens at a range of ages from late gestation to weaning with Alizarin red S (for bone) and Alcian blue (for cartilage) allowed for confirmation of complete ossification of bones that were incompletely ossified or unossified when examined in fetuses, as well as the evaluation of cartilage. Histomorphometry measurements, including growth plate thickness in 35 day old rats, can be used to evaluate effects of drug treatment on bone mineralization, and provide structural and dynamic bone turnover variables for comparison among groups. This study demonstrates that conventional radiography, DXA and pQCT scanning, can be used *in vivo* to monitor skeletal growth at axial and appendicular sites. These data, combined with histology and histomorphometry evaluations, can provide a comprehensive assessment of the effects of a test agent on the developing skeleton.

GE Lunar Prodigy DXA Accurately Predicts Skeleton Ash but not Fat and Lean Composition in Growing (1 to 60 kg) Pigs. D. K. Schneider*, T. D. Crenshaw. Animal Sciences, University of Wisconsin -Madison, Madison, WI, USA.

In earlier studies with neonatal pigs (J Bone Miner Res 11:S471) differences were observed between DXA measurements in live pigs and skeletal ash (ASH) determined following dissection of the entire skeleton. Bone mineral content (BMC) by DXA overestimated ASH. Technology for dual energy X-ray absorptiometry (DXA) has changed with introduction of improved detectors and scan modes in new models. Accuracy of the new instruments must be re-assessed. In preliminary work with neonatal pigs (1 to 6 kg) using the small animal scan mode for Prodigy (J Bone Miner Res 16:S459), ash was accurately predicted, but fat and lean composition was over-estimated. To further test accuracy of the GE Lunar Prodigy, 24 pigs ranging from 1.3 to 58.6 kg were scanned using various scan modes (Prodigy software version 8.10.027) across weight ranges. Pigs were killed then dissected to separate the skeleton, soft tissue and viscera contents. Each of the three fractions was ground and the water, fat, protein and ash contents were determined. Recovery of tissue weight following dissection and grinding was 95.5%. Calculation of the percentage of total body Ca recovered in skeletal tissue was 97.2%. Using the small animal (below 20 kg), adult standard (20 to 46 kg), and adult thick (above 46 kg) scan modes revealed a near perfect fit for DXA prediction of dissected skeletal ash (ash, g = 3.34 + 1.001*DXA BMC, R²= 0.999), but inaccurate predictions of body fat (fat, g = -11.8 + 1.89*DXA Fat, R² = 0.978) and body lean tissue (lean, g = 373 + 0.834 DXA Lean, R² = 0.99). Correction equations are needed to adjust predictions of fat and lean composition if the small animal, adult standard, and adult thick scan modes are used at the designated weight ranges. Alternate modes (pediatric and adult thin modes) failed to accurately predict skeletal ash, fat, or lean. Therefore, correction equations are needed to accurately predict body composition if pediatric or adult thin scan modes must be used.

Proximal Tibia Bone and Muscle Parameters Assessed by pQCT in Dialysis Patients with and without Fracture. C. Gordon[1], L. Beaumont*[1], S. Jamal[2]. [1]Radiology, McMaster University, Hamilton, ON, Canada, [2]St. Michael's Hospital, University of Toronto, Toronto, ON, Canada.

Introduction: Elevated levels of circulating parathyroid hormone (PTH) may be responsible for a reduction in the cortical bone mineral status in dialysis patients leading to an increased risk of fracture. In addition, the reduced mobility in these patients may result in muscle weakness that could also contribute to bone loss and an elevated fracture risk. Using peripheral quantitative computed tomography (pQCT), the aim of this study was to investigate whether there are differences in cortical bone density, bone geometry and muscle cross-sectional area and fat cross-sectional area in a group of dialysis patients with and without fracture. Methods: We studies a total of 43 men and women 50 years and older on maintenance hemodialysis for at least one year. Self reported low trauma or prevalent vertebral fractures assessed by morphometry were identified in 19 subjects. A timed six-minute walk was used to assess mobility in all subjects. Bone parameters and muscle cross-sectional area were measured at the proximal one-third tibia using a Stratec XCT 2000 pQCT scanner. A paired t-test was used to test statistical differences between the fracture and non-fracture subjects. Results: Dialysis subjects without fracture were able to walk twice the distance in six-minutes compared with those patients with fracture ($p < 0.0001$). pQCT measures showed a non-significant mean decrease in total bone mineral content (13%, p=0.06), density (11%, p=0.1) and area (3%, p=0.7) between the fracture and non-fracture group. Significantly lower mean values for cortical content and area were noted in patients with fracture ($p<0.04$). Modest, but significant reductions in geometrical parameters such as cortical area (21%, p=0.04), cortical thickness (18%, p=0.04), section modulus (24%, p=0.03), and the axial strength strain index (26%, p=0.03) were also noted for the fracture group. A 10% reduction in calf muscle cross-sectional area was also detected for the fracture group. This mean difference, however, was not statistically significant (p=0.2). Conclusion: Despite a significant reduction in mobility, calf muscle area was not significantly different in dialysis patients with and without low trauma fractures. The modest but significant differences in cortical bone content and geometry detected between the fracture and non-fracture patients suggests that the increased fracture risk is primarily due to PTH imbalance. However, a timed walking test may also be a simple but effective indictor of increased fracture risk and underlying muscle weakness.

Multi-Modality Study of the Compositional and Mechanical Implications of Hypomineralization in a Rabbit Model of Osteomalacia. S. S. Anumula*[1], J. Magland*[1], H. Zhang*[1], H. Ong*[1], S. W. Wehrli*[2], F. W. Wehrli[1]. [1]LSNI, Department of Radiology, University of Pennsylvania, Philadelphia, PA, USA, [2]NMR Core Facility, Children's Hospital of Philadelphia, Philadelphia, PA, USA.

Water plays a pivotal role in the physiology and function of bone. Water serves as a medium for diffusion-mediated transport of molecules to and from osteocytes and is largely responsible for the bone's viscoelastic properties. Further, during mineralization, mineral crystals take the place of collagen surface-adsorbed water under volume retention. Here, we examine the hypotheses that (a) water content can be measured *in situ* by solid-state proton NMR imaging, (b) that water is inversely related to mineral content, and (c) that the method is able to distinguish osteomalacic from normal bone. Hypomineralization was induced in a group of 5 rabbits (TR) using a previously developed protocol and the data compared with those of 5 control (CO) animals. ^{1}H images were acquired at 400 MHz from excised cortical bone by 3D ^{1}H solid-state imaging (SSI) of the tibia at a resolution of 183 μm. Porosity and degree of mineralization of bone (DMB) were measured by μ-CT at 16μm resolution in the presence of calibration phantoms made of different concentrations of hydroxy apatite. Mechanical properties were measured as well using 3-point bending. Significantly higher water content was found by SSI in the TR group than in the CO group (19.87±3.03% *vs*. 16.61±2.22%; p=0.04). This result parallels the higher porosity found for the TR group (1.94 ± 0.72 *vs*. 0.62 ± 0.3 %; p = 0.003), with positive correlations observed between bone water and porosity (r^2= 0.52; p=0.02) Conversely, DMB was lower in the TR group (1279.2 ± 25.68 *vs*. 1356.1±18.0 mg/cm^3; p=0.0003). SSI-measured water content correlated negatively with DMB and with ash weight (r^2=0.55; p=0.01 for the latter). Further, osteomalacic bone was mechanically impaired as indicated by reduced elastic modulus in N/mm^2 (522.10 ± 166.49 *vs*. 769.32 ± 231.5; p=0.05) and ultimate strength (20.4 ± 3.34 *vs*. 28.3 ± 3.21 N/mm^2; p=0.003) relative to the control group. Finally, water content and mechanical quantities were inversely related to one another (ultimate strength; r^2= 0.49; p=0.04 and elastic modulus; r^2= 0.72; p=0.004). The data validate the above hypotheses and suggest that proton SSI of bone water can distinguish subtle differences in mineralization density and therefore may provide a new means for noninvasive assessment of DMB.

Evaluation of a Contrast-Detail Phantom to Measure Image Quality of DXA Scanners Performing Vertebral Fracture Assessment. L. G. Jankowski[1], M. A. Costello*[2], S. B. Broy[1]. [1]Center for Arthritis and Osteoporosis, Illinois Bone and Joint Institute, Morton Grove, IL, USA, [2]Section of Endocrinology, University of Chicago Hospitals, Chicago, IL, USA.

While conventional radiographs are the current gold-standard for the detection of vertebral fractures, recent improvements in the image resolution of dual-x-ray absorptiometry (DXA) scanners have allowed their use to obtain low-dose images of the thoracolumbar spine for vertebral fracture assessment (VFA). Checks of system image resolution and contrast are not included in the quality assurance protocols provided by DXA manufacturers for these devices. We assessed whether a commercially available contrast-detail phantom designed for conventional radiography could be adapted for use with DXA scanners to monitor system imaging performance. A commercial radiographic contrast-detail phantom (CDRAD 2.0, Nijmegen St.Radboud, Netherlands) was scanned on a GE-Prodigy and Hologic Discovery SL DXA scanner. To simulate soft-tissue, the phantom was placed between two 4cm acrylic plates and images were acquired using the respective manufactures' VFA acquisition modes, and analyzed using their standard display software. Standard computed digital radiographs (CR) were obtained in the same configuration for comparison. Images were evaluated under identical viewing conditions by two independent observers. Using the grading system provided by the phantom manufacturer, an inverse Image Quality Figures (IQF) was calculated for GE-Prodigy in dual energy (GE-DE) and single energy (GE-SE) display modes, and for the Hologic Discovery in standard (Hologic-IVA) and high-definition (Hologic HD) modes. This parameter is directly proportional to overal image quality. The mean IQF values for the two observers were 0.93, 0.24, 0.21, 0.91, and 0.94, for CR, GE-DE, GE-SE, Hologic IVA, and Hologic-HD phantom images respectively. The CDRAD 2.0 contrast-detail phantom can be adequately imaged and analyzed on DXA scanners performing VFA, and may have value in detecting image degradation of DXA systems over time if incorporated into DXA system quality control protocols. The Hologic IVA and IVA-HD scan modes delivered similar IQF values that were equal to digital computed radiography, and were four times better than GE Prodigy in either dual-energy or single energy imaging modes.

Changing Bone Densitometers in Clinical Practice: Effect on Precision Error. S. M. Hunt*, J. C. Fertile*. Martha Jefferson Hospital, Charlottesville, VA, USA.

Precision error in bone densitometry is directly related to the ability to monitor change in a patient's bone mineral density (BMD). Lower precision error reduces the least significant change (LSC), allowing a smaller measured change in BMD to be identified as biological rather than related to instrument variability. Precision error is influenced by the type of densitometer, the patient population, and by operator experience and training. Densitometry providers should determine their precision error after changes in densitometers or operators. Our hospital recently changed from using 3 Discovery systems to 3 Prodigy Advance systems. As part of the upgrade process, we evaluated the effect of changing densitometers on precision in our practice. A total of 35 subjects were scanned on one of three Discovery (Hologic) systems and on one of three Lunar Prodigy Advance (GE Healthcare) systems. Subjects were measured 3 times each, with repositioning between scans, at the spine (L1-L4) and femur on both densitometers. Average subject age was 61 ± 10 years; 30 women and 5 men participated. Fourteen subjects were scanned on scanner pair A (Discovery A + Prodigy A), 10 subjects on scanner pair B, and 11 subjects on scanner pair C. The clinic's technologists acquired and analyzed all the scans. BMD precision error was calculated as the root-mean-square standard deviation (RMS-SD) and coefficient of variation (RMS-%CV) for the repeated measurements. To directly compare the precision error between the devices, all Hologic values were converted to Lunar-equivalent BMD (1). The 4 technologists who worked with both Hologic and Lunar

systems had more experience using Hologic (>5 yrs, 3 yrs, 3 yrs, 3 yrs) than Lunar (< 4 months for all). The 1 technologist who worked only with Lunar systems had < 4 months experience. Precision data for each manufacturer were pooled. Discovery precision error was significantly higher (between 30% - 90%) at the spine (1.5% vs. 1.0%, p=0.011), femur neck (2.3% vs. 1.8%, p=0.024), and femur total (1.9% vs. 1.0%, p<0.0001) regions. There was no significant difference in precision at the trochanter region. We conclude that precision error with the Lunar Prodigy Advance densitometers was significantly lower compared to the Hologic Discovery, even when the technologists had less experience on the Lunar systems.

Changing from a Hologic to a Lunar Bone Densitometer: Effect on BMD and Precision Error. C. Albanese, R. Passariello*, M. Dante*. University of La Sapienza, Rome, Italy.

In a clinical osteoporosis practice today, patient management may involve comparison of bone mineral density (BMD) values obtained from different bone densitometers. The ability to identify a significant change in patient BMD obtained by two different densitometers is affected by two factors: how well the measurements between the different densitometers correlate and how large the precision error is. Lower precision error allows a smaller measured change in BMD to be identified as biological rather than related to instrument variability. Precision error is influenced by type of densitometer, patient population, and by operator experience and training. In our institution we recently introduced a Lunar Prodigy system while in the past measurements were performed on a Hologic QDR4500. We evaluated the effect of changing densitometers on precision and how well the measurements from these two densitometers correlate. A total of 42 women had bilateral femur scans on a QDR4500W (Hologic) system and a Lunar Prodigy (GE Healthcare) system. Subjects were measured twice on each system with repositioning between scans. Average subject age was 65 ± 7.5 years (50-80 yrs). Different technologists operated the Lunar and Hologic systems. BMD precision error was calculated as the root-mean-square standard deviation and coefficient of variation (CV) for the repeated measurements. To directly compare the precision error between the devices (1), all Hologic values were converted to Lunar-equivalent BMD. Only subjects with two measurements on both systems were included in the CV calculation. There was a strong correlation between QDR4500 and Prodigy total femur BMD values (r = 0.97). QDR4500 precision error at the total femur region was significantly higher that Prodigy precision error: left total femur (2.0% vs. 1.0%, p<0.0001), right total femur (1.4% vs. 0.9%, p<0.01). We conclude that BMD values between the Hologic QDR4500 and the Prodigy can be cross-calibrated. Precision error with the Lunar Prodigy densitometer was significantly lower at the total femur region compared to the Hologic QDR4500. This lower precision error with the new densitometer allows earlier detection of clinically relevant changes in patient BMD.

A Call for Consensus Regarding Focal Structural Defects. K. E. Hansen, N. Binkley, D. Malone*, R. Christian, D. Krueger, N. Vallarta-Ast, R. Blank. Medicine, University of Wisconsin Osteoporosis Research Program & Clinical Center, Madison, WI, USA.

The International Society for Clinical Densitometry (ISCD) has published criteria by which to exclude vertebrae from lumbar spine densitometric analysis. Previously we reported that when applying these exclusion criteria there is only moderate agreement between interpreters, with poorest agreement regarding the identification of focal structural defects (FSD). To further investigate the utility of the ISCD vertebral body exclusion criteria, we assessed intra-observer reproducibility and specifically whether interpreters identify FSD consistently on two separate occasions. Five ISCD-certified physicians applied the ISCD vertebral exclusion criteria to 90 de-identified lumbar spine DXA printouts on two occasions at least four weeks apart, using a standardized worksheet to record exclusions and final T-scores. Three ISCD-certified technologists obtained the scans in a precision study; subjects included 64 women and 26 men with a mean age, weight, and L1-L4 T-score of 59.1 ± 9.3 years, 71.7 ± 13.8 kg and 0.1 ± 1.2, respectively. Interpreters had no access to their initial notes, when reviewing bone density studies on the second occasion. Resulting data were analyzed where appropriate with descriptive, Pearson's correlation coefficient, and kappa (κ) test statistics. Overall, intra-observer T-score reproducibility was excellent, with very high correlation coefficients (R=0.97-0.99) and small absolute differences in final lumbar spine T-score (range, 0.017 ± 0.126 to 0.140 ± 0.364) between paired analyses. With application of specific exclusion criteria, intra-observer κ were generally good or excellent, with over 60% of values falling between 0.6-1.0. In contrast, half of intra-observer κ values were <0.60 (moderate or fair) with application of the FSD exclusion criterion. Moving caudally from L1 to L4, all interpreters excluded more vertebrae due to FSD. Notably, enormous inter-observer variability in vertebral body exclusion due to FSD was observed. For example, the five physicians excluded L4 on both occasions in 10, 21, 32, 50 and 78% of these scans. In conclusion, interpreters demonstrate high intra-observer T-score reproducibility when applying the ISCD exclusion criteria on two occasions at least four weeks apart. However, the definition of FSD varies greatly between observers and could potentially impact on patient diagnosis and treatment. Since FSD are a major source of lower inter-observer and intra-observer agreement, standardized definitions regarding what constitutes an FSD should in principle improve the quality and consistency of lumbar spine DXA interpretation.

DXA Is Very Useful and Cost-Effective to Detect an Early Suspicious Osteolytic Bone Metastasis. I. Park[1], I. Lee*[2]. [1]Orthopedic Surgery, Kyungpook University Hospital, Taegu, Republic of Korea, [2]Endocrinology, Kyungpook University Hospital, Taegu, Republic of Korea.

The purpose of this study is to introduce the new clinical application of DXA as one of the useful methods to detect early suspicious osteolytic bone metastasis to prevent a pathologic fracture. At least 30 to 40% of bone mass should be decreased to differentiate an osteolytic bone lesion on plain radiographs. So, additional computed tomography(CT) or MRI and/or PET or bone scan should be necessary when bone metastasis is suspected, but plain radiographs failed to reveal it. Bone mineral density of 21 suspicious early bone metastasis were evaluated by a DXA(GE-Lunar Prodigy) to compare the BMD of both sides. Out of these 21 cases, 15 were confirmed with bone scan and/or MRI and/or PET/CT. Our results were as follows: First, DXA could detect an osteolysis of as low as 7 % of difference in BMD with comparison to the opposite normal control area. It is essential that region of interest should cover the entire osteolytic area. Second, DXA is more cost effective than MRI and/or PET/CT when a patient could not afford it. Third, on proximal femoral area where bone metastasis is very common, this method could be still effective even retrospectively with already acquired DXA data as long as both hip areas were checked.

Low Levels of Knowledge, Confidence, and Self-Reported Use of Bone Density Testing among Family Medicine Residents. M. M. Luckey[1], S. Albert*[2], C. A. Berry*[2]. [1]Saint Barnabas Osteoporosis and Metabolic Bone Disease Center, Mount Sinai Medical Center, Livingston, NJ, USA, [2]Center for Health & Public Service Research, New York University School of Public Health, New York, NY, USA.

Despite the availability of evidence-based guidelines, simple diagnostic tests and effective therapy, less than one-third of patients with osteoporosis are identified or treated. Intervention by primary care providers will be required to change this number; however systematic training in osteoporosis is not routine in most postgraduate residency programs which could leave physicians without the confidence, knowledge and experience needed to make osteoporosis surveillance and treatment a routine part of primary care practice We sought to evaluate the levels of knowledge, confidence and bone density testing among Family Medicine residents attending thirty-one 1 and 1.5 day long *BetterBones* Osteoporosis Workshops provided by the Academy of Family Medicine Residency. Prior to the workshop residents completed a multiple-choice test of knowledge and a questionnaire regarding their current clinical practices, confidence in their ability to diagnosis and treat osteoporosis and the number of bone density tests ordered in the past 3 months. 717 Family Medicine residents (199 PGY2s; 487 PGY 3s and 30 fellows) from 256 residency training programs attended workshops between March 2003 and December 2004. Pre-workshop test scores of knowledge were low (58 ± 14%) and did not vary significantly by year of attendance at the workshop or by increasing PGY year. Only 20% of the 304participants queried expressed confidence in their knowledge and competence to diagnose and treat this disease. Among 561 residents seeing at least 20 women over age 50/ month (mean 56± 35 (SD)women/per month), 70% reported ordering ≤ 1 bone density test/ month and 25% had ordered no densitometry tests in the past 3 months . The calculated rate of bone density testing was <4% of women ≥ 50 years being tested. Higher levels of confidence, but not pre-workshop knowledge, were significantly correlated with self-reported bone density testing (Pearson r= 0.3, p<.001). These results indicate that intervention is required among family medicine residents to increase the appropriate detection of osteoporosis and that interventions that increase confidence may be particularly important.

