ADDENDUM
to the
2004 Abstracts

26th Annual Meeting of the
American Society for Bone and Mineral Research
Washington State Convention & Trade Center
Seattle, Washington, USA
October 1-5, 2004

On the following pages are five abstracts which were presented during the Late-Breaking Abstract Session on Monday, October 4, 2004, from 10:00 to 11:15 a.m., in Room 6E of the Washington State Convention & Trade Center.

We have provided these materials to afford our readership the information necessary to correctly cite these abstracts. To facilitate this, we have provided the citation under each abstract.

Also included is one abstract which was inadvertently left out of the *Abstracts* book. This abstract was presented on Monday, October 4, 2004, at Poster Session III in Exhibit Hall 4ABC of the Washington State Convention & Trade Center.

LB1
Evidence that Fgf23 Is the Phosphatonin in Hyp Mice.
S. Liu, J. Zhou*, W. Tang*, L. D. Quarles. Internal Medicine, University of Kansas Medical Center, Kansas City, KS, USA.

X-linked hypophosphatemia (XLH) is caused by inactivating mutations of the endopeptidase, PHEX, which leads to the accumulation of an unknown circulating phosphaturic factor, called phosphatonin. FGF23 is a phosphaturic hormone produced by bone and is a candidate for phosphatonin. Inactivating PHEX mutations leads to increased serum levels of FGF23 in XLH and the Hyp mouse homologue of this disease. To determine if elevated fgf23 levels mediate the hypophosphatemia in Hyp mice, we generated fgf23 null mice and crossed them onto the Hyp background to create combined fgf23 and Phex deficient mice. We examined male mice with the following genotypes: $fgf23^{+/+}$, $fgf23^{+/-}$and $fgf23^{-/-}$, and $fgf23^{+/+}$/Hyp, $fgf23^{+/-}$/Hyp and $fgf23^{-/-}$/Hyp. Consistent with successful deletion of fgf23, we observed undetectable serum fgf23 levels in $fgf23^{-/-}$ mice compared to the normal levels in $fgf23^{+/+}$ mice (35.0 ± 4.9 pg/ml). The absence of circulating fgf23 levels in $fgf23^{-/-}$ mice resulted in higher mean serum phosphate levels compared to wild-type ($fgf23^{+/+}$) littermates (14.1 vs 11.0±0.3 mg/dL). In contrast, Phex deficient Hyp mice displayed markedly elevated serum fgf23 levels (2285.9 ± 377.8 pg/ml) that were associated with low mean serum phosphate concentrations (5.9±0.4 mg/dL). Superimposed fgf23 deficiency resulted in undetectable circulating fgf23 levels in combined $fgf23^{-/-}$/Hyp mice, and a 50% reduction in fgf23 levels (1241.0±396.7 pg/ml) in Hyp mice heterozygote for fgf23 null allele ($fgf23^{+/-}$/Hyp). The hypophosphatemia in Hyp mice was corrected in proportion to the degree of superimposed fgf23 deficiency. In $fgf23^{-/-}$/Hyp mice lacking any fgf23, the serum phosphate levels were indistinguishable from values in $fgf23^{-/-}$ mice (14.1±1.2 vs. 14.1 mg/dL). In combined heterozygous $fgf23^{+/-}$/Hyp mice, which had a partial reduction in fgf23 levels, the serum phosphate concentrations attained intermediate levels (7.5±0.5 mg/dL) that where greater than values in Hyp mice. These data confirm an essential role of fgf23 in the physiological regulation of serum phosphate and suggest that fgf23 is phosphatonin, the circulating factor causing hypophosphatemia in Hyp mice.

Central Interleukin-1 Receptor Signaling Regulates Bone Mass.
I. Goshen*, A. Bajayo*, S. Feldman*, E. Shohami*, R. Yirmiya*, I. Bab. The Hebrew University of Jerusalem, Jerusalem, Israel.

The pro-inflammatory cytokine interleukin-1 (IL-1), acting via the hypothalamic IL-1 receptor type 1 (IL-1R1), activates pathways known for their association with the restrain of bone formation, such as the hypothalamo pituitary-adrenocortical (HPA) axis and the sympathetic nervous system. In addition, IL-1 has been implicated as a mediator of the bone loss induced by sex hormone depletion. To address more specifically the skeletal regulatory role of central IL-1R1 signaling, we characterized the bone phenotype of young $IL\text{-}1R1^{-/-}$ mice and mice with astrocyte-targeted overexpression of the human IL-1 receptor antagonist, under the control of the murine glial fibrillary acidic protein promoter (IL-1raTG mice). The genetically manipulated mice showed normal body weight and food consumption. Although a previous histomorphometric study reported a normal bone mass in the $IL\text{-}1R1^{-/-}$ mice, a present micro-computed tomographic (μCT) analysis demonstrated impaired femoral elongation and radial growth in these animals as well as in the IL-1raTG mice. Moreover, the trabecular bone density in the distal femoral metaphysis and lumbar vertebrae of both mouse lines was markedly lower as compared to their wild-type controls. Similar decreases were also seen in the trabecular thickness, number and connectivity. These data demonstrate a low bone mass (LBM) phenotype resulting from the absence of central IL-1R1 signaling. Whereas previously reported studies suggest a role for skeletal IL-1R1 signaling in bone loss, the present findings implicate the central IL-1R1 signaling as a positive regulator of bone mass accrual.

The B6.C3H-4 Congenic Mouse Strain Carrying a Volumetric BMD Quantitative Trait Locus (QTL) Prevents Ovariectomy-Induced Bone Loss.

W. G. Beamer[1], K. L. Shultz[1], K. M. Delahunty*[1], C. J. Rosen[2], L. R. Donahue[1]. [1]The Jackson Laboratory, Bar Harbor, ME, USA, [2]Maine Ctr for Osteoporosis Research and Education, Bangor, ME, USA.

We have previously reported mapping 10 QTLs for femoral BMD utilizing F2 intercross progeny derived from progenitor inbred mouse strains C57BL/6J (B6, low BMD) and C3H/HeJ (C3H, high BMD). The strongest correlations for femoral BMD in F2 female mice were with regions on Chr 1, 4, and 18, each of which accounted for 5 to 10% of the variance in femoral BMD. Transfer of the individual BMD QTL regions from C3H to the B6 genetic background by backcrossing yielded congenic strains, B6.C3H, that recapitulated the BMD effects and the heritability properties predicted from the F2 data.

A remarkable feature of the progenitor strains, B6 and C3H, is the difference in responses of their bone mass to loss of gonadal steroid. Groups of 4 month old B6 and C3H females were treated by ovariectomy or sham surgery, held for six weeks, then necropsied for data on femoral dimensions, and femoral cortical and trabecular parameters by pQCT. Both progenitor strains showed subtle increases in the distal trabecular volume. The ovariectomized B6 mice lost femoral cortical bone mineral, mid-diaphyseal thickness, and volume when compared to sham controls. In contrast, similarly aged and ovariectomized C3H females fully maintained all cortical bone parameters when compared to sham controls. To determine whether the resistance of cortical bone in C3H mice to ovariectomy was a property associated with a specific BMD QTL, B6.C3H congenic strains carrying QTLs for Chrs 1, 4, 6, 8, and 18 were ovariectomized or sham treated at 4 months, held for 6 weeks, and pQCT data was obtained on isolated femurs. The B6.C3H-4T congenic females behaved like their C3H progenitor strain in that no loss of femoral cortical bone parameters was observed in response to ovariectomy. In contrast the B6.C3H-1T, -6T, -8T, and -18T mice behaved like their B6 progenitor and lost significant cortical bone mineral, volume, and mid-diaphyseal thickness. These results demonstrate: a) congenic strain sets carrying BMD QTLs on different chromosomes facilitate investigations defining function and regulation of bone; b) the cortical bone protective effect observed in C3H is associated with C3H alleles for the BMD QTL on Chr 4 and not with Chrs 1, 6, 8 or 18; and c) the protective effect appears limited to the cortical bone. Although nested subline mapping has reduced the Chr 4 BMD QTL from 39 to 7 cM in size (18.3 Mb; 433 known, 400 predicted genes), a smaller genetic segment will facilitate expression studies for candidate genes.

Targeted Expression of BIG-3 Leads to Accelerated Osteoblast Differentiation During Embryonic Development.

F. Gori, C. P. Raftery*, M. M. Donohue*, M. B. Demay. Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, Boston, MA, USA.

Skeletal development and growth occurs via two major processes, intramembranous and endochondral ossification, and requires coordinated activities of complex signaling pathways. Among the local signaling pathways that are known to play a role in these processes is the bone morphogenetic protein (BMP) pathway. We identified a novel BMP-2-induced gene named BIG-3 (BMP-2 Induced Gene 3kb) that dramatically accelerates the program of osteoblastic differentiation in MC3T3-E1 cells. BIG-3 encodes a novel protein belonging to the highly conserved family of WD-40 repeat proteins found in all eukaryotes. BIG-3 accelerates osteoblast differentiation *in vitro* and is developmentally expressed during embryogenesis being first detected at day 13.5 post coitus (pc) throughout the mesenchymal condensation. To identify a role for BIG-3 *in vivo*, a BIG-3 transgene was targeted to osteoblasts of mice using the 2.4-kb fragment of the mouse α (1) I collagen promoter. Two lines of transgenic mice were generated and qualitatively similar results were obtained with both transgenic lines. The expression of the BIG-3 transgene was confirmed by Northern analyses of calvarial RNA. *In situ* hybridization analyses of histological sections of newborn tibiae showed specific expression of the transgene in bone. Alizarin Red and Alcian blue staining of whole mount preparations at embryonic day 14.5, 15.5, and in newborn transgene positive and transgene negative littermates, showed that the expression of the transgene results in an accelerated mineralization and bigger skeleton compared to that of wild-type littermates. At embryonic day 15.5, the posterior and lateral processes of the lumbar vertebrae of transgenic mice were calcified while they were not in their wild-type littermates demonstrating accelerated skeletal maturation. Von kossa staining of forelimb sections of 14.5 dpc embryos showed mineral deposition in transgenic but not in wild-type embryos demonstrating that the presence of the transgene leads to accelerated mineral deposition. *In situ* hybridization analyses of histological sections of 14.5 dpc embryos demonstrated earlier and more extensive expression of type I collagen and osteopontin.

These data demonstrate that BIG-3 is developmentally expressed in osteoblasts during endochondral ossification, and that targeted overexpression of this novel protein to osteoblasts leads to an acceleration of differentiation during skeletal development.

Large-scale Evidence for Differential Genetic Effects of ESR1 Gene Polymorphisms on Osteoporosis Outcomes: The GENOMOS Study.

J. Ioannidis*[1], S. Ralston[2], S. Bennett*[3], M. Brandi[4], D. Grinberg[5], F. Karassa*[1], B. Langdahl[6], J. van Meurs[7], L. Mosekilde[6], S. Scollen*[8], O. Albagha*[2], M. Bustamante*[5], A. Carey*[3], A. Dunning*[8], A. Enjuanes*[5], J. van Leeuwen[7], C. Mavilia*[4], L. Masi[4], F. McGuigan[2], X. Nogues[5], H. Pols[7], D. Reid[2], S. Schuit*[7], R. Sherlock*[3], A. Uitterlinden[7]. [1]University of Ioannina, Ioannina, Greece, [2]University of Aberdeen, Aberdeen, United Kingdom, [3]Oxagen Limited, Abingdon, United Kingdom, [4]University of Florence, Florence, Italy, [5]University of Barcelona, Barcelona, Spain, [6]Aarhus University, Aarhus, Denmark, [7]Internal Medicine, Erasmus MC, Rotterdam, Netherlands, [8]Cambridge University, Cambridge, United Kingdom.

Osteoporosis has a strong genetic component but the genes involved are ill-defined. Many candidate gene studies, however, have been hampered by small sample size, lack of standardization, and inconclusive results. We therefore started a program of prospective meta-analyses of polymorphisms involving standardized genotyping of 18,917 subjects (n=4,268 men), in 8 European centres, in relation to BMD of femoral neck and lumbar spine, fractures at any site (n=4944), and vertebral fractures (n=1067). We first studied 3 polymorphisms in the estrogen receptor alpha (*ESR1*) gene: the intron 1 polymorphisms *Xba*I and *Pvu*II, and the promoter TA-microsatellite, and haplotypes thereof.

No between-center heterogeneity was observed for any outcome in any genetic contrast. None of the 3 polymorphisms or haplotypes thereof had any statistically significant effect on BMD in adjusted or unadjusted analyses and estimated differences between genetic contrasts were <0.01 g/cm^2. Conversely, we found significant fracture risk reduction for the XbaI "X" allele. E.g., in XX homozygous women, the odds of fractures were reduced by 19% (p=0.002) and vertebral fractures by 35% (p=0.003). Genotype effects on fractures were independent of BMD, and remained similar in adjusted analyses. This study, which represents the largest gene-disease association study ever performed to-date with individual-level data, has shown that *ESR1* is a susceptibility gene for osteoporosis and that variation at the *Xba*I site determines fracture risk by mechanisms independent of BMD. The large sample size makes the study statistically robust, but the effects we observed were modest illustrating the limited contribution of single genetic markers to fracture risk. Our study demonstrates the value of adequately powered studies with standardized genotyping and clinical outcomes in defining effects of common genetic variants on complex diseases.

The Role of the Sodium/Calcium Exchanger Isoforms NCX-1 and NCX-3 in Osteoblasts.

F. S. Harman*[1], D. Sosnoski*[2], V. Gilman*[2], C. V. Gay[2]. [1]Intercollege Graduate Degree Program in Physiology, Penn State University, University Park, PA, USA, [2]Biochemistry and Molecular Biology, Penn State University, University Park, PA, USA.

Original characterization of calcium transport in bone from interstitial fluid for mineralization of a mature, extracellular matrix has been described as being a function of osteoblasts. The presence of the plasma membrane calcium ATPase (PMCA) calcium transporter as a unidirectional effector of calcium efflux from osteoblasts has been described. Cytochemical studies indicate that PMCA is differentially located on the lumenal side of the osteoblast facing bone marrow suggesting an unlikely role in calcium transport directly sent to the mineralizing extracellular matrix. The sodium-calcium exchanger (NCX) of osteoblasts has been characterized as an ion transporter that exchanges the influx of sodium ions for the efflux of calcium ions and has been established to be located on the apical or secretory side of the osteoblasts facing the extracellular matrix. Further, both NCX-1 and NCX-3 isoforms have been identified in osteoblasts. The purpose of this work is to determine the roles of NCX-1 and NCX-3 isoforms in calcium transport using MC3T3E1 osteoblasts, siRNA knock-down technology, and fluorescence changes in the marker calcium-green-1 (CG-1) following administration of a bolus of $CaCl_2$. Changes in calcium flux were detected using BioRad® timecourse software interfaced with a confocal microscope. Transfection studies have been completed with NCX-1 and NCX-3 siRNA that inhibit translation of the specific isoform allowing for a functional analysis of the opposite isoform during the timecourse. Transfection with the sequence 5'-AAAGATTCCGTGACTGCCGTT-3' blocks the synthesis of NCX-1 allowing for functional analysis NCX-3. Conversely, transfection with the sequence 5'-AATGCCGTCAATGTCTTCCTG-3' blocks the synthesis of NCX-3 allowing for functional analysis of NCX-1. Cells were also transfected with siRNA from Ambion™ to block glyceraldehyde phosphate dehydrogenase (GAPDH) synthesis as a transfection control which both NCX-1 and NCX-3 are functional. Inhibitors of PMCA and other calcium flux channels were used to isolate NCX-1 and NCX-3. With NCX-1, NCX-3, GAPDH individually inhibited, the slope of CG-1 fluorescence pixel intensity curve was -0.95±0.08, -0.45±0.12, and -0.53±0.13 respectively. These data suggest that NCX-3 clears the cytoplasm of calcium approximately two times faster than NCX-1 operating alone or in conjunction with NCX-3. Thus, NCX-3 may be located on the endoplasmic reticulum (ER) membrane as well as the plasma membrane, or it may represent a more efficient exchanger of calcium flux than NCX-1.

The *Journal of Bone and Mineral Research* (ISSN: 0884-0431) provides a forum for papers of the highest quality pertaining to all areas of the biology and physiology of bone, the hormones that regulate bone and mineral metabolism and the pathophysiology and treatment of disorders of bone and mineral metabolism. All authored papers and editorial news and comments, opinions, findings, conclusions or recommendations in the *Journal* are those of the author(s) and do not necessarily reflect the views of the *Journal* and its publisher, nor does their publication imply any endorsement. The *Journal of Bone and Mineral Research* is the official journal of the American Society for Bone and Mineral Research and is published monthly plus a special issue in September by the American Society for Bone and Mineral Research, 2025 M Street, N.W., Suite 800, Washington, DC 20036-3309, USA. Address reprint/offprint inquiries to Cadmus Journal Services Reprints at US (800) 407-9190 or (410) 819-3967. Periodicals postage paid in Washington, DC and additional offices. POSTMASTER SEND ADDRESS CHANGES TO: Journal of Bone and Mineral Research, P.O. Box 2759, Durham, NC 27715, USA. 2004 Subscription Rates: U.S. Personal $495.00, Institutional: $535.00; Canada/Mexico: Personal $515.00; Institutional $560.00; Overseas: Personal $570.00; Institutional: $575.00. Single issue $50.00. Subscription term is January – December.

Claims for missing issues will be serviced at no charge if received within six months of issue date {journal@jbmr.org, or fax (US) 919-620-8465}. Duplicate copies cannot be sent to replace issues not delivered because of failure to notify publisher of change of address. Please notify ASBMR of new address six (6) weeks in advance of moving date. All subscriptions are payable in advance in U.S. funds drawn on a U.S. bank. If not fully satisfied, notify publisher for a refund on all unmailed issues.

Address advertising and commercial reprint inquiries to Mr. Steve Kavalgian, Mill River Media LLC, 141 Boston Post Rd. Old Lyme, CT 06371-1303, USA; (860) 434-6889 (phone); (860) 434-9744 (fax); millrivermedia@aol.com (e-mail). Advertisements are subject to editorial approval.

The *Journal of Bone and Mineral Research* is a **Journal Club**™ selection. The *Journal* is indexed by *Index Medicus, Current Contents/Life Science, CABS (Current Awareness in Biological Sciences), Excerpta Medica, Cambridge Scientific Abstracts, Chemical Abstracts*, *Reference Update, Science Citation Index*, and *Nuclear Medicine Literature Updating and Indexing Service*.

AMERICAN SOCIETY FOR BONE AND MINERAL RESEARCH (ASBMR)

OFFICERS

President: Robert A. Nissenson, Ph.D.
President-Elect: Sylvia Christakos, Ph.D.
Past-President: Clifford J. Rosen, M.D.
Secretary-Treasurer: Marc K. Drezner, M.D.

COUNCIL

Daniel Bikle, M.D., Ph.D.	*Term expires 2006*	Sundeep Khosla, M.D.	*Term expires 2005*
Dennis Black, Ph.D.	*Term expires 2004*	Barbara Lukert, M.D.	*Term expires 2004*
Jane Cauley, Ph.D.	*Term expires 2006*	Vicki Rosen, Ph.D.	*Term expires 2006*
John Eisman, M.B.B.S., Ph.D.	*Ex-officio*	Gary Stein, Ph.D.	*Term expires 2005*
Susan Greenspan, M.D.	*Term expires 2005*	Larry Suva, Ph.D.	*Term expires 2004*

PAST PRESIDENTS

Louis V. Avioli, M.D.	*1979-1980*	Mark R. Haussler, Ph.D.	*1991-1992*
Lawrence G. Raisz, M.D.	*1980-1981*	Steven L. Teitelbaum, M.D.	*1992-1993*
Claude D. Arnaud, M.D.	*1981-1982*	Henry M. Kronenberg, M.D.	*1993-1994*
Stephen M. Krane, M.D.	*1982-1983*	Ernesto Canalis, M.D.	*1994-1995*
William A. Peck, M.D.	*1983-1984*	John P. Bilezikian, M.D.	*1995-1996*
Paula H. Stern, Ph.D.	*1984-1985*	Gregory R. Mundy, M.D.	*1996-1997*
B. Lawrence Riggs, M.D.	*1985-1986*	Michael Rosenblatt, M.D.	*1997-1998*
Norman H. Bell, 4M.D.	*1986-1987*	Jane E. Aubin, Ph.D.	*1998-1999*
Gideon A. Rodan, M.D., Ph.D.	*1987-1988*	David Goltzman, M.D.	*1999-2000*
John G. Haddad, Jr., M.D.	*1988-1989*	Robert Marcus, M.D.	*2000-2001*
Armen H. Tashjian, Jr., M.D.	*1989-1990*	Robert R. Recker, M.D.	*2001-2002*
Frederick R. Singer, M.D.	*1990-1991*	Clifford J. Rosen, M.D.	*2002-2003*

PAST SECRETARY-TREASURERS

Norman H. Bell, M.D.	*1977-1985*	Steven R. Goldring, M.D.	*1997-2000*
Gregory R. Mundy, M.D.	*1985-1991*	Andrew F. Stewart, M.D.	*2000-2003*
Arnold J. Kahn, Ph.D.	*1991-1997*		

PAST COUNCILORS

Constantine Anast, M.D.	*1980-1982*	Marie Demay, M.D.	*2000-2003*
Claude D. Arnaud, M.D.	*1979-1980*	Richard Eastell, M.D., F.R.C.P.	*2000-2003*
Andrew Arnold, M.D.	*1999-2002*	John Eisman, MBBS, Ph.D.	*1994-1997*
Jane E. Aubin, Ph.D.	*1991-1994*	Murray J. Favus, M.D.	*1992-1995*
Roland Baron, D.D.S., Ph.D.	*1991-1994*	David Feldman, M.D.	*1982-1986*
John P. Bilezikian, M.D.	*1987-1990*	Lorraine A. Fitzpatrick, M.D.	*1998-2001*
Lynda F. Bonewald, Ph.D.	*1995-1998*	Francis Glorieux, M.D., Ph.D.	*1988-1991*
Arthur E. Broadus, M.D., Ph.D.	*1990-1993*	Julie Glowacki, Ph.D.	*1999-2002*
Ernesto Canalis, M.D.	*1989-1992*	Steven R. Goldring, M.D.	*1993-1996*
Janet M. Canterbury, M.D.	*1981-1984*	Ralph S. Goldsmith, M.D.	*1980-1983*
Sylvia Christakos, Ph.D.	*1989-1992*	David Goltzman, M.D.	*1984-1988*
Thomas L. Clemens, Ph.D.	*1998-2001*	Maxine Gowen, Ph.D.	*2000-2003*
Jack W. Coburn, M.D.	*1981-1984*	John G. Haddad, Jr., M.D.	*1982-1985*
David V. Cohn, Ph.D.	*1982-1985*	Mark R. Haussler, Ph.D.	*1982-1985*
Cary W. Cooper, Ph.D.	*1980-1981*	Hunter H. Heath III, M.D.	*1985-1988*
Steven R. Cummings, M.D.	*1996-1999*	Helen L. Henry, Ph.D.	*1985-1988*
Bess Dawson-Hughes, M.D.	*1996-1999*	Keith A. Hruska, M.D.	*1989-1992*
Hector F. DeLuca, Ph.D.	*1979-1980*	Arnold J. Kahn, Ph.D.	*1986-1989*

AMERICAN SOCIETY FOR BONE AND MINERAL RESEARCH (ASBMR)

PAST COUNCILORS (Continued)

Frederick S. Kaplan, M.D.	*1997-2000*
Stephen M. Krane, M.D.	*1979-1981*
Barbara E. Kream, M.D.	*1985-1988*
Henry M. Kronenberg, M.D.	*1986-1989*
Jane B. Lian, Ph.D.	*1991-1994*
Robert Marcus, M.D.	*1995-1998, 1999-2002*
T.J. Martin, M.D.	*1987-1990*
Stephen Marx, M.D.	*1983-1986*
Toshio Matsumoto, M.D.	*1999-2002*
Gregory R. Mundy, M.D.	*1983-1985*, *1995-1997*
Robert Nissenson, Ph.D.	*1993-1996*
Anthony W. Norman, Ph.D.	*1980-1982*
Philip A. Osdoby, Ph.D.	*1997-2000*
Susan M. Ott, M.D.	*1988-1991*
A. Michael Parfitt, M.D.	*1990-1993*
Nicola C. Partridge, Ph.D.	*1993-1996*
William A. Peck, M.D.	*1979-1981*
John T. Potts, Jr., M.D.	*1979-1981*

GENERAL INFORMATION

ASBMR MEETING LOCATION

All ASBMR 26th Annual Meeting sessions will take place in the Washington State Convention & Trade Center, unless otherwise stated. The Washington State Convention & Trade Center is located at 800 Convention Place, Seattle, Washington, USA.

AUDIO- AND VIDEOTAPING

ASBMR expects that attendees will respect each presenter's willingness to provide free exchange of scientific information without the abridgement of his or her rights or privacy and without the unauthorized copying and use of the scientific data shared during his or her presentation. In addition, ASBMR expects that attendees will respect Exhibitors' desires not to have their products or booths photographed or videotaped. Cameras or recording devices will not be permitted in the Exhibit Halls, the Poster Sessions, or the Oral Scientific Sessions **without the prior written permission of the ASBMR Convention Management.**

The use of cameras, audiotaping devices, and videotaping equipment is strictly prohibited within all Oral Scientific Sessions, the Exhibit Halls, and the Poster Sessions without the express written permission of the ASBMR Convention Management. Unauthorized use of this taping equipment may result in the confiscation of the equipment or the individual may be asked to leave the Scientific Session or Exhibit Hall. These rules will be strictly enforced.

USE OF ASBMR NAME AND LOGO

ASBMR reserves the right to approve use of its name in all material disseminated to the media, public and professionals. ASBMR's name, meeting name, and meeting logo may not be used without permission. Use of the ASBMR logo is prohibited. Materials should be directed to ASBMR Executive Director Joan Goldberg. All ASBMR corporate supporters and exhibitors should share their media outreach plans with the ASBMR Executive Director before release.

No abstract presented at the ASBMR 26th Annual Meeting may be released to the press before its official presentation date and time. Press releases must be embargoed until one hour after the presentation.

ASBMR MEETING CONTENT AND EMBARGO POLICY

Abstracts submitted to the ASBMR 26th Annual Meeting are embargoed - that is, unavailable for public release in written, oral and electronic communications - until one hour *after* the abstract has been presented.

The ASBMR is sensitive to issues of commercial confidentiality and relevant aspects of the U.S. Securities and Exchange Commission (SEC) regulations. Therefore, the ASBMR reminds all readers that all must adhere to the U.S. Securities and Exchange Commission regulations and treat all scientific information as confidential until the embargo has been lifted – one hour after the abstract has been presented. Any reader of, or listener to, ASBMR Annual Meeting content may be viewed as an "insider" by the SEC due to knowledge of information included in abstracts, particularly clinical trial abstracts. SEC regulations may call for criminal penalties for using such information.

CONTINUING MEDICAL EDUCATION CREDITS

The Federation of American Societies for Experimental Biology (FASEB) is accredited by the Accreditation Council for Continuing Medical Education to sponsor continuing medical education for physicians. This activity has been planned and implemented in accordance with the Essential Areas and Policies of the Accreditation Council for Continuing Medical Education through the joint sponsorship of FASEB and the ASBMR.

Category I Continuing Medical Education (CME) credits toward the American Medical Association Physician's Recognition Award will be offered at this meeting. This meeting has been certified for CME Category I Credits on an hour-for-hour basis for up to 48 credit hours. CME application forms will be available in the *On-site Program* Book, which will be distributed at the meeting. There is a $45 application fee, payable to FASEB upon submission of the form. For more information, please contact:

FASEB Office of Scientific Meetings and Conferences
Tel: ..... (301) 530-7010
Fax: ..... (301) 530-7014
E-mail: ..... pmcgovern@faseb.org

Meeting Objective

The ASBMR 26th Annual Meeting is designed to allow members to present new developments in education, research and clinical practice related to bone and mineral metabolism. The program objectives include updating attendees on the recent advances in osteoporosis and other diseases of bone and mineral metabolism, vitamin D and other steroids, peptide calciotropic hormones, mechanical loading and exercise, bone acquisition and pediatric bone disease, cartilage and connective tissue matrix, and growth factors.

As a result of their attendance, participants should have enhanced their knowledge of osteoporosis, other diseases of bone, basic bone biology and its correlation to mineral metabolism, as well as their ability to treat and care for their patients. Attendees should have developed a clearer understanding of the interrelationship among basic research, clinical research and patient care through the discussions that are expected to take place. The ASBMR 26th Annual Meeting program should produce an enhanced appreciation of the investigative, diagnostic and therapeutic aspects of metabolic bone disorders.

Target Audience

The program is designed for researchers, physicians, clinicians, and other allied health professionals with interests in endocrinology, physiology, cell biology, pathology, molecular biology, genetics, epidemiology, internal medicine, rheumatology, orthopedics, dentistry, nephrology, and pharmacology.

DISCLOSURE/CONFLICT OF INTEREST

The Federation of American Societies for Experimental Biology (FASEB) requires that audiences at FASEB-sponsored educational programs be informed of a presenter's (speaker, faculty, author, or contributor) academic and professional affiliations, and the existence of any significant financial interest or other relationship a presenter has with the manufacturer(s) of any commercial product(s) discussed in an educational presentation. This policy allows the listener/attendee to be fully knowledgeable in evaluating the information being presented. The Program will note those speakers who have disclosed relationships, including the nature of the relationship and the associated commercial entity.

All authors of submitted abstracts completed the disclosure statement in the online submission program. Invited speakers who are not required to submit an abstract received a form in the mail that they completed and returned.

Disclosure may include any relationship that may bias one's presentation or which, if known, could give the perception of bias. These situations may include, but are not limited to:

DISCLOSURE KEY

1. stock options or bond holdings in a for-profit corporation or self-directed pension plan
2. research grants
3. employment (full or part-time)
4. ownership or partnership
5. consulting fees or other remuneration
6. non-remunerative positions of influence such as officer, board member, trustee, or public spokesperson
7. receipt of royalties
8. speaker's bureau

For full-time employees of industry or government, the affiliation listed in the *2004 Abstracts* will constitute full disclosure.

Disclosures for invited speakers and abstract presenters are provided at the end of the session listing for invited speakers (see *On-Site Program* book) and directly after the body of an abstract for abstract submissions. If there is no conflict of interest or disclosure listed, this means that the invited speaker and/or abstract presenter indicated no conflicts to disclose.

The disclosure information will correspond to the key above. If disclosures are given, the company name, along with the respective disclosure relationship number will be listed (for example: Company Name, 2, 8.).

2004 ABSTRACTS BOOK

Supported by an unrestricted educational grant from Roche and GlaxoSmithKline

This *2004 Abstracts* book is distributed on-site at the Annual Meeting to all ASBMR members and non-member attendees. Non-member subscribers to *JBMR* will receive the *2004 Abstracts* book by mail. ASBMR members who do not attend the Annual Meeting will receive their copy of the *2004 Abstracts* book by mail following the meeting. The entire ASBMR Scientific Program (invited speaker sessions, lectures, and abstract-based oral and poster presentation information), as well as the 2004 Ancillary Program (working groups and industry-supported symposia), are included in full detail in the *Onsite Program* book and on the ASBMR website at www.asbmr.org.

AWARD PRESENTATIONS

The following ASBMR Awards will be presented immediately following the morning Plenary Symposia and Plenary Lectures in the Room 6ABC of the Washington State Convention and Trade Center — the Gideon A. Rodan Excellence in Mentorship Award, the Fuller Albright Award, the Louis V. Avioli Founders Award, the Frederic C. Bartter Award, the William F. Neuman Award, and the Shirley Hohl Service Award. Please refer to the schedule found in the inside cover of this book for award presentation times.

ASBMR VIRTUAL EXHIBIT HALL

The ASBMR Virtual Exhibit Hall (www.asbmrexhibits.com) showcases exhibitors and their products, many of which are present at this year's ASBMR 26th Annual Meeting. Visitors to the ASBMR Virtual Exhibit Hall are able to learn more about exhibitor's products and services, easily contact them for further information, and enjoy an Exhibit Hall experience at their leisure year-round.

MEET-THE-NIH LOUNGE

Looking for another opportunity to ask U.S. National Institutes of Health and Center for Scientific Review staff about your grant proposal or idea? Plan to visit the Meet-the-NIH Lounge in Room 307 of the Washington State Convention & Trade Center, and get your questions answered. Program staff from the National Institute of Arthritis and Musculoskeletal and Skin Diseases, the National Institute of Diabetes and Digestive and Kidney Diseases, the Center for Scientific Review and more will be on-hand to meet with you.

YOUNG INVESTIGATOR LOUNGE

All Young Investigator Annual Meeting attendees are cordially invited to drop by the Young Investigator's Lounge located in Room 308 of the Washington State Convention & Trade Center. Expand your network of colleagues and make new friends.

ASBMR HALF-DAY SYMPOSIUM: STEM CELL BIOLOGY

This session will be held on Friday, October 1, 2004, from 9:30 am to 12:00 noon in Room 6ABC of the Washington State Convention & Trade Center. Several issues of critical importance to clinicians and researchers in the field will be discussed.

NEW INVESTIGATOR/NEW MEMBER BREAKFAST

Sponsored by the ASBMR Membership Development Committee

Supported by an unrestricted educational grant from Merck & Co., Inc.

The New Investigator/New Member Breakfast will be held on Saturday, October 2, 2004, from 7:00 am to 8:00 am in Room 4C-4 of the Washington State Convention & Trade Center. New Investigators (those early in their research careers) and new ASBMR members are invited to join the ASBMR Council, the Membership Development Committee and colleagues for an informational breakfast. Highlights will include opening remarks by the President of ASBMR, Dr. Robert Nissenson, an overview of the meeting and sessions of particular interest to new investigators and new members by the Program Chairs, Dr. Marie Demay and Dr. Eric Orwoll. Program Directors from US NIH Institutes and Centers, along with ASBMR member senior scientists will be available for discussion at specially marked tables. Attendees should look for table signs advertising a speciality or NIH Institute or Center of interest. Or attendees can make their own signs to join with colleagues who have similar interests. Breakfast will be provided.

SPECIAL SESSION FOR ALLIED HEALTH PROFESSIONALS

Sponsored by the ASBMR Membership Development Committee

Supported by an unrestricted educational grant from Merck & Co., Inc.

This session will be held on Saturday, October 2, 2004, from 12:00 noon to 2:00 pm in Rooms 606-607 of the Washington State Convention & Trade Center. This special session is designed for nurses, clinical research study coordinators, physical therapists, and other allied health professionals working in the area of clinical metabolic bone disease. An overview of the ASBMR 26th Annual Meeting will be given along with lectures on "Male Osteoporosis" and "Use of Bone Turnover Markers in the Evaluatioan of Osteoporosis." There is no additional fee or registration required for this session, nor will food and beverages be served. However, you are welcome to purchase lunch from the concession area of Hall 4ABC in the Washington State Convention & Trade Center.

GRANT WRITING WORKSHOP: TIPS ON GETTING FUNDED

Sponsored by the ASBMR Membership Development Committee

The Grant Writing Workshop will be held on Saturday, October 2, 2004, from 12:30 pm to 2:00 pm, in Room 4C-4 of the Washington State Convention & Trade Center. New investigators (those early in their research careers) and new members are invited to attend a workshop on the grant writing process, including advice on grantsmanship and the peer-review process. A panel discussion, based on questions and feedback from the audience, will be led by U.S. NIH represenatives and experienced ASBMR members from academia, including an international representative. Funding source information and opportunities will also be provided. This is a valuable opportunity for new investigators to gain helpful tips and information directly from these representatives and to become familiar with the different programs. There is no additional fee or registration required for this session, nor will food or beverages be served. However, attendees are welcome to purchase lunch from the concession area in the Hall 4ABC in the Washington State Convention & Trade Center.

BIOTECHNIQUES WORKSHOP: BIOLUMINESCENT IMAGING

Sponsored by the ASBMR Education Committee

This session will take place from 12:30 pm to 2:00 pm on Sunday, October 3, 2004, in Rooms 611-615 of the Washington State Convention & Trade Center. There is no additional fee or registration required for this session, nor will food and beverages be served. However, you are welcome to purchase lunch from the concession area in Hall 4ABC in the Washington State Convention & Trade Center.

RESPONSIBLE CONDUCT IN BONE AND MINERAL RESEARCH

Sponsored by the ASBMR Membership Development Committee

The session on Responsible Conduct in Bone and Mineral Research will be held on Sunday, October 3, 2004, from 12:30 pm to 2:00 pm in Rooms 602-604 of the Washington State Convention & Trade Center. This session, geared to new investigators, will begin with an overview of the various ethical issues that basic and clinical investigators encounter during their research careers. This will be followed by presentations that focus on: 1) the ethical issues of research publications, and 2) human subjects in research. There is no additional fee or registration required for this session, nor will food and beverages be served. However, you are welcome to purchase lunch from the concession area in Hall 4ABC in the Washington State Convention & Trade Center.

CAREER OPTIONS FOR SCIENTISTS

Sponsored by the ASBMR Education Committee

The Career Options for Scientists Workshop will be held on Monday, October 4, 2004, from 12:30 pm to 2:00 pm in Rooms 611-614 of the Washington State Convention & Trade Center. This year's Workshop will focus on "Private Choices – Professional Career Building: Navigating One's Career." Three speakers will give their perspectives on how they balance career and family choices. This workshop is organized for scientists at all levels in their careers, but particularly those who face challenging situations in their private lives, such as raising a family. There is no additional fee or registration required for this session, nor will food and beverages be served. However, you are welcome to purchase lunch from the concession area in Hall 4ABC in the Washington State Convention & Trade Center.

CLINICAL ROUNDTABLES

The Clinical Roundtable sessions are two informal sessions geared toward the practicing clinician, offering insight into treatment and diagnosis of bone diseases. These two special sessions will feature a focused discussion on topical issues of clinical relevance. Each session will feature two speakers and include ample time for discussion. The clinical roundtable on "Combination Therapy for Osteoporosis" will be held on Sunday, October 3, 2004, from 12:30 pm to 1:30 pm in Rooms 606-607 of the Washington State Convention & Trade Center. The session on "How Long Should We Treat with Anti-Resportive Drugs?" will be held on Monday, October 3, 2004, from 12:30 pm to 1:30 pm in Rooms 606-607 of the Washington State Convention & Trade Center. There is no additional fee or registration required for these sessions, nor will food and beverages be served. However, you are welcome to purchase lunch from the concession area in Hall 4ABC in the Washington State Convention & Trade Center.

MEET-THE-PROFESSOR SESSIONS

The Meet-the Professor Sessions are a series of informal sessions designed to provide an opportunity for meeting attendees to interact with experts in an intimate setting and discuss specific clinical and research topics. Interested individuals must sign up on-site for the sessions; tickets are extremely limited and are required for admission. These sessions are held from 12:30 pm to 1:30 pm on Friday, Saturday, Sunday, and Monday of the meeting. If you are interested in attending one of these sessions, we encourage you to sign up at your earliest convenience at the Registration Desk at the Washington State Convention & Trade Center. There is no additional fee required for this session, nor will food and beverages be served. However, you are welcome to purchase lunch from the concession area in Hall 4ABC in the Washington State Convention & Trade Center.