Bone Microarchitecture Evaluation *In Vivo* in Humans. M. A. Dambacher[1], M. Neff[2], H. Radspieler*[3], R. Rizzoli[4], P. Delmas[5], L. Qin[6]. [1]Metabolic Bone Diseases, Center for Osteoporosis, Zollikerberg, Switzerland, [2]Bone Diseases, Center for Osteoporosis, Zürich, Switzerland, [3]Center for Osteoporosis, München, Germany, [4]Metabolic Bone Diseases, University Hospital Geneva, Geneva, Switzerland, [5]Metabolic Bone Diseases, Hopital E. Herriot Lyon, Lyon, France, [6]Orthopaedics and Traumatology, Chinese University, Hong Kong, China.

The non-invasive and quantitative/qualitative 3D bone structure analysis became available in humans with the help of high resolution pQCT (XtremeCT, Scanco Medical Ltd). The new high resolution pQCT enables the simultaneous acquisition of a stack of 100 tomograms with a maximal diameter of 126mm. The isotropic resolution is 120µm (10% MTF, isotropic voxel size 82µm). The tomograms are taken 7mm proximal from the endplate of the distal radius and/or 20mm of the distal tibia (see fig). The data acquisition time is about 3 minutes. The reproducibility is <±1% for structure elements. In praxi it is now routinely possible to quantify in vivo in humans the microarchitectural features as number of trabeculae, trabecular and cortical thickness, trabecular spacing and endosteal surface in addition to the volumetric BMD of trabecular and cortical bone. Such quantitative characterization will give better insight in pathogenesis and treatment of osteoporosis, as well as an improved individual fracture prediction.

Is there an Alternative to Basic Fuchsin Bulk Staining for the Assessment of Microcracks in Human Iliac Crest Bone Biopsies? B. Burt-Pichat*, M. E. Arlot, J. P. Roux*, P. J. Meunier, P. D. Delmas. INSERM unit 403, C. Bernard University, Lyon, France.

There is increasing interest in microcracks because 1/ they appear to trigger targeted remodelling; 2/ their accumulation in animal treated with high doses of bisphosphonates may lead to reduce bone toughness. Bulk staining with the fluorochrome on the bone specimen prior to embedding and sectioning is necessary to differentiate true microcracks from artefacts due to sectioning, but the most commonly used fluorochrome, basic fuchsin (BF), causes blurring and fading of tetracycline double labeling (TDL) performed in vivo before human iliac crest biopsies. The aim of this study was to validate another bulk staining that preserved TDL. Sixteen iliac crest biopsies taken in ewes after TDL were separated into two parts. One half was stained with the following fluorochromes: basic fuchsin in ethanol solution (BF), fluorescein, green calcein, blue calcein, alizarin complexon and xylenol orange, all either in ethanol- or water-based solution, either individually or in combination. Microcracks were analyzed on three 100 µm thick sections with both white light, epifluorescence and laser confocal microscopy, equipped with adequate filters. The other half biopsies were processed without bulk staining as control for TDL. In addition, all specimens were stained with Goldner's trichrome, solochrome cyanin R, toluidine blue and May-Grunwald Giemsa on 7 µm thick sections to analyze the quality of histomorphometric stainings. Finally, tests were performed on human iliac crest biopsies with TDL. The assessment of microcracks was similar in terms of number and length in sections stained with both BF and other fluorochromes either in ethanol or in water solution. With fluorochromes in water solution TDL was no more visible or blurred when compared to the one of the paired half biopsy. With fluorochromes in ethanol solution, TDL was similar to the labeling seen on the paired half biopsy, except for fluorescein that induced fading of TDL. For all fluorochromes, further stainings were of adequate quality for histomorphometry. Among all the analyzed fluorochromes calcein appears to yield the best results and was selected for microdamage bulk staining in human iliac crest biopsies. In conclusion bulk staining with calcein in ethanol solution 1/ stained microcracks similarly to basic fuchsin, 2/ did not induce fading of TDL 3/ was visible in both epifluorescence and laser confocal microscopy 4/ preserved the quality of classical histomorphometric stainings.

Hip Fracture Susceptibility in Elderly Men and Women Is Explained by Bone Instability Rather than by BMD. F. Rivadeneira[1], C. de Laet[2], T. J. Beck[3], M. C. Zillikens*[1], J. J. Houwing*[4], A. Hofman*[1], A. G. Uitterlinden[1], H. A. P. Pols[1]. [1]erasmus Medical Center, Rotterdam, The Netherlands, [2]Scientific Institute of Public Health, Brussels, Belgium, [3]Johns Hopkins University, Baltimore, MD, USA, [4]LUMC, Leiden, The Netherlands.

Aim To elucidate what are the main structural properties of bone which determine the risk of hip fracture in elderly men and women. **Methods** This study is part of a large prospective population-based cohort including 147 incident hip fracture cases in 4806 individuals with hip structural analysis at baseline (mean follow-up 8.6 years). Narrow-neck BMD, bone width, cortical thickness, section modulus (index of bending strength) and buckling ratio (BR, a crude index of bone instability is the ratio of the distance from the center of mass to the estimated cortical thickness) were compared in relation to fracture using logistic regression together with areas under the ROC curve. Relative risks (hazard ratios from Cox regressions) of hip fracture per standard deviation were determined to model the one-year risk of fracture and the distribution of fractures across absolute parameter values. **Results** Hip fracture cases in both genders have lower BMD, thinner cortices, greater bone width, lower strength and higher instability (BR) (Table). Differences in BR (18-24%) are about two-fold those observed for BMD (11-13%). No significant difference is observed between the areas under the ROC curves of BMD (0.76) and BR (0.77). Risk at every level of BR is higher in women than men, while for BMD this increase in risk is only seen at very low BMD levels (Figure 1). Similarly, men have a greater risk of fracture at a given cortical thickness, while women have greater fracture risk at a given neck width. The interaction between neck width and cortical thickness is significant (p=0.01) in women and appears to be measured by the BR. In contrast to the displacement observed with BMD, fracture distribution appears to occur at the same absolute levels of bone instability (BR) in both men and women (Figure 2). **Conclusions** Even though buckling ratio does not offer additional predictive value over BMD, these findings suggest that bone instability (related to cortical thickness and bone width) plays a key role on local susceptibility to hip fracture. Further, a similar biomechanical instability threshold applies to both genders despite the known sexual dimorphism of bone.

A Potential Method of Bone Viscoelasticity Measure *In Vivo*. Z. Bechor*, J. S. Merritt*, H. M. S. Davies. Veterinary science, Melbourne University, Werribee, Victoria, Australia.

This study was designed to develop a method of measuring bone viscoelasticity in vivo.Biot's Poroelastic Theory predicts bone fluid flows as a result of a hydrostatic pressure gradient (1) and Biot's viscoelasticity theory predicts creep or stress relaxation due to fluid flow (1). Ultrasound speed (SOS;Sunlight, Equs, Tel-Aviv, Israel) was measured before (to provide a standard) and during applied hydrostatic pressure on a dorsomedial site on the first phalanx of the right and left forelimbs (RP1 and LP1) in five horses. In vivo hydrostatic pressure (undrained) was induced by elevating one forelimb, which increased intramedullary pressure and cortical hydrostatic pressure in the opposite forelimb (the weight bearing limb). In a previous study (2) it was observed in vitro that a reduction in SOS (drained condition) occurred when fluid flowed from a cut bone surface. The SOS measure was continued for 2-3 minutes and any delayed drop in SOS was recorded as a drained condition.The results showed a significant increase of 7% in the SOS on the right and 6.4% on the left (RP1, p = 0.02, SD+/- 32.5, LP1, p = 0.01, SD+/-40.1) in the undrained condition compared with the standard. There was a delayed reduction in SOS of 62m/s on the right P1 in four horses, but these results were not significantly different from the standard (p=0.09, SD+/-32.5). This viscoelastic test suggested that fluid pressure and fluid flow have an important role in the dorsomedial region of the cortical bone of P1 in horses. Our previous study (2) on the dorsal midshaft of the third metacarpal bone (MC3) showed a lower viscoelastic and higher elastic behaviour in response to hydrostatic pressure. Site morphology and microstructure differences such as porosity and dynamic changes in osteon dimensions might be reasons for differences between bone responses to hydrostatic pressure. In conclusion, this experiment demonstrated that a simple loading test like this may give site specific data on bone, poroelastic and viscoelastic properties.References:1. Three-Dimensional Microarchitecture of the New Bone Formation on the Prosthetic Implant: Reproducibility of Micro CT Assessment. Y. Jiang[1], J. Zhao[1], Y. H. An*[2]. [1]Osteoporosis and Arthritis Research Group, University of California San Francisco, San Francisco, CA, USA, [2]Orthopaedic Research Laboratory, Medical University of South Carolina, Charleston, SC, USA.

This study was designed to evaluate the precision of micro CT quantification of three-dimensional (3D) microarchitecture of the new bone formation inside the porous titanium prosthesis implanted in rabbits. Capturing true 3D bone micro architecture may improve our ability to understand the process of new bone formation on the surface of the implant, and to estimate the bone biomechanical properties in terms of fracture resistance as the mechanical competence of bone is a function of its apparent density and 3D distribution. Such changes can not be evaluated by 2D histological sections. We examined 20 titanium prosthesis implants in the distal femur of rabbits. The implants have different sizes of pore, and have different coating materials. The specimens were scanned using a Scanco micro CT with isotropic resolution of 20 µm. 3D structural parameters were directly measured without stereological model assumptions as in 2D histomorphometry. Values of 0 and 3 for the structure model index represent a perfect plate structure and an ideal cylindrical rod structure, respectively, while values ranging from 0 to 3 indicate a structure with both plates and rods of equal thickness, depending on the volume ratio of rods and plates. Round spheres have an structure model index of 4. Negative values indicate bone structure with concave surface as the Swiss cheese. Over 1 month later, the specimens were re-scanned and re-analyzed. The root mean square coefficient of variation of the 3D microstructural parameters of the newly formed bone was calculated as a measure of reproducibility. The results showed that the The root mean square coefficient of variation was 1.7% for bone volume fraction, 2.2% for connectivity density, 2.3% for structure model index, 1.4% for trabecular number, 3.1% for trabecular thickness, 0.8% for trabecular separation, 1.1% for degree of anisotropy. In conclusion, micro CT can reproducibly quantify 3D microarchitecture of the new bone formation inside the pores of the titanium prosthesis implants, which may find application in studying effects of different size of pores and different coating materials on osteogenesis.

Male Idiopathic Osteoporosis. Illiac Bone Biopsy Study by Micro-TC. M. Ciria[1], J. Blanch[1], L. Perez-Edo[1], M. Mariñoso*[2], D. Chappard[3], S. Serrano*[2], J. Carbonell*[1], A. Diez-Perez[4]. [1]Rheumatology, Institut Municipal d'Asisténcia Sanitària, Barcelona, Spain, [2]Pathology, Institut Municipal d'Asisténcia Sanitària, Barcelona, Spain, [3]Rheumatology, University of Angers, Angers, France, [4]Internal Medicine, Institut Municipal d'Asisténcia Sanitària, Barcelona, Spain.

There are few histomorphometric studys about male idiopathic osteoporosis (MIO). Our group found a decrease of osteoblasts and trabecular number in classic histomorphometric studies of illiac bone biopsies, showing a decreased formation levels and a normal resorption levels. The aim of the present study is to examine the microarchitecture of cancellous bone with micro-TC technics. We included 16 of 23 illiac bone biopsies performed in male with normocalciuric idiopathic osteoporosis, diagnosed by densitometric study. The control group included 11 age-mached, healthy men. Micro-TC study was performed with Microtomographie X-Skyscan. We studied bone volume / total volume (BV/TV), bone surface / bone volume (BS/BV), trabecular thickness (Tb.Th), trabecular separation (Tb.Sp), and trabecular number (Tb.N). Results: Bone volume / total volume, trabecular number and trabecular separation was lower in osteoporotic group than in control group. Tb.Th was similar in both groups (Table 1). Conclusions: In our sample, male normocalciuric idiopathic osteoporosis showed a low trabecular number and a high trabecular separation, with a maintenance of trabecular thickness. This findings differ of the postmenopausic osteoporosis.

Components of Micro-Architecture and Bone Density that Contribute to Biomechanical Characteristics of Bone. A Study in Ewe Femora. P. P. Geusens[1], Y. Jiang[2], J. Zhao*[2], S. Boonen[3], M. Azria[4]. [1]Limburgs Universitair Centrum, Diepenbeek, Belgium & Department of Rheumatology, University Hospital, University of Maastricht, The Netherlands, Diepenbeek, Belgium, [2]Osteoporosis and Arthritis Research Group, Department of Radiology, University of, San Francisco, CA, USA, [3]Leuven University Center for Metabolic Bone Diseases and Division of Geriatric Medicine; K.U.Leuven, Leuven, Belgium, [4]Novartis, Basel, Switzerland.

Many components of bone quality contribute to the different aspects of biomechanical competence of bone, including bone mineral density (BMD) and microarchitectural parameters. We analysed the correlation between biomechanical characteristics and measurements of BMD and microarchitecture in the femora of adult ewes. Methods. Twenty-eight middle aged (5-8 years old) ewes were part of a study of the effect of calcitonin on bone after ovariectomy (OVX) (JBMR, 2005:125). The animals were euthanized 6 months post-OVX. The femoral neck BMD was measured by dual x-ray absorptiometry (DXA). Compressive testing was performed on femoral trabecular cylinder cores of 8 mm in diameter and 10 mm in length with the axis of the cylinder aligned with the axis of the neck. Microarchitecture of femoral neck was examined with a magnetic resonance imager at 9.4 Tesla in axial, coronal, and sagital planes at contralateral site. Uni- and multivariate analyses were performed between biomechanics, BMD and MR. Results. In univariate analysis, strength and stiffness were correlated with DXA and with several components of microarchitecture (Table). Toughness correlated with MR, but not with BMD. In a multivariate stepwise regression analysis, strength and stiffness correlated with BMD and TV/BV, while toughness was related to the mean length of the branches. Conclusions. Biomechanical characteristics show variable correlations with BMD and microarchitecture. These results indicate that microarchitecture of trabecular bone contributes significantly to its biomechanical characteristics, independent of BMD measured in the femoral neck.

First Data of Forearm and Tibia Bone Micro Architecture in Young, Healthy Women, Using High Resolution 3DpQCT *In Vivo* . M. Backstroem*[1], G. Armbrecht*[1], G. Beller*[1], J. Reeve[2], C. Alexandre[3], R. Rizzoli[4], A. Berthier*[5], L. Braak*[5], R. Binot*[6], B. Koller*[7], D. Felsenberg[1]. [1]Zentrum für Muskel und Knochenforschung, Radiologie, Charité - Universitätsmedizin, Berlin, Germany, [2]Department of Medicine and Institute of Public Health, Bone Research, University of Cambridge, Cambridge, United Kingdom, [3]Faculte de Medicine, LBBTO, University of St. Etienne, Saint-Etienne, France, [4]Division des maladies Osseuses, Department de Medicine Interne, Hopital cantonal Universitaire de Geneve, Geneva, Switzerland, [5]Institut de Medecine et Physiologie Spatiale, Medes, Toulouse, France, [6]European Space Agency, Noordwijk, Netherlands Antilles, [7]Scanco Medical Ltd, Zürich, Switzerland.

At present, there are no normative data available for micro architectural parameters such as Bone Volume to Total Volume (BV/TV), Trabecular Number (Tb.N) and Trabecular Thickness (Tb.Th) of distal radius and tibia assessed using an in vivo, non invasive 3DpQCT with high resolution. Our aim was to assess first data and to investigate whether there are any differences between radius and tibia. Twelve women, aged 25-40 (mean 31,4±4,46) with BMI 18,9-23,0 (mean 20,99±1,45) were measured with a 3DpQCT with a nominal isotropic resolution of 100 µm (XtremeCT, Scanco Medical Ltd). A total scan length of 9 mm in axial direction, starting 9,5 mm and 22,5 mm proximal of the distal endplate in radius respective tibia, divided into 110 slices were simultaneously measured over a scan time of less than 3 minutes. Total effective dose were less than 5 µSv per scan. ANOVA was used for statistical evaluations. No significant differences were found between radius and tibia. To be sure that the age and BMI distribution mirrored the whole group, statistical analysis were carried out on 1) age groups 25-30 and 31-40 years old (6 subjects per group) and 2) BMI 18,9-21,0 and 21,1-23,0 (5 vs. 7 subjects per group). The parameters were first compared between the groups for radius and then for tibia, followed by a comparison of the parameters within the group but between radius and tibia. No significant differences were found. Hence, the group can be considered as homogenous and the reference data as a good reflection of the studied group.

Table 1: Mean values ± standard deviations for the entire group of young healthy women (25-40 years).

	RADIUS			TIBIA		
BV/TV	0,138	±	0,024	0,143	±	0,018

Validation of Histomorphometric Indices in the Vertebral Spine of C57/BL Mice. S. Petersen*, S. Syberg*, N. R. Jorgensen. Osteoporosis Research Unit, Dep. of Clinical Biochemistry 339, Copenhagen University Hospital Hvidovre, Hvidovre, Denmark.

Bone histomorphometry is a widely used technique to determine bone formation, bone resorption, and other indices related to bone turnover. It is used in both human and animal samples, but only few methodological studies have described the optimal method to determine these parameters in mouse models. The aim of this study was therefore to establish and validate a standardized technique to measure indices of bone formative and resorptive activity, as well as cortical and trabecular thickness, and bone volume on bone slices of the vertebral lumbar spine from mice. Four-month old C57/BL mice were sacrificed, and lumbar spine was collected for histomorphometry. Sectioning and staining were performed according to standard methods. Fluorescent labeling for formative indices was performed 2 and 10 days prior to sacrification. On each slide (5 for formative indices and 5 for all other indices), sections from 4-8 vertebrae (from L1 and down) were present. Mineralizing surface as percentage of bone surface (MS/BS, %), eroded surface as percentage of bone surface (ES/BS, %), bone volume in % of total volume (BV/TV, %), cortical thickness (C.Th, µm), and trabecular thickness (Tb.Th, µm), were determined. Further, mineral appositional rate (MAR, µm/day) and bone formation rate/V (BFR/BV, %/year) were also calculated. Ranges of the mean and coefficient of variation (CV%) are shown in table 1 for comparisons between the different vertebrae and within the vertebrae but between the different sections. No differences were found between the different sections. However, for most indices, differences between vertebrae were found, indicated by * in table 1. In conclusion, when measuring histomorphometric indices, it is important to determine these on specific lumbar vertebrae, when comparing with other animals, as there is a significant variation in most indices between the different vertebra.Table 1.

Index	Intervertebral comparison range	CV%	Intersection comparison range	CV%
MS/BS (%)	42.7-47.4*	1.7-5.2	43.6-46.5	4.8-5.9
ES/BS (%)	5.6-6.2	5.4-13.2	5.7-6.3	4.5-11.0
BV/TV (%)	17.7-32.3*	1.1-10.3	22.8-24.7	21.1-27.1

***In Vivo* Assessment of Trabecular Bone Structure in Human Vertebrae Using High Resolution Computed Tomography.** W. Timm*[1], C. Graeff*[1], J. Vilar*[2], T. N. Nickelsen[3], T. Nicholson*[3], L. Lehmkuhl*[4], R. Barkmann*[1], C. C. Glüer[1]. [1]Med. Physik, Klinik f. Diag. Radiologie, UK SH, Kiel, Germany, [2]Dept. of Radiology, Hospital Dr. Peset, Valencia, Spain, [3]Eli Lilly & Company, Windlesham, United Kingdom, [4]Charité, Berlin, Germany.