WELCOME RECEPTION AND PLENARY POSTER SESSION

Supported by an unrestricted educational grant from Merck & Co., Inc.

On Friday, October 1, 2004, from 5:15 pm to 7:00 pm, attendees and registered guests are invited to attend the ASBMR Welcome Reception and Plenary Poster Session in Exhibit/Poster Hall 4ABC of the Washington State Convention & Trade Center . Simply display your badge for admission. Guests may purchase a badge for $30 at registration, which will allow entrance to the Welcome Reception and Exhibit Hall.

ASBMR SOCIAL EVENT

Supported by Amgen

Experience Music Project (EMP) is a hands-on interactive museum that entertains and engages visitors of all ages as they discover and explore American popular music including rock, jazz, hip-hop, punk, soul, gospel, country and blues. EMP is the place to see amazing music-related artifacts including musical instruments like one of the first electric guitars, an extensive recorded sound archive, film, photographs, fanzines, stage costumes, hand-written song lyrics and rare song sheets. You can find your own rhythm and cut a CD in the museum's Sound Lab or jump up on stage with friends to start your own band and live out your rock'n roll fantasies. ASBMR guests will have exclusive access to the entire museum for this evening. Additionally, ASBMR will host a live dance band in the Sky Church - a room at the museum with a 70-foot high ceiling and the world's largest indoor video screen. So grab a quick dinner after the day's sessions and join us for drinks, desserts, dancing and a music experience you won't forget.

The EMP is located near Seattle's famous Space Needle at the Seattle Center. ASBMR guests can use their badges for a free ride on the monorail for the two-minute trip from downtown Seattle to the Seattle Center. Staff will direct you for the short walk from the monorail station to the museum. Please check for signs at the ASBMR registration desk regarding the monorail. At the time of this printing it is under repair. If the monorail is unavailable, shuttle buses will be provided.

Tickets are required for admission and must be purchased in advance for $30. You are encouraged to pre-register for this event. If available tickets remain, they will be sold on-site at the ASBMR Registration Counter in the South Lobby of the Washington State Convention & Trade Center.

REGISTRATION HOURS

All on-site registration will take place in the South Lobby of the Washington State Convention & Trade Center.

Thursday, September 30, 2004 ..... 9:00 am - 5:00 pm
Friday, October 1, 2004 ..... 7:00 am - 6:30 pm
Saturday, October 2, 2004 ..... 7:00 am - 5:30 pm
Sunday, October 3, 2004 ..... 7:00 am - 5:30 pm
Monday, October 4, 2004 ..... 7:30 am - 5:00 pm

EXHIBIT HALL HOURS

The Exhibit Hall is located in Hall 4ABC of the Washington State Convention & Trade Center. For meeting attendees, **lunch will be available for purchase in the hall** during Exhibit hours.

Friday, October 1, 2004 ..... 5:15 pm - 7:00 pm
Saturday, October 2, 2004 ..... 9:15 am - 4:30 pm
Sunday, October 3, 2004 ..... 9:30 am - 4:30 pm
Monday, October 4, 2004 ..... 9:30 am - 4:30 pm

SPEAKER READY ROOM

Supported by an unrestricted educational grant from Mission Pharmacal Company

Speakers must check into the Speaker Ready Room 24 hours in advance of their presentation. At that time, speakers may review their slides. The Speaker Ready Room is located in Room 304 of the Washington State Convention & Trade Center. Review of slides must occur at least 24 hours prior to your presentation. The Speaker Ready Room will be open during the following times:

Speaker Ready Room Hours

Thursday, September 30 ..... 12:00 noon – 5:00 pm
Friday, October 1 ..... 7:00 am – 5:30 pm
Saturday, October 2 ..... 7:00 am – 6:00 pm
Sunday, October 3 ..... 7:00 am – 5:30 pm
Monday, October 4 ..... 7:00 am – 5:30 pm
Tuesday, October 5 ..... 7:00 am – 11:00 am

SPEAKER LOUNGE

Supported by an unrestricted educational grant from the Alliance for Better Bone Health
(Procter & Gamble Pharmaceuticals and Aventis Pharmaceuticals)

The Speaker Lounge will be located in Room 305 of the Washington State Convention & Trade Center. The lounge provides a relaxing atmosphere for the oral presenters and invited speakers to rest, mingle with one another and to catch up on office work. The room will be equipped with computers, fax, copier, phone/modem lines, snacks and beverages, sofas and chairs. The Speaker Lounge will be available from Friday, October 1, to Monday, October 4, from 7:00 am to 4:00 pm, and on Tuesday, October 5, from 7:00 am to 11:00 am.

POSTER SESSIONS

All poster sessions will be held in Exhibit/Poster Hall 4ABC of the Washington State Convention & Trade Center. Authors must be at their posters for 1 hour of the designated poster sessions on Saturday through Monday and must be available to answer questions during this period, as well as during the designated morning or afternoon coffee breaks. Authors of odd-numbered posters should be present from 9:30 am to 10:00 am and from 11:45 am to 12:30 pm on their designated days. Authors of even-numbered posters should be present from 1:30 pm to 2:30 pm and from 4:00 pm to 4:30 pm

Poster numbers are listed in this *2004 Abstracts* book prefixed with a letter that denotes the day of presentation, i.e., F (Friday), SA (Saturday), SU (Sunday), M (Monday). These letters are not posted on the boards. **Presenters should mount their posters on the board bearing their assigned numbers, disregarding the letter prefix. ASBMR accepts no liability for posters or poster materials and will not adjudicate disputes between abstract presenters.**

Plenary Poster presenters and Young Investigator Award recipients presenting posters should mount their posters on Friday, October 1, 2004, between 3:00 pm and 5:00 pm. Plenary Poster presenters and Young Investigator Award recipients presenting posters are expected to be present during the Welcome Reception and Plenary Poster Session on Friday, October 1, from 5:15 pm to 7:00 pm. Plenary Poster presenters and Young Investigator Award recipients presenting posters will follow the odd/even hours for presenters during Poster Session I on Saturday, October 2, 2004. Plenary Posters will remain posted until Saturday, October 2, at 6:00 pm. Young Investigator Award posters will remain posted for the duration of the meeting.

Please note that children 12 years of age and under will not be permitted in the poster area or the Exhibit Hall at any time.

Presenter Check-in:
Since only poster presenters are allowed in the Exhibit/Poster Hall during the below poster set-up and dismantle hours, please go to the poster presenter check-in table to receive a security pass. The table will be located by the entrance to the Hall 4C. To speed the check-in process, please have your poster board number ready.

NOTE: Posters remaining after Poster Dismantling times will be discarded.

POSTER PRESENTATION SCHEDULE

ASBMR MEMBERSHIP

The ASBMR Membership Booth will be located in booth 218 in Exhibit Hall 4ABC. Come by and meet the ASBMR staff, pick up information about the Society, and check out the on-line versions of the *Journal of Bone and Mineral Research* and 5th Edition of the *Primer on Metabolic Bone Diseases and Disorders of Mineral Metabolism*, as well as the ASBMR Bone Curriculum website. You will also be able to order copies of the 5th Edition of the *Primer.*

The ASBMR Membership Counter is located in the Registration Area in the South Lobby and will be prepared to accept 2005 ASBMR membership renewal payments.

ASBMR JOB PLACEMENT SERVICE

The ASBMR Job Placement Service is easily accessible year-round on-line. You can access the most up-to-date job and candidate listings using the ASBMR Job Placement Service Website. Simply submit your resume or job announcement using the on-line forms at **www.asbmr.org**. After your forms are submitted and payment is received, you will be able to use your self-assigned login name and password to access the On-line Placement Service database anytime you wish.

Employers enrolled in the service will be entitled to display unlimited job announcements on-line and on-site at the meeting on the bulletin board located in the Registration Area of the South Lobby of the Washington State Convention & Trade Center. In addition, employers will have access to candidates' Curricula Vitae.

Employers and candidates may request further information by accessing the ASBMR On-line Job Placement Service at www.asbmr.org.

ASBMR MEDIA OFFICE

The ASBMR Media Office will be in operation during the ASBMR 26th Annual Meeting to facilitate media-related activities during the meeting. The Media Office will be located in Room 306 of the Washington State Convention & Trade Center.

Hours of Operation

Friday, October 1, 2004	9:00 am - 5:00 pm
Saturday, October 2, 2004	8:00 am - 5:00 pm
Sunday, October 3, 2004	8:00 am - 5:00 pm
Monday, October 4, 2004	8:00 am - 5:00 pm
Tuesday, October 5, 2004	8:00 am - 11:00 am

SPECIAL NOTICES — SAFETY TIPS

- Remove your convention badge outside the meeting sites. Do not wear your badge outside or advertise that you're a visitor and not familiar with your surroundings.
- Walk with another person rather than alone. Avoid alleys, walkways between buildings, and deserted parking lots.
- Remain alert, be aware of your surroundings, and carry your handbag in front of you.
- While in your hotel room, always lock your door. Know where emergency exits are in your hotel.
- Place any valuables in a hotel safety deposit box rather than leaving them in your room or carrying them with you.
- Keep a copy of your passport and travel papers in a safe place.

DOES THE ASBMR HAVE YOUR EMAIL ADDRESS?

Next year all important ASBMR Annual Meeting materials will be found on the ASBMR Website… and we will broadcast email to everyone on our correspondence list early notice of the Call for Abstracts, Preliminary Program, Registration and Housing information, Abstracts Online, and more! **So you don't miss out** on early notices and regular updates, please send all your contact information to the ASBMR, including your email address.

American Society for Bone and Mineral Research
2025 M Street, NW, Suite 800
Washington, DC 20036-3309, USA
Tel: (202) 367-1161
Fax: (202) 367-2161
E-mail: ASBMR@smithbucklin.com

ANNUAL MEETING EVALUATION

The 2004 Annual Meeting Evaluation will be accessible online following the 26th Annual Meeting. An email will be sent to all meeting attendees who provided their email addresses at the time of registration. The email will provide a hyperlink to the online evaluation site. It will also be accessible via the ASBMR home page at www.asbmr.org. We strongly encourage and welcome all attendees to provide us with feedback on the meeting. Your input is very important to us.

FUTURE ANNUAL MEETING DATES

September 23-27, 2005
ASBMR 27th Annual Meeting
Nashville, Tennessee, USA

September 15-19, 2006
ASBMR 28th Annual Meetinhg
Philadelphia, Pennsylvania, USA

September 16-20, 2007
ASBMR 29th Annual Meeting
Honolulu, Hawaii, USA

September 12-16, 2008
ASBMR 30th Annual Meeting
Montreal, Quebec, Canada

HOW THE PROGRAM WAS SELECTED

The 2004 ASBMR Program Co-Chairs and President began the process of program development well before the 2003 Annual Meeting in Minneapolis. We are grateful for the advice and suggestions from previous Program Co-Chairs. The overall structure of the 2004 meeting is similar to that of recent ASBMR meetings with an emphasis on short abstract presentations in oral and poster format. Each day opens with a plenary session: the Gerald D. Aurbach Memorial Lecture on Saturday, a Plenary Symposium on BMP Antagonists on Sunday and a second Plenary Symposium on New Insights into Bone Strength will be held on Monday, and the Louis V. Avioli Memorial Lecture closing the meeting on Tuesday. State-of-the-Art Sessions are scheduled for Saturday and Sunday afternoons. An effort was made to select State-of-the-Art topics that have not been covered in recent ASBMR Annual Meetings. A symposium on exciting advances in stem cell biology will be held on Friday morning. The four Mini-Symposia on Friday afternoon cover diverse clinical and basic science areas that were selected by the Program Co-Chairs with substantial input from the ASBMR membership via web based surveys and 2003 Annual Meeting online evaluations.

A major scientific focus of the meeting continues to be the presentation of abstracts in oral and poster formats. Each Program Co-Chair was responsible for approximately half of the abstract program (nearly 2000 abstracts were submitted). The same abstract categories were utilized as for the 2003 Annual Meeting. Program Co-Chairs, in consultation with the President, identified Chairs for each category. Nine additional reviewers were selected for each category, and these were chosen to reflect the diverse geographical distribution of our membership. Authors were asked to identify up to three categories into which their abstracts would fit, in order of priority. Program Co-Chairs then confirmed the most suitable category for review, re-assigning about 20% of abstracts to other categories based on content. Abstracts sent for review were blinded. Reviewers were instructed to abstain from reviewing any abstract with which they were in conflict. Abstracts were rated by reviewers on a 5-point scale, and the scores were tabulated by Coe-Truman Technologies, ASBMR's abstract processing vendor. The highest rated abstracts from each category were selected for the plenary oral sessions. The next highest rated abstracts were selected for concurrent oral sessions. Highly rated abstracts that were not selected for the oral program were assigned to the plenary poster session. Overall, approximately 11% of the submitted abstracts were assigned to the oral program. Each category had similar percentage representation on the oral program, with only minor variation due to differences in the spread of scoring between categories.

We have again included a Late-Breaking Abstract Session at the 2004 Annual Meeting. It will be held after the Plenary Symposium on Monday morning, and will run concurrently with a combined basic and clinical Plenary Oral Session. This session is for abstracts of broad interest where the findings were not available in time for submission at the regular abstract deadline. The procedure for selection of abstracts for the Late-Breaking Abstract Session is similar to that used for the other oral sessions and the merit of these abstracts must reach or exceed the level of those selected for the regular oral program.

As in previous years, the recipients of the ASBMR Young Investigator Awards, the ASBMR Outstanding Abstract Award, the ASBMR Award for Outstanding Research in the Pathophysiology of Osteoporosis, and the ASBMR President's Book Award were selected on the basis of abstract score and eligibility.

We are grateful to our many colleagues who provided suggestions and advice about topics and speakers for symposia and lectures. We also thank the abstract reviewers and the staff of the ASBMR Business Office, with special thanks to Lizzy Koenst and Amy Werner. Finally, we appreciate the valuable input of the staff of Coe-Truman Technologies. We believe that the hard work and dedication of everyone involved has again resulted in an outstanding scientific program for our annual meeting.

Sincerely,

Robert A. Nissenson, Ph.D., *President*
Marie Demay, M.D., *Program Co-Chair*
Eric Orwoll, M.D., *Program Co-Chair*

FRIDAY, OCTOBER 1, 2004
DAY-AT-A-GLANCE

Time/Event/Location
All events will be held at the Washington State Convention & Trade Center, unless otherwise noted.)

9:30 am - 12:00 noon
Stem Cell Biology Symposium
Room 6ABC

12:30 pm - 1:30 pm
Meet-the-Professor Sessions
Rooms 601, 615-620
Ticket required. See ticket for room assignment.

2:00 pm - 3:30 pm
Mini-Symposium A: Craniofacial Development
Room 6ABC

2:00 pm - 3:30 pm
Mini-Symposium B: Paget's Disease
Room 6E

3:45 pm - 5:15 pm
Mini-Symposium C: PTH/PTHrP Actions
Room 6E

3:45 pm - 5:15 pm
Mini-Symposium D: Pediatric Bone Biology: Disorders of Development and Growth
Room 6ABC

5:15 pm - 7:00 pm
Welcome Reception and Plenary Poster Session
Exhibit Hall 4ABC

Ancillary Program - Working Groups

7:00 pm - 9:30 pm
Fluid Flow in Bone Working Group
Room 4C-4

7:00 pm - 9:30 pm
Nutrition and Bone Health Working Group
Rooms 602-604

7:00 pm - 9:30 pm
Working Group on Musculoskeletal Rehabilitation for Patients with Osteoporosis
Rooms 618-620

7:15 pm - 9:45 pm
In Vivo Working Group
Rooms 608-609

7:15 pm - 10:00 pm
Working Group on Biochemical Markers of Bone Turnvover
Rooms 611-614

Ancillary Program - Industry-Supported Symposia (ISS)

7:00 pm - 9:30 pm
Changes on the Horizon? The Future of Osteoporosis Diagnosis, Prevention and Management
Grand Ballroom, Sheraton Seattle Hotel & Towers

7:00 pm - 9:00 pm
Optimizing the Treatment of Osteoporosis: Evolutions and Solutions
Grand Ballroom 1 and 2, The Westin Seattle

SATURDAY, OCTOBER 2, 2004
DAY-AT-A-GLANCE

Time/Event/Location
(All events will be held at the Washington State Convention & Trade Center, unless otherwise noted.)

7:00 am - 8:00 am
New Investigator/New Member Breakfast
Room 4C-4

8:00 am - 6:00 pm
Posters Open
Exhibit Hall 4ABC

8:00 am - 8:10 am
Welcome and Announcements
Room 6ABC

8:10 am - 9:10 am
Gerald D. Aurbach Memorial Lecture
Room 6ABC

9:10 am - 9:15 am
Presentation of William F. Neuman Award
Room 6ABC

9:15 am - 4:30 pm
Exhibits Open
Exhibit Hall 4ABC

9:15 am - 9:20 am
Presentation of Fuller Albright Award
Room 6ABC

9:20 am - 9:25 am
Presentation of Gideon A. Rodan Excellence in Mentorship Award
Room 6ABC

9:25 am - 9:30 am
Presentation of Gideon and Sevgi Rodan IBMS Fellowship Awards
Room 6ABC

9:30 am - 10:00 am
Coffee Break
Odd Posters Present
Exhibit Hall 4ABC

10:00 am - 11:30 am
Plenary Orals I - Basic (1001-1006)
Room 6E

Plenary Orals II - Clinical/Translational (1007-1012)
Room 6ABC

11:30 am - 2:30 pm
Poster Session I (Presentations SA001 - SA589)
11:30 am - 12:30 pm Odd numbers
1:30 pm - 2:30 pm Even numbers
Exhibit Hall 4ABC

12:00 noon - 2:00 pm
Special Session for Allied Health Professionals
Rooms 606-607

12:30 pm - 1:30 pm
Meet-the-Professor Sessions
Rooms 601, 615-620
Ticket required. See ticket for room assignment.

12:30 pm - 2:00 pm
Grant Writing Workshop: Tips on Getting Funded
Room 4C-4

2:30 pm - 4:00 pm
Concurrent Oral Sessions

1) Osteoblasts I (1013 - 1018)
Room 6E

2) Osteoporosis - Epidemiology I (1019 - 1024)
Room 6ABC

3) Osteoclasts I Rooms (1025 - 1030)
Rooms 608-609

4) Mechanical Loading: In Vitro (1031 - 1036)
Rooms 602-604

5) BMPs and Other Growth Factors I (1037-1042)
Rooms 611-614

6) Bone Acquisition and Pediatric Bone Disease I - (1043-1048)
Rooms 606-607

4:00 pm - 4:30 pm
Coffee Break
Even posters present
Exhibit Hall 4ABC

4:30 pm - 6:00 pm
State-of-the-Art Lectures A: Hormone Action on Non-Traditional Targets
Room 6ABC

4:30 pm - 6:00 pm
State-of-the-Art Lectures B: Collaborating with Industry: Issues for Individual Investigators
Room 6E

6:00 pm - 7:00 pm
ASBMR Annual Business Meeting
Rooms 611-614

Ancillary Program - Working Groups

7:00 pm - 9:15 pm
Non-Invasive Assessment of Trabecular Bone Microarchitecture Working Group
Room 606-607

7:00 pm - 10:00 pm
Post Transplantation Bone Disease Working Group
Rooms 618-620

7:00 pm - 10:00 pm
Working Group on Hormone-Receptor Interactions
Rooms 608-609

7:15 pm - 9:30 pm
Bone Remodeling and Stress Fracture Working Group
Rooms 602-604

7:15 pm - 10:00 pm
Pediatric Bone and Mineral Working Group
Room 4C-4

Ancillary Program - Industry-Supported Symposia (ISS)

7:00 pm - 9:30 pm
The Evolving Management of Bone Disease: Changes on the Horizon
Room 6E

7:00 pm - 10:00 pm
The Role of Bone Strength in the Diagnosis and Treatment of Osteoporosis
Grand Ballroom, Sheraton Seattle Hotel & Towers

SUNDAY, OCTOBER 3, 2004
DAY-AT-A-GLANCE

Time/Event/Location
(All events will be held at the Washington State Convention & Trade Center, unless otherwise noted.)