The deficiencies of bone densitometry for monitoring osteoporosis treatment are well established. Here we introduce a method for in vivo structural analysis of trabecular bone at a central fracture site, the spine. In the Eurofors multi-center study, T-12 vertebrae were scanned with high resolution computed tomography (HRCT) in 67 osteoporotic women on Teriparatide treatment (20 µg per day). Measurements were repeated after 6 and 12 months. Microstructural variables were named analogous to standard histomorphometry nomenclature; a prefix "a" (for "apparent") was added to indicate that variables are affected by the limits in spatial resolution (e.g. aBV/TV). The voxel size of the scans was 156 to 187µm in-plane and 300 to 500µm through-plane. All scans were calibrated and trabecular bone was segmented with a threshold of 250 mg/cm^2. The chosen threshold assured a continuous cortical shell, physiological aBV/TV values, and good separation of bone structure versus pseudo structure in soft tissue. Structural variables were calculated by StructuralInsight software developed in-house. Differences in spatial resolution of the different CT scanners used had a significant influence on measured structural variables (not affecting longitudinal analyses) and were compensated for. Structural information could be measured reproducibly: each variable was highly correlated with the same variable at the following visit (r^2= 0.85 to 0.94). Long term precision errors for aBV/TV and aTb.N. were 12,5% and 11,2%, respectively, corresponding to monitoring time intervals of 1 and 1.2 years. Structural information was independent of BMD and BV/TV: For a given visit, structural variables were only weakly correlated with aBV/TV (r^2= 0.06 to 0.24) or BMD (r^2= 0.01 to 0.27), except for aTb.N, which was highly correlated to aBV/TV (r^2= 0.95). Correlation between BMD and aBV/TV was r^2= 0.27 at baseline. In multivariate correlation models, the best predictor for a structural variable in a return visit was the same variable at baseline (partial correlation rp^2=0.65 to 0.86), compared to BMD at baseline (rp^2 = 0.04 to 0.21) and aBV/TV at baseline (rp^2 = 0.01 to 0.22). We conclude that structural analysis provides consistent information independent of BMD in spite of spatial resolution and image noise limits. This method allows to non-invasively study structural changes in vivo at one of the most relevant fracture sites requiring follow-up times in the individual patient of about 1 year.

Relationships between pQCT Indicators of Bone Mass, Mineral Density, Design and Strength in Forearms and Legs of Normal Men and Pre and Post MP Women. R. Capozza*[1], G. Cointry*[2], S. Ferretti*[2], S. Feldman*[2], N. Fracalossi*[2], L. Sarrio*[2], P. Reina*[2], M. Ferretti*[2], M. Ferullo*[2], G. Marchetti*[2], E. Roldan[2], J. Ferretti[2]. [1]Scientific direction, GADOR S.A., Buenos aires, Argentina, [2]Center for P-Ca Metabolism Studies (CEMFoC), Fac of Medicine, Natl Univ, Rosario, Argentina.

Aim. To describe the interrelationships between different bone properties and the muscle interaction with their biological determination. **Methods.** The associations between bone mass pQCT indicators (BMC, cortical area, trabecular density), design (CSMIs), mineral density (cortical vBMD) and strength (BSIs) and of muscle strength (CSA) in forearm (4 and 66% sites) and legs (4, 14, 38 and 66% sites) of 40 men, 60 pre MP women and 100 post MP women aged 25-85y were analyzed. **Results.** Indicators of bone mass, design and strength were higher in men than in pre MP women. Mass and strength (not design) indicators decayed significantly after MP. Cortical vBMD, higher in women than men, decayed more dramatically than other indicators after MP. *Distribution/mass* (MI/CortCSA) and *distribution/quality* (MI/CortvBMD) curves showed that MIs tended to stabilize after MP, despite the bone mass reduction. The intracortical distribution of vBMD fell dramatically with a discontinuity of the areas of highest-density voxels (>1.0 cm^{-1} attenuation threshold) after MP. The natural 1:1 and 1:1.5 proportionalities between trabecular and cortical BMC in 4% *vs* 14% and *vs* 38% leg sites respectively also decayed after MP. All bone indicators correlated with muscle area in both 66% sites showing a single, saturation relationship for men and pre MP women, and a lower slope for post MP women. **Interpretation.** Results suggest 1) Bone mass varies allometrically with body size and biomechanically with regional muscle strength in fertile individuals 2) Estrogen deficiency determines a loss of mass and especially mineralization (enhanced microporosity) of cortical bone, maintaining the diaphyseal design relatively stable, thus slowing the development of bone fragility 3) Bone *mechanostat* remains healthy (yet metabolically disturbed) after MP 4) Comparison of BMC between trabecular or cortical sites in the same individual allows detecting a faster deterioration of the former, as determined in "systemic" (primary or endocrine-metabolic) osteopenias 5) In practice a *Z-scorization* of the described natural relationships will provide suitable reference charts for original, biomechanical diagnosis of osteoporosis, and a differential diagnosis between "disuse" (with normal bone/muscle proportionality) and "systemic" (reduced bone/muscle proportionality and the trabecular/cortical bone mass ratio) osteopenias with differential therapeutic implications.

Trabecular Bone Quality Evaluation By Using The Porous Mediums Connectivity Concept. A. C. A. Souza*[1], D. Barbieri*[2], R. Schneider*[1], W. L. Roque*[3]. [1]Institute of Geriatrics, PUCRS University, Porto Alegre, Brazil, [2]Dep of Bio Engeneering, PUCRS University, Porto Alegre, Brazil, [3]Department of Mathematics, Universidade Federal do RGS, Porto Alegre, Brazil.

The mechanical competence of trabecular bone is a function of both, bone mass and architecture. BMD is an important tool for osteoporosis diagnosis; however, it does not evaluate the bone structural and architectural quality. The modeling and visualization study of porous mediums in the trabecular bone, are very important for the comprehension of physical and geometrical properties. In general, the medium porosity is determined by visual calculation, based on the porous number counting that estimates the porous space percentage. The objective of this study is to develop a technique to identify the connectivity of the trabecular three-dimensional porous space by using the study of dissectors. A study of dissectors is a sequence of parallel tomographic images of thin slices with a separation L among surfaces took from a vertebral specimen. The porous are identified by using segmentation algorithms and their characteristics, as perimeter and area. The connectivity between porous of neighbor slices is identified in the orthogonal direction. The three-dimensional porous space connectivity is calculated by using the Euler-Poincaré volumetric characteristics technique. The final objective is to calculate an index that relates the number of isolated parts (N) to the number of connections in the porous space (C), and to the number of completely enclosed cavities (H). The Euler-Poincaré derived index reflects the trabecular structural and architectural quality. Seven cadaver collected vertebrae were scanned by Hologic 4500A DEXA and by a Siemens Somatom Plus CT. The vertebrae were scanned using resolution of 512 x 512 pixels, slices of 2.0 mm thickness. The images were segmented by an image processor software and the Euler-Poincaré derived index was calculated for every vertebra. Vertebrae 1 and 2 had BMD values compatible to osteoporosis and the Euler-Poincaré derived index confirmed low connectivity (low trabecular density and high porosity), revealing architectural deterioration. Vertebrae 3 and 4 had an osteopenic BMD values, however the index exhibited good trabecular connectivity, indicating good architectural structure. Vertebrae 5, 6 and 7 produced normal BMD values and the Euler-Poincaré derived index confirmed good trabecular structure. Despite vertebra 5 had lower BMD than 6 and 7, its trabecular connectivity index was better than 6 and 7. It can be concluded that trabecular porous connectivity evaluation provides important information for clinical decision related to bone structural quality, which is not seen through DEXA.

Improved Precision of Hip Structure Analysis Using Optimized Projection Images from Segmented 3D CT Scans of the Hip. J. K. Brown[1], Q. Qiao*[2], J. M. Weigert[3], B. Khoo*[4], T. J. Beck[2]. [1]Mindways Software Inc., Austin, TX, USA, [2]Radiology, Johns Hopkins University, Baltimore, MD, USA, [3]Radiology, Imaging Center of West Hartford, West Hartford, CT, USA, [4]Med. Technology & Physics, Sir Charles Gairdner Hospital, Nedlands, Australia.

The hip structure analysis (HSA) method was developed to derive bone cross-sectional properties at certain locations in the proximal femur from 2D DXA data so that the bone mass data could be interpreted mechanically. A major limitation on HSA precision is that inconsistent femur position alters projected dimensions so that changes in time or differences between subjects cannot be distinguished from actual geometric differences. This is especially important in the measurement of cross-sectional moments of inertia (CSMI) and section moduli (Z) that are rotationally dependent in cross-sections that are not axially symmetric. CTXA™ (Mindways Software Inc.) is a commercial application that generates DXA-like projection data compatible with the HSA method from a 3D QCT data set. Whereas the projection view obtained from a DXA device is determined at the time of data acquisition, the CTXA™ projection view is done retrospectively during post-acquisition processing thus providing greater projection-view control than can be achieved in conventional DXA. We used paired CT scans from 24 adult subjects with repositioning between scans done at a single visit. Scans were acquired with a helical CT scanner (GE NX/i) at 100 mA, 120 kVp and a section spacing of 3 mm. CTXA images with pixel spacing of 0.7 mm in both directions were exported to the HSA program. Coefficients of variation were computed from data pairs and compared to average values from Hologic DXA scanners generated from paired scans with repositioning in a large clinical trial(Khoo B, et al, 2005 BONE In Press). Results are compared in the Table for the narrow-neck and shaft regions. For the shaft region only 15 subjects could be used due to shaft cut-off in some CTXA images. In this preliminary study precision by CTXA is considerably improved in all geometric parameters especially in CSMI and Z. It is likely that some further improvement can be obtained by optimizing the HSA algorithm and the CT scan protocol. The major advantage of higher precision is that research studies should be able to demonstrate significant geometric effects with smaller numbers of subjects than required for DXA.

		%CV	
Region	**Parameter**	**Hologic DXA Scanners**	**CTXA**
Narrow-Neck	Bone Cross-Sectional Area	3.0%	0.9%
	Outer Diameter	2.3%	0.5%
	Cross-sectional Moment of Inertia	5.1%	1.9%
	Section Modulus	4.1%	1.4%
	Buckling Ratio	4.9%	1.6%
Shaft	Bone Cross-Sectional Area	2.4%	1.3%
	Outer Diameter	1.1%	0.4%
	Cross-sectional Moment of Inertia	3.7%	1.3%

Image Resolution Properties of Conventional DXA Scanners and Implications for Measuring Structural Geometry. Q. Qiao*[1], B. Khoo*[2], R. I. Price[2], T. J. Beck[1]. [1]Radiology, Johns Hopkins University, Baltimore, MD, USA, [2]Sir Charles Gairdner Hospital, Nedlands, Australia.

Hip Structure Analysis (HSA) uses dimensional information from DXA scans in measuring cross-sectional geometry but scanner spatial resolution properties influence the ability to do so accurately. Because DXA scanner resolution is less important in BMD analysis, this has not been thoroughly evaluated. We measured the resolution of the Hologic QDR1000W, QDR4500A and QDR4500W, and the GE/Lunar Prodigy. An L-shaped copper foil was placed flat in a 20 cm thick stack of 1 cm thick tissue equivalent plastic and imaged with the DXA scanner. To evaluate effects of resolution on bone height above the tabletop, the copper foil was imaged after placing it between plastic layers in 1 cm increments from the bottom to the top of the stack. Using an oversampling method to eliminate aliasing, pixel distributions across the edge of the foil image were fitted to a sigmoid function and the first derivative was derived as the point-spread function (PSF). The modulation transfer function (MTF) was then determined from the Fourier transform of the normalized PSF. Resolution was evaluated separately in vertical (along table axis) and horizontal (across table) directions. The resolution limit was defined at the spatial frequency where the MTF fell to 1%. All scanners showed MTF asymmetry with better resolution in the vertical than horizontal direction; resolution was best for objects at the tabletop. Results measured at 10 cm above the tabletop (typical height of an adult femur in a hip DXA scan), are shown in the Figure. All scanners conformed reasonably well with theoretical resolutions based on scanner specifications. All four had comparable horizontal resolution, with a slight advantage for the GE/Lunar Prodigy. The main differences were in vertical resolution with the highest value in the QDR4500A. In practical terms, resolution differences between scanners are modest. The considerable MTF asymmetry means that blurring of bone margins is greater when the long axis of the bone is vertically oriented (edges blurred horizontally) than when oriented horizontally (edges blurred vertically). For ideal geometry measurements, the resolution should be closer to 1 line pair/mm and should not vary with orientation of the bone in the image. Current commercial DXA scanners are less than ideal in this respect.

Assessing Changes in Bone Structure and Strength of the Mid-femur in Children Using Magnetic Resonance Imaging. C. M. Modlesky[1], D. L. Johnson*[1], F. Miller*[2]. [1]Department of Health, Nutrition and Exercise Sciences, University of Delaware, Newark, DE, USA, [2]Department of Orthopaedics, AI duPont Hospital for Children, Wilmington, DE, USA.

Magnetic resonance imaging (MRI) has been used to assess the structure and strength of the mid-femur in adults and adolescents; however, these measurements have not been acquired in children. Furthermore, changes in these bone parameters during a typical intervention period have not been evaluated. The purpose of this study was to assess the changes in bone structure and strength of the mid-femur in typically developing children during a 9 month period using MRI. 10 children (5 girls and 5 boys) 8 to 11 years of age and within the 10th and 90th percentiles for height, weight and body mass index completed the study. Approximately 24 images (1 cm thick separated by 0.5 cm) of the entire femur were collected twice, 9 months apart, using a GE 1.5 T MRI (TR= 750, TE = 14, 1 NEX,

512 x 512 matrix, FOV = 20 cm). Images representing the middle third of the femur were identified and total bone volume, cortical bone volume, medullary volume, cross-sectional moment of inertia in the medial-lateral ($CSMI_{ml}$) and anterior-posterior ($CSMI_{ap}$) directions, section modulus in the medial-lateral (Z_{ml}) and anterior-posterior (Z_{ap}) directions, and polar moment of inertia (J) were assessed using a custom software program. There was a significant increase ($P < 0.05$) in total bone volume (13.0 %), cortical bone volume (12.2 %), medullary volume (14.4 %), $CSMI_{ml}$ (16.3 %), $CSMI_{ap}$ (20.0 %), Z_{ml} (10.1 %), Z_{ap} (16.1 %) and J (18.4 %). Furthermore, total bone volume, cortical bone volume, medullary volume, $CSMI_{ml}$, $CSMI_{ap}$, Z_{ml}, Z_{ap} and J measured at the original time point were strongly correlated with the same measures taken 9 months later (r = 0.975, 0.959, 0.984, 0.956, 0.931, 0.964, 0.966, and 0.949, respectively, $P < 0.05$). The findings suggest that measures of bone structure and strength of the mid-femur in typically developing children increase by approximately 10 % to 20 % during a 9 month period. Moreover, the assessment of the structure and strength of the mid-femur in children using MRI is very reliable.

Defining Cortical Bone by pQCT: *In Vitro* and *In Vivo* Accuracy of Bone Geometry. S. Kontulainen, D. Liu*, M. Jamieson*, H. Macdonald*, S. Manske*, T. Oxland*, H. McKay. Orthopaedics, University of British Columbia, Vancouver, BC, Canada.

Peripheral quantitative computerized tomography (pQCT) is a relatively new technique to measure bone and to date there have been no validity studies or guidelines as to which modes and thresholds are the most accurate to analyse growing, mature or aging bone. The advantage of pQCT technology is its ability to measure the size, geometry and apparent volumetric density of a bone cross-section - all properties of bone that influence its mechanical integrity. Strength indices that estimate bone integrity are dependent on the measurements of total and cortical cross-sectional areas (ToA and CoA, respectively). Thus, accurate measurement of bone geometry is essential. Our first objective was to compare ToA and CoA values derived from several XCT-5.50 (Stratec) analysis protocols and MRI to histomorphometry in vitro. Our second objective was to determine the accuracy of different pQCT analysis protocols in healthy children by comparing in vivo pQCT results to MRI-derived ToA and CoA at the tibia. The overall goal of the study was to propose practical recommendations for pQCT analysis protocols that can be used to evaluate the growing skeleton in clinical practice and research. For *in vitro* accuracy, 18 human cadaver tibiae [donors' mean age 74 yrs (SD 6)] were measured with XCT-2000 and 1.5 Tesla MRI at 25% of the total length from the distal plateau. After scanning, histomorphometry from the same site was performed to obtain criterion ToA and CoA. For in vivo accuracy, 16 healthy girls [mean age 12.1 yrs (SD 0.5)] were measured with pQCT and MRI (criterion standard) at tibia 30% site. Several combinations of XCT analysis modes and thresholds (including manufacturer's defaults) were used to determine the most accurate protocol to represent the ToA and CoA criterion standards *in vitro* and *in vivo*. We determined the accuracy by calculating the %-difference between the criterion and measured value. For *in vitro* scans the most accurate measurement of ToA was obtained using CONTMODE 3 with an outer threshold of 169 mg/cm^3 (-1.1%). The most accurate mode for CoA analysis was CORTMODE 4 with an inner threshold of 670 mg/cm^3 (0.6%). For *in vivo*, ToA was analysed most accurately (-0.1%) when CONTMODE 1 was used with an outer threshold of 200 mg/cm^3, and CoA (-0.2%) when CORTMODE 4 with an inner threshold of 480 mg/cm^3 was used. Therefore, for paediatric bone, we recommend CONTMODE 1 with outer threshold 200 mg/cm^3 to define ToA. For CoA measurements we recommend CORTMODE 4 with the outer threshold 200 mg/cm^3 and inner threshold 480 mg/cm^3. These analysis protocols are different from those recommended by the manufacturer (Stratec).

Longitudinal Changes in 3D Microarchitecture of Paired Iliac Crest Bone Biopsies in Postmenopausal Women with Osteoporotic Vertebral Fracture. J. J. Zhao, Y. Jiang. Osteoporosis and Arthritis Research Group, University of California San Francisco, San Francisco, CA, USA.

This study was to compare true longitudinal postmenopausal osteoporotic changes in three-dimensional (3D) trabecular architecture, which may improve our ability to understand the pathophysiology of osteoporosis and other bone disorders, and to estimate bone biomechanical properties in terms of fracture resistance as the mechanical competence of trabecular bone is a function of its apparent density and 3D distribution. During aging and diseases such as osteoporosis, trabecular plates are perforated and connecting rods are dissolved, with a continuous shift from one structural type to the other, which can not be evaluated by 2D histological sections. In histomorphometry, there is debate about whether trabecular thinning occurs, or rather trabecular disappearance occurs with aging and/or menopause based on 2D sections using the parallel plate model. We examined 16 paired iliac crest bone biopsies (32 specimens), from 16 postmenopausal women with osteoporotic vertebral fractures and the hip/lumbar BMD at least 1 SD below the mean value in normal young women. The first biopsy was taken at age of 68 (±7) yrs, 10 (±9) yrs since menopause, while the second one 2 (±0.5) years later. The subjects were not treated with anti-resorptive or anabolic agent for osteoporosis. The specimens were scanned using a Scanco micro CT with isotropic resolution of 17 µm. 3D trabecular structural parameters were directly measured without stereological model assumption. Structure model index 0 represent an ideal plate structure and 3 represents rod structure. There was a significant change between paired bone biopsies in 3D trabecular bone volume fraction (14.8±1.3% vs. 11.3±0.8%, baseline vs. follow up), trabecular thickness (158±8 µm vs. 142±6 µm), structural model index (1.66±0.12 vs. 1.94±0.10), and connectivity density (6.1±0.6 mm^{-3} vs. 4.9±0.5 mm^{-3}). There was a trend of decreased 3D trabecular number, increased trabecular separation and degree of anisotropy, increased 3D cortical porosity, and decreased cortical thickness, in the follow up biopsies compared with baseline samples. Thus, 3D trabecular microstructure deteriorates in the iliac crest of postmenopausal osteoporotic women without active treatment. Trabecular thinning does occur and trabeculae shift from a plate-like structural type to a rod-like pattern, and become less connected.

Genetic Markers for Ancestry Are Correlated with Bone Density and Size in African Americans. C. M. Kammerer[1], J. R. Shaffer*[1], D. Reich*[2], E. Ziv*[3], D. C. Bauer*[3], J. Li*[3], A. B. Newman*[1], J. A. Cauley[1], T. B. Harris*[4], F. Tylavsky*[5], J. M. Zmuda[1]. [1]U. Pittsburgh Graduate School of Public Health, Pittsburgh, PA, USA, [2]Harvard Medical School, Boston, MA, USA, [3]UCSF, San Francisco, CA, USA, [4]National Institute on Aging, Bethesda, MD, USA, [5]U. Tennessee Health Science Center, Memphis, TN, USA.