Ancillary Program - Industry-Supported Symposia (ISS)

6:00 am - 8:00 am
Parathyroid Hormone: Meeting the Challenge of Osteoporosis
Grand Ballroom, Sheraton Seattle Hotel &Towers

8:00 am - 6:00 pm
Posters Open
Exhibit Hall 4ABC

8:00 am - 9:30 am
Plenary Symposium I: BMP Antagonists: Basic Science to Human Disease
Room 6ABC

9:30 am - 4:30 pm
Exhibits Open
Exhibit Hall 4ABC

9:30 am - 9:35 am
Presentation of Frederic C. Bartter Award
Room 6ABC

9:35 am - 10:00 am
Coffee Break
Odd Posters Present
Exhibit Hall 4ABC

10:00 am - 11:30 am
Plenary Orals I - Basic (1049 - 1054)
Room 6E

Plenary Orals II - Clinical/Translational (1055 - 1060)
Room 6ABC

11:30 am - 2:30 pm
Poster Session II (Presentations SU001 - SU586)
11:30 am - 1:30 pm Odd numbers
1:30 pm - 2:30 pm Even numbers
Exhibit Hall 4ABC

12:30 pm - 1:30 pm
Clinical Roundtable: Combination Therapy for Osteoporosis
Rooms 606-607

12:30 pm - 1:30 pm
Meet-the-Professor Sessions
Rooms 601, 615-620
Ticket Required. See ticket for room assignment.

12:30 pm - 2:00 pm
Responsible Conduct in Bone and Mineral Research
Rooms 602-604

2:30 pm - 2:00 pm
Biotechniques Workshop: Molecular Bioluminescent Imaging
Rooms 611-614

2:30 pm - 4:00 pm
Concurrent Oral Sessions

7) PTH Actions (1061-1066)
Room 6E

8) Osteoporosis - Diagnosis and Treatment (1067-1072)
Room 6ABC

9) Bone, Cartilage, Connective Tissue Matrix (1073-1078)
Rooms 611-614

10) Genetics of Bone and Mineral Disorders (1079-1084)
Rooms 606-607

11) Steroids: Molecular (1085-1090)
Rooms 608-609

12) Cancer and Bone (1091-1096)
Rooms 602-604

4:00 pm - 4:30 pm
Coffee Break
Even Posters Present
Exhibit Hall 4ABC

4:30 pm - 6:00 pm
State-of-the-Art Lecture A: Osteoclast Biology
Room 6ABC

4:30 pm - 6:00 pm
State-of-the-Art Lecture B: Research Methods in Skeletal Genetics
Room 6E

8:30 pm - 11:30 pm
ASBMR Social Event
Experience Music Project at Seattle Center
Ticket required.

MONDAY, OCTOBER43, 2004
DAY-AT-A-GLANCE

Time/Event/Location
(All events will be held at the Washington State Convention & Trade Center, unless otherwise noted.)

8:00 am - 4:30 pm
Posters Open
Exhibit Hall 4ABC

8:00 am - 9:30 am
Plenary Symposium II: New Insights Into Bone Strength
Room 6ABC

9:30 am - 4:30 pm
Exhibits Open
Exhibit Hall 4ABC

9:30 am - 9:35 am
Presentation of Shirley Hohl Service Award
Room 6ABC

9:35 am - 10:00 am
Coffee Break
Odd Posters Present
Exhibit Hall 4ABC

10:00 am - 11:30 am
Plenary Oral Session (1097-1102)
Room 6ABC

10:00 am - 11:30 am
Late-Breaking Abstracts Session
Room 6E

11:30 am - 2:30 pm
Poster Session III (Presentations M001 - M585)
11:30 am - 12:30 pm Odd numbers
1:30 pm - 2:30 pm Even numbers
Exhibit Hall 4ABC

12:30 pm - 2:00 pm
Career Options for Scientists Workshop
Rooms 611-614

12:30 pm - 2:00 pm
Clinical Roundtable: How Long Should We Treat with Anti-Resorptive Drugs?
Rooms 606-607

12:30 noon - 1:30 pm
Meet-the-Professor Sessions
Rooms 601, 615-620
Ticket required. See ticket for room assignment.

2:30 pm - 4:00 pm
Concurrent Oral Sessions

13) Osteoblasts II - *(1103-1108)*
Room 6E

14) Osteoporosis - Epidemiology II - *(1109-1114)*
Room 6ABC

15) Steroid Receptor Actions - (1115-1120)
Rooms 602-604

16) Osteoporosis - Pathophysiology I - (1121-1126)
Rooms 608-609

17) Chondrocyte Biology - (1127-1132)
Rooms 606-607

18) Bone Acquisition and Pediatric Bone Disease - (1133-1138)
Rooms 611-614

4:00 pm - 4:30 pm
Coffee Break
Even Posters Present
Exhibit Hall 4ABC

4:30 pm - 6:00 pm
Concurrent Oral Sessions

19) Osteoblasts III - (1139-1144)
Room 6E

20) Mechanical Loading: In Vivo - (1145-1150)
Rooms 602-604

21) Osteoporosis - Pathophysiology II - *(1151-1156)*
Rooms 608-609

22) Other Disorders of Bone and Mineral Metabolism I- (1157-1162)
Rooms 606-607

23) Peptide Hormones - (1163-1168)
Rooms 611-614

24) Osteoporosis - Treatment I - (1169-1174)
Room 6ABC

Ancillary Program - Working Groups

6:15 pm - 8:35 pm
Physical Activity Working Group
Rooms 608-609

6:30 pm - 9:30 pm
Adult Bone and Mineral Working Group
Room 4C-4

6:30 pm - 8:30 pm
Molecular Biology and Pathology of Bone Working Group
Rooms 611-614

6:30 pm - 9:30 pm
Vitamin D Working Group
Rooms 602-604

7:00 pm - 9:15 pm
Working Group on Aging and the Human Skeleton
Rooms 615-617

DISCLOSURE/CONFLICT OF INTEREST

The Federation of American Societies for Experimental Biology (FASEB) requires that audiences at FASEB-sponsored educational programs be informed of a presenter's (speaker, faculty, author, or contributor) academic and professional affiliations, and the existence of any significant financial interest or other relationship a presenter has with the manufacturer(s) of any commercial product(s) discussed in an educational presentation. This policy allows the listener/attendee to be fully knowledgeable in evaluating the information being presented. The Program will note those speakers who have disclosed relationships, including the nature of the relationship and the associated commercial entity.

All authors of submitted abstracts completed the disclosure statement in the online submission program. Invited speakers who are not required to submit an abstract received a form in the mail that they completed and returned.

Disclosure may include any relationship that may bias one's presentation or which, if known, could give the perception of bias. These situations may include, but are not limited to:

DISCLOSURE KEY

1. stock options or bond holdings in a for-profit corporation or self-directed pension plan
2. research grants
3. employment (full or part-time)
4. ownership or partnership
5. consulting fees or other remuneration
6. non-remunerative positions of influence such as officer, board member, trustee, or public spokesperson
7. receipt of royalties
8. speaker’s bureau

For full-time employees of industry or government, the affiliation listed in the *2004 Abstracts* will constitute full disclosure.

Disclosures for invited speakers and abstract presenters are provided at the end of the session listing for invited speakers and directly after the body of an abstract for abstract submissions. If there is no conflict of interest or disclosure listed, this means that the invited speaker and/or abstract presenter indicated no conflicts to disclose.

The disclosure information will correspond to the key above. If disclosures are given, the company name, along with the respective disclosure relationship number will be listed (for example: Company Name, 2, 8.).

Osteoblast-Specific Deletions of Apc and B-catenin Dramatically Alter Bone Development. S. L. Holmen*[1], C. R. Zylstra*[1], A. Mukherjee*[2], R. E. Sigler*[1], M. C. Faugere*[3], M. L. Bouxsein[4], T. L. Clemens[2], B. O. Williams[1]. [1]Van Andel Research Institute, Grand Rapids, MI, USA, [2]Department of Pathology, University of Alabama at Birmingham, Birmingham, AL, USA, [3]Department of Medicine, University of Kentucky, Lexington, KY, USA, [4]Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center, Boston, MA, USA.

Mutations in the Wnt co-receptor Lrp5 produce striking alterations in bone mass in both humans and mice but the mechanisms responsible for Wnts actions in bone are unclear. Wnts activate several signaling cascades including the canonical pathway that inhibits APC-mediated degradation of ß-catenin with consequent activation of TCF/LEF transcription of target genes. We used Cre-mediated recombination to investigate the role of the canonical pathway in osteogenesis by selectively deleting the genes encoding ß-catenin and Apc. Mice carrying floxed ß-catenin and Apc alleles were mated to mice expressing the Cre recombinase driven by the human osteocalcin promoter (J Biol Chem. 277:44005). Mice deficient in ß-catenin were smaller than their littermates and died within five weeks with dramatic reductions in bone at all skeletal sites. MicroCT analysis of the femur showed severe cortical thinning and a complete absence of trabecular elements.Mice heterozygous for this mutation also had lower bone mass. By contrast, mice deficient in Apc exhibited a dramatic increase in bone acquisition. Metaphyseal bone was hypervascularized and poorly mineralized, whereas osteoid in the dyaphysis was more completely mineralized and entirely filled the marrow cavity. Interestingly, osteoclasts were virtually absent from these bones, possibly due to a decrease in the bone marrow precursor availability. Consistent with this, most Apc mutants died within two weeks of birth with evidence of anemia. To determine the effect of loss of ß-catenin and APC on osteoblast differentiation in vitro, primary calvaria osteoblasts isolated from mice homozygous for the floxed alleles were infected with adenoviral vectors expressing either Cre or GFP and allowed to differentiate in mineralizing medium. Osteoblasts lacking ß-catenin showed increased proliferation associated with a reduction in Runx-2 and osteocalcin expression and a delay in mineralization. By contrast, osteoblasts deficient in Apc demonstrated premature and upregulated expression of osteoblast marker genes. We conclude that canonical Wnt signaling is critically important in controlling normal bone acquisition in mice and likely accounts for how Lrp5 affects bone mass accrual in humans. Our results also suggest that this signaling pathway functions during development to control the pace of osteoblast differentiation.

Beta-catenin Is Essential for Normal Bone Development. M. J. Hilton*, F. Long. Department of Internal Medicine - Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA.

Canonical Wnt signaling occurs through a receptor complex that includes the Frizzled family members and the Low Density Lipoprotein Receptor-Related Proteins 5 or 6 (LRP5/6), which leads to nuclear accumulation of Beta-catenin and activation of Wnt responsive genes. Recent genetic evidence analyzing mutations of LRP5 has indicated that canonical Wnt signaling positively regulates bone mass in the postnatal skeleton. Since Wnt signaling occurs normally during embryogenesis in the absence of LRP5, it is not known whether canonical Wnt signaling is required for osteoblast development in the embryo. Here we have addressed this issue by genetically removing Beta-catenin from all skeletogenic tissues by using the Cre-LoxP technology. Specifically, we have generated embryos of the *Dermo1*-Cre; *Beta-catenin* $^{c/c}$ genotype using the *Dermo1*-Cre "knock-in" line of mice which activates Cre expression in the mesenchymal condensations during early skeletogenesis. These mutant animals die at birth and analyses of embryonic skeletons clearly show a complete lack of bone formation throughout the body. Our results indicate that Beta-catenin is essential for osteoblast differentiation and molecular analysis has revealed an early arrest in the differentiation of the osteoblast lineage. Furthermore, consistent with previous studies, the Beta-catenin mutants also exhibit reduced chondrocyte proliferation and severely delayed chondrocyte maturation. The work presented here clearly demonstrates that Beta-catenin acts a positive regulator of osteoblast differentiation, chondrocyte proliferation, and chondrocyte maturation.

Over-Expression of Activated NFATc1 plus RANKL Rescues the Osteoclastogenesis Defect of NF-κB p50/p52 Double Knockout Splenocytes. F. Li*[1], K. Matsuo[2], L. Xing[1], B. F. Boyce[1]. [1]Univeristy of Rochester, Rochester, NY, USA, [2]Keio University, Tokyo, Japan.

Expression of NF-κB p50 and p52, c-Fos, and NFATc1 is essential for RANKL- and TNF-mediated osteoclast (ocl) formation. NFATc1 is a downstream target for c-Fos in RANKL-induced osteoclast formation, but it is not known if it is a target of NF-κB. To examine this possibility, we used M-CSF-dependent splenocytes from NF-κB p50 and p52 double knockout (dKO) or control mice. NFATc1 expression, using real time PCR, was similar in splenocytes from dKO and control mice treated with M-CSF for 3d. In contrast, RANKL significantly increased NFATc1 expression in these M-CSF-dependent splenocytes (MDS) from wt, but not from dKO mice (fold induction over time 0 in control vs dKO: at 2 and 24 hr, 12+/-0 vs 3+/-0). To determine if retroviral expression of NFATc1 can rescue the ocl formation defect of dKO cells, we infected dKO MDS with a constitutively active nuclear form of NFATc4 (ΔNFAT), c-Fos or GFP in the presence or absence of RANKL. ΔNFAT plus RANKL induced ocl formation from dKO MDS (# Ocls/well: ΔNFAT/RANKL, 48+/-11; GFP/RANKL, 0+/-0; c-Fos/RANKL, 158+/-11). ΔNFAT overexpression alone did not induce ocl formation. IL-1 and TNF also induced some ocl formation from ΔNFAT-expressing dKO MDS, but less effectively than RANKL (#ocls/well: ΔNFAT/IL-1, 6+/-1; ΔNFAT/TNF, 10+/-2; ΔNFAT/PBS, 0+/-0; TNF alone, 0+/-0). We showed previously that c-Fos plus IL-1 induces ocl formation from wild-type MDS in the absence of RANKL. ΔNFAT plus IL-1 had a similar but less osteoclastogenic effect (# Ocls/well: c-Fos/IL-1, 58+/-6 vs ΔNFAT/IL-1, 31+/-3). To examine if c-Fos plus IL-1 stimulates NFATc1 expression or vice verse, the expression of NFATc1 or c-Fos was compared between IL-1-treated c-Fos-infected or ΔNFAT-infected wild-type spleen cells. c-Fos plus IL-1 increased NFATc1 expression by 4 fold, but c-Fos or IL-1 had no effect. In contrast, ΔNFAT plus IL-1 had no effect on c-Fos expression. Finally, We compared the expression of NFATc1 in wt and dKO MDS treated with RANKL or TNF and found that while RANKL increased NFATc1 expression in both wt and dKO cultures, TNF increased its expression only in the wt MDS. In summary, our results indicate that NFATc1 is a downstream target for NF-κB in RANKL-mediated osteoclastogenesis, but other cytokines such as IL-1 and TNF may also work through the NFAT pathway in the absence of NF-κB signaling.

Dentin Matrix Protein-1 (DMP-1) Plays a Key Role in Osteocyte Function through Regulation of Mineralization and Response to Mechanical Strain. H. F. Rios*[1], Y. Xie*[1], S. Kotha*[1], D. Nicholella*[2], D. Nicholella*[2], L. Ye[1], L. Bonewald[1], J. Q. Feng[1]. [1]Oral Biology, UMKC, Kansas City, MO, USA, [2]Mech and Matls Engr, SW Res Ins., San Antonio, TX, USA.

Mechanical load determines bone architecture. Increased load yields increased bone, whereas decreased load leads to bone loss. Osteocytes appear to sense and translate mechanical strain into biochemical signals of formation or resorption. Dmp 1 is an extracellular matrix protein of unknown function, highly expressed and regulated by mechanical strain in osteocytes.

Dmp1 Knockout (KO) mice appear normal at birth suggesting that it does not play a role in embryonic bone development or mineralization. However, by 2-3 wks of age an increase in subchondral bone is observed, potentially a compensatory response to locomotion, which is rapidly reversed with age. Osteoid formation, not true bone formation, is accelerated in these mice. Histological analysis of Dmp1 KO mice at 1, 3 and 7.5 mos show highly expanded, irregular periosteal and endosteal osteoid. Using Raman microscopy, a decrease in mineral compared to matrix is also observed with age. Calcein/Alizarin red labeling is increased and extremely diffuse on both the endosteal and periosteal surfaces in the KO mice. Expression of non-collagenous matrix proteins such as biglycan, decorin, bone sialoprotein, osteopontin, osteocalcin are dramatically increased, whereas no differences were observed in collagen I by immunohistochemistry. By transmission and backscatter electromicroscopy, the mineral, when present is patchy and poorly organized. Osteocytes within osteoid have normal size and dendricity, but the morphology of the dendritic processes is abnormal with a 'buckling' of the membrane surface. In addition, there are clear differences in the osteocyte lacunae: those in the KO bone are larger than those in the WT bone. The long bones are less stiff, have greater total deformation, and yield at lower load levels compared to long bones from WT mice. Compressive loading at 60 Hz shows strains 1.7 times higher in *Dmp 1* KO mice than normal and heterozygous mice ($p<0.05$), indicating a significant change in the material (elastic moduli) and/or structural (stiffness) properties. These KO mice display multiple pathological fractures, likely a consequence of reduced bone mineral. Therefore, the osteocytes in these mice are constantly being subjected to higher strain levels than osteocytes in WT bone. These 'hyperstrained' osteocytes appear to signal increased bone formation that in the absence of Dmp1 results in increased osteoid, not bone. Together these data suggest that DMP 1 is critical for osteocyte function postnatally though its dual role in controlling mineralization and response to mechanical strain.

Cooperative Signaling of Fibroblast Growth Factor Receptors 1 and 2 in Skeletal Development. H. Kanazawa[1], K. Yu*[1], A. Jacob*[1], I. H. Hung*[1], J. M. Partanen*[2], D. M. Ornitz*[1]. [1]Molecular Biology and Pharmacology, Washington University Medical School in St. Louis, St. Louis, MO, USA, [2]Institute of Biotechnology, University of Helsinki, Helsinki, Finland.

Many craniosynostosis syndromes are caused by the mutations in fibroblast growth factor receptors (FGFRs) 1 and 2. In addition to craniofacial abnormalities, these patients often have short stature and malformations of the hands and feet. Although FGFR1 and FGFR2 each have important roles in skeletal development, redundancy between FGFR1 and FGFR2 is unknown. To address the combined affect of loss of function of both genes on skeletal development we have generated Fgfr1/Fgfr2 double conditional knockout (DCKO) mice using the mesenchymal osteoprogenitor-specific Dermo1 (Twist2)-cre gene. Taking advantage of Cre-loxP system, we mated Dermo1-Cre/Fgfr1delta/+;Fgfr2delta/+ mice with Fgfr1flox/flox;Fgfr2flox/flox mice to generate DCKO mice. The phenotype of DCKO mice was much more severe than deletion of either Fgfr1 or Fgfr2 alone. All DCKO mice died immediately after birth because of cleft palate. Compared to controls, sagittal sutures of DCKO mouse skulls were widely opened secondary to hypoplastic nasal and frontal bone growth. DCKO mice also had a hypoplastic squamous bone, missing tympanic rings, shortened or truncated zygomatic arch, and a shortened and malformed mandible. Costchondral gaps and the vertebral neuronal arch were severely deformed. In the limb, DCKO mice showed joint fusion at the elbow and knee. The hindlimb was more affected than the forelimb and proximal bones were more affected than distal bones. Long bones were shorter and wider compared to control mice. Osteopontin expression was examined in E16.5 and E.17.5 calvariae by whole mount in situ hybridization. The expression level of Osteopontin was elevated in DCKO in the frontal bone area compared to controls. These data demonstrate an essential and redundant role for both FGFR1 and FGFR2 in both axial and appendicular skeletal development. Moreover craniofacial abnormalities in DCKO mice suggested a potential role for FGFR signaling in neural crest cells that contribute to craniofacial skeletal development.