Bone density (BMD) and size (length) differ among ethnic groups and these differences may have a genetic basis. Recently, researchers have developed methods to map disease genes in admixed populations, e.g. African Americans (AA), which derive portions of their genomes from different ancestral groups. Admixture mapping depends on the extended linkage disequilibrium that is present in admixed populations. If the differences in BMD and related phenotypes among ethnic groups are due to differences in allele frequency at susceptibility genes, then individuals with low BMD will have increased ancestry from the population with lower BMD. We used data collected on 1794 European Americans (EA) and 1281 AA (52% women) from the Health Aging and Body Composition Study (ages 68 to 80 yrs). We first determined that, as expected, DEXA measurements of areal BMD of the hip, and computed tomography measurements of volumetric BMD of the spine were significantly higher among AA than EA. Although total height did not differ between groups, trunk length was significantly decreased and leg length was increased in AA compared to EA. Using genotype data on 45 ancestry informative markers, we performed model-based clustering methods to estimate the proportion of European ancestry (median = 0.18, range, 0.0 to 0.66) for each AA. After adjusting for significant demographic and lifestyle variables, we observed that an increased proportion of European ancestry was significantly associated with decreased areal femoral neck BMD (r = -0.11), volumetric total spine BMD (r = -0.13), and trabecular spine BMD (r= -0.15; $p<0.01$ for all three traits). Although there was no relationship with total height, increased European ancestry was associated with increased trunk length (r = 0.17) and decreased leg length (r=-0.17, $p<0.0001$ for both). Based on the mean differences between EA and AA, the relationship between admixture and BMD or body length was in the expected direction. Furthermore, the predicted differences in BMD between AAs who had 0% versus 100% European ancestry ranged from 0.76 to 0.88 standard deviations, similar to the reported mean BMD differences between African and European populations. These results demonstrate a novel relationship between degree of European ancestry and several skeletal measures. Use of ancestry informative markers in admixed populations has great potential to detect genes for BMD and related traits.

Identification of Mouse Chromosomes Influencing Bone Morphology and Composition. H. Courtland[1], A. Hill*[2], J. Singer*[3], E. S. Lander*[3], J. H. Nadeau*[2], K. J. Jepsen[1]. [1]Orthopaedics, Mount Sinai Scool of Medicine, New York, NY, USA, [2]Case Western Reserve University, Cleveland, OH, USA, [3]MIT, Cambridge, MA, USA.

Research using inbred mice has demonstrated that three bone traits (area, moment of inertia, and ash content) explain 66-88% of inter-strain variability in fracture-related whole bone mechanical properties [1]. Given that the genetic determinants of these bone traits are poorly understood, we conducted a phenotypic analysis to map each trait to one or more chromosomes within the mouse genome. B6-i^A Chromosome Substitution Strains (CSSs) were used for this investigation. Each CSS is inbred and identical to the B6 host except that chromosome (i) is replaced with the corresponding intact chromosome from the A donor [2]. A total of 19 (17 autosomes, X, Y) CSSs were characterized in this study. Femurs from 14-16 week old (adult) B6 and B6-i^A mice (n=2-25 per group) were used in this analysis. Right femurs were taken for measurements of cortical area (CtAr) and moment of inertia (Jo) with analyses performed using IMAQ Vision Builder software. Left femurs were ashed at 600C for determination of ash content relative to wet weight. Significant differences in body weight-corrected mean trait values (as compared to host) were determined using genome-wide corrected multiple comparisons ($p<0.004$)[2, 3]. This investigation revealed several strains with mean trait values significantly different from B6 indicating that substituted chromosomes in these strains harbor one or more QTLs for our measured bone traits. Male B6-(2, 4, X and Y)^A and female B6-16^A strains had mean ash content values that were smaller and larger than B6, respectively. CtAr mean values lower than B6 were found in male B6-(1, 9, 19, 14, 18, X and Y)^A and female B6-(2, 3, 10 and 12)^A while higher mean values were found in male B6-3^A and female B6-(6, 11 and 13)^A. Jo results were similar, though not identical, to those of CtAr with mean values lower than B6 in male B6-(1, 10, 14, 15, 16, 17 and X)^A and female B6-(2, 3, 12, 15 and 17)^A. Larger Jo values were found in male B6-3^A and female B6-(6 and 13)^A. Our results revealed only one significant chromosome substitution shared between male and female mice. Thus, genetic regulation of CtAr, Jo, and ash content appears to be sex-dependent. Although substitution of individual A chromosomes permitted B6 mice to gain one or more A phenotypes (small CtAr, small, Jo and large ash)[4], no single chromosome substitution

caused all three traits to manifest as an A phenotype. Instead, multiple chromosomes were found to independently regulate bone traits both positively and negatively depending on genetic background.

Single Chromosome Substitutions Regulate Mouse Bone Growth Patterns. H. Courtland[1], A. Hill*[2], J. Singer*[3], E. S. Lander*[3], J. H. Nadeau*[2], K. J. Jepsen[1]. [1]Orthopaedics, Mount Sinai Scool of Medicine, New York, NY, USA, [2]Case Western Reserve University, Cleveland, OH, USA, [3]MIT, Cambridge, MA, USA.

Adult bone traits are the result of complex genetic variation in growth patterns. Two traits, cortical area (CtAr, tissue amount) and moment of inertia (Jo, tissue distribution), have distinct relationships to femur diameter and vary based on changes in the relative rate of expansion of the persiosteal and endosteal surfaces. Thus, bones that are built differently can differ in Jo and/or CtAr and the ratio of these traits indicates differences in skeletal growth patterns. For example, B6 femurs have a greater Jo for a given CtAr than A/J (A) femurs [1] and this affords them a more robust (structurally efficient) skeleton. The goal of this study was to explore the genetic determinants of femur Jo/CtAr variation using mouse B6-i^{A} Chromosome Substitution Strains (CSSs). Each B6-i^{A} CSS is inbred and identical to a B6 host except that chromosome (i) is replaced with the corresponding intact chromosome from the A donor [2]. A total of 19 (17 autosomes, X, Y) CSSs were characterized in this study. Femurs from 14-16 week old (adult) B6 and B6-i^{A} mice (n=2-25 per group) were used in this analysis. Right femurs were taken for measurements of CtAr and Jo with analyses performed using IMAQ Vision Builder software. Significant differences in body weight-corrected mean Jo/CtAr values (as compared to host) were determined using genome-wide corrected multiple comparisons ($p<0.004$)[2,3]. This investigation revealed several strains with mean Jo/CtAr values significantly different from B6 indicating that substituted chromosomes harbor one or more QTLs influencing bone growth patterns. Jo/CtAr mean values lower than B6 (decreased structural efficiency) were found in male B6-(1, 2, 12, 14, 15, 17 and 18)^{A} and female B6-(4, 11, 12, 15 and 17)^{A} while higher mean values (increased structural efficiency) were found in male B6-3^{A} and female B6-(6, and 13)^{A}. Many chromosomal substitutions reduced the structural efficiency of the B6 host suggesting that A mice have one or more genes on multiple chromosomes significantly influencing the way bone is deposited during growth. However, only one substitution (B6-15^{A}) reduced structural efficiency completely to the A mean value, and since this was found only in male mice, genetic regulation of femur structural efficiency is likely sex-dependent. A-substitutions increasing structural efficiency beyond B6 may be a result of host-donor interactions that enhance existing B6 growth patterns through new favorable allelic interactions or a result of removing negative allelic regulation inherent in the mouse genome.

Biomechanical Differences between C3H and B6 Inbred Strains of Mice Depend on Geometric Differences, not on Material Differences. G. H. van Lenthe[1], L. R. Donahue[2], R. Müller[1]. [1]Institute for Biomedical Engineering, ETH and University Zurich, Zurich, Switzerland, [2]The Jackson Laboratories, Bar Harbor, ME, USA.

Thanks to recently developed genome-wide screening techniques major research efforts have been started to identify the genetic influence on components of bone strength, such as bone volume, bone geometry, and bone material properties. The gold standard to determine bone material properties is to estimate them from three-point bending tests, using Euler-Bernoulli beam theory. However, beam theory is only valid when certain conditions are met, e.g. constant cross section and large support width. Those conditions are not fully met for bones, hence, results can be inaccurate. The objective of this study was to assess whether deviations from beam idealizations affects outcomes of three-point bending tests; specifically, we assessed those effects for two commonly used mouse inbred strains C57BL/6J (B6) and C3H/HeJ (C3H). Fifteen femora of four-month old mice were µCT scanned using a 20 µm resolution. After reducing voxel size to 30 µm micro-finite element models were created that simulated a three-point bending test. Bones were tested in antero-posterior direction; distance between the supports was 5 mm. Assuming an arbitrary Young's modulus (E) of 5 GPa, the force necessary to obtain a prescribed displacement of the loader was calculated. Then, Young's modulus was estimated (E_estim) as if this test was a standard mechanical test, using the commonly used equation based on beam theory. Young's modulus was underestimated for all femora (Table 1), which was mostly caused by the fact that shearing displacements are not accounted for by beam-theory. Owing to their relatively thin cortex, underestimation was higher for B6 than for C3H caused by higher local deformation; furthermore, underestimation was higher for males than females.

	female	male
B6	35%	26%
C3H	61%	52%

Table 1: Estimated Young's modulus as percentage of true modulus (E_estim/E).

We conclude that Young's moduli as determined from three-point bending tests on murine femora are strongly underestimated. These effects are size-dependent, hence, are affected by sex and inbred strain. Applying our findings to reported data on B6 and C3H mice (with E ranging from 2.2 GPa for B6 males to 5.3 GPa for C3H females) indicate that these differences are not true differences, but that E ≈ 8.6 GPa for all B6 and C3H males and females; hence, reported differences for E can be explained solely by geometric effects.

Allelic Imbalance in Human Osteoblasts: A Novel Experimental Tool to Extend Association Genetics into Functionality. E. Grundberg*[1], T. Pastinen*[2], T. J. Hudson*[2], A. Kindmark*[1], O. Nilsson*[3], H. Brändström*[1]. [1]Department of Medical Sciences, Uppsala University, Uppsala, Sweden, [2]Genome Quebec Innovation Centre, McGill University, Montreal, PQ, Canada, [3]Department of Surgical Sciences, Uppsala University, Uppsala, Sweden.

Osteoporosis is considered as a complex polygenic disease involving interactions between multiple genes and the environment. Several approaches are currently being used to identify the genes underlying the disease. Genome-wide linkage studies and association studies, using single nucleotide polymorphisms (SNPs) in candidate genes are common strategies. However, most of the SNPs studied have no functional validation. A new approach for identification of regulatory SNPs has recently been described using quantitative detection of allele-specific transcripts. Allele ratios in RNA samples derived from heterozygous individuals are compared with the corresponding genomic DNA samples. Presence of a regulatory SNP will result in allelic imbalance, where a deviation from the 50:50 ratio between the two alleles is expected. The aim of this study was to investigate presence of allelic imbalance in three genes involved in sex hormone regulation of bone, the Estrogen receptor alpha (ERalpha), RIZ1 and CYP19 gene encoding aromatase. Deindentified trabecular bone samples were obtained from 70 donors undergoing bone graft procedures and the bone specimens were cultured until the cells that migrated from the bone reached confluency. RNA and DNA from each sample were isolated using standard procedures. For exclusion of low expressed candidate genes, microarray analysis was performed using total RNA from human trabecular bone cells hybridized to Affymetrix HG-U133A GeneChips. In average, assays for two publicly available SNPs located within coding regions in the genes were designed. Genotyping of the selected SNPs were performed using Fluorescence polarization-single base extension to allow quantitative detection of allele-specific transcripts. The method was successfully validated by analyzing an imprinted gene, MEST, and a gene previously reported to have allelic imbalance in lymphoblastoid cell lines, BTN3A2. None of the SNPs in the selected genes showed a statistically significant deviation from the 50:50 ratio and were considered not to have allelic imbalance. In conclusion, this screening tool using primary cultures of human trabecular bone cells will help us to identify regulatory polymorphisms in candidate genes for osteoporosis and thereby identify genes which contribute to the development of osteoporosis.

Genes Decrease Osteoporosis Risk also Decrease Risk of Obesity. L. J. Zhao*, Y. J. Liu*, R. R. Recker, H. W. Deng. Osteoporosis Research Center, Creighton University, Omaha, NE, USA.

It is widely known that increasing body weight (and thus higher risk to obesity) is associated with higher bone mineral density (BMD) (and thus lower risk to osteoporosis). This dogma has been widely held and creates an apparent dilemma since some molecular, cell developmental and intervention studies have suggested otherwise so that a decreasing risk in obesity may actually result in lower risk to osteoporosis. Therefore, we performed this large-scale quantitative genetic analysis to tackle this dilemma by asking the question: Do factors (particularly genes) that decrease osteoporosis risk tend to increase or decrease risk to obesity? Using DXA, we obtained measurements of bone mass, fat mass and lean mass, body weight, and information on age, sex, and life-style and medical history, on 4,489 Caucasians from 512 pedigrees. We evaluated the impact of shared genetic and environmental factors on bone mass, fat mass, lean mass, and BMI (body mass index) by analyzing genetic, environmental, and phenotypic correlations between them via uni- and bi-variate quantitative genetic analyses, with BMD ***unadjusted*** or ***adjusted*** for body weight. BMD is measured at spine, hip and distal forearm. Fat mass, lean mass, BMI, and BMD all have strong genetic determination, with heritability all >0.4 ($p<0.001$). When BMD is NOT adjusted for body weight, fat mass, lean mass and BMI are ***positively*** correlated (both genetically and environmentally) with BMD ($p<0.001$), consistent with the widely held dogma that increasing obesity risk (e.g., by increasing BMI and fat mass) tend to decrease risk to osteoporosis (by increasing BMD). However, interestingly, when BMD is adjusted for body weight, the genetic and environmental correlations between fat mass and BMD became ***negative*** ($p<0.01$). This result indicates that increasing fat mass (and thus obesity risk) is ACTUALLY associated with decreasing BMD (and thus increased risk to osteoporosis), IF the mechanic loading effect of body weight on BMD is adjusted. Our study, for the first time, may provide a solution to the dilemma by showing that, both genes and environmental factors that tend to decrease risk to osteoporosis (by increasing BMD) may also decrease risk to obesity (by decreasing fat mass) if the effect of mechanic loading on BMD due to body weight is adjusted for. Therefore, our study not only suggests that interventions through molecular pathways (based on discovered genes) and/or environmental or life-style modifications (such as nutritional supplements or exercises) tend to work favorably for the health care of both osteoporosis and obesity, but also re-assuring the effects of appropriate weight bearing, mechanical loading (and thus exercise) on a healthy skeletal system.

Identification of Gender Specific Quantitative Trait Loci (QTL) for Trabecular and Cortical Bone in an F2-Intercross between GK and F344 Inbred Rat Strains. S. Lagerholm[1], K. Åkesson[1], H. Luthman*[2]. [1]Department of Clinical Sciences, Malmö, Clinical and Molecular Osteoporosis Research Unit, Malmö, Sweden, [2]Department of Clinical Sciences, Malmö, Medical Genetics Unit, Malmö, Sweden.

Genetic localization and identification of naturally occurring genetic variation (polymorphism) that regulate phenotypes, such as bone density in distinct trabecular and cortical compartments, allow penetration of the molecular pathophysiology of osteoporosis and development of new markers for the disease. Our primary aim was to identify chromosome regions genetically linked with peripheral quantitative computed tomography (pQCT) measures of trabecular and cortical bone quantity of tibia in (GKxF344)F2 rat intercross progeny. Material and methods: The GK rat is an established model for spontaneous multifactorial type-2 diabetes. Skeletal changes have been observed, making the rat well suited for studies of the association between osteoporosis and type-2 diabetes. F344 is a non-diabetic strain. The F2 progeny (121 male and 110 female rats) were genotyped for 181 genome-wide microsatellite markers at an average distance of 10 cM. For skeletal phenotypes, tibia was measured by pQCT at 7 months. Chromosomal location, order of markers, and the identification of QTLs were evaluated using MAPMAKER/QTL. Results: The observed difference of bone phenotypes in the F2-progeny between males and females, encouraged gender separated genetic linkage analyses to reduce non-genetic variance and optimize identification of gender specific QTLs. Three genome-wide significant QTLs (LOD ≥4.1) were identified in males (Chr 1, 7, and 15) and seven suggestive loci (LOD 2.8-4.0 on Chr 5, 6, 8, 10, 12, 14, and 17). In females, one significant QTL on Chr 18 was identified and eight suggestive loci were mapped on (Chr 1, 2, 3, 4, 7, 8, 10, and 12). The QTL on Chr 1 was linked with several cortical bone traits in both genders. The female specific locus on Chr 18 overlaps a QTL for insulin regulation, and the Chr 1, 7, and 10 loci overlap QTLs for body weight and glucose. Our results indicate that there are gender-gene interactions in the genetic regulation of trabecular and cortical bone quality. This study has expanded our knowledge about gender specific genetic regulation of bone traits, and despite the relatively small population, we are able to detect significant QTLs with significant impact on pQCT-phenotypes associated with bone quantity and quality. The results provide a platform for gene identification using congenic strains and advanced intercross populations generated between GK and F344.

PTHR1 Polymorphisms Influence BMD Variation through Effects on the Growing Skeleton. C. Vilarino-Guell*[1], P. Y. Woon*[1], L. J. Miles*[1], E. L. Duncan*[1], FAMOS Consortium*[2], ALSPAC Study*[3], C. D. Steer*[3], J. H. Tobias[4], J. A. Wass*[1], M. A. Brown[1]. [1]Botnar Research Centre, University of Oxford, Oxford, United Kingdom, [2]OXAGEN, Abingdon, United Kingdom, [3]Community Based Medicine, University of Bristol, Bristol, United Kingdom, [4]Clinical Sciences at South Bristol, University of Bristol, Bristol, United Kingdom.

We sought to investigate whether polymorphisms in the *PTHR1* gene are associated with BMD in families in a subset of which we have previously demonstrated linkage of chromosome 3p21 with BMD, the region in which *PTHR1* is encoded. We also studied the effects of these polymorphisms in peak BMD in the Children in Focus subset (n=785, mean age 118 months) of the Avon Longitudinal Study of Parents and Children (ALSPAC). The *PTHR1* gene including its 14 exons, their exon-intron boundaries, and 1500 bp of its promoter region were screened for polymorphisms by dHPLC and sequencing in 36 osteoporotic cases. Eleven SNPs, one tetranucleotide repeat and one tetranucleotide deletion were identified. A cohort of 730 families, consisting of 1236 men (39%) and 1926 women (61%), ascertained with probands with low BMD (z<-1.5) was genotyped for the 5 most informative SNPs (minor allele frequency >5%). Total association between *PTHR1* polymorphisms and lumbar spine (LS), femoral neck (FN), and total hip (TH) raw BMD measures corrected for age, gender and height was tested using the program QTDT. In our osteoporosis families, a minor association was noted between LS BMD and alleles of a known functional tetranucleotide repeat (U4) in the *PTHR1* promoter region (p=0.04). Haplotypes composed of two to three markers consisting of combinations of SNPs rs4683301, rs724449, rs2242116 and rs1531137 were also associated with LS, FN and TH BMD (p=0.04-0.008). This association was more pronounced in the youngest tertile of the population (age 16-44 years, p=0.03-0.0007). Similar association was found for the ALSPAC cohort; two marker haplotypes of SNPs rs4683301 and rs724449 were associated with height (p=0.008), and total body less head BMD (p=0.02), corrected for age and gender. The strong positive association findings in our osteoporosis dataset support a role for genetic variation in *PTHR1* in population BMD. A significant role for this polymorphism in osteoporosis risk is further supported by previous data demonstrating that the same alleles of this polymorphism affect height, bone resorption and *PTHR1* transcription. The finding that the association of *PTHR1* with BMD was strongest in the youngest age tertile of the FAMOS families, and in the ALSPAC cohort, suggests a greater role for *PTHR1* variation in peak bone BMD than in bone loss in later life.