Genetic Evidence of Androgen Receptor Function in Osteoclasts: Generation and Characterization of Osteoclast-specific Androgen Receptor Knockout Mice. T. Nakamura*[1], T. Watanabe*[1], Y. Nakamichi[1], T. Fukuda*[1], T. Matsumoto*[1], K. Yoshimura*[1], J. Miyamoto*[1], Y. Yamamoto*[1], H. Shiina*[1], S. Tanaka*[1], M. Sakari*[1], T. Sato*[1], D. Metzger*[2], P. Chambon*[2], S. Kato[1]. [1]Laboratory of Nuclear Signaling, Institute of Molecular and Cellular Biosciences, University of Tokyo, Tokyo, Japan, [2]Institut de Genetique et de Biologie Moleculaire et Cellulaire, CNRS/ INSERM/ ULP, College de France, Strasbourg, France.

Androgen actions appear essential for normal skeletal development and maintenance, particular in males. In fact, we have demonstrated by a gene disruption approach that AR function is essential for normal bone remodeling through suppression of bone resorption in male mice(Kawano.H et al *PNAS*, 2003). However, the primary bone cell-type for AR function remains to be established, though no clear expression of AR in mammalian osteoclasts was reported.

To directly examine AR function in osteoclasts, we used a Cre/*lox*P system to disrupt AR gene in mice osteoclasts. To drive Cre expression specifically in the osteoclasts, we carried out the targeted insertion of the Cre gene in the Cathepsin K gene (*Ctsk*) locus and generated Ctsk-Cre knock-in mice. Expression analysis of lacZ gene in CAG-CAT-Z reporter mice demonstrated that Cre-mediated recombination took place in a osteoclast-specific manner in Ctsk-Cre mice. Among the progeny of crosses betweeen Ctsk-Cre and floxed AR mice, males with $Ctsk^{Cre/+}$; AR^{flox}/Y genotype were selected as osteoclast-specific AR knockout (Oc-ARKO) mice for detailed analysis. Unexpectedly, histomorphometric analysis of the lumber spine from Oc-ARKO mice showed significantly increased number of osteoclasts and the other bone resorption parameters compared with control mice. This was further reflected in the increased levels of urinary deoxypyridinoline. The bone formation parameters were also increased in Oc-ARKO mice, with increased thickness of the region between two calcein-labeled layers. The Oc-ARKO mice bone phenotype suggests that AR serves as a critical regulator in osteoclasts.

Results of a 5 Year Double Blind, Placebo Controlled Trial of Calcium Supplementation (CAIFOS); Clinical Fracture Outcomes. R. L. Prince[1], A. Devine[1], S. S. Dhaliwal*[2], I. M. Dick[1]. [1]School of Medicine and Pharmacology, University of Western Australia, Western Australia, Australia, [2]School of Public Health, Curtin University of Technology, Western Australia, Australia.

Osteoporotic fracture is a major public health problem for elderly women. Prevention approaches can involve pharmacological treatment targeted at high risk individuals or a public health approach treating the whole population. We chose the latter approach to test the hypothesis that calcium supplementation (calcium carbonate 600mg twice per day) compared to identical placebo would reduce the clinical osteoporotic fracture rate by at least 27% over 5 years in women older than 70.

1460 women mean age 75 were recruited from the whole population using a recruitment letter strategy. Responders were excluded if they were on bone active treatment, calcium supplementation or had diseases that may have prevented them completing the 5 year study. Of the responders 18% were eligible and agreed to commence the study. Baseline calcium intake was determined from a food frequency questionnaire. Clinical osteoporotic fractures, verified by x-ray, were ascertained from diaries collected 4 monthly. All fractures, except those of the phalanges or skull, were included in the analysis. Study outcomes were examined using the Cox proportional hazard model to calculate hazards ratios and 95% confidence intervals (HR).

Baseline calcium intake was 970±354 mg/day. In all, 235 individuals (16.1%) sustained 296 fractures during the study. 67 patients died (4.6%), 165 (11.3%) withdrew completely and 305 (20.9%) ceased the medication but continued in the study. Thus 923 (63.2%) completed the study per protocol. The risks of death (HR 0.76: 0.47-1.23), withdrawal (HR 0.86: 0.63-1.16) or cessation of medication (HR 0.98: 0.80-1.21) was not different in the calcium versus the placebo group.

Calcium supplementation resulted in a 34% reduction in fracture in the per protocol patients (HR 0.66: 0.46-0.95). These results were not altered by age, BMI, hip BMD, baseline calcium intake or prevalent baseline fracture entered as covariates individually or in combination. The treatment effect was slightly stronger if vertebral fractures were not included (HR 0.63: 0.42-0.93). In an intention to treat analysis calcium supplementation did not reduce fractures significantly compared to placebo (HR 0.85:0.66-1.10, p=0.23).

These data demonstrate that elderly females who remain compliant with calcium supplementation of 1200 mg per day can reduce their 5 year risk of osteoporotic fracture from an average risk of 16% to an average risk of 10%. These data justify an increased emphasis on calcium supplementation as part of a public health approach to fracture prevention.

Deletion of the β2 Adrenergic Receptor Prevents Bone Loss Induced by Isoproterenol in Mice. H. Z. Ke, G. XU*, A. L. Brault*, H. Qi, D. T. Crawford*, H. A. Simmons, M. Li, T. A. Brown. Pfizer Global Research and Development, Groton, CT, USA.

Isoproterenol (Iso), a β-adrenergic receptor agonist, has been shown to reduce bone mass by decreasing bone formation. Since Iso interacts with all three β-adrenergic receptors (β1-β3), the receptor subtype responsible for its negative effects on bone is not completely understood. The purpose of this study was to determine the role of β2 in Iso-induced bone loss using the β2 knock-out (KO) mice. Male wild-type FVB/N (WT) or KO mice at 4 months of age were treated with vehicle or Iso at 30 mg/kg/d for 8 weeks by i.p. injection. PQCT analysis showed a significant decrease in total bone mineral content in both the distal femoral metaphysis (DFM, -15%) and femoral shaft (FS, -11%) in Iso-treated-WT mice compared with WT controls. Further, trabecular density in DFM and cortical thickness in FS were significantly decreased, while endocortical circumference in FS increased significantly in Iso-treated-WT mice compared with WT controls. A significant decrease in trabecular bone volume (-60%) was observed by micro-CT analysis of DFM in Iso-treated-WT mice compared with WT controls. These data indicate that Iso induced significant bone loss on endocortical and trabecular surfaces. Histomorphometric analysis of trabecular bone on the 4th lumbar vertebral body indicates that Iso treatment in WT mice increased bone turnover as evident by a significant increase in mineralizing surface (+99%), mineral apposition rate (+32%), bone formation rate/BS (+158%), osteoclast surface (+83%) and osteoclast number (+63%) as compared with WT controls. Unlike the findings in WT mice, treatment with Iso in β2 receptor KO mice did not induce significant changes in total bone mineral content, trabecular bone volume, osteoclast surface and osteoclast number compared with vehicle-treated KO controls. In mouse calvarial osteoblast culture, Iso dose-dependently increased cAMP production at concentrations between 60 nM and 5 uM with the maximal increase of 1441 folds at 5 uM in WT osteoblasts, but not in KO osteoblasts, indicating that β2 receptor directly regulates the stimulating effects of Iso on osteoblast. In summary, Iso induces bone loss by increasing both bone resorption and formation in WT mice *in vivo*. These data are in contrast with a previous report in which Iso induces bone loss by inhibiting osteoblastic bone formation. Deletion of the β2 receptor blocks high turnover bone loss induced by Iso, therefore, β2 adrenergic receptor mediates the negative bone effects of Iso. These data reveal that antagonizing β2 receptor provides therapeutic potentials for skeletal disorders such as osteoporosis.

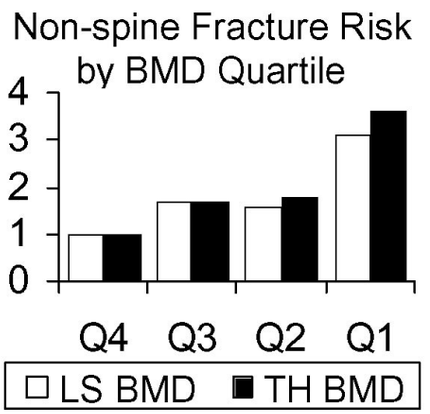
Hip and Spine BMD and Prediction of Hip and Other Fractures in Men. First Results from the Osteoporotic Fractures in Men (MrOS) Study. P. M. Cawthon[1], S. R. Cummings[1], B. K. S. Chan*[2], J. A. Cauley[3], K. E. Ensrud[4], D. C. Bauer[5], H. A. Fink[4], D. M. Black[5], E. S. Orwoll[2]. [1]Research Institute, California Pacific Medical Center, San Francisco, CA, USA, [2]Oregon Health Sciences University, Portland, OR, USA, [3]University of Pittsburgh, Pittsburgh, PA, USA, [4]University of Minnesota, Minneapolis, MN, USA, [5]University of California, San Francisco, CA, USA.

Background: The relationship between measurements of hip and spine bone mineral density (BMD) and the risk of hip and other fractures has not been established for men.
Methods: 5,989 men age ≥65 from six U.S. communities had BMD measured by DXA. 181 non-spine fractures (including 30 hip fractures) were validated during 2.6 years of >99% complete follow-up.
Results: Total hip BMD was a stronger predictor of hip fracture than was lumbar spine BMD (Table). All BMD measures (femoral neck, total hip and lumbar spine) were strongly and similarly predictive of non-spine fractures (Figure).



We estimate that among men aged ≥65, the annual risk of fractures for men with osteoporosis (N=103, total hip T score ≤ -2.5) is 3.7% (hip) and 7.4% (non-spine), versus 0.1% (hip) and 1.0% (non-spine) in men with higher BMD (N=5,886).
Conclusion: Measurements of hip and spine BMD in men strongly predict hip and non-spine fractures. Measurements at the hip are superior to measurements at the spine for predicting hip fracture. Men with 'osteoporosis' have a high yearly risk of fracture.

Age-Adjusted RR/SD by fracture type

BMD site	Hip Fracture	Non-spine Fracture
Total hip (TH)	3.6 (2.5,5.2)	1.8(1.5,2.1)
Lumbar spine (LS)	1.8 (1.2, 2.9)	1.7 (1.4, 2.0)

Disclosures: ***P.M. Cawthon****, None.*

Measles Virus Nucleocapsid (MVNP) Gene Is Sufficient to Induce a Pagetic Bone Phenotype in Vivo. G. D. Roodman[1], S. V. Reddy[2], N. Kurihara[2], J. J. Windle[3], L. A. Ehrlich*[2], H. Zhou*[4], D. Dempster[4], M. Subler*[3]. [1]Univ of Pittsburgh & VA Med Ctr, Pittsburgh, PA, USA, [2]Univ of Pittsburgh, Pittsburgh, PA, USA, [3]VA Commonwealth Univ, Richmond, VA, USA, [4]Helen Hayes Hosp, W Haverstraw, NY, USA.

Paget's disease (PD) is the most exaggerated example of abnormal bone remodeling with increased bone resorption and excessive new bone formation. However, its etiology is unclear. A viral etiology for PD has been suggested based on the presence of paramyxoviral-like nuclear inclusions, detection of MVNP mRNA or protein in osteoclasts (OCL) from PD lesions, and in vitro studies showing that transfection of normal OCL precursors with the MVNP gene results in formation of OCL that express a pagetic phenotype (increased numbers of OCL; increased responsivity to 1,25-$(OH)_2D_3$, RANK ligand and TNF-α increased expression of the TAF_{II}-17 gene, and increased bone resorption capacity). A genetic component is also involved in PD and mutations in at least 2 genes have been linked to familial PD. It is our hypothesis that MVNP induces the abnormal OCL activity in PD, and the genetic factor enhances basal OCL activity to amplify this process. This suggests that MVNP should be sufficient to induce PD if expressed in large numbers of OCL. To test this hypothesis, we targeted MVNP to cells in the OCL lineage in transgenic mice using the tartrate resistant acid phosphatase promoter. The MVNP transgenic mice were viable and expressed low levels of MVNP in bone. Histomorphometric analysis, ex vivo studies of OCL formation, measurement of serum alkaline phosphatase and radiologic studies were then performed in 17 MVNP or 16 wild-type (WT) mice from 3-14 mths of age. Overall, there was a 64% increase in OCL perimeter (P = 6.0002) and 37% increase in osteoblast (OBL) perimeter in MVNP mice. In a mouse that was 14 mths of age, there was a 225% increase in OBL perimeter and 149% in OBL perimeter. This was accompanied by increased cancellous bone volume (83%), trabecular width (47%) and number (25%) with a marked increase in the amount of woven bone. In contrast, cancellous bone volume decreased between 3-12 mths in WT mice, while cancellous bone volume in MVNP mice increased over the same time period. Ex vivo studies showed that the numbers of OCL formed in marrow cultures from MVNP mice were increased, the OCL were hyper-responsive to 1,25-$(OH)_2D_3$, RANK ligand and TNF and had an increased bone resorbing capacity compared to WT cultures. Serum alkaline phosphatase levels were significantly increased in the MVNP mice by 8-12 mths of age compared to the WT mice [156 ± 24 units vs. 101 ± 20 (mean ± SD) $p < 0.04$]. These results demonstrate that expression of MVNP in OCL in vivo results in a bone phenotype that is characteristic of PD and support a pathophysiologic role for MVNP in PD.

Role of Dickkopf 1 (Dkk) in Myeloma Bone Disease and Modulation by the Proteasome Inhibitor Velcade. B. O. Oyajobi[1], I. R. Garrett[2], A. Gupta*[1], M. Banerjee*[1], X. Esparza*[2], A. Flores*[2], J. Sterling[1], G. Rossini*[2], M. Zhao[1], G. R. Mundy[1]. [1]Cell & Structural Biology, Univ Texas Hlth Sci Ctr at San Antonio, San Antonio, TX, USA, [2]OsteoScreen, Inc., San Antonio, TX, USA.

Myeloma bone disease is characterized by increased osteoclastic bone resorption and impaired osteoblast activity. The secreted antagonist of Wnt signaling, Dkk1 has recently been implicated as a mediator of the osteoblast dysfunction in myeloma. In myeloma patients, Dkk1 was shown to be preferentially and abundantly expressed in tumor-infiltrated bone marrow (Tian et al., 2003). Since Dkk1 appears to play an important role in myeloma, we examined (i) its effects on bone; (ii) the cell source in myeloma; (iii) its modulation by proteasome inhibitors which have recently been shown to enhance bone formation in normal mice (Garrett et al., 2003). Excess Dkk1 reduced new bone formation induced by proteasome inhibitors in cultured neonatal mouse calvariae. Dkk1 was not detected in the Radl 5TGM1 and 5T33 murine myeloma cells nor in human myeloma (RPMI 8226, U266) and B lymphoblastoid (ARH-77, IM-9) cell lines. In contrast, Dkk1 was strongly expressed in all murine and human cell lines of mesenchymal origin tested (2T3, C2C12, C3H10T1/2, MC3T3-E1, 14M1, MG-63, HOBIT), with highest expression in 14M1, a marrow stromal cell line spontaneously derived from a 5T14 myeloma-bearing mouse. Dkk1 expression was even more markedly enhanced in co-cultures of 5TGM1 and bone marrow stromal ST2 cells in vitro. To determine the relationship in myeloma between osteoblast function, Dkk1 expression and its regulation by proteasome inhibitors, we used the Radl 5T model of myeloma bone disease. We found cancellous bone volumes and bone formation rates (assessed by fluorochrome-labeling) were significantly reduced in 5TGM1-bearing C57BL/KaLwRij mice and Dkk1 was detectable in whole marrow flushed from diseased bones of tumor-bearing mice suggesting osteogenic cells express Dkk1 in myeloma in vivo. Low nanomolar concentrations of Velcade™ the first-in-class proteasome inhibitor to be used in patients, stimulated new bone formation in neonatal mouse calvariae, inhibited IL-1-stimulated bone resorption, and induced apoptosis of 5TGM1, RPMI 8226 and U266 myeloma cells. We found Velcade at nanomolar concentrations inhibited Dkk1 expression in 14M1, 2T3, MG-63 cells and in the bone organ cultures dose- and time-dependently. Taken together, our data indicate that the strikingly beneficial effects of proteasome inhibition now being reported in myeloma patients likely results from its multiple effects on inducing tumor cell death whilst concomitantly promoting osteogenesis by reducing Dkk-1 expression and inhibiting osteoclastic bone resorption.

Runx2 Contributes to Pathogenesis of Osteoarthritis through Chondrocyte Hypertrophy and Matrix Breakdown in Articular Cartilage under Mechanical Stress. S. Kamekura[1], K. Hoshi[1], U. Chung[1], Z. Maruyama*[2], T. Komori[2], K. Nakamura[1], H. Kawaguchi[1]. [1]Orthopaedic Surgery & Tissue Engineering, University of Tokyo, Tokyo, Japan, [2]Osaka University, Osaka, Japan.

Osteoarthritis (OA), one of the most common skeletal disorders, is induced by accumulated mechanical stress to joints; however, little is known about the molecular mechanisms by which the stress leads to cartilage degradation and osteophyte formation. To apply approaches from mouse genomics, we created experimental OA models in mice by producing instability in the knee joints using a microsurgical technique. Immunohistochemical and in situ hybridization analyses of these models revealed that the hypertrophic differentiation of chondrocytes with type X collagen expression and the matrix breakdown associated with MMP-13 expression were visible in the early stage of OA. Since both chondrocyte hypertrophy and MMP-13 expression are known to be positively regulated by a transcriptional activator Runx2, we compared the susceptibility of OA between heterozygous Runx2-deficient mice (Runx2+/-) and the wild-type (WT) littermates. Although homozygous Runx2-deficient mice died just after birth, Runx2+/- developed and grew normally without abnormalities of major organs except for cleidocranial dysplasia as previously reported. Both genotypes showed no abnormality in the articular cartilage under physiological conditions during observation periods up to 26 weeks of age. When OA was induced by medial ligament transection and menisectomy in the knee joints of 8-week-old male mice, the cartilage degradation assessed by Safranin-O staining and the cartilage destruction in superficial and middle layers were apparent in the WT joints within 8 weeks after surgery. The cartilage destruction reached the deep layer across the tidemark within 12 weeks. Contrarily, in the Runx2+/- joints the cartilage degradation was much milder and the destruction was confined within the superficial layer even after 12 weeks. Substantial osteophyte formation was seen in the WT knee 12 weeks after surgery, which was not seen in Runx2+/-. Mankin's score (0-14), a histological index of OA severity, at 12 weeks was 9.2±0.7 and 4.3±0.5 in WT and Runx2+/-, respectively (mean±SEM for n=8 / genotype, $p<0.01$). Immunohistochemistry and in situ hybridization revealed the expressions of type X collagen and MMP-13 within 8 weeks in the WT joints, both of which were rarely seen in Runx2+/-. We thus conclude that Runx2 haploinsufficiency prevented OA progression by suppressing chondrocyte hypertrophy and matrix breakdown under mechanical stress without affecting the physiological skeletal growth or turnover, suggesting that Runx2 could be a therapeutic target for OA.