Idiopathic Osteoporosis in Men Is Familial and Sex Specific. E. S. Kurland[1], D. J. McMahon[1], J. S. Powell*[1], T. L. Colvin*[1], D. A. Greenberg*[2], J. P. Bilezikian*[3]. [1]Department of Medicine, Columbia University, New York, NY, USA, [2]Department of Statistical Genetics and Biostatistics, Columbia University, New York, NY, USA, [3]Department of Medicine and Pharmacology, Columbia University, New York, NY, USA.

Many men with osteoporosis do not have a definable etiology and thus, are said to have idiopathic osteoporosis (IOM). To explore a possible genetic basis to IOM, we studied family members (FM) of 67 men. Eighty-one 1st degree relatives from 32 of these 67 probands (48%) were included. The mean age of the 67 probands was 49.4 ± 1.6 years (SEM) with mean lumbar spine (LS), femoral neck (FN) and 1/3 radius (RAD) Z-scores of -2.8 ± 0.1, -1.5 ± 0.1, -1.1 ± 0.2 respectively. Age and Z-scores did not differ significantly for the subset of 32 probands from whom the FM were recruited from the 35 probands whose FM were not studied. FM completed a questionnaire that included information on past medical, social history and medications. Identifiable secondary causes of osteoporosis were grounds for exclusion of FM. Bone mineral density (BMD) was measured at the LS, FN and RAD by DXA (Hologic or Lunar). Sex-specific reference databases were used for men and women. FM characteristics were as follows: 43 men (53%) and 38 women (47%) with mean ages of 44.6 ± 2.9 and 46.0 ± 3.0 yrs respectively (NS). Of the 81 FM, 38% were siblings [18 brothers (B), 13 sisters (S)], 26% parents [10 fathers (F) 11 mothers (M)] and 36% children [15 sons, 14 daughters (D)]. Age was comparable between males and females within these family subsets (NS). An average of 3 FM were recruited per proband (range 1-8). Mean Z-scores at the 3 sites measured were as follows for males compared with females: -1.5 ± 0.2 and -0.7 ± 0.2, -0.6 ± 0.2 and -0.3 ± 0.2, + 0.2 ± 0.3 and +0.5 ± 0.2 for LS, FN and RAD respectively ($p < 0.05$ for LS comparison, unpaired t-test). BMD was most significantly different for sons as compared with D as follows: -2.0 ± 0.3 and -0.6 ± 0.3, -0.7 ± 0.3 and +0.1 ± 0.2, -0.2 ± 0.4 and +0.6 ± 0.2 for LS, FN and RAD respectively ($p < 0.05$ at LS). For male relatives most severely affected (i.e., Z-score < -2.0), 47% of the sons (7/15) met this criterion at the LS in contrast to only 7% of D (1/14; $p < 0.02$ chi-square). For brothers, there was a trend at the LS, with 39% (7/18) affected as compared with only 8% (1/13) for S ($p = 0.09$ chi-square). Parents (F and M) were affected to the same extent, 10% compared to 9%. These results suggest that IOM is familial, is not a sex-linked disorder- as father to son transmission occurs- but may be influenced by sex i.e. modified by the gender of the person expressing the genetic trait. Further family studies with particular emphasis on fathers, sons and brothers may help elucidate the genetic, hormonal and other factors that potentiate the expression of this disorder.

Genetic Loci Influencing Age-Related Declines in Bone Quality. D. H. Lang[1], N. A. Sharkey[1], G. P. Vogler*[2], D. J. Vandenbergh*[2], D. A. Blizard*[3], J. T. Stout*[3], G. E. McClearn*[2]. [1]Kinesiology, Pennsylvania State University, University Park, PA, USA, [2]Biobehavioral Health, Pennsylvania State University, University Park, PA, USA, [3]Center for Developmental and Health Genetics, Pennsylvania State University, University Park, PA, USA.

This study was designed to increase our understanding of the genetic architecture responsible for age-related declines in bone quality. While peak bone mass has been shown to be a predictor of fracture risk it fails to completely explain the increased number of spontaneous fractures occurring in the aged population. Insight into the genetic regulation of the intrinsic material properties, material distribution, and bone architecture could provide new avenues for preventing increased fracture risk in aged individuals. The primary aim of this work was to identify quantitative trait loci (QTL) for age-related differences in skeletal measures of strength and architecture between 200 day and 800 day BXD recombinant inbred (RI) mouse strains. Three-point bending tests were used to assess the mechanical integrity of femora and tibiae and a shear test was performed on the femoral neck. Strain means were used in QTL analyses to search for chromosomal regions influencing skeletal phenotypes at 200 and 800 days of age. Additionally, the difference in RI strain means between 800 and 200 day skeletal phenotypes was used in QTL analyses to search for chromosomal regions influencing change in bone quality as a function of age. Of primary interest are the QTLs for phenotypes reflecting decrements in bone quality as a function of age. Therefore the QTL results from the sex-specific interval mapping analyses summarized in Table 1 only include those traits displaying age-related strain differences (middle column) and with LOD scores of 3.3 or greater in one of the three analyses described previously. The most interesting results are those on chromosomes 2, 3, 4, 5, and 9 where significant QTLs were identified for age-related differences, but were not identified in the specific 200 and 800 day analyses. The identification of QTLs for skeletal phenotypes at a distinct point in time does not necessarily indicate that the QTL is influencing age-related changes in bone quality. QTLs influencing a change in bone integrity as a function of age may be fundamentally more important in relation to osteoporosis and fracture risk in old age.

Table 1: QTL interval mapping results. *A-data adjusted for animal size, U-unadjusted, and B-both

Effect of Deficiency of L-Gulonolactone Oxidase on Mouse Gene Expression Profiling . W. Gu[1], Y. Jiao*[1], J. Yan*[1], X. Li*[2], W. G. Beamer[3]. [1]University of Tennessee Health Science Center, Memphis, TN, USA, [2]University of Chicago, Chicago, IL, USA, [3]The Jackson Laboratory, Bar Harbor, ME, USA.

Human species and guinea pigs are unable to synthesize ascorbic acid (Vitamin C) because of, unlike rodents, lack of the enzyme L-gulonolactone oxidase. Recently, we discovered a deletion, which includes all 12 exons in the gene for L-gulonolactone oxidase (LGO), from the spontaneous fractures (*sfx*) mouse, which is characterized by a spontaneous bone fracture seen around 6 weeks of age. However, it is not known if any other genetic elements also exist in the deleted region. To confirm the LGO is the only gene in the deleted region that causes the *sfx* disease, we have conducted an experiment to feed the *sfx* mice with Vitamin C and compare their phenotype with that of normal mice. We then conducted a study using microarray to analyze the impact of lacking of LGO on the gene expression of three tissues, Femur, kidney, and liver. Finally, we conducted semi-quantitative PCR to confirm selected genes from microarray analysis. Our study shows that although the size of the deletion on chromosome 14 is as large as 38 kb in *sfx* mice, it contains only the LGO gene. The *sfx* mice with Vitamin C in food grew at the same rate as their wild type littermates. On the aspect of gene expression profiles, we found that, in addition to the difference between normal and sfx mice, there were also differences among bone, kidney, and liver. Further comparison of the genes that differed by more than 2 of log2 values indicated that there were a small number of genes that change expression profiles in all of these three tissues, namely 11. While changes of expression profiles of 83 genes were the same between the liver and kidney, 30 were the same between the liver and bone and 44 between kidney and bone. The expression levels of five genes were further analyzed using semi-quantitative PCR. Among these five genes, expression of four of them was down regulated and one was up regulated. In addition, we found that one gene expressed only in bone. This gene also showed sex difference on its expression. It was down regulated in the male but not in the female mice. While the expression levels of other genes did not show the sex difference.

Hierarchical Clustering of Differentially Expressed Genes in Femoral Bone from Domestic and Wild Type Chickens Reveals Alterations of Specific Signalling Pathways. C. L. Rubin*[1], P. Savolainen*[2], J. Lundeberg*[2], L. Andersson*[3], A. Kindmark[1]. [1]Dep. Med. Sciences, Metabolic Bone Diseases, Uppsala, Sweden, [2]Dep. of Biotechnology, Royal Institute of Technology (RIT), Stockholm, Sweden, [3]Dep. of Animal Breeding and Genetics, Swedish Univ. of Agricultural Sciences, Uppsala, Sweden.

With the aim of identifying differentially expressed genes, a global expression analysis of femoral bone RNA from individuals of two divergent lines of chicken was performed using cDNA-microarrays. Hierarchical clustering of the microarray data was performed to identify similarities in expression of differentlially expressed genes. The domestic White Leghorn (WL) chicken and the wild ancestor, the Red Junglefowl (RJF) are separated by several thousand years of evolution. During domestication, selection in the WL for growth and egg-laying traits has resulted in profound phenotypic differences between the two lines. By performing Quantitative Trait Loci- (QTL) analyses of a WL and RJF intercross, we have previously identified genetic regions harbouring elements responsible for differences in several bone traits. Twenty individuals, (5 male and 5 female from each population) were sacrificed at 250 days of age (approved by local ethics committee). Femoral bones were snap frozen in liquid nitrogen and stored at -70°C. 20 µg of purified RNA from each individual and 20 µg reference RNA were subjected to cDNA synthesis and were labelled with either Cy3 or Cy5 in a dye swap manner, and were then hybridized onto the cDNA-microarray (developed at RIT and comprising 13000 putatively unique chicken clones). The raw fluorescence data was subjected to filtration, normalization and statistical tests in the software R. The Log2 transformed values of the ratio of flourescence (sample/reference) for each individual were used as input files in the hierarchical clustering, which was performed in the software Cluster. In the microarray analysis we identified 579 transcripts as differentially expressed between WL and RJ (measured by an empirical Bayesian approach, the B-test). Of the transcripts displaying differential expression, several belong to distinct signalling pathways and cluster together with a higly correlated pattern of expression, indicating that their expression is controlled by the same regulatory factors, possibly the genes or genetic elements responsible for the QTLs. Future plans include clustering of microarray data from different tissues of the same chicken individuals. This may reveal other affected signalling pathways or may add further information regarding the pathways identified in the analysis of bone tissue.

The D727E Polymorphism of the Human Thyroid Stimulating Hormone Receptor Is Associated with Bone Mineral Density and Bone Loss in Women from the UK. O. M. E. Albagha*[1], R. Natarajan*[1], D. M. Reid[1], S. H. Ralston[2]. [1]Medicine & Therapeutics, University of Aberdeen, Aberdeen, United Kingdom, [2]Rheumatic Disease Unit, University of Edinburgh, Edinburgh, United Kingdom.

Genetic factors are important in the pathogenesis of osteoporosis and regulation of bone mass, but most genes responsible remain to be defined. Recent reports, using thyroid stimulating hormone receptor (TSHR) knockout mice, have shown that TSH exerts direct effects on bone cells through TSHR by inhibiting both osteoclastic bone resorption and osteoblastic bone formation (Abe *et al*, Cell 2003). *TSHR* null mice have severe osteoporosis at all skeletal sites and die by 10 weeks of age, whereas *TSHR*$^{+/-}$ mice thrive normally but have pronounced osteoporosis and focal osteosclerosis. In this study, we investigated the role of *TSHR* gene as a candidate for regulation of bone mass by examining the association between a common polymorphism (D727E) of the *TSHR* gene and bone mineral density (BMD) in a population based study of ~1250 women randomly selected from Scotland who were followed-up for ~ 6 years. The D727E polymorphism was detected using PCR-direct DNA sequencing, BMD was measured using DXA. Genotype frequencies (D/D= 1078, D/E= 171, E/E= 8) were in Hardy-Weinberg equilibrium and were similar to those previously reported in white populations. We observed a significant association between D727E polymorphism and BMD, so that women having the D/D genotype had significantly reduced lumbar spine (LS) and femoral neck (FN) BMD (mean ± sem; LS= 0.999 ± 0.005; FN= 0.831 ± 0.004) compared to those without this genotype (LS= 1.028 ± 0.013, p=0.029; FN= 0.852 ± 0.009, p=0.036). The result remained significant after adjustment for confounding factors (age, body mass index, menopausal status and HRT use) using general linear model ANOVA (LS p-value=0.037; FN p-value=0.048). Analysis of D727E in relation to bone loss showed that annual rates of LS bone loss for women with D/D genotype were about 2 fold higher (-0.670 ± 0.036) than those without this genotype (-0.318 ± 0.103; p=0.0004) and the results remained significant after adjustment for confounding factors (p=0.003). A similar trend was observed for rates of FN bone loss but results were of borderline significance (unadjusted p= 0.04; adjusted p = 0.14). In conclusion, the work presented here is the first to report a significant association between polymorphisms of the human *TSHR* gene and BMD which suggest that allelic variation at the *TSHR* gene might be important for regulation of BMD in humans, raising the possibility that *TSHR* genotyping could be useful genetic marker for BMD and susceptibility to fractures. However, the exact mechanism by which this polymorphism affects BMD remains to be determined

Variation in the PTH and PTHLH Genes, Serum PTH Levels and Bone Mineral Density in Elderly Women. M. Tenne*, P. Gerdhem, K. Obrant, H. Luthman*, K. Åkesson. Dept of Orthopaedics, Dept of Clinical Sciences, Malmö, Malmö, Sweden.

Parathyroid hormone (PTH) is a key regulator of calcium metabolism, whereas parathyroid hormone-like hormone (PTHLH) secretion has been observed in tumors, causing hypocalcaemia of malignacy, but it has also a physiological role during early bone growth. PTH and PTHLH act through the same receptor, the PTH/PTHLH receptor, a class B G-protein-coupled receptor. In addition, a second receptor the PTHR2 receptor has been identified. The physiological activity induced by PTH and PTHLH is depending on the N-terminal domain for ligand binding, where amino acid substitutions may have critical adverse effects on high-affinity ligand binding and biological activity. PTH hypersecretion induce bone resorption, whereas intermittent injection of PTH increase bone mass and is used for treatment of osteoporosis. To explore the effects of genetic variation in the PTH/PTHLH system, we have evaluated variations in genes for PTH and PTHLH in relation to osteoporosis associated traits in elderly women. The study group includes 1044 elderly women, all 75-yrs old, from the Malmö Osteoporosis Prospective Risk Assessment study (OPRA). They are extensively phenotyped: bone mineral density (BMD), quantitative calcaneus ultrasound, serum PTH, bone metabolic markers, fracture, health and life style, and followed for up to 8 years. Six polymorphic loci at the PTH locus on chromosome 11 were identified in the International HapMap Genotype Database, and three loci at the PTHLH locus on chromosome 12. The determined single nucleotide polymorphism (SNPs) allow for haplotype dissection of the gene to provide further inference of the locus. Of the PTH SNPs, two are located downstream, one in the intron and three upstream, while two PTHLH SNPs are located in the gene and one 2000 bp upstream. Two PTH SNPs were associated with serum PTH concentrations. Interestingly, homozygocity for the least frequent allele (TT) in same SNPs were associated with a history of previous fracture. One of the SNPs was associated with lower spinal BMD (p=0.007) at baseline, whereas no association was evident for the other measured sites, or for annual bone loss. We did not find any association between the analyzed polymorphisms of PTHLH and serum PTH or

bone variables. The PTH system is of major importance for regulation of bone turnover particularly in the elderly. This is to our knowledge the first study evaluating variation in the PTH/PTHLH gene regions. Genetic analyses of this regulatory system by genotypes and haplotype dissection provide insights to the functional links between serum levels and the clinically significant end-points of bone mass and fracture in elderly women.

Regulatory Polymorphisms in the Vitamin D Receptor Gene Cause Reduced Expression. Y. Fang*[1], A. Alesio*[2], M. Jhamai*[1], F. Rivadeneira[1], J. van Leeuwen[1], F. Jehan*[2], H. Pols*[1], A. Uitterlinden[1]. [1]Internal Medicine, Erasmus Medical Center, Rotterdam, The Netherlands, [2]Endocrinology, Bone & Development, Inserm U561, Hopital Saint Vincent de Paul, Paris, France.

Introduction Vitamin D receptor (VDR) gene polymorphisms are associated with complex diseases, including osteoporosis, but with inconsistent results. We previously analysed LD haplotype blocks in Caucasians across the VDR gene, and found haplotype alleles of the promoter and 3'untranslated region (UTR) associated with increased fracture risk and decreased body height. To investigate the underlying mechanism, we performed functional experiments for individual polymorphisms and haplotypes in both the VDR promoter and 3'UTR areas. **Material & Methods** To examine promoter SNPs electrophoretic gel mobility shift assay (EMSA) were done using HEK293 or CaCo2 nuclear extracts, and luciferase reporter constructs were assayed in HEK293. We measured VDR mRNA level for the 3'-UTR variations by transfecting constructs with VDR cDNA and the entire 3'UTR of either the hap_u1 (risk) allele or the hap_u2 (protective) allele in osteoblast cell lines MG63 and SV-HFO, and in HEK293, CaCo2 and COS1. mRNA stability was determined in MG63 at 0-8-24 h after inhibiting transcription. **Results** For the 1e/1a promoter we found that the "G" weaker binding (by EMSA) alleles at a known Cdx-2 site (1e-G-1739A) and a novel GATA binding site (1a-A-1012G) are both on the promoter risk ea_hap1 haplotype allele. We transfected reporter constructs containing 2 kb 1a-promoter sequence, and observed 53% lower expression of the risk ea_hap1 allele vs. ea_hap2 or 3 (Fig1, $p=5\times10^{-7}$, n = 51 exp.). For the 3'UTR variants the normalized VDR mRNA level of hap_u1 was 15% lower for all cell lines combined with similar patterns in all individual cell lines (Fig2a, $p=2\times10^{-6}$, n = 53). We observed a 30% faster mRNA decay of hap_u1 vs. hap_u2 in the MG63 (Fig2b, p=0.02, n = 9). **Conclusion** We demonstrate *in vitro* that risk haplotypes in both the VDR promoter and the 3'-UTR cause a modest reduction in mRNA level in potential target cells. We postulate these subtle functional effects to underlie the associations we reported for fracture and height, by resulting in a modestly reduced sensitivity for vitamin D signalling.

Association Between Genetic Polymorphisms of Enzymes Involving Mevalonate Pathway (*GGPS1*, *FDPS*) and Therapeutic Response to Bisphosphonate. J. Choi*[1], D. Kang*[1], D. Kim*[2], H. Song*[3], S. Cho*[4], S. Kim[4], J. Lee*[5], Y. Chung[3], C. S. Shin[4]. [1]Preventive Medicine, Seoul National University College of Medicine, Seoul, Republic of Korea, [2]Internal Medicine, Dankook University College of Medicine, Cheon-An, Republic of Korea, [3]Endocrinology and Metabolism, Ajou University School of Medicine, Suwan, Republic of Korea, [4]Internal Medicine, Seoul National University College of Medicine, Seoul, Republic of Korea, [5]DNA Link, Seoul, Republic of Korea.

Nitrogen containing bisphosphonates (N-BP) inhibit the enzymes of the mevalonate biosynthetic pathway including farnesyl pyrophosphate synthetase (FDPS) and geranylgeranyl diphosphate synthase (GGPS1), which result in inhibition of prenylation of small GTP-binding proteins in osteoclasts and disruption of the cytoskeleton. To investigate the relationship between *FDPS* and *GGPS1* genetic polymorphisms and changes in BMD before and after N-BP treatment in Korean, 137 patients aged 32-82 years (60.4±10.23, mean±SD) were enrolled in this study. BMD at lumbar spine and femoral neck was measured by dual-energy X ray absorptiometry. PCR and direct sequencing were used to identify the polymorphisms of *FDPS* and *GGPS1* in 48 healthy Korean; among five and eight SNPs screened, respectively, those of which the variant allele frequencies are more than 10% were selected (*FDPS* IVS1-98G>T, IVS9+66G>T and *GGPS1* -8188A/[Del] and IVS3-12~13T[Ins]). Genetic polymorphisms were determined by single base primer extension assay. The difference changes (%) of the BMD according to the genotypes of *FDPS* and *GGPS1* were analyzed by Kruskal-Wallis test. The response of BMD at lumbar spine to N-BP significantly increased in subjects with *GGPS1* -8188 A[Del] or IVS3-12~13 T[Ins] allele, respectively (p=0.010 and p=0.007); 9% changes of BMD at lumbar spine in subjects with *GGPS1* variant allele (both -8188 A[Del] and IVS3-12~13T[Ins]) vs. only 5% with no variant allele of *GGPS1*. When we defined the non-responder group as subjects, who had BMD lost or unchanged after N-BP treatment, 14.1% of subjects were included. After adjustment for age, gender and initial BMD, the significant association remained between drug responsiveness and genetic polymorphisms of *GGPS1* (p=0.006 and p=0.015, respectively). However, these associations were not found in the femoral neck BMD. No significant association was observed between BMD changes and *FDPS* polymorphisms.