Effects of Global or Targeted Deletion of the Ep4 Receptor on the Response of Cultured Osteoblasts to Prostaglandin E2. L. G. Raisz[1], C. A. Alander*[1], P. Zhan*[1], M. D. Breyer*[2], B. E. Kream[1], C. C. pilbeam[1]. [1]Department of Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]Department of Medicine, Vanderbilt University, Nashville, TN, USA.

Prostaglandin E2 (PGE2) is a potent stimulator of bone resorption and formation. These effects are attributed to stimulation of cAMP production through two receptors, EP2R and EP4R. Mice with global deletion of EP4R die at birth due to failure to close the ductus arteriosus. To circumvent this problem, we developed a targeted deletion of EP4R using combinations of mice heterozygous for global EP4R gene deletion, mice with exon 2 of EP4R flanked by Lox-P sites, and mice carrying an osteoblast-targeted 2.3 kb type I collagen promoter fused to Cre recombinase (Col 2.3-Cre). Males heterozygous for EP4R gene deletion and for Col 2.3-Cre were mated to females homozygous for floxed EP4R. This resulted in 4 genotypes: (A) wild type, (B) heterozygotes with a deletion of EP4R targeted to cells expressing Col 2.3-Cre, (C) heterozygotes with global deletion of EP4R, and (D) a combined knockout in which one EP4R allele was absent globally and the other deleted only in cells expressing Col 2.3-Cre. Calvarial cells were obtained from 5-8 week old mice by sequential collagenase digestion and cultured in a growth medium. Alkaline phosphatase (AP) activity, expressed as nM/mg protein, was measured at 12-14 days of culture. In group A control cultures (wild type) AP activity was 6.6 ± 0.7, which was significantly reduced to 3.6 ± 0.4 ($P<0.01$) in the presence of NS-398 (0.1 µM), a selective inhibitor of inducible cyclooxygenase (COX-2). NS-398 did not decrease AP activity in group D (combined knockout) cells. Since these data suggested that endogenous prostaglandins, acting through EP4R, have an effect on osteoblastic differentiation, studies of the effect of exogenous PGE2 were carried out in the presence of NS-398. Continuous treatment with PGE2 (1µM) significantly increased AP activity ($P<0.01$) in A cells (35.0 ± 3.1) as well as in heterozygous B (13.4 ± 2.0) and C cells (12.9 ± 2.3), but not in D cells (5.2 ± 1.0). The stimulated AP activities in B and C cells were significantly lower than in A cells ($P<0.01$). These results suggest that 1) targeted deletion of EP4R in cells of the osteoblastic lineage could be accomplished using the Col 2.3-Cre construct, 2) activation of EP4R is critical for the ability of PGE2 to enhance osteoblast differentiation, and 3) the level of expression of EP4R may be rate limiting, since EP4R heterozygotes had decreased PGE2 responses.

TOPGAL Mice Demonstrate Wnt Signaling During Bone Development, Growth and Mechanical Loading. J. R. Hens*[1], K. Wilson*[1], P. Dann*[1], E. Fuchs*[2], M. C. Horowitz[1], J. Wysolmerski[1]. [1]Yale University, New Haven, CT, USA, [2]Rockefeller University, New York, NY, USA.

The canonical Wnt signaling pathway appears to control bone mass in both humans and mice. Activation of this pathway leads to the accumulation of β-catenin within the nucleus, where it combines with TCF-family transcription factors to regulate gene expression. We used TOPGAL mice, which harbor a TCF/β-catenin-responsive β-galactosidase (β-gal) transgene to determine which bone cells were targets of canonical Wnt signaling during bone development, bone growth and normal bone turnover *in vivo*.

Signaling was active in the cartilaginous skeleton in embryos, in clusters of chondrocytes within the growth plates of growing long bones and in the cartilaginous portions of the ribs. TOPGAL transgene expression was detected in chondroclasts at the chondro-osseous junction, but not in osteoclasts in mature bone. Wnt signaling was activated within forming joints and within cells surrounding the intervetebral discs of the spinal column. Signaling was active in some osteoblasts (OB) in embryos and neonatal mice, but not in OB in adult mice. In contrast, Wnt signaling was activated prominently in osteocytes and persisted in this cell type with age.

We also examined primary cultures of calvarial OB from TOPGAL mice for β-gal production. None was detected when these cells were cultured on plastic and only rare positive cells were seen when grown on Type I collagen. To confirm that cultured OB were competent to activate Wnt signaling, we used RT-PCR to score expression of Wnt related molecules. At the proliferating and post-confluent stages, 9FZs, 4TCFs, 5SFRPs, LRP5 and 6 and DKK1 and 2 were present. Wnts 1, 3, 3a, 7a, 8a, and 8b were not expressed, but all 12 other Wnts were detected.

Finally, we examined the consequences of mechanical load on Wnt signaling in OB. Cells were loaded for 2 h at 2.5-3% elongation at 0.3 Hz alternating with 1 h rest intervals using a Flexercell® device. In cells grown on Type I Collagen, this treatment led to clear activation of canonical Wnt signaling after 12 hours.

In summary, as detected by TOPGAL transgene expression, canonical Wnt signaling is active in many cell types within the developing and growing skeleton. Interestingly, the TOPGAL transgene is more prominently expressed in osteocytes than OB and expression is absent from OB in adult bone. These data suggest that canonical Wnt signaling may be a direct modulator of OB function during bone modeling but not during normal bone remodeling. Furthermore, the persistent activation of Wnt signaling in osteocytes *in vivo* and the ability of deformation to activate signaling *in vitro* suggest that canonical Wnt signaling participates in the regulation of bone mass in response to physical forces.

Activity of the Mdm2 Oncogene Supports Runx2 Expression and Osteoblast Differentiation during Embryonic Skeletogenesis. C. J. Lengner[1], H. A. Steinman*[1], J. Gagnon*[1], B. E. Kream[2], G. S. Stein[1], J. B. Lian[1], S. N. Jones*[3]. [1]Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA, [2]Department of Medicine, University of Connecticut Health Center, Farmington, CT, USA, [3]Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA.

The Mdm2 oncogene can promote cell proliferation through its ability to negatively regulate the activity of the p53 tumor suppressor. Loss of Mdm2 results in p53 accumulation and ultimately results in exit from the cell cycle or apoptosis. Mdm2 null mice exhibit early embryonic lethality that can be rescued by deletion of p53. Mdm2/p53 null mice are phenotypically normal, indicating that the primary function of Mdm2 is p53 regulation. We have observed an increase in Mdm2 expression during the process of osteoblast differentiation that has led us to examine the role of Mdm2 during the process of skeletogenesis. To address this question, we have utilized a murine genetic system for tissue-specific Mdm2 ablation. In this system a conditional Mdm2 allele (Mdm2 flox) is excised during embryogenesis by Cre recombinase under control of the Type I Collagen promoter (Coll I-Cre). We find that deletion of Mdm2 in pre-osteoblasts upon activation of the Coll I-Cre transgene results in impaired skeletal formation. Bones of $Mdm2^{flox/flox}$ Coll I-Cre (Mutant) embryos are shorter, exhibit increased porosity, and have less mineral content than their $Mdm2^{flox/+}$ Coll I-Cre (Wildtype) littermates. To characterize the molecular basis for the decreased bone quality observed in these animals, we isolated calvarial pre-osteoblasts and induced them to differentiate *ex vivo*. In these cultures, mutant pre-osteoblasts proliferate identically to pre-osteoblasts isolated from wild type littermates and both cell types reach confluence concomitantly. In post-confluent cultures, however, the Coll I-Cre transgene becomes active in multilayering pre-osteoblasts resulting in Mdm2 excision and subsequently preventing the increase in Mdm2 expression observed in wild type cultures. The loss of Mdm2 in these cells prevented multilayered nodule formation *ex vivo* due to inhibition of post-confluent cell division. Further, mutant cultures that have ablated Mdm2 activity fail to activate the master osteogenic transcriptional regulator Runx2, and therefore fail to induce osteoblast associated phenotypic genes such as Alkaline Phosphatase and Osteocalcin. Thus, Mdm2 is genetically upstream of the mechanism mediating the bone-specific induction of Runx2. In addition, Mdm2 performs a novel osteogenic function that supports progression of osteoblast differentiation and post-confluent nodule formation.

A Mutation in the *Osteoactivin/Gpnmb* Gene Alters Bone Remodeling in Mice. M. C. Rico[1], M. G. Anderson*[2], A. M. Virgen*[1], J. L. Castañeda*[1], S. W. M. John*[2], S. N. Popoff[1], F. F. Safadi[1]. [1]Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

Osteoactivin/Gpnmb is a glycosylated protein implicated in osteoblast matrix production and mineralization. Previous studies from our laboratory have demonstrated that a synthetic osteoactivin peptide induces osteoblast differentiation associated with increased alkaline phosphatase activity, nodule formation, osteocalcin production and calcium deposition *in vitro*, and stimulates bone formation *in vivo.* A mutation on chromosome 6 of the *osteoactivin/Gpnmb* gene in mouse strains DBA/2J(D2) and Black 6 (B6) results in a premature stop codon leading to the production of a truncated osteoactivin/Gpnmb protein. Western blot and RT-PCR analyses confirmed the absence of osteoactivin/Gpnmb protein and message in the mutant when compared to control bones. Radiological analysis revealed an increase in bone size and radioopacity in the *osteoactivin/Gpnmb* mutant compared to control animals. Histological analysis also showed a decrease in adipocytes at the bone marrow cavity in *osteoactivin/Gpnmb* mutants compared to age- and gender-matched normal controls. Micro-CT measurements of femurs in the B6 mice revealed an increase in bone volume (BV/TV) (75%), trabecular number (Tb.N) (40%), and trabecular thickness (Tb.Th) (25%), and a decrease in trabecular space (Tb.Sp) (53%) in *osteoactivin/Gpnmb* mutants versus control. These data suggest that Osteoactivin/Gpnmb plays an important role in bone formation/remodeling. Total RNA isolated from long bones of *osteoactivin/Gpnmb* mutant and control animals were subjected to microarray analysis for differentially expressed genes using the mouse genome 430A GeneChip Array from Affymetrix. The expression of multiple bone-related genes was altered. These included sclerostin, an osteocyte-derived negative regulator of bone formation, which was increased (3.3-fold) in *osteoactivin/Gpnmb* mutants compared to controls. Wisp1 (Wnt-induced secreted proteins-1/CCN4), a novel CCN member that has been shown to mediate cell adhesion, extracellular matrix production and cell migration, was decreased (3.7-fold) in *osteoactivin/Gpnmb* mutants compared to controls. Further analysis of these genes may enhance our understanding of the mechanism(s) of action of osteoactivin/Gpnmb in bone formation/remodeling. These data support the hypothesis that osteoactivin/Gpnmb is a novel bone protein that regulates osteoblast differentiation and bone formation. Future studies using this mutation will help to elucidate the mechanism(s) of action and signaling pathways associated with osteoactivin/Gpnmb function in bone.

Transgenic Mice Over-Expressing Dkk-1 in Osteoblasts Develop Osteoporosis. J. Li, I. Sarosi*, S. E. Morony, D. Hill*, Y. Wang*, W. Qiu*, S. Adamu*, M. Grisanti*, K. Hoffmann*, T. Gyuris*, H. Nguyen*, R. Cattley*, P. J. Kostenuik, S. S. Simonet, D. L. Lacey. Amgen Inc., Thousand Oaks, CA, USA.

Skeletal homeostasis is maintained by a delicate balance between osteoclasts and osteoblasts. Imbalance can lead to skeletal pathologies with altered bone mineral density (BMD). Recently, strong human and murine molecular genetic data have pointed to the Wnt co-receptor LRP5 as a critical regulator of bone formation. Several loss-of-function mutations in the LRP5 gene cause osteoporosis-pseudoglioma (OPPG) syndrome in humans. Accordingly, LRP5 knockout mice have low BMD due to a defect in osteoblast proliferation and function, and these mice phenotypically resemble human OPPG patients. Conversely, gain-of-function mutations in LRP5 lead to high bone mass (HBM) in humans and transgenic mice. Dickkopf-1 (Dkk-1) is a secreted Wnt signaling inhibitor that directly binds to LRP5. In vitro signaling analysis of one of the HBM LRP5 mutation G171V demonstrated that the molecular defect in HBM LRP5 signal transduction may result from loss of Dkk inhibition to LRP5. To investigate the role of Dkk-1 in osteoblast biology, we have generated transgenic mice that over-express the murine Dkk-1 gene in the osteoblast lineage driven by rat Col1a1 promoter. RNA analysis confirms the over-expression of Dkk-1 transgene in transgenic bone tissue. Radiographically, decreased radiodensity was observed in the long bones and vertebral columns of high-expressor adult transgenic mice. Calvaria from the transgenics were very thin and flattened while also being discontinuous in places. BMD measurements of the tibial metaphysis by pQCT demonstrated that total, cortical and trabecular BMDs were significantly decreased when compared with wild-type littermate controls. In addition, serum concentration of osteocalcin, an osteoblast marker, is also significantly reduced in the Dkk-1 transgenics. Preliminary histologic analysis revealed that the transgenics had less trabecular bone present in the long bones and vertebrae. The transgenics also had very thin calvaria with some areas of bone being replaced by connective tissue. Moreover, bone histomorphometry analysis indicates that osteoblast cell number (NOb/TAr) and bone volume (BV/TV) are both decreased in the transgenics, while osteoclast parameters (NOc/TAr) remain unchanged. In summary, our current data demonstrates that transgenic over-expression of Dkk-1 in osteoblasts leads to a low bone mass phenotype. Therefore, these results not only confirm the critical function of Wnt signaling in bone biology, but also further support the important role that Dkk-1 may play in osteoblast biology and bone mass regulation.

α1 Collagen Promoter-Directed Overexpression of Dkk1 in Mice Causes Dwarfism and Very Short Limbs. J. Guo, F. R. Bringhurst, H. M. Kronenberg. Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

Dickkopf1 (Dkk1) is a secreted protein that acts as a Wnt pathway inhibitor by binding to and antagonizing Lrp5/6. Using microarray technology, we observed a dramatic down-regulation of Dkk1 mRNA after PTH treatment of embryonic tibia ex vivo. The PTH/PTHrP receptor (PTHR) has been shown to play an important role not only in embryonic endochondral bone development but also in postnatal bone modeling and remodeling. To determine whether suppression of Dkk1 mediates PTHR actions during bone development, we first examined the effect of PTH on Dkk1 mRNA expression, using bone explants. Using in situ hybridization we found that Dkk1 is expressed early in the perichondral cells adjacent to prehypertrophic and hypertrophic regions in the tibia at E14.5. Treatment of cultured tibiae and femurs at E14.5 with hPTH (100 nM) for 6 hr led to a fall of Dkk1 mRNA, as shown by in situ hybridization and confirmed by real-time PCR. Similar inhibition of Dkk1 mRNA expression in osteoblastic cells was also observed in cultured rudiments at E15.5 and 16.5 in a time-dependent manner with a maximal effect at 8 hr of treatment. These observations suggest that PTH-induced down-regulation of Dkk1 might mediate some actions of PTHR on bone development and remodeling. To examine the role of Dkk1 in osteoblast differentiation and the role of suppression of Dkk1 in PTH action on bone, we generated a mouse model in which Dkk1 is overexpressed under the control of a 2.3 kb fragment of the mouse alpha1(I) collagen promoter. Mutant mice are small, with very short limbs and deletion of digits, suggesting that Dkk1 transgenic mice may phenocopy Lrp6-/- and perhaps Lrp5-/- abnormal bone development. Studies *in vivo* and *in vitro* will determine how non-suppressible Dkk1 expression affects PTH/PTHrP action.

A Tale of Two Steroids: Testosterone and Estradiol Are Related to Incident Fracture Risk in Older Men. E. S. Orwoll[1], L. Lambert[1], L. Marshall[1], J. Cauley[2], M. Nevitt[3], D. Bauer[3], E. Barrett-Connor[4], S. R. Cummings[5]. [1]Bone and Mineral Research Unit, Oregon Health & Science University, Portland, OR, USA, [2]U Pittsburgh, Pittsburgh, PA, USA, [3]U California, San Francisco, San Francisco, CA, USA, [4]U California, San Diego, San Diego, CA, USA, [5]San Francisco Coordinating Center at CPMC, San Francisco, CA, USA.

The effects of gonadal function on skeletal health in older men are controversial; no data exist concerning the influence of sex steroids on incident fracture risk. The relationships of serum estradiol (E) and testosterone (T) levels to fracture risk were studied in the MrOS cohort. 5995 community dwelling men ≥65 yrs recruited at 6 clinical sites in the US were extensively characterized, including measures of anthropometry, neuromuscular function and BMD. Sensitive methods were used to assay baseline AM total sex steroid, SHBG and albumin levels in archived serum from a randomly selected subset of 2618 men; bioavailable steroid levels (bE, bT) were derived from mass action equations. Incident non-vertebral fractures in that cohort were documented during an average follow-up of 2.7 yrs. Multivariate proportional hazards regression analysis was used to assess the independent relationships of variables to fracture risk. The overall fracture rate was 12.8 per 1000 person-years, and participant follow-up was ~98%. Baseline bE was positively related to baseline total hip BMD ($p<0.001$) but bT was not related to BMD ($p= 0.45$). However, in age adjusted analyses bT and bE were each inversely related to incident fracture risk (hazard ratio [HR] per SD decrease in bE= 1.4; CI 1.0-1.8, and in bT= 1.4; 1.1-1.7). BMD was also strongly related to fracture risk (HR 1.6; 1.3-2.1). The inclusion of bT, bE and BMD in the model attenuated the association of bE with fracture risk (HR 1.1; 0.8-1.5), but did not materially alter the bT-fracture risk relationship (HR 1.3; 1.0-1.6). After further adjustment for fall history, body composition, and race, lower levels of bT (HR 1.24; 1.0-1.6) were independently related to fracture risk, while the effect of estrogen remained insignificant (HR 1.1; 0.8-1.6). In sum, lower levels of bT and bE are both related to increased incident fracture risk in older men. The association of bE appears to be mediated to a large extent by BMD. In contrast, bT is not related to BMD and its effects on fracture risk are apparently the result of other pathways. These analyses indicate that gonadal function exerts important effects on fracture risk in older men via complex mechanisms. Moreover, they suggest that sex steroid measures may be useful in assessing fracture risk and that therapies based on sex steroid action could be effective in preventing fractures in older men.

Plasma Retinol and Retinyl Esters as Predictors of Incident Osteoporotic Fracture in Elderly Women. M. E. Barker*[1], E. V. McCloskey[2], S. Saha*[1], F. Gossiel*[2], H. J. Powers*[1], A. Blumsohn[2]. [1]Human Nutrition Unit Division of Clinical Science (North), University of Sheffield, Sheffield, United Kingdom, [2]Bone Metabolism Group Division of Clinical Science (North), University of Sheffield, Sheffield, United Kingdom.

Recent studies have suggested that higher Vitamin A intake may account for a component of fracture risk and lower BMD, and that supplemental Vitamin A may be harmful even within recommended limits. No studies have examined the relationship between biochemical retinol status and fracture in older women.

We examined plasma retinol, retinyl palmitate and β-carotene as predictors of incident fracture in a large prospective study of British women over age 75 (n=2790, 312 incident osteoporotic fractures, 92 incident hip fractures; mean follow-up duration 3.9 years). Fasting blood samples (09:00-11:00) were collected at baseline.

In a case control analysis (3 controls per case) using Cox proportional hazards regression, plasma retinol, retinyl palmitate and β-carotene were assessed as univariate predictors of all osteoporotic fractures and hip fracture in particular. Baseline BMD at the total hip (Hologic QDR4500), age, 25(OH)D, sβCTX, bone ALP, weight, height, and smoking were considered as covariates in a multivariate model.