Polymorphisms in the RANKL Gene Are Not Associated with Bone Mass or Risk of Osteoporotic Fractures. L. B. Husted, M. Carstens*, L. Stenkjær*, B. L. Langdahl. Endocrinology, Aarhus University Hospital, Aarhus Sygehus, Aarhus C, Denmark.

Interaction between receptor activator of nuclear factor-kappa B (RANK), RANK ligand (RANKL) and osteoprotegerin (OPG) controls recruitment and activity of osteoclasts. Genetic variant in these three genes are therefore possible contributors to the genetic background of osteoporosis. We have previously demonstrated that polymorphisms in the OPG gene are associated with changes in bone mass and risk of osteoporotic fractures. In this study we wanted to examine the RANKL gene for polymorphisms and the influence of such polymorphisms on bone mass and risk of osteoporotic fractures. We have examined the promoter (1128 basepairs upstream from the transcription initiation site) and the 5 exons for polymorphisms in 50 osteoporotic patients and 50 normal individuals using sequencing. We identified six polymorphisms: Three in the promoter: C-693-G, C-643-T and T-290-C, two in exon 1: C233-G and C252-T and one in intron 2: A513+14-G. The three promoter polymorphisms and C252-T were in almost complete linkage disequilibrium. C252-T is a conservative polymorphism, whereas C233-G is changing the 36th aminoacid from proline to arginine, however, this polymorphism was only found in 2% of the examined alleles. We examined the effect of T-290-C and A513+14-G on bone mass and risk of osteoporotic fractures in 720 osteoporotic patients and normal controls. The T-290-C polymorphism did not influence height and weight. In individuals with the TT, TC and CC genotypes BMD(ls) was 0.901±0.175 g/cm^2, 0.901±0.178 g/cm^2 and 0.898±0.173 g/cm^2, respectively, ns. No differences in BMD at any of the hip sites were demonstrated. Furthermore, prevalence of the TT, TC and CC genotypes was 30.4%, 44.7% and 24.9% in patients with vertebral fractures, respectively, and 29.8%, 47.6% and 22.5% in normal controls, respectively, chi-sq=0.60, ns. Prevalence of the AA, AG and GG genotypes of the A513+14-G polymorphism was 71.7%, 25.0% and 3.3% in patients with vertebral fractures, respectively, and 67.3%, 30.2% and 2.5% in normal controls, respectively, chi-sq=1.99, ns. BMD(ls) was slightly reduced in the rare genotype, GG, 0.857±0.236 g/cm^2 compared with 0.901±0.176 g/cm^2 in the AA and 0.905±0.167 g/cm^2 in the AG genotypes, however the difference did not reach significance. No differences were found between genotypes in BMD at the different hip sites, height and weight.In conclusion: We have found 6 polymorphisms in the RANKL gene. None of these are associated with bone mass and risk of osteoporotic fractures.

ESR2 Influences the Risk of Osteoporotic Fracture in Postmenopausal Women. M. C. Zillikens*[1], F. Rivadeneira[1], J. van Meurs[1], T. Beck[2], J. Houwing*[3], A. Hofman*[1], J. van Leeuwen[1], C. van Duijn*[1], H. A. Pols[1], A. Uitterlinden[1]. [1]Erasmus Medical Center, Rotterdam, The Netherlands, [2]Johns Hopkins University, Baltimore, MD, USA, [3]LUMC, Leiden, The Netherlands.

Aim We examined the role of variants in the *ESR2* gene (alone and in interaction with *ESR1* and *IGF1*) in relation to the risk of osteoporotic fracture. **Methods** We studied six SNPs in the *ESR2* gene (Fig 1) in a large population-based cohort of elderly men and women (n=6343). Results refer to the most frequent haplotype (*haplotype 1*) estimated from the *intron 2* and *3'UTR* SNPs. Interaction was studied with *ESR1* (*XbaI*, *PvuII haplotype 1*) and *IGF1* (*CA_n promoter repeat*). Outcomes included vertebral fracture (X-ray screening in 3469 individuals), incident non-vertebral fracture (mean follow-up 8.6 years), BMD and geometry from hip structural analysis (HSA). **Results** Female homozygous carriers (HM) of *haplotype 1* in the *ESR2* gene had increased risk of vertebral and fragility fracture (Fig 2). HM women had 1.1% (p=0.06) less vertebral area and 3.8% higher (p=0.001) buckling ratio (an index of bone instability). Non-carriers of *haplotype 1* in either of the estrogen receptor genes (NC/NC) were the reference. Women homozygous carriers (HM) of *ESR2 haplotype 1* and non-carriers (NC) of *haplotype 1* in *ESR1* (which have higher ER1 sensitivity-black bars) have 3.5 (*95%CI* 1.4 - 8.4) and 1.8 (*95%CI* 1.0 - 3.4) increased risk of vertebral (Fig 3) and fragility fracture (Fig 4); with *p interaction* = 0.06 and 0.10 for the risk of vertebral and fragility fracture, respectively. These interactions were stronger in women homozygous for the *192-bp* allele of the *IGF1* promoter polymorphism (*p interaction* = 0.002 and 0.01 for the risk of vertebral and fragility fracture, respectively) which have higher IGF-I levels. Similar gene interactions were observed for BMD and bone geometry (HSA). In men, no such effects were observed. **Conclusions** Presence of the *ESR2 haplotype 1* (alone or in interaction with variants of *ESR1* and *IGF1*) influences the risk of osteoporotic fracture in postmenopausal women.

Genetic Variation in Estrogen Receptor Alpha and Interleukin-6 Is Associated with Bone Mass Acquisition in Prepubertal Girls and Boys: Interaction with Calcium Supplements. P. Pennisi*[1], T. Chevalley[2], D. Manen*[2], F. Herrmann*[2], M. Brandi[3], R. Rizzoli[2], S. Ferrari[2]. [1]Dept. of Internal Medicine, University Hospital of Catania, Catania, Italy, [2]Div. of Bone Diseases, Geneva University Hospital, Geneva, Switzerland, [3]Dept. of Internal Medicine, University Hospital of Florence, Florence, Italy.

Estrogens regulate interleukin-6 (IL6) expression. Polymorphisms in estrogen receptor alpha (ESR1) and IL6 genes are associated with BMD, bone turnover and/or fracture risk in post-menopausal women. Whether genetic variation in ESR1 and IL6 plays a role on bone mass acquisition however remains unknown. We examined the association of ESR1-XbaI and IL6 -174 G>C polymorphisms with BMD and their interaction with calcium intake in 139 girls and 232 boys who received calcium supplements (800mg/d) or placebo for 1 yr. BMD at lumbar spine (LS), total hip (TH), femoral neck (FN), ultra distal (UR) and total radius (TR) was evaluated by DXA at baseline (mean age ±SD, 7.6±0.4 yrs) and after 1 and 2 yrs (age, 9.9±0.5 yrs). Genotypes distribution was similar in both genders (rare alleles: ESR1 XX, 12%, IL6 CC, 15%). ESR1 genotypes were associated with BMD at most skeletal sites (p=0.01-0.06 adjusted for age, weight and height), with a borderline interaction with sex (Pinter≤0.09). Indeed, xx females had 2-6% higher BMD compared to Xx and/or XX (LS p=0.04 and p=0.03; FN p=0.004 and p=0.05; TH p=0.009 and ns; TR p=0.005 and ns at baseline and after 2 yrs, respectively), whereas males did not. ESR1 genotypes were not associated with BMD gain in absence of calcium supplements, but a significant interaction with calcium supplements occurred on hip (Pinter=0.03). Indeed, calcium supplements increased FN and TH BMD gain 2-3x above placebo among XX, but not among carriers of the x allele. At baseline, IL6 -174 genotypes were associated with BMD at LS (+4% in GG compared to CC and GC, p=0.001), but not at other skeletal sites, and without evidence of interaction with sex. After two years, this association became weaker (p=0.05), since GG from both genders had a 26% lower LS BMD gain during yr 2 in absence of calcium supplements (p=0.01 vs CC and GC, adjusted for age, pubertal stage, and changes in height and weight). Calcium supplements significantly increased TR and UR BMD gain in males and females (p=0.006 and p=0.05, respectively), without evidence of interaction with IL6 genotypes In conclusions, ESR1-XbaI and IL6 promoter -174G>C polymorphisms are associated with BMD and BMD gain in prepubertal children. Whereas IL6 genetic variation appears to modulate bone mass acquisition at LS irrespective of sex and calcium intake, the broad influence of ESR1 genotypes on BMD was more prominent in females and may depend on the level of calcium intake.

Two New Single Nucleotide Polymorphisms in the CYP19 Gene. Association with BMD in a Cohort of 256 Spanish Postmenopausal Women. S. Balcells*[1], A. Enjuanes*[2], N. Garcia-Giralt*[2], A. Supervia*[3], X. Nogues[3], S. Ruiz-Gaspa*[2], M. Bustamante*[1], L. Mellibovsky*[3], D. Grinberg*[1], A. Diez-Perez[3]. [1]Genetics, University of Barcelona, Barcelona, Spain, [2]IMIM, Barcelona, Spain, [3]Hospital del Mar, Barcelona, Spain.

Background. Current evidence suggests that extragonadal estrogens play an important role in determining bone mineral density (BMD). Estrogen biosynthesis is catalyzed by the P450aromatase, encoded by the *CYP19* gene. An association analysis of promoter SNPs with BMD was conducted. **Materials and Methods**. Promoter regions of the *CYP19* gene were functionally explored by means of a luciferase reporter gene assay in MG-63 cells. Sequencing of relevant regions was performed to screen for new SNPs. Association analyses with BMD was carried out in a cohort of 256 Spanish postmenopausal women. **Results**: Promoter pII proved to be potent in driving transient luciferase expression in MG-63 cells. A region upstream of exon I.3, including exon I.6, was identified as containing repressor elements of promoter pII. In screening these *CYP19* promoter regions, two new SNPs (Aro1 and Aro2) located in exon I.6 and promoter I.6 respectively, were found. Aro1, but not Aro2, was associated with lumbar spine BMD in the cohort of Spanish postmenopausal women. Homozygotes AA (16% of the women) had significantly higher lumbar spine BMD as compared to GG or GA individuals (p = 0.029). **Conclusions**: This study describes the Aro1 polymorphism, located in the exon I.6 region upstream of the *CYP19* gene, which shows a previously undescribed association with lumbar spine BMD.

Apolipoprotein E Genotype Is a Determinant of Serum Vitamin K, but not BMD, in Older Men and Women. M. D. Crosier[1], M. K. Shea*[2], J. M. Ordovas*[2], C. M. Gundberg[3], B. Dawson-Hughes[2], S. L. Booth[2]. [1]USDA Human Nutrition Research Center on Aging, Tufts University, Boston, MA, USA, [2]Human Nutrition Research Center on Aging, Tufts University, Boston, MA, USA, [3]Yale University, New Haven, CT, USA.

Apolipoprotein E (*APOE*) is a determinant of triglyceride-rich lipoprotein (TRL) clearance, and has a potential role in the regulation of bone formation. Vitamin K is a cofactor for the gamma-carboxylation of osteocalcin, and is carried by TRL. It has been proposed that *APOE*'s role in bone formation is mediated through the delivery of the fat-soluble vitamin K to osteoblasts. Cross-sectional associations of *APOE* with biochemical measures of vitamin K status [serum phylloquinone (vitamin K-1) and percent undercarboxylated osteocalcin (%ucOC)] were examined in 407 older men and women (mean age:68y; 60% women) selected for low vitamin K intake (<100 µg/day) as criteria for participation in a vitamin K clinical trial. All subjects had bone mineral density (BMD) of the hip, spine and total body measured by DXA. *APOE* was genotyped using a Taqman probe-based 5' nuclease assay. The distribution of the *APOE* genotypes were 3/3 263 (64.6%); 3/4 79 (19.4%); 2/3 47 (11.5%); 4/4 7 (7.1%) 2/4 11 (2.7%). All analyses were conducted at baseline, prior to randomization in the clinical trial. *APOE* genotype was significantly associated with serum phylloquinone concentrations (p=0.04), independent of serum triglycerides. Those with the E2/3 genotype had higher serum phylloquinone concentrations [mean (SD) 1.96 (2.65) nmol/L] compared to those with other genotypes (range of means: 0.94 to 1.17 nmol/L) (p=0.02). There was no association of *APOE* genotype with %ucOC or with BMD at any anatomical site. However, *APOE* genotype was associated with total osteocalcin concentrations (p=0.001); those with the E4/4 genotype had higher serum total osteocalcin concentrations [mean (SD) 12.6 (5.50) ng/mL] compared to those with other genotypes (range of means: 7.1-8.4 ng/ml). Limitations of this study are its cross-sectional design, small sample size and the potential for selection bias as these were primarily Caucasian individuals with low vitamin K intake. In conclusion, *APOE* genotype may be a non-dietary determinant of serum phylloquinone concentrations in older men and women. *APOE* genotype is also associated with serum concentrations of osteocalcin, which is a marker of bone formation, but not %ucOC, which is a marker of vitamin K status. The role of *APOE* genotype in the response of age-related bone loss to vitamin K supplementation needs to be determined.

Allelic Combinations of the CYP17 and CYP19 Genes: Skeletal and Hormonal Phenotypes. N. Napoli[1], R. Del Fiacco*[1], S. Mumm[1], A. Fakhri*[2], G. B. Rini*[1], R. C. Villareal[1]. [1]Medicine, Washington University School of Medicine, St. Louis, MO, USA, [2]Medicine, St. Lukes Hospital, St. Louis, MO, USA.

The T to C substitution in the promoter region of CYP17, and the G to A in Val^{80} of CYP19, have been found to be associated with differences in the risk for osteoporosis. Since both genes coexist, it is likely that allelic combinations may predict bone density better than a particular allele of one gene alone. Our aim is to characterize the skeletal and hormonal phenotypes of the different allelic combinations of the T→C (CYP 17) and the G→A (CYP 19) base substitutions. One hundred seventy nine postmenopausal Caucasian women (mean age 64.09±0.6) participated in the study. Genotyping was performed by PYROSEQUENCING, serum estradiol (E_2) by ultrasensitive radioimmunoassay, sex-hormone-binding globulin by immunoradiometric assay and BMD by DEXA. For the CYP17, women with the C allele (TC+CC) had significantly lower spine BMD compared

to those with the TT genotype (0.924±0.01, 0.974±0.01, p=0.02). The same trend was observed for BMD of the proximal femur sites, but the differences were not significant. For the CYP 19, women with the A allele (GA+AA) have significantly lower BMD of the total femur (0.844±0.01, 0.896±0.01, p<0.01), femoral neck (0.701±0.01, 0.744±0.01, p=0.01) trochanter (0.642±0.01, 0.672±0.01, p=0.05) and intertrochanter (1.012±0.01, 1.0812±0.02, p=0.004) as compared to the GG genotype. There was no significant difference in BMD of the spine observed for this polymorphism. There were no significant differences in total and FEI among the variants of both polymorphisms, however, significant correlations between BMD in all regions of the proximal femur and FEI were observed among women carrying either the C (CYP17) or the A (CYP 19) allele (all p<0.01) as compared to no correlation between BMD at any site and estradiol levels in those without these alleles. Women with a combination of the C (CYP17) and the A (CYP19) alleles have the lowest BMD in the mainly trabecular regions of the spine (p=0.03), femoral neck (p=0.03), and trochanter (p=0.04) in comparison to other allelic combinations. There were no significant differences in the total E_2 and FEI among the different allelic combinations, however, significant stronger correlations were observed between BMD of the proximal femur and FEI in women carrying both alleles than either the C or the A allele alone. Our study indicated that the combined presence of the C (CYP 17) and the A (CYP 19) is associated with the worst bone density phenotype in both the spine and proximal femur. Our results also showed that BMD in these variants are more estrogen-dependent than other variants, and may be more sensitive to changes in circulating levels of estradiol than others.

Postprandial Changes of Serum Fibroblast Growth Factor 23(FGF23) Levels on High Phosphate Diet in Healthy Men. Y. Nishida*, H. Yamanaka-Okumura*, Y. Taketani, T. Sato*, K. Nashiki*, H. Yamamoto, E. Takeda. Clinical Nutrition, Health Biosciences, Tokushima, Japan.

Serum fibroblast growth factor 23 (FGF23) has been found as a novel phosphate (Pi) regulating hormone. Blood FGF23 levels are not only elevated in phosphate wasting disorders, but also are detectable in healthy individuals. Recent studies indicate that FGF23 may be implicated in the physiological regulation of Pi homeostasis in response to dietary Pi changes. To examine the postprandial changes of serum FGF23 levels, we performed a randomized crossover study loading meal with three different Pi amount in 8 healthy male volunteers (age 20-34). 1) P400; 400mg Pi provided as normal meal, 2) P800; 800mg Pi as normal meal and 400mg Pi supplement, 3) P1200;1200mg Pi as normal meal and 800mg Pi supplement. Pi supplement was administered orally as a solution of neutral sodium and phosphate (mixture of Na_2HPO_4 and NaH_2PO_4). Calcium and other nutrients in each experimental meal were same (200mg of calcium per meal). Blood samples were collected at 0(12:00 a.m.), 0.5, 1, 1.5, 2, 3, 4, 6, and 8h following each meal, and serum concentrations of Pi, Ca, creatinine (CRE), $1,25(OH)_2D_3$, intact-PTH, and intact-FGF23 were measured. Urine samples of after meals were also collected at 1-h intervals for 8h, and urinary concentrations of Pi, Ca, and CRE were measured. Serum intact-FGF23 was determined by the Human FGF23 ELISA kit (Kinos Inc., Tokyo, Japan). Urinary Pi excretion and serum Pi levels increased rapidly and dose-dependently (p<0.05). Urinary Ca excretion tended to decrease in response to phosphate loading but no change in serum levels of Ca and $1,25(OH)_2D_3$. Serum intact-PTH levels in P1200 were significantly elevated at 1h and 4h compared with those of P400. Serum intact-FGF23 levels among all meals did not show any meaningful change until 6h. However, the mean serum intact-FGF23 level in P1200 at 8h increased by 29% than that of 0h, and was also significantly higher than that of P400 at 8h (P<0.05). In conclusion, postprandial serum intact-FGF23 levels were not affected immediately after single intake of high phosphate diet despite that of intact-PTH was rapidly increased.

FGF-23, FGF-7, sFRP-4, and MEPE Expression in Tumor Induced Osteomalacia. M. A. Habra*[1], S. E. HUANG*[1], G. J. Cote[1], W. A. Murphy*[2], R. L. Katz*[3], R. F. Gagel[1], M. J. Klein*[1], A. O. Hoff[1]. [1]Department of Endocrine Neoplasia and Hormonal Disorders, The University of Texas, M.D.Anderson Cancer Center, Houston, TX, USA, [2]Division of Diagnostic Imaging, The University of Texas, M.D.Anderson Cancer Center, Houston, TX, USA, [3]Department of Pathology, The University of Texas, M.D.Anderson Cancer Center, Houston, TX, USA.