Plasma retinol, retinyl palmitate and β-carotene were not significant univariate predictors of either hip fracture or any fracture (all $P>0.05$). For all osteoporotic fractures the hazard ratio was 0.95 (95% CI 0.86-1.06) for a 1SD increase in plasma retinol. There was a tendency for increased plasma retinol to predict benefit rather than harm in terms of fracture (Table) and BMD ($r=0.07$, $P=0.012$). Vitamin A supplementation was associated with a significantly lower risk of any fracture (hazard ratio 0.76, 95% CI 0.60-0.96). In multivariate analysis, only age, total hip BMD and weight were associated fracture risk ($P<0.05$). In conclusion, we have found no evidence to support any skeletal harm associated with higher dietary retinol intake or modest retinol supplementation in this population.

Unadjusted hazard ratios for incident osteoporotic fracture (95% CI)

Quartile of plasma retinol	Hazard ratio	P
Q1 (low)	1.00	
Q2	1.15 (0.96-1.38)	0.128
Q3	0.89 (0.73-1.09	0.273
Q4	0.85 (0.69-1.05)	0.132
Per 1 SD increase	0.95 (0.86-1.06)	0.371

Adipocyte Hormones and Fracture Risk in Older Men and Women. J. A. Cauley[1], A. Kanaya[2], F. Harris*[2], E. Strotmeyer[1], J. Lee*[2], J. M. Zmuda[1], D. Bauer[2], S. Cummings[3], F. Tylavsky*[4], T. Harris*[5], K. Ensrud*[6], A. Newman[1]. [1]U of Pittsburgh, Pittsburgh, PA, USA, [2]UCSF, San Francisco, CA, USA, [3]California Pacific Medical Center, Research Institute, San Francisco, CA, USA, [4]U of Memphis, Memphis, TN, USA, [5]NIA, Bethesda, MD, USA, [6]U of Minnesota, Minneapolis, MN, USA.

Men and women with higher body weight have higher bone mass and suffer fewer fractures. Biomechanical factors are important in mediating this association but biochemical factors secreted by adipose tissue may also contribute. Leptin regulates energy homeostasis and has direct action on bone but studies in humans are not consistent. Adiponectin has anti-inflammatory properties and may also contribute. Unlike leptin, adiponectin levels are lower in obese subjects. To test the hypothesis that leptin and adiponectin predict fractures independent of body weight, we analyzed data from the Health Aging and Body Composition Study of 3,075 white and black, well functioning men and women age 70-79 y. Leptin and adiponectin concentrations were measured in fasting serum at baseline by radioimmunoassay. Total hip BMD was measured by DXA (Hologic 4500A). 228 non-traumatic fractures were confirmed by x-ray report over a mean follow-up of 4.7 years. Cox proportional hazards models were used to estimate the Relative Hazard (RH) (95% Confidence Interval, CI) of fracture by quartile of adipocyte adjusting for age, gender, race and body weight. There was an inverse association between adiponectin and BMD even after adjusting for weight, but there was no association between leptin and BMD. Leptin was not associated with the risk of fracture (Table). Subjects with higher adiponectin levels tended to be at higher risk of fracture, but these results were not significant. The RH (95% CI) of fracture in subjects in Quartiles 2 through 4 compared to Quartile 1 was 1.44 (0.97, 2.14) (p=0.07). Models in which we substituted total body fat for body weight yielded similar results. In summary, circulating levels of leptin are not related to fractures. Subjects with higher adiponectin levels may be at increased risk of fracture, independent of body weight.

Table: Relative Hazard (95% CI) of Fracture by Quartile of Leptin and Adiponectin

	Leptin (ng/ml)		Adiponectin (µg/ml)	
Quartile	RH (95% CI)†	RH (95% CI)±	RH (95% CI)†	RH (95% CI)±

Reduced Nerve Function Is Related to Lower Hip BMD and Heel QUS in Older White and Black Adults. E. S. Strotmeyer[1], J. A. Cauley[1], A. V. Schwartz[2], N. de Rekeneire*[3], H. E. Resnick*[4], B. Goodpaster*[1], R. Shorr*[5], F. A. Tylavsky[5], A. I. Vinik*[6], T. B. Harris*[3], A. B. Newman*[1]. [1]University of Pittsburgh, Pittsburgh, PA, USA, [2]University of California, San Francisco, CA, USA, [3]National Institute on Aging, Bethesda, MD, USA, [4]MedStar Research Institute, Hyattsville, MD, USA, [5]University of Tennessee Health Science Center, Memphis, TN, USA, [6]Eastern Virginia Medical School, Norfolk, VA, USA.

Bone tissue is innervated, yet little is known about the impact of nerve function on bone mineral density (BMD). Poor nerve function may contribute to lower BMD and higher fracture risk, particularly in those with diabetes complications of neuropathy. The Health, Aging, and Body Composition Study included yearly prospective exams in white and black men and women age 70-79 years and physically able at baseline from Pittsburgh and Memphis. Nerve function in legs/feet was assessed at year 4 by pain/numbness self-report, 1.4 and 10 g monofilament detection, vibration threshold, and peroneal motor nerve conduction velocity and amplitude. Total hip BMD, heel broadband ultrasound attenuation (BUA), total fat and lean mass were measured at year 5 (QDR 4500A, Sahara QUS; Hologic Inc, Bedford, MA). Participants with year 4-5 data (N=2200) were 48% men and 37% black. Poor nerve function (lower monofilament detection, higher vibration threshold, lower amplitude, lower velocity) was associated with lower BUA (Table 1). Results were similar for hip BMD and significant for monofilament and amplitude testing.

Table 1. BUA (dB/MHz)* by nerve test groups/quartiles

	1	2	3	4	p
Monofilament	70.4	71.0	73.2	-	0.007
Vibration threshold	72.9	73.2	71.3	71.5	0.11
Amplitude	69.6	70.9	72.8	74.1	<0.001
Velocity	70.3	70.7	71.8	74.1	0.002

*adjusted for gender, race, clinic site, age, diabetes, total lean and fat mass, lean and fat mass changes, strength, physical performance score

Lower monofilament detection and amplitude independently associated with lower heel BUA (p<0.01) and marginally associated with lower hip BMD in regression adjusted for Table 1 covariates and leg pain/numbness, falls, smoking, drinking, exercise, bone-active medications, and diabetes-related complications. Nerve function was thought to increase risk of fractures due to increased falls but may have a direct effect on bone, independent of falls and DM. Results suggest that for both diabetic and non-diabetic adults, those with poorer nerve function have lower heel BUA and BMD; although whether those with impaired nerve function are at higher risk for fracture is still unknown.

Quantitative Ultrasound Predicts Hip and Non-spine Fracture in Men: the MrOS Study. D. C. Bauer[1], J. A. Cauley[2], K. E. Ensrud[3], S. Ewing*[4], E. S. Orwoll[5]. [1]Medicine, UCSF, San Francisco, CA, USA, [2]Epidemiology, University of Pittsburgh, Pittsburgh, PA, USA, [3]Medicine, University of Minnesota, Minneapolis, MN, USA, [4]Epidemiology, UCSF, San Francisco, CA, USA, [5]Medicine, Oregon Health Sciences Univerity, Portland, OR, USA.

Quantitative ultrasound (QUS) predicts fracture risk among older women, but there are few prospective studies among older men. We studied the ability of QUS and BMD measurements to predict hip and other non-spine fractures in MrOS, a population-based study of older men.

Calcaneal QUS (Hologic Sahara) and femoral neck BMD (Hologic QDR 4500W) were measured in 5608 men >65 recruited from 6 US centers. At baseline duplicate QUS measurements with repositioning were obtained; if the first two BUA results differed by at least 10 dB/MHz, or if either was non-linear, a 3rd measurement was obtained. The mean of the two closest values was used. Subsequent hip and other non-spine fractures were documented by review of x-rays or x-ray reports. The relationships between QUS and fractures were examined with proportional hazard models adjusted for age and clinic, and results are presented as relative hazard (RH) with 95% confidence intervals (CI). Using logistic regression, receiver operator curves (ROC) were constructed and area under the curve (AUC) calculated to determine the overall ability of QUS, BMD or the combination of QUS+BMD to predict fracture outcomes. Analyses excluding non-linear measurements (one or more occurred in 16% of men) gave similar results and are not shown.

At baseline the mean (±SD) age was 73.6 ±5.8, BUA was 81.7±19.7 dB/Mz and BMDfn was 0.784±0.129 g/cm2. During a mean follow-up of 2.6 years with 99% complete follow-up, 164 men suffered a non-spine fracture, including 30 hip fractures. Lower BUA (per SD) was associated with an increased risk of hip (RH=1.97, CI: 1.32, 3.54) and non-spine fracture (RH=1.65, CI: 1.38, 1.96). The AUC were similar for BUA alone, BMDfn alone and the combination of BUA+BMD (Table), indicating that once BUA or BMD is known, the other measurement does not add useful information. Other QUS parameters (speed of sound and QUI) gave similar results.

We conclude that QUS measurements predict the risk of hip and other non-spine fracture in older men, and do so nearly as well as hip BMD measurements. Combined measurements of QUS and BMD are not superior to either measurement alone.

Table: AUC for BUA alone, BMDfn alone and the Combination of BUA+BMDfn

Fracture Type	AUC BUA	AUC BMD	AUC BUA+BMD
Non-spine	0.67	0.68	0.69
Hip	0.84	0.85	0.85

SSRI Use Is Associated with Lower BMD among Men. E. M. Haney*[1], B. K. S. Chan[1], L. Lambert[1], J. Cauley[2], K. Ensrud[3], E. Orwoll[1], M. Blizniotes[1]. [1]Department of Medicine, Oregon Health & Science University, Portland, OR, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]Univeristy of Minnesota, Minneapolis, MN, USA.

Functional serotonin transporters have recently been discovered in osteoblasts and osteocytes, and disruption of the serotonin transporter gene in mice results in osteopenia. Selective serotonin reuptake inhibitors (SSRIs) are a widely used class of anti-depressant medications that function by blocking the serotonin transporter and have been associated with hip fracture. We hypothesized that SSRI use would be associated with decreased bone mineral density (BMD).

5,995 men participating in the Osteoporotic Fractures in Men (MrOS) cohort had medications assessed and BMD at the femoral neck, greater trochanter, and lumbar spine measured by DXA (QDR4500W, Hologic, Inc). Other measures were obtained from self-reported questionnaires. We fit regression models on each BMD variable controlling for other covariates to assess the contribution of SSRI use to BMD.

158 men (2.7%) reported SSRI use. In multi-variate analyses, BMD among SSRI users was 3.2% lower at the femoral neck, 2.3% lower at the total hip, and 3.5% lower at the lumbar spine (see Table). These associations were not significantly different across SF-12 mental score quartiles. There was no significant interaction between SSRI use and trazodone and/or tricyclic use, nor did the use of these medications confound the relationship between SSRI use and BMD.

Adjusted BMD (g/cm2) for SSRI users vs. nonn-users (mean, s.d.)

	SSRI users	SSRI non-users	P value
Trochanter	0.752 (0.124)	0.766 (0.119)	0.162
Femoral Neck	0.760 (0.123)	0.785 (0.118)	0.011
Total Hip	0.936 (0.132)	0.958 (0.127)	0.034
Lumbar Spine	1.035 (0.187)	1.073 (0.180)	0.012

adjusted for age, site, use of trazodone and/or tricyclic anti-depressants, SF-12 mental and physical summary scores, average height, total lean mass, race, smoking, neuromuscular function (chair stands), medical history, multivitamin use, steroid and bisphosphonate use.

This cross-sectional study demonstrates that femoral neck and lumbar spine BMD are significantly lower among older men using SSRIs. If these results are confirmed in other populations, people using SSRIs might be targeted for osteoporosis screening.

Osteoclast Inhibitory Lectin (OCIL) Is Required for Normal Bone Remodelling *in vivo* and Inhibits Osteoblast Function *in vitro*. A. Nakamura*[1], J. M. W. Quinn[1], N. A. Sims[2], C. T. Gange*[1], H. Zhou[1], V. Kartsogiannis[1], E. H. Allan*[1], T. J. Martin[1], K. W. Ng[3], M. T. Gillespie[1]. [1]St. Vincent's Institute of Medical Research, Fitzroy, Australia, [2]Dept. Medicine, The University of Melbourne, Fitzroy, Australia, [3]Dept Diabetes and Endocrinology, The University of Melbourne, Fitzroy, Australia.

OCIL is a C-type lectin expressed by osteoblasts which binds sulphated glycosaminoglycans and NK cell receptors and was originally identified by its ability to inhibit osteoclast differentiation *in vitro*. To determine whether OCIL is required for normal bone metabolism, we generated OCIL null mice (*ocil*$^{-/-}$) and examined their bones by histomorphometry.

Ocil$^{-/-}$ mice were fertile and grossly normal, but tibial trabecular bone volume and cortical thickness were significantly lower (by 22% and 15% respectively) in 10 week old *ocil*$^{-/-}$ mice relative to age matched wild type mice. This osteopenia was associated with high bone turnover, showing a 153% increase in osteoclast surface (OcS/BS), consistent with previously described anti-osteoclastogenic action of OCIL. In addition, osteoblast surface (ObS/BS), and osteoid volume (OV/BV) were approximately treble that of control mice. We thus examined OCIL action on osteoblasts mineralisation and osteoblast marker gene expression by primary osteoblasts and pre-osteoblastic KUSA O cells *in vitro*. While OCIL did not affect proliferation or cell morphology in osteoblasts and KUSA O cells it profoundly inhibited mineralisation by these cells when treated with ascorbate and β-glycerophosphate for 21 days. Under these conditions, KUSA O mRNA expression of osteopontin, alkaline phosphatase, BSP and osterix were unaffected, but osteocalcin expression was strongly inhibited within the first 3 days, which occurred in a dose-dependent manner. This was also noted when cells were treated with ascorbate for 14 days prior to OCIL addition. Insulin/dexamethasone/IBMX-stimulated adipocyte differentiation of KUSA O cells was also inhibited by OCIL. Furthermore, OCIL expression was elevated in clonal sub-lines of KUSA O that could not mineralise, differentiate into adipocytes or express osteocalcin. In addition, BMP-2 treatment of KUSA O resulted in a decrease in OCIL mRNA expression.

Our data indicates *ocil*$^{-/-}$ mice show increased osteoblast numbers and function as well as increased osteoclast numbers. The finding that OCIL reduces osteoblast function *in vitro*, an effect that may be related to reduced osteocalcin production is consistent with the in vivo findings. The combined effects of OCIL to inhibit osteoclast and osteoblast formation, and studies from the *ocil*$^{-/-}$ mice, confirm that OCIL plays an important role in both bone resorption and formation.

In Vivo and in Vitro Evidence that Activation of NFAT1/NFATc2 Is Critical to Osteoclast Differentiation. F. Ikeda[1], T. Matsubara[1], K. Hata*[1], S. V. Reddy[2], R. Nishimura[1], T. Yoneda[1]. [1]Dept Biochem, Osaka Univ Grad Sch Dent, Osaka, Japan, [2]Div Hematol Oncol, Univ Pittsburgh Cancer Inst, Pittsburgh, PA, USA.

RANKL is a key cytokine in the regulation of osteoclast differentiation. Recently, a transcription factor NFAT2/NFATc1 has been identified as a target of RANKL by microarray profiling and is shown to play an important role in osteoclast differentiation in vitro. However, the role of NFAT family in the regulation of osteoclast development in vivo has not been clarified yet. NFAT2 deficient mice were embryonic lethal and mice deficient in each of other NFAT family members failed to show distinctive phenotype in bone presumably due to the compensation by other family members. To obtain compelling evidence for an important role of NFAT family in osteoclastogenesis in vivo, we generated transgenic mice in which constitutive-active NFAT1 was specifically expressed in osteoclast lineage under the control of TRAP gene promoter. These transgenic mice (TG) were fertile but much smaller than the wild-type (WT) mice. Radiograph and micro CT analyses demonstrated that bone mass was clearly reduced in TG compared with WT. Histological examinations revealed a significant reduction in trabecular bone volume in TG. Ex vivo experiments using M-CSF-dependent spleen macrophages isolated from TG or WT mice showed that the number of osteoclast-like cells formed was increased in TG compared with WT, suggesting that the decreased bone mass in TG is due to an increase in osteoclast formation. We then studied the mechanism underlying NFAT activation in vitro. Of interest, western analysis demonstrated that NFAT1/NFATc2 was expressed in un-stimulated osteoclast precursors derived from bone marrow macrophages, while NFAT2 expression was not detected, suggesting that NFAT1 is constitutive and NFAT2 may be inducible. Consistent with this notion, overexpression of NFAT1 in M-CSF-dependent spleen macrophages using retrovirus system induced NFAT2 expression. Furthermore, NFAT1 overexpression induced TRAP-positive multinucleated osteoclast-like cell formation and elevated TRAP gene promoter activity. Since activated NFAT1 exhibits nuclear translocation, sub-cellular localization of NFAT1 in the monocytic RAW264.7 cells was examined. Upon treatment with soluble RANKL, NFAT1 was translocated into the nucleus. In conclusion, our results for the first time demonstrate that NFAT1 activation is important to osteoclastogenesis both in vivo and in vitro. Our data suggest that the underlying mechanism is that RANKL-activated NFAT1 promotes osteoclast formation through inducing NFAT2 expression and upregulating the TRAP gene transcription following nuclear translocation.

IKKα Is Required for NFATc1 Upregulation during Osteoclastogenesis. M. L. Chaisson*, A. P. Armstrong*, M. E. Tometsko*, W. C. Dougall. Cancer Biology, Amgen, Inc., Seattle, WA, USA.

Signaling via the TNFR family member RANK is required for osteoclast differentiation. We have recently demonstrated a role for the IκB kinase α (IKKα) during RANK-mediated osteoclastogenesis, as IKKα $^{-/-}$ hematopoietic fetal liver cells fail to form large, multinucleated osteoclasts when cultured in the presence of RANKL. These defects occurred despite normal activation of NF-κB p65/p50 (as measured by IκBα degradation and resynthesis) and MAP kinases p38, JNK, and ERK. However, IKKα was required for activation of the non-canonical NF-κB pathway involving processing of p100 into p52. As recent studies have also implicated the transcription factor NFATc1 as a critical component of RANKL-mediated osteoclastogenesis, we wished to determine if NFATc1 activation was perturbed in the absence of IKKα. We analyzed mRNA from wild-type and IKKα$^{-/-}$ fetal liver cells treated for 6 days with CSF-1 +/- RANKL. In wild-type cells, RANKL treatment increased NFATc1 gene expression by >10-fold , but in IKKα$^{-/-}$ cells, no significant increases were observed in NFATc1 expression following RANKL treatment. To determine if a relationship existed between NFATc1 upregulation and p100 processing, we examined the timing of p100 processing and NFATc1 protein expression in both wild-type and IKKα$^{-/-}$ cells treated with RANKL. In wild-type cells, p100 processing was activated 24 hours after RANKL treatment and was followed by a dramatic increase in NFATc1 protein levels at 48 hours. However, in IKKα$^{-/-}$ cells, RANKL treatment failed to stimulate p100 processing or significantly increase NFATc1 protein levels. To determine if inhibition of p100 processing affected NFATc1 upregulation, we treated RAW264.7 cells with the proteasome inhibitor MG132 prior to RANKL treatment. MG132 blocked both p100 processing and NFATc1 upregulation, indicating that a proteasome-dependent event is required for NFATc1 upregulation in response to RANKL. As IκBα degradation is also dependent on proteasome activity, we next determined if TNFα, which activates IκBα degradation but not p100 processing, could increase expression of NFATc1 in osteoclast precursor cells. Treatment of either RAW264.7 cells or CSF-1 derived wild-type fetal liver cells with TNFα did not lead to increased NFATc1 protein. Interestingly, while TNFα treatment in combination with RANKL rescues osteoclast differentiation in IKKα$^{-/-}$ cells, we did not observe p100 processing or increased NFATc1 protein in IKKα$^{-/-}$ cells treated with TNFα + RANKL, suggesting that osteoclastogenesis can occur independently of IKKα and NFATc1. Taken together, these data indicate a novel regulatory role for IKKα and p100 processing in the upregulation of NFATc1 during osteoclastogenesis.