Tumor-induced osteomalacia (TIO) is a rare syndrome associated with the overproduction of fibroblast growth factor-23 (FGF23) by a variety of mesenchymal tumors. The role of other factors (matrix extracellular phosphoglycoprotein (MEPE), FGF-7 and secreted frizzled related protein 4 (sFRP-4)) in the development of TIO is unclear. The aims of the study is to evaluate serum FGF-23 levels before and after the resection of a tumor potentially causing TIO and to analyze the expression of FGF-23 and the other genes in TIO. Two patients with TIO and 6 healthy volunteers were studied. Patient 1 (84 year-old man), presented with myalgia, fatigue, and multiple fractures. After years of evaluation, an expanding soft tissue mass near the left tenth rib was discovered in an area that was previously thought a healed rib fracture. Phosphate abnormalities were corrected after the resection of the mass that was a hemangiopericytoma. Patient 2 (74 year-old man) continued to have clinical features of TIO after the resection of a left femur hemangiopericytoma and still requires vitamin-D and phosphate replacement. After IRB approval, we measured serum FGF-23 levels in the 2 patients with TIO and in 6 healthy controls using a two-site immunoassay for the FGF-23 C-terminus (Immutopics, San Clemente, CA). Mean serum FGF-23 was 24.7±14.4 RU/mL in volunteers, while patient 1 had serum FGF23 level of 2438 RU/mL prior to tumor resection that decreased to 26 RU/mL after surgery. Patient 2 with persistent TIO had serum FGF-23 level of 812 RU/mL. We used RT-PCR to study the expression of FGF-23, FGF-7, MEPE, and sFRP-4 in tumor tissue from patient 1 and control cell lines (HEK 293, HeLa, and U251). Tumor tissue expressed all 4 genes. While the expression of FGF-23 was limited to tumor tissue and a known positive control cell line (HEK 293), FGF-7 and sFRP-4 were expressed in the tumor and all cell lines. MEPE expression was identified in tumor tissue only. In summary, we confirmed the usefulness of measuring serum FGF-23 for diagnostic and follow-up purposes in TIO. We have also described TIO caused by a hemangiopericytoma expressing FGF-23 as well as FGF-7, MEPE and sFRP4. While this could suggest a potential association between several genes involved in phosphate metabolism, the expression of FGF-23 and MEPE appears to be more specific to tumor cells and thereby these two factors appear to be more significant for the development of TIO

Regulation of Fgf-23 Gene Expression in Bone by Dietary Phosphorus Is Independent of Phex Function . F. Perwad*[1], M. Y. H. Zhang*[1], T. Yamashita*[2], H. S. Tenenhouse*[3], A. A. Portale[1]. [1]Pediatrics, University of California San Francisco, San Francisco, CA, USA, [2]Pharmaceutical Research Laboratories, Kirin Brewery Co. Ltd., Gunma, Japan, [3]Pediatrics and Human Genetics, McGill University, Montreal, PQ, Canada.

X-linked hypophosphatemia in humans (XLH) and mice (*Hyp*) is caused by inactivating mutations in the *PHEX/Phex* gene and is characterized by hypophosphatemia due to renal phosphate (Pi) wasting, rickets, growth retardation, and inappropriately low renal production of $1,25(OH)_2D$. Increased circulating FGF-23 is implicated in the pathogenesis of disordered Pi and vitamin D metabolism in XLH, but the mechanism whereby loss of PHEX function leads to increased serum FGF-23 concentrations is unknown. We have reported that in normal mice, dietary Pi intake regulates serum FGF-23 concentrations, and this effect is mediated by changes in serum Pi concentration. To determine whether serum FGF-23 concentration is regulated normally by dietary Pi in *Hyp*, we fed wild-type (WT) and *Hyp* mice diets with varying Pi content (0.02 to 1.65%) for 5 days. In WT mice, changes in dietary Pi intake from low (0.02%) to high (1.65%) induced a 7-fold increase in serum FGF-23 and a 3-fold increase in serum Pi concentrations. Serum FGF-23 concentrations varied directly and significantly with serum Pi concentrations across all diet groups (R=0.80, p<0.001). In *Hyp* mice, serum FGF-23 concentrations were 5- to 25-fold higher than those in WT mice, regardless of Pi intake. Nevertheless, serum FGF-23 levels in *Hyp* mice fed the 1.65% Pi diet were 3-fold higher than those in mice fed the 0.02% Pi diet (600 ± 284 vs 232 ± 99 pg/ml, respectively, p<0.01). In *Hyp*, the relationship between serum FGF-23 and Pi concentrations was direct and significant (R=0.60, p<0.001), similar to that observed in WT mice. To determine whether dietary Pi regulates serum FGF-23 concentrations by regulating *fgf-23* gene expression in bone, we fed WT and *Hyp* mice either 0.02% or 1% Pi diets, each for 5 days. In mice fed the 1% Pi diet, the abundance of *fgf-23* mRNA relative to that of GAPDH mRNA in calvaria was 30-fold higher in *Hyp* mice than in WT mice. Futhermore, feeding the 0.02% Pi diet induced an 85% suppression in *fgf-23* mRNA abundance in both WT and *Hyp* mice, compared with the abundance in each species fed the 1% Pi diet. The present data demonstrate that dietary Pi regulates serum FGF-23 concentration in both WT and *Hyp* mice, and suggest that changes in serum FGF-23 concentration reflect, at least in part, regulation of *fgf-23* gene expression in bone. The findings in *Hyp* mice provide evidence that regulation of FGF-23 gene expression in bone by dietary Pi is independent of PHEX function.

Augmentation of Demineralized Bone Matrix by a Synthetic FGF-2 Mimetic. X. Lin*[1], P. O. Zamora*[2], L. A. Pena*[1], S. L. Campion*[2], K. Takahashi*[2]. [1]Medical, Brookhaven National Laboratory, Upton, NY, USA, [2]BioSurface Engineering Technologies, Inc., College Park, MD, USA.

Demineralized bone matrix (DBM) is a bone graft material widely used in various orthopedic procedures. DBM contains bone morphogenetic proteins (BMPs) and other growth factors that are thought to be key to the ability of DBM to form new bone. However, the amounts of these growth factors are very low thus the osteoinductive potential of DBM is far from satisfactory in clinical settings. We recently described a synthetic peptide mimetic of FGF-2, designated F2A4-K-NS, which increased cell proliferation, cell migration, and angiogenesis, suggesting that it may have utility in bone repair. The purpose of this study is to evaluate whether this agonist mimetic could augment ectopic bone formation following subcutaneous implant of DBM in athymic rats. DBM (50 mg/implant) with and without F2A4-K-NS (20-, 100-, and 200 ng/implant) in a thermostable gel was injected s.c.on the backs of athymic rats. After 28 days the implant was explanted, fixed, and examined by X-ray analysis and by histological methods including von Kossa's staining. Examination of the implant sites did not reveal edema, necrosis, or tissue swelling on the underlying muscle or skin. The carrier (thermostable gel alone) explants showed only a small amount of radio-opacity examined by soft X-ray. The DBM explants exhibited radio-opacity with discrete foci with an overall density of 3.5 $X10^5$ pixels/ROI. When the carrier contained DBM plus F2A4-K-NS, an increase in radio-opacity was clearly evident in all 3 dose groups (5.0, 5.3 and 4.6 $X10^5$ pixels/ROI, respectively). A statistically significant increase in density was found for specimens in the 20- and 100 ng group. Micro-CT confirmed that when compared to either carrier only or DBM without peptide, the use of DBM plus F2A4-K-NS resulted in higher density and a larger physical size as indicated by a higher bone surface area. von Kossa's stain revealed that there was few calcium deposits in the carrier only samples. Inclusion of DBM in the carrier resulted in an increased amount of von Kossa's staining primary associated with the

DBM granules. When the carrier contained DBM plus F2A4-K-NS, the DBM granules were strongly positive for von Kossa's staining and the amount of staining was more uniformly distributed throughout the specimens. Quantitative analysis revealed that the relative amount of staining is higher in all F2A4-K-NS groups compared to DBM implants. A statistically significant increase in staining was found for specimens containing 100- and 200 ng when compared to the DBM alone group. **Conclusions:** The synthetic peptide F2A4-K-NS, a mimetic of FGF-2, augmented DBM-induced ectopic bone production in athymic animals.

Fibroblast Growth Factor (FGF)-23 in Patients with Hypoparathyroidism: Its Role in Serum Phosphate Regulation. H. Yamashita[1], Y. Yamazaki*[2], H. Hasegawa*[2], T. Yamashita*[2], S. Fukumoto[3], T. Shigematsu*[4], J. J. Kazama*[5], M. Fukagawa[6], S. Noguchi*[1]. [1]Surgery, Noguchi Thyroid Clinic, Beppu, Oita, Japan, [2]Pharmaceutical Research Labs, KIRIN Brewery CO. LTD., Takasaki, Japan, [3]Department of Internal Medicine, Tokyo University Hospital, Tokyo, Japan, [4]Division of Nephrology, Tokyo-Jikeikai Medical School, Katsushika, Japan, [5]Division of Clinical Nephrology and Rheumatology, Niigata University Graduate School of Medicine, Niigata, Japan, [6]Division of Nephrology & Dialysis Center, Kobe University School of Medicine, Kobe, Japan.

Hypoparathyroidism is a complication of thyroidectomy that causes hyperphosphatemia due to enhanced reabsorption of phosphate in the kidney by decreased parathyroid hormone (PTH) secretion and increased phosphate absorption from the alimentary tract induced active vitamin D administration. FGF-23 is a hormone-like factor that is thought to be important in phosphate homeostasis. However, the physiologic role of FGF-23 in hypoparathyroidism is not clear. We examined changes in serum levels of calcium, phosphate, intactPTH, and FGF-23 (normal range 10-50 ng/L) in 8 patients (7 women, 1 man, mean age 51 years) who developed transient hypoparathyroidism after thyroidectomy. We also examined serum levels of FGF-23, calcium, and phosphate in 14 patients (10 women and 4 men, mean age 50 years) with hypoparathyroidism which continued more than 1 year after thyroidectomy. Serum phosphate reached its peak level (6.1 ± 0.5 mg/dL) 2 or 3 days after development of hypoparathyroidism, followed by a peak in the serum FGF-23 level (87±39 ng/L). Serum levels of calcium, phosphate, and FGF-23 normalized after recovery of parathyroid function. The FGF-23 level was high (47±31 ng/L , range 20-133 ng/L) in stage of hypoparathyroidism. There was a significant positive correlation between serum phosphate and FGF-23 levels. Serum FGF-23 increased in patients with hypoparathyroidisma and hyperphosphatemia and normalized along with normalized phosphate levels after recovery of parathyroid function. A significant positive correlation between serum phosphate and FGF-23 levels was identified, suggesting a possible feedback mechanism involving FGF-23 for the maintenance of serum phosphate homeostasis.

Restoration of Cancellous Bone Connectivity and Strength in Ovariectomized Mice Treated with Basic Fibroblast Growth Factor and Followed by an Anti-Resorptive Agent. W. Yao[1], G. Balooch[2], R. Nalla*[3], J. Zhou*[2], Y. Jiang[2], T. Wronski[4], N. Lane[1]. [1]Medicine, UCDMC, Sacramento, CA, USA, [2]UCSF, San Francisco, CA, USA, [3]Lawrence Berkeley National Labaratory, Berkeley, CA, USA, [4]University of Florida, Gainesville, FL, USA.

The purpose of this study was to determine if bFGF and risedronate (Ris) would affect connectivity density (CD) and bone strength in OVXed mice. Six mos. Swiss-Webster mice were OVXed and left untreated for 4 wks. to develop cancellous osteopenia. Then were treated with bFGF (1 mg/kg, sc, 5×/wk) for 3 wks. At wks. 8, one group of bFGF-treated mice was sacrificed and the other two groups were switched to vehicle or Ris (5µg/kg, sc, 3x/wk) for 5 weeks. Endpoints evaluated included bone turnover markers by ELISA, distal femur architecture by uCT; bone formation by histomorphometry, and biomechanics of the 4th lumbar vertebrae (LVB). OVXed mice had significant reductions in BV/TV, CD, and bone strength, accompanied by elevated DPD/Cr, OC, MAR and BFR/BS ($p<0.05$). Treatment with bFGF resulted in higher BV/TV, Tb.N, CD, bone strength and higher bone turnover and bone formation in comparison to sham controls ($p<0.05$) Discontinuation of bFGF resulted in partial loss of gained BV/TV (50%) by 5 weeks with elevated DPD/Cr (40%) compared to the sham controls. However, BV/TV, Tb.N, CD, bone formation indices, and bone strength were still close to the sham levels. Treatment of OVXed mice with bFGF for 3 weeks followed by Ris sustained the elevated BV/TV, CD, and bone strength, which were almost double those of the sham control levels. DPD/Cr was 28% lower, whereas OC and BFR/BS were similar to sham controls after Ris administration. Thus, in osteopenic mice, bFGF treatment completely restored the lost bone mass and connectivity. However, the increment in distal femur BV/TV and CD gained by 3 weeks of bFGF treatment was partially lost after 5 weeks of treatment termination, whereas Ris maintained BV/TV and CD. Basic FGF treatment also increased bone strength by 195% in LVB compared to the OVXed group, the bone strength was sustained at least for 5 weeks after bFGF withdrawal; and Ris further increased bone strength by 41% compared to the bFGF-treated group. In conclusion, short-term bFGF administration restored trabecular bone mass, connectivity and bone strength and these parameters were maintained by Ris in osteopenic mice after withdrawal of bFGF treatment.

Dietary Phosphate Regulates Serum FGF-23 Concentrations in Healthy Men. D. Antoniucci[1], D. Sellmeyer[1], T. Yamashita*[2], A. Portale[1]. [1]University of California, San Francisco, CA, USA, [2]Pharmaceutical Research Laboratories, Kirin Brewery Co. Ltd., Takasaki, Japan.

Phosphate (Pi) homeostasis is determined primarily by renal handling of Pi, which is regulated by dietary Pi intake, parathyroid hormone (PTH) and $1,25(OH)_2D$. Recent evidence has accrued that fibroblast growth factor 23 (FGF-23), a circulating protein produced by osteogenic cells, also affects Pi homeostasis. States of excess FGF-23 are associated with hypophosphatemia due to renal Pi wasting, osteomalacia, and inappropriately low $1,25(OH)_2D$ concentrations. In contrast, FGF-23 gene ablation in mice is associated with increased serum Pi and $1,25(OH)_2D$ concentrations. An increase in dietary Pi intake increases urinary Pi excretion and decreases $1,25(OH)_2D$ production, whereas the converse occurs in response to dietary Pi restriction. To determine whether serum FGF-23 is regulated by dietary Pi and thereby might mediate the physiological response to changes in dietary Pi, we studied 13 healthy men during a 4-week dietary Pi intervention study. Throughout the study, all subjects consumed a diet that provided 500 mg of Pi per day (intakes are reported per 70 kg body weight). Calcium, sodium, potassium, magnesium and energy intakes were kept constant. Goal total oral Pi intake was achieved by supplementing the diet with a solution of neutral sodium and potassium Pi. The study had three diet periods, each of the same duration: 1) control Pi intake = 1,500 mg/day; 2) supplemented Pi intake = 2,300 mg/day; 3) restricted Pi intake = 625 mg/day, achieved by replacing the sodium and potassium Pi supplement with sodium and potassium chloride. Fasting blood and 24-hour urine samples were obtained on days 7-10 of each diet period. Serum FGF23 was measured by a sandwich ELISA that detects full-length FGF23 (Kainos Laboratories, Tokyo, Japan). As shown in the table, changes in dietary Pi induced significant changes in serum FGF-23 and $1,25(OH)_2D$ concentrations and in urinary Pi excretion.

Effect of changing dietary Pi on serum and urinary parameters (mean ± SD).

	Serum		Urinary Excretion
Phosphorus intake	**FGF-23 (pg/ml)**	**$1,25(OH)_2D$ (pg/ml)**	**Phosphorus (mg/day)**
Control (1500 mg/d)	28.9 ± 5.7	32 ± 9	1165 ± 293
Supplemented (2300 mg/d)	30.7 ± 8.7	29 ± 10	2069 ± 591[a]
Restricted (625 mg/d)	19.6 ± 7.0[a,c]	40 ± 16[b,c]	593 ± 199[a,c]

Mean value differs from that during 1500 mg/day dietary Pi intake: [a]$P < 0.001$; [b]$P < 0.05$.
Mean value differs from that during 2300 mg/day dietary Pi intake: [c]$P < 0.001$; [d]$P < 0.05$.

With restriction of dietary Pi to 625 mg/d, serum FGF-23 concentrations were significantly lower, and $1,25(OH)_2D$ significantly higher, than values on the control or supplemented Pi intakes. These data demonstrate that dietary Pi regulates serum FGF-23 concentrations in healthy men, and suggest that regulation of $1,25(OH)_2D$ production by dietary Pi is mediated, at least in part, by changes in circulating FGF-23.

Identification of Essential Molecule Responsible for Tissue Specific FGF23 Signaling. I. Urakawa*[1], Y. Yamazaki*[1], T. Shimada*[1], K. Iijima*[1], H. Hasegawa*[1], J. Yasutake*[1], T. Fujita[2], S. Fukumoto[2], T. Yamashita[1]. [1]Pharmaceutical Research Laboratories, Kirin Brewery Co., Ltd., Takasaki Gunma, Japan, [2]Department of Internal Medicine, The University of Tokyo Hospital, Tokyo, Japan.

The latest member of FGFs, FGF23, is a humoral factor that regulates renal phosphate reabsorption and metabolism of bioactive vitamin D. Although many FGFs show autocrine/paracrine effects, FGF23 is an endocrine factor, which is produced in bone and effects in kidney. Despite the unique activity of FGF23, either a special mechanism or molecules responsible for FGF23 signaling has been unclear. To elucidate the mechanism of FGF23 signaling, we searched early genes responsive to FGF23 in mice. Messenger RNA was purified from mouse kidneys one hour after FGF23 or vehicle administration and hybridized with a cDNA array including 2400 mouse cDNAs. As a result of that, we identified that mRNA abundance of early growth response gene-1 (Egr-1), which is known

as an immediate early response transcription factor, was increased within 30 minutes after FGF23 administration. Egr-1 expression is known to be downstream of ERK activation. In fact, we revealed that FGF23 induced ERK phosphorylation in mouse kidney within 10 minutes. Although the ERK phosphorylation and Egr-1 induction are ubiquitously equipped cellular mechanisms, these responses to FGF23 were observed only in kidney, pituitary and parathyroid glands, but not in other organs such as the heart, lung, liver and spleen. These findings indicated that FGF23 induced the activation of ERK followed by Egr-1 expression in these tissues probably through an FGF23 receptor specifically present in the kidney, pituitary gland, and parathyroid gland. To clarify the molecular mechanism responsible for the tissue-specificity, we purified a molecule that directly interacts with FGF23 from mouse renal homogenate. The tissue expression profile of this molecule corresponded to the tissue specificity of FGF23 signaling. Finally, FGF23 signaling was reproduced by the forced expression of this molecule in cells irresponsive to FGF23. These findings indicate that the molecule identified in this study constitutes a unique receptor for FGF23.

Effect of Growth Hormone Replacement on FGF-23 and Phosphate Metabolism in Adult Growth Hormone Deficiency. B. H. Durham[1], F. Joseph*[2], H. D. White*[2], A. M. Ahmad*[2], J. P. Vora*[2], W. D. Fraser[1]. [1]Clinical Chemistry, Royal Liverpool University Hospital, Liverpool, United Kingdom, [2]Endocrinology, Royal Liverpool University Hospital, Liverpool, United Kingdom.

Renal tubular phosphate reabsorption, best expressed as the renal threshold for phosphate reabsorption in the proximal tubule [ratio of tubular maximal reabsorption of phosphate (TmPO4) to glomerular filtration rate (GFR) (TmPO4/GFR)] plays a predominant role in phosphate homeostasis. Serum phosphate concentrations increase following growth hormone replacement (GHR) in adult growth hormone deficiency (AGHD) with an increase in TmPO4/GFR. Fibroblast growth factor-23 (FGF-23) is a phosphate regulating peptide that decreases circulating phosphate concentrations by decreasing TmPO4/GFR and is regulated by circulating phosphate in a feed back mechanism. Twenty-one AGHD patients and 16 controls were consented to the study and compared at baseline. AGHD patients were randomly assigned to two groups. Group 1 (n = 11) were commenced on GH alone and group 2 (n =10) were commenced on a daily dose of 1g of oral phosphate-Sandoz at 2200h as an adjunct to the GH. Patients were hospitalised at 0, 1 and 3 months for a period of 25-h and half-hourly blood and 3 hourly urine samples were collected for phosphate,1,25(OH)2VitD, FGF-23 [C-terminal] and to calculate TmPO4/GFR. A higher FGF-23 concentration was associated with lower TmPO4/GFR, plasma phosphate and 1,25(OH)2VitD concentration in adult growth hormone deficient (AGHD) patients as compared to normal control subjects. Administration of GH alone increased TmPO4/GFR and 1,25(OH)2VitD by 1 month and plasma phosphate by 3 months. Adjunct phosphate supplementation increased plasma phosphate by 1 month with no change in TmPO4/GFR and 1,25(OH)2VitD. FGF -23 increased more rapidly (1 month compared to 3 months) and by a greater percentage with adjunct phosphate intake compared to GH alone. Inappropriately increased FGF-23 concentration may contribute to the phosphate depletion in untreated AGHD patients. FGF-23 increased with the increase in phosphate following GHR, but the net predominant effect of GH resulted in a positive phosphate balance possibly due to direct GH and IGF-1 effects. The more marked increase in FGF-23 following phosphate supplementation in addition to GH restricted the tubular reabsorption of phosphate and increase in 1,25(OH)2VitD concentration to maintain phosphate concentration within the normal range. GHR restores FGF-23 regulation by phosphate and FGF-23 has a role countering increasing phosphate concentration by altering the renal handling of phosphate and 1,25(OH)2VitD .

Analysis of FGF23 Production by Osteoblastic Cells Treated with 1,25-Dihydroxyvitamin D. J. Yasutake*[1], T. Shimada*[1], Y. Yamazaki*[1], I. Urakawa*[1], K. Iijima*[1], H. Hasegawa*[1], T. Fujita[2], S. Fukumoto[2], T. Yamashita[1]. [1]Pharmaceutical Research Laboratories, KIRIN Brewery CO., LTD, Takasaki, Gunma, Japan, [2]Department of Internal Medicine, The University of Tokyo Hospital, Tokyo, Japan.

FGF23 is a circulating polypeptide that plays an essential role in phosphate and vitamin D metabolism by controlling renal functions in a hormonal manner. Recent studies strongly suggested that cells in the osteoblast-lineage are major sources supplying circulating FGF23. Since both FGF23 transgenic mice and FGF23 null mice showed evident abnormality in bone, this molecule may serve as a local regulator of bone metabolism. On the other hand, recent studies also indicated that phosphate and 1,25-dihydroxyvitamin D (1,25D), the potential bone metabolism modulators, trigger the production of FGF23. To address the relationship between bone metabolism and FGF23, we investigated the mode of FGF23 production by osteoblastic cells in vitro.Mouse osteoblastic MC3T3-E1 cells were cultured with αMEM supplemented with 10% FBS to form a confluent monolayer on day 3 and allowed to differentiate by adding β-glycerophosphate and ascorbic acid. FGF23 mRNA abundance progressively increased up to day 24, but FGF23 protein concentrations in conditioned medium peaked by day 14. These findings suggest that the competency of FGF23 production seems to depend on a certain stage of differentiation. Then, we treated cells in various stages in this culture system with 1,25D for 72 hours and determined FGF23 concentrations in conditioned media. Treatment with 1,25D enhanced FGF23 concentration in conditioned media at every stage, while the maximum increase was observed on day 6, suggesting that 1,25D-inducible FGF23 production is also dependent on a stage of cell differentiation. Interestingly, at this stage the 1,25D treated conditioned medium showed a 1.7-fold increase in phosphate concentration. To clarify the relationship between the alteration of phosphate metabolism and FGF23 production after treatment with 1,25D, time courses of changes in concentrations of phosphate and FGF23 in conditioned medium, phosphate transport activity, and FGF23 mRNA abundance were examined. Significant increases in FGF23 mRNA abundance and protein were observed after 12 and 24 hours, respectively. Phosphate transport activity decreased after 10 hours whereas phosphate concentration was not affected for 24 hours. These findings suggest that 1,25D and possibly local phosphate metabolism may be important in the regulation of FGF23 production by cells in a certain stage of osteoblast-lineage.

Isolation and Culture of Chondrocytes from the Resting and Proliferating Zones of Developing Bovine Rib Growth Plate: Modulation of FGF-2 Binding by Perlecan. J. R. Hassell, P. Govindraj*, L. West*. Research, Shriners Hospitals for Children - Tampa, Tampa, FL, USA.

FGF-2 is a known regulator of chondrocyte proliferation in the developing growth plate. Perlecan is a heparan sulfate proteoglycan present in the growth plate and the perlecan null mouse shows reduced proliferation of the chondrocytes in the growth plate and defective endochondral ossification. The purpose of this study is to evaluate the effect of perlecan on the binding of FGF-2 to chondrocytes isolated from resting and proliferating zones of growth plates. Ribs were isolated from late second or early third trimester bovine fetuses, fractured at the bone/hypertrophic zone junction and growth plates serially sectioned into five, 1 mm sections. Slice 1, which contains chondrocytes from the hypertrophic zone was discarded and chondrocytes were isolated from each of slices 2 (lower proliferative), 3 (upper proliferative), 4 (intermediate) and 5 (resting) by sequential digestion with pronase followed by collagenase overnight and plated at 1 x 10^5 cells/cm^2 in serum free DMEM. Chondrocytes from slice 2 incorporated 4 - 8 fold more ^{3}H-thymidine and chondrocytes from slice 3 incorporated 2 - 4 fold more ^{3}H-thymidine as compared to chondrocytes from slices 4 and 5 over a 48h culture period. All chondrocytes incorporated $^{35}S0_4$ into a matrix associated with the cell layer and a soluble matrix in the medium. Western blots using an antiserum to perlecan showed perlecan to be in the matrix associated with the cell layer and in the matrix secreted into the culture medium. Based on digestion with chondroitinase ABC, the perlecan secreted into the medium contained more chondroitin sulfate than the cell layer perlecan. [^{125}I] FGF-2 bound to both the low affinity and high affinity receptors present in the cell layer. Competition studies show that cold FGF-2 had no effect on [^{125}I] FGF-2 binding to the low affinity receptor but reduced binding to the high affinity receptor by 55 - 75%. The addition of perlecan to the media, however, reduced [^{125}I] FGF-2 binding to both the low and high affinity receptor by ~60%. The results of these studies show that chondrocytes isolated from the resting and proliferating zones of the growth plate and plated in serum free DMEM retain their zone specific level of proliferation and produce a cell-associated matrix as well as soluble matrix containing perlecan. The results suggest that perlecan may serve as the low affinity receptor for FGF-2 and act to keep FGF-2 off the high affinity receptor.

Bone Mineral Density in Active Female Adolescents with Stress Fracture. K. J. Loud[1], L. J. Micheli*[2], S. K. Bristol*[3], S. B. Austin*[3], C. M. Gordon[4]. [1]Adolescent & Sports Medicine, Children's Hospital Medical Center, Akron, OH, USA, [2]Sports Medicine, Children's Hospital, Boston, MA, USA, [3]Adolescent Medicine, Children's Hospital, Boston, MA, USA, [4]Adolescent Medicine & Endocrinology, Children's Hospital, Boston, MA, USA.

The purpose of this study was to examine skeletal health among active female adolescents with a stress fracture, a potential marker of compromised bone quality. Otherwise healthy active females aged 13-22 years diagnosed with their first stress fracture by x-ray, bone scan, computed tomography, or magnetic resonance imaging at the sports medicine clinic of an urban tertiary care pediatric center were recruited. Subjects were enrolled prospectively and matched 2 controls per case. The project was approved by the local IRB. Height and weight were measured directly and information collected on physical activity, demographics, dietary intake, family history, medical history, and menstrual history by validated self-administered surveys. A-P areal bone mineral density (aBMD, g/cm^2) was measured at the lumbar spine using an Hologic 4500 dual emission x-ray absorptiometry scanner. All analyses were conducted using STATA v8 statistical software, with conditional logistic regression modeling utilized to account for matching. Two-tailed p-values < 0.05 were considered significant. The mean age of the 144 participants was 16.1 $\pm$ 2.2 years. 97.9% (141) were Caucasian. 91.7% (121) were post-menarcheal, with mean age at menarche 13.0 $\pm$ 1.1 years. Two had an eating disorder. Mean daily intakes of calcium and vitamin D were 1103 $\pm$ 502 mg and 253 $\pm$ 159 IU, respectively. Cases had a marginally higher body mass index than controls (22.0 kg/m^2 vs. 21.1 kg/m^2, p = 0.09). A family history of osteoporosis or osteopenia was significantly associated with stress fracture [odds ratio (OR) = 3.87, 95% confidence interval (CI): 1.50, 9.99], while family history of stress fracture, frequent fractures, or “brittle bones” was not (OR = 0.58, 95% CI: 0.16, 2.17). The spinal aBMD Z-score among the 36 participants with stress fracture was -0.11 (95% CI: -0.46, 0.24); cases with irregular menses ($\leq$ 9/year or amenorrhea $\geq$ 3 months) had a significantly lower spinal aBMD Z-score than those with regular menses (-0.85 vs. 0.10, p = 0.02). In conclusion, this study demonstrates that BMD is compromised by menstrual irregularity and that active adolescent girls often consume inadequate quantities of calcium and vitamin D. Although subjects with stress fracture

demonstrated apparently normal spinal aBMD, the magnitude of the association between stress fracture and family history of osteopenia suggests that further investigations of intrinsic measures and genetic markers of bone quality are warranted in this population.

Effects of Exercise Protocol and Equipment on Bone Formation Stimulation. K. E. McAlpine[1], J. A. Tindall*[2]. [1]Denver Research Institute, University of Denver, Evergreen, CO, USA, [2]University of Colorado, Denver, CO, USA.

The purpose of this research was to evaluate the effectiveness of exercise protocol(s) utilizing resistance (composite) rods exercise equipment or free weights, to stimulate bone formation and bone resorption reduction. Subjects were paired for gender, age, height, weight, exercise experience, and fitness level. Three groups of paired participants were matched for inclusion into a free weight protocol, a composite rod protocol, or a control. This research utilized 2 treatments (free weight - treatment 1; composite rod - treatment 2) and 2 exercise protocols (same exercises in both treatments - protocol 1; modified exercises on the composite device - protocol 2). Protocol 2 involved a variety of modified exercises and physiological stimulation as a comparison between treatments. Subjects were selected in matched pairs and randomized; one participant from the paired match was placed into one of the first protocols (composite rod or free weight) and the second into the other. A third group, also with paired matches within the other groups, was utilized as a control for the composite rod equipment. Blood and urine bone biomarkers, total body fat composition, and DEXA scans of the hips and lumbar spine were performed prior to and at the end of the study for each participant. After a familiarization period of 2 weeks with the exercises and equipment, subjects began a 17 week, progressive load increase, exercise program. Each subject was required to take RDA recommendations for calcium and vitamin D and record their intake. Increases in osteocalcin ($p=0.016$) and reductions in serum and urine NTX were seen similarly in both protocols, but were significantly greater than the control group. Osteocalcin showed the greatest correlation (t test $p=0.937$) between the modified exercise protocol for the composite rod and the free weight exercise protocol. The use of the resistant rods in conjunction with protocol 2 provided similar stimulation for bone formation and reduction in bone resorption as protocol 1 using free weights. This research indicates that use of composite rod devices in conjunction with protocol 2 may provide a significant benefit for both the elderly and in microgravity situations where use of free weights may be more harmful, impractical, or impossible. The composite rod equipment could be utilized as suitable backup to the IRED and more complex future, long-term space travel, exercise devices. The composite rod equipment combined with the modified exercises, appears to provide equivalent results for bone formation as compared to free weights and therefore, is a more valuable backup mechanism than elastic bands currently used for space-travel exercise equipment failure.

Direct Loading in a Low Estrogen Environment in Prepubescent Female Rats. V. R. Yingling, G. Taylor*. Physical Education & Exercise Science, Brooklyn College (CUNY), Brooklyn, NY, USA.

The timing of puberty has emerged as an influential factor in the development of peak bone mass and strength. An increased age at puberty correlates with low bone mass in young women and an increased incidence of stress fractures. Low estrogen levels during bone development may decrease peak bone mass accrual in young adults by minimizing the mechanosensitivity of bone to physiologic loading. The purpose of this study was to determine if delayed puberty using gonadatropin-releasing hormone antagonist (GnRH-a) injections affects the response of cortical bone to compressive loading in female rats. Ten Sprague-Dawley rats (21 days of age) were randomly placed into 2 groups. The control group (C) established baseline data for compressive loading on the ulna. The low estrogen group (LE) was given GnRH-a injections (Cetrorelix) beginning at 25 days of age until sacrifice at 38 days. The right ulnae of both groups were loaded to approximately 4000 ustrain from day 32-36 using the following loading parameters; magnitude: 3.2 N, duration: 360 cycles/day, frequency: 2 Hz. Calcein injections (10 mg/kg) were given on days 29 and 36 and the rats were sacrificed on day 38. The right and left ulnae were dissected and prepared for histomorphometric analysis. The study was approved by the Institutional Animal Care and Use Committee at Brooklyn College (City University of New York). A delay in puberty resulted from the GnRH-a injections as confirmed by the delayed vaginal opening (3 of 5 animals never reached puberty during the protocol) and the decreased estradiol levels (18%) in the LE group. A significant increase in the total area perimeter (Ta.Pm) (4.51 %) and marrow perimeter (Ma.Pm) (26.31%) in the left ulna resulted in the LE group. There was no effect on mineralized surface (MS, %), mineral apposition rate (MAR, um/day) or bone formation rate (BFR, um/year) on the periosteal surface in either the left or right ulna of both the C or LE groups. On the endosteal surface, there was a decrease in BFR (32.84 %) in the LE group and compressive loading increased BFR in the C group, but had no effect in the LE group. This decrease in endocortical BFR in the LE group results in an increased Ma.Pm and loading does not stimulate bone formation at the endocortical surface. In summary, the GnRH-a injection protocol did suppress estradiol levels and delay puberty in the LE group; furthermore, BFR was suppressed at the endocortical surface. A delay in pubertal timing may affect bone's response to loading on the endosteal surface as evidenced by the lack of response in the LE group with an increased BFR in the C group. However, five days of loading did not affect periosteal BFR in either the C or LE groups suggesting that a longer loading protocol may be necessary.

Body Fat Influences Bone Mass Mainly by Physical Loading - 2-Year Longitudinal Study in Pubertal Girls. Q. Wang[1], P. Nicholson*[1], M. Alén*[1], H. Suominen[1], A. Koistinen*[2], H. Kröger*[3], S. Cheng[1]. [1]Department of Health Sciences, University of Jyväskylä, 40014 Jyväskylä, Finland, [2]Central Hospital of Central Finland, 40014 Jyväskylä, Finland, [3]University of Kupio, Kupio, Finland.

Fat tissue affects bone mass (BM) by at least two independent mechanisms: physical loading and hormonal activity. Arms and legs are similarly exposed to genetic and endocrine makeup, nutrient intake, medication, and life-style factors such as smoking, while the effects of physical loading such as weight-bearing and muscular activity may be very different in these two bone sites. Therefore, investigating the relationship of BM of arm and leg with limb-matched lean mass (LM) and total body fat mass (FM) provides an indirect assessment of the physical loading effect of FM on BM. The study population consisted of 258 healthy girls, aged 10-13 years. BM, LM and FM were assessed by a dual-energy X-ray absorptiometry (GE Lunar Corp., Madison, WI USA) at baseline and after 2 years' follow-up. A multivariate hierarchical linear model was used to assess the relationship between total body FM and limb-matched LM-adjusted BM (BM/LM) of the upper and lower limbs. The results showed that BM/LM was similar (60 vs. 60g/kg) for arm and leg. The variation in BM explained by the limb-matched LM was also similar for the arm and leg ($R^2 = 0.836$ vs. 0.858). The correlation between leg BM/LM and total body FM was significantly higher than that between arm BM/LM and total body FM ($r = 0.403$ vs. 0.135, $p<0.001$). The change of total body FM (ΔFM) correlated with ΔBMC/ΔLM of the leg but not with that of the arm ($r = 0.16$ vs. -0.03). The results indicate that physical loading is the major mechanism by which FM affects BM.

Strontium Ranelate Improves Intrinsic Bone Tissue Quality. P. Amman*[1], I. Badoud*[1], S. Barrauld*[1], P. Chatelain[2], R. Rizzoli*[1]. [1]Division of Bone Diseases, Department of Rehabilitation and Geriatrics, University Hospital, Geneva, Switzerland, [2]Division Rhumatology, Institut de Recherches Internationales Servier, Courbevoie, France.

Strontium ranelate treatment improves bone mechanical properties. The increased energy to failure achieved with strontium ranelate is essentially due to an increase of plastic energy suggesting that bone formed under treatment can withstand greater deformation before fracture. In the hydroxyapatite crystal, Sr is concentrated in the hydrated crown at the surface of the mineral. To investigate whether strontium ranelate treatment could positively influence tissue quality, intrinsic bone tissue quality (elastic modulus, hardness and dissipated energy) was evaluated by nanoindentation test performed at the level of trabecular nodes and cortex under physiological or dry conditions in vertebrae of rats treated for 26 months with strontium ranelate at a daily dose of 0 (control) or 900 mg/kg (n=12 per group). Results are means±SEM, *$p<0.05$, **$p<0.01$, ***$p<0.001$ vs control by Student-t test. In intact vertebral body, strontium ranelate significantly increased vs control group ultimate strength (+23%, $p<0.05$), total energy (+71%, $p<0.05$), plastic energy (+143%, $p<0.01$). At the level of trabecular bone, strontium ranelate treatment resulted in significant increase of elastic modulus, hardness and dissipated energy vs control in physiological but not in dry condition. There is a less pronounced effect in cortex which might be related to the lower concentration of strontium achieved in cortical as compared to trabecular bone. The fact that this positive influence disappeared when bone samples were dried, suggests that the organic matrix might be implicated. By analogy with biomaterial or enamel treatment with cation, presence of strontium in bone could reduce the progression of microcrack in bone. By a step-way regression analysis, intrinsic bone tissue quality is predominant in predicting bone strength. These results show for the first time a direct action of strontium ranelate on bone tissue quality, which could explain part of the mechanism of action and the reduction in fracture risk in postmenopausal osteoporotic patients treated with strontium ranelate.

Bone Treatment	Cortical Control	Cortical strontium ranelate	Trabecular Control	Trabecular strontium ranelate

Exercise and Bone Growth during Puberty: Effects of Estrogen Receptor α Polymorphism. S. Cheng[1], M. Suuriniemi*[1], H. Suominen[1], A. Mahonen*[2], H. Kröger[2], M. Alén*[1], T. Calex-study group*[1]. [1]Univ. of Jyväskylä, Jyväskylä, Finland, [2]Univ. of Kuopio, Kuopio, Finland.

Our previous cross-sectional data showed that physically active pre- and peri-pubertal girls (n=217) with a heterozygote *ER*α genotype (Pp) had significantly higher bone mass, density, and cortical thickness at loaded bone sites than their less active counterparts. The girls with homozygote genotypes did not seem to benefit from physical activity. To further explore this observation, we compared the girls with sustained high physical activity (HHPA, mean=4.3 hours/week during leisure time) to girls with low physical activity (LLPA, mean=1.7 hours/week) in a 4-year range when the girls underwent puberty within different *ER*α genotypes (PP, Pp, pp). Bone mineral content (BMC), areal density (aBMD), volumetric density (vBMD), cross-sectional area (CSA), cortical thickness (CTh), moment of resistance (SSI), and ultrasound attenuation (BUA) were assessed in whole body (WB),

femur neck (FN), lumbar spine (LS), distal radius (DR), tibia shaft (TS), and calcaneus (C) using different modalities. The girls in the HHPA group with Pp had significantly higher values of aBMD in the WB (p=.027), FN (p=.028) and LS (p=.026), and higher BMC in the FN (p=.008) and LS (p=.028), CSA (p=.033), BMC (p=.007), CTh (p=.005), SSI (p=.011) in the tibia, and BUA (p=.019) in the C at 24 months than the LLPA group with Pp. The HHPA group with pp also had higher BMC (p=.034) and BMD (p=.03) of the FN than the LLPA group with pp. When using a hierarchical multilevel regression model controlled for growth, the HHPA group with Pp tended to have consistently higher bone values throughout the menarche compared to the LLPA group (Fig). A similar trend was found in pp for some bone sites. As in our previous report, girls with a homozygote genotype PP did not benefit from high PA, while the benefit from PA was sustained in girls with a heterozygote genotype Pp. Furthermore, the *p* allele seems to be beneficial for bone growth while the *P* allele recessively impairs the osteostimulatory effect of physical activity.