The Alternative NF-κB Pathway, via RelB, Is Critical for Stimulated Osteoclastogenesis. D. V. Novack, T. Johnson*, M. Alhawagri*. Medicine, Washington University, St. Louis, MO, USA.

Osteoclasts (OCs) are derived from M-CSF-dependent myeloid bone marrow progenitors under the influence of RANKL. Like some other members of the TNF family (BAFF, CD40L, Lτβ), RANKL activates both the classical and alternative NF-κB pathways. The classical pathway is activated rapidly by the IKK complex, leading to nuclear translocation of p65/p50. The alternative pathway is controlled by NIK, whose activation leads to processing of p100, the precursor of p52 and the IκB for RelB. Over several hours, RelB/p52 complexes accumulate in the nucleus. Blockade of both classical and alternative NF-κB pathways, such as in p50$^{-/-}$/p52$^{-/-}$ mice, abolishes OC differentiation at a very early stage. We previously found that, in the absence of NIK, p100 is not processed, and accumulates in the cytoplasm where it can bind p65 and RelB, inhibiting their nuclear translocation, and resulting in decreased OC formation. Thus, although NIK is directly involved with the alternative pathway, removal of NIK perturbs the classical pathway as well.

To specifically assess the role of the alternative pathway in pathological bone loss, we analyzed the role of RelB in RANKL signaling and osteoclastogenesis. Like NIK$^{-/-}$ cultures, RelB$^{-/-}$ precursors generate few mature spread OCs when grown in M-CSF and RANKL. Classical NF-κB signaling based on p65 is similar to WT in both RelB$^{-/-}$ macrophages and preOCs, in contrast to NIK$^{-/-}$ preOC cultures which have diminished p65 signaling. These data suggest that RelB itself is important for optimal osteoclastogenesis, and we next investigated RANKL-mediated RelB signaling more fully. In WT cells, RelB mRNA and protein expression are induced by RANKL 3x within the first 24 hours. In this same time period, nuclear RelB levels rise 10x, indicating regulation beyond increased expression. In OC precursors lacking NIK, RelB is expressed at similar levels to WT, but is not found in the nucleus, due to its cytoplasmic retention by p100. We therefore asked if osteoclastogenesis could be rescued in NIK$^{-/-}$ cultures by retrovirus-mediated overexpression of RelB, which might overwhelm the binding capacity of p100. In contrast to NIK$^{-/-}$ cultures transduced with control empty pMX, NIK$^{-/-}$ cultures with pMX-RelB generate OCs similar to empty pMX-transduced WT controls. In summary, we show for the first time that RelB is required for optimal OC formation in vitro, and that overexpression of RelB can compensate for the absence of NIK. The alternative NF-κB pathway controlled by NIK and RelB regulates pathological induction of osteoclastogenesis, and represents a potential target for therapy of diseases mediated by OC overactivity, such as osteoporosis.

The LIM-Only Protein, FHL2, Suppresses TRAF6-Mediated Osteoclastogenesis. S. Bai[1], J. Chen*[2], F. P. Ross[1], S. L. Teitelbaum[1]. [1]Department of Pathology, Washington University School of Medicine, St. louis, MO, USA, [2]Medicine, University of California at San Diego, La Jolla, CA, USA.

TRAF6 associates with the cytoplasmic domain of RANK, an event central to normal osteoclastogenesis. We used the yeast two-hybrid system with a mouse embryo cDNA library to identify novel proteins which interact with TRAF proteins with the aim of determining their role in osteoclast recruitment and function. By this approach, and subsequent co-immunoprecipitation, we discovered TRAF6 interacts with FHL2, a LIM-only protein which functions, in a cell-dependent manner, as a transcriptional co-activator or co-repressor. We also find that full-length FHL2 is required for its interaction with TRAF6 and the TRAF domain of TRAF6 recognizes FHL2. Consistent with a role in modulating TRAF6 mediated osteoclastogenesis, FHL2 mRNA and protein are undetectable in marrow macrophages and increase *parri passu* with osteoclast differentiation. Furthermore, when overexpressed in different cell lines, FHL2 inhibits TRAF6-induced NF-κB activity, indicating FHL2 may act as a repressor in RANKL/RANK signaling. Supporting this contention, 1) IκB-α phosphorylation is enhanced in FHL2-/- osteoclasts and overexpression of FHL2 in WT macrophages inhibits RANKL induced IκB-α phosphorylation and osteoclastogenesis; 2) FHL2-/- macrophages differentiate into enlarged osteoclasts with highly developed actin rings earlier than WT osteoclasts; 3) resorption pits excavated on dentin by FHL2-/- osteoclasts are more numerous and deeper than WT. The interaction between RANK and TRAF6 is dose-dependently reduced by the presence of FHL2 in 293T cells overexpressing the proteins, indicating that the osteoclast suppressive properties of FHL2 reflects its impact on TRAF6-mediated RANK signaling. Finally, FHL2 interacts with HDAC-1 in the nucleus, again indicating FHL2 acts as a transcriptional co-repressor in RANKL/RANK signaling. FHL2 thus presents itself as a novel anti-resorptive target.

LIGHT (TNFSF14), A Novel Mediator of Normal and Pathological Bone Resorption. J. Edwards*[1], S. Sun*[2], C. Shipman*[1], N. Athanasou[1], A. Sabokbar[1]. [1]Botnar Research Centre, University of Oxford, Oxford, United Kingdom, [2]Xian Medical School, Military Hospital, China.

Members of the TNF super-family are involved in a broad range of biological functions such as cell proliferation and differentiation, apoptosis, lymphoid organogenesis and bone homeostasis. LIGHT, a recently identified TNF family member, is a type II transmembrane protein which is transiently expressed, and shed, from the surface of activated T cells and immature dendritic cells. LIGHT signals through two receptors, HVEM and LTβ receptor, which are found on the surface of T-cells and stromal cells respectively. As activated T-cells and T-cell products have been implicated in osteoclastogenesis, and a number of pathological bone disorders such as rheumatoid arthritis (RA), we sought to determine i) whether LIGHT can regulate RANKL/cytokine-induced murine/human osteoclast formation ii) the cellular mechanism by which LIGHT influences osteoclastogenesis and iii) if LIGHT is present in the serum of RA patients.

We found that LIGHT dose dependently (0-150 ng/ml) induces osteoclast formation and lacunar resorption in long-term cultures of murine RAW 264.7 cells and human CD14+ peripheral blood monocytes in the presence of M-CSF but in the absence of RANKL. Osteoclast formation was not inhibited by the addition of OPG and RANK:Fc. Neutralizing antibody studies showed that LIGHT-induced osteoclast formation was not mediated through other known promoters of osteoclastogenesis such as TNFα or IL-8. In addition, blocking of the HVEM receptor did not affect the process of osteoclast formation. However, addition of blocking antibodies to the p75 component of the TNF receptor resulted in 75.1% inhibition in LIGHT-induced osteoclast formation ($p<0.001$), suggesting that LIGHT may act via this receptor.

Combined treatment with LIGHT and RANKL induced 85.1% ± 2.2% mean resorption; this was significantly greater than treatment with LIGHT (19.1% ±2.3%) or RANKL (49.6% ±5.9%) alone ($p<0.0001$). In contrast, combined treatment with LIGHT and TNFα did not result in a significant increase in bone resorption compared to treatment with each factor alone. Serum analysis of LIGHT by ELISA demonstrated a significant increase ($p<0.05$) in RA samples (233.2 ± 31.1 pg/ml) when compared to age/gender matched controls (102.2 ± 21.1 pg/ml).

Our results suggest that LIGHT stimulation can induce osteoclast formation independent of RANKL; it also promotes RANKL-mediated osteoclastogenesis and may be a novel mediator of bone resorption in inflammatory (T-cell associated) conditions in which there is extensive osteolysis.

Osteocytes Communicate Fluid-Flow Mediated Effects to Osteoblasts Altering Their Phenotype. A. F. Taylor*, M. Saunders*, Z. Zhou*, H. Donahue. Orthopaedics and Rehabilitation, Penn. State College of Medicine, Hershey, PA, USA.

A major tenet of bone cell biology is that *in vivo* the osteocyte network senses mechanical perturbations and coordinates the required osteogenic response via communication with osteoblasts. However, while it has been demonstrated *in vitro* that osteocytes can communicate with osteoblasts via both gap junctional intercellular communication (GJIC) and through the secretion of soluble factors there is, surprisingly, no direct evidence that osteocytic cells communicate physiologically relevant (i.e. osteogenic) information to osteoblastic cells. To address this issue we developed an *in vitro* system that models the osteocyte-osteoblast network *in vivo*.

Osteocytic MLO-Y4 and osteoblastic hFOB 1.19 cells were cultured on opposite sides of perforated membranes (tracer studies confirmed a migration rate through the membrane of less than 2%). This system enabled us to apply physiological levels of fluid shear to MLO-Y4 cells while permitting them to be in direct contact with hFOB 1.19 cells that are not themselves exposed to flow induced shear stress. Dye transfer analysis with calcein-AM showed that MLO-Y4 cells are coupled via gap junctions to hFOB 1.19 cells cultured on the opposite side of the membrane. GJIC between MLO-Y4 and hFOB 1.19 cells was completely blocked by the application 30μM α-GA to the culture system.

Fluid shear was applied to the system by a rotating disc placed 500μm above the membrane, resulting in the network of MLO-Y4 cells experiencing a defined gradient of fluid shear. The shear gradient ranges from 0 at the center of the membrane to a maximal rate of fluid shear (τ max) at the edge of the membrane, a system we believe is more physiologically relevant than the uniform field generated by parallel plate models.Using this model we exposed MLO-Y4 cells to a τ max of 5 dynes/cm^2 for 1 hour and post incubated the co-cultures for 2 hours at 37^{0}C. Under these conditions a highly significant increase in alkaline phosphatase activity was detected in the hFOB 1.19 cells in contact with flowed MLO-Y4, compared to un-flowed control co-cultures ($P<0.01$). Interestingly, when hFOB1.19 were exposed either to direct flow (via the rotating disc or parallel plate system) or to conditioned media from flowed MLO-Y4 they did not display an increased alkaline phosphatase activity. Thus, osteocytic cells not only detect and communicate flow-induced signals to osteoblasts but, remarkably, enhance the signal enabling osteoblasts to respond to a signal they cannot themselves detect.

Osteogenesis after Mechanical Loading Requires the P2X$_7$ Nucleotide Receptor. J. Li[1], D. Liu[2], H. Z. Ke[3], R. L. Duncan[2], C. H. Turner[2]. [1]Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Orthopedic Surgery, Indiana University School of Medicine, Indianapolis, IN, USA, [3]Groton Laboratories, Pfizer Global Research and Development, Groton, CT, USA.

The P2X$_7$ nucleotide receptor (P2X$_7$R) is an ATP-gated ion channel expressed in bone cells. Mice with a null mutation of the P2X$_7$R have reduced periosteal bone formation and increased trabecular bone resorption compared to wildtype (WT) controls. The observed phenotype resembles the effects of disuse on the skeleton, suggesting that the P2X$_7$R may be necessary for the proper skeletal response to mechanical loading. We measured the skeletal response to loading in P2X$_7$R knockout (KO) mice. Axial loading of the ulna (2 Hz for 120 cycles) for 3 days induced new lamellar bone formation on the periosteal surface at midshaft in WT mice, but this response was greatly attenuated in KO mice ($p < 0.01$ by ANCOVA). Sensitivity to mechanical loading, as shown by the bone formation rate per unit of mechanical strain (in μstrain), was reduced by 61% in female or 73% in male KO mice (Figure A). To further study the role of P2X$_7$R in osteoblastic response to mechanical loading, calvarial cells isolated from newborn KO and WT mice were subjected to a steady laminar fluid flow at 12 dynes/cm^2 fluid shear stress (FSS). FSS caused release of ATP from the bone cells of both KO and WT mice within one minute. Thirty minutes of FSS induced P2X$_7$R mediated pore formation, as determined by measuring cellular uptake of YO-PRO-1 (MW=630) in WT cells, but not in KO cells. Sixty minutes of FSS significantly increased prostaglandin (PG) E_2 release by 120% ($p=0.03$) in WT cells, but PGE_2 release in KO cells was not significantly increased by FSS ($p = 0.52$) (Figure B). These data suggest that ATP signaling through the P2X$_7$R is necessary for FSS-induced membrane pore formation and PGE_2 release in calvarial osteoblasts. We conclude that the P2X$_7$R is a key to mechanotransduction in osteoblasts. A functioning P2X$_7$R is necessary for mechanically induced release of prostaglandins by bone cells and subsequent osteogenesis.

Glutamate Signalling and LTP-like Mechanisms Account for Loading Memory in Osteoblasts. E. A. Bowe*, T. Notomi*, A. Horner*, T. Skerry. Royal Veterinary College, London, United Kingdom.

It is well known that the skeleton does not require long durations of exercise for maximal response to loading. This suggests either that cells are immediately and constantly sensitive to short durations of strain change, or that some cellular mechanism retains the information that a bone has been loaded. Since the discovery that glutamate functions in bone as an intercellular signalling agent, the possibility has been raised that the same long term potentiation (LTP) mechanisms that account for memory in the CNS could also occur in osteoblasts. NMDAR-dependent LTP occurs as a result of specific interactions of NMDA and AMPA type glutamate receptors with post-synaptic density proteins and in particular post-synaptic calcium calmodulin dependent kinase II (CaMKII).

To test the hypothesis that persistent loading responses are altered by interference with NMDAR-dependent LTP mechanisms in osteoblasts, we applied physiological strains (3400με at 1Hz) for 1,2,10, 20,40 and 80 minutes to ROS 17 2.8 cells plated onto coverslips (3 x10^5 cells/slip), using a 4 point bending device. 48 hours later, cell proliferation was assessed by Western blotting of lysates for PCNA corrected to β-actin. A dose dependent relationship was apparent between duration of loading and cell proliferation up to 10 minutes. After that time there was no further increase in proliferation, suggesting that 10 minutes of loading saturated the adaptive mechanism in these cells in vitro.

Further experiments were performed in which the same 10 minutes of loading of identical triplicate cultures had been preceded with treatments with either the NMDA receptor antagonist MK801 (100 μM), the AMPA receptor antagonist NBQX (50 μM) or the CaMKII antagonist KN93 (50 μM). In addition, plasmid based siRNA knockdown of either GluR2 or GluR3 subunits of the AMPA receptor were performed before loading. Control cultures were treated with vehicle, empty vector or GFP containing vector as appropriate.

Control cultures had a robust response to loading, with a 2 fold increase in proliferation. In contrast, MK801, NBQX and KN93 all abolished proliferative response to loading without affecting cell survival, as did GluR3 knockdown. Interestingly, GluR-2 knockdown induced apoptosis so no measurements of proliferation were possible, confirming previous data showing that glutamate signalling is essential for bone cell survival.

These results demonstrate that selective doses of agents that modulate processes involved in NMDAR-dependent LTP mechanisms remove the responsiveness of cells to what are saturating durations of loading, without affecting cells' viability. We interpret this to be evidence for strain memory in bone that resembles the mechanism in the brain.

Specific Activation of the H-Ras Isoform Is Required for Mechanical Strain Inhibition of RANKL. J. Rubin, T. C. Murphy*, J. Rahnert*, M. S. Nanes, X. Fan. Medicine, Emory University and VAMC, Decatur, GA, USA.

Mechanical strain causes a magnitude dependent decrease in receptor activator of NFκB-ligand (RANKL) expression in murine stromal cells; this inhibition requires activation of the ERK1/2 kinase. To gain insight into the events leading to mechanical activation of ERK1/2, we examined proximal molecules in this MAPK signaling pathway. Ras proteins represent a family of GTPases that have variable location and specificity within the cell. At least 3 isoforms, H-, N- and K-Ras, are directly linked to ERK1/2 activation. We first asked whether mechanical strain caused Ras activation. For this study, strain was applied to primary murine stromal cells (2%, 0.2 Hz for 10 min, Flexcell Loading Station). Cell lysates were mixed with agarose immobilized Raf-1-GST which binds only activated Ras (i.e., Ras-GTP). Strained cells had measurable Ras-GTP while unstrained cells had little activated Ras unless treated with GTP. Post strain, activated Ras was easily measurable after capture by Raf-1-GST. The specificity of activated Ras was probed by western blot using Ras antibodies specific for H-, N- or K-Ras. The H-Ras isoform was activated by mechanical strain; N- and K-Ras isoforms were unaffected. We next wished to show that specific activation of the H-Ras isoform was necessary for downstream inhibition of RANKL expression. To this end we generated a silencing RNA for H-Ras using an Ambion "Silencer" siRNA Construction kit. Transduction with 40 nM siH-Ras caused a >70% decrease in H-Ras mRNA and protein 48h later; siH-Ras had no effect on K-Ras expression. Stromal cells were transduced with nothing (control), negative siRNA (siRNA-control) or the siH-Ras 24h prior to application of strain, which was continued overnight. Strain lowered RANKL expression to 76 ± 2% that of unstrained cells in both control and siRNA-control conditions (at 100 ± 5%). In those cells transduced with siH-Ras, the strain effect was completely abrogated. Interestingly, in both unstrained and strained cells treated with siH-Ras, expression levels of RANKL were significantly greater than in unstrained control and siRNA-control cells, ~135 ± 15% (no difference between unstrained and strain condition). This effect may indicate that H-Ras levels exert regulatory control over basal RANKL. In conclusion, mechanical strain downregulation of RANKL expression requires that the H-Ras isoform be activated, leading to downstream phosphorylation of ERK1/2. Our data suggests that the mechanotransducer sensitive to physiologic levels of strain may be identified through discrete associations with the H-Ras GTPase.

Identification of an Osteocyte-specific, Mechanically Regulated Region of The Dentin Matrix Protein 1 Promoter. W. Yang[1], I. Kalajzic*[2], Y. Lu*[1], D. Guo[1], M. A. Harris[3], J. Gluhak-Heinrich*[3], L. F. Bonewald[1], J. Q. Feng[1], D. W. Rowe*[2], S. E. Harris[1]. [1]U. of Missouri at Kansas City, Kansas City, MO, USA, [2]U. of Connecticut Health Center, Farmington, CT, USA, [3]U. of Texas Health Science Center at San Antonio, San Antonio, TX, USA.

Dentin matrix protein 1 (DMP1) is selectively expressed in osteocytes, is activated in response to mechanical loading, and is thought to play a role in regulation of local mineralization within osteocyte lacunae and canaliculi. Finding enhancers specific to osteocytes and responsive to loading will lead to insights into how mechanical signals are transmitted to the genome in an osteocyte specific manner. The transcriptional activity of three cis-regulatory regions, -9624 to +1996, -7892 to +4439 and -2433 to +4439, of the DMP1 gene were studied using the 2T3 cell line in which endogenous DMP1 expression increases 20 fold with osteoblast-osteocyte differentiation. Constructs containing the mouse DMP1 gene regions, driving Green Fluorescent Protein (GFP) were stably transfected and GFP expression monitored over time. During the differentiation , GFP showed a localized increase within the early stages of mineralized matrix formation, with all three promoter constructs. Greatest GFP expression was observed with constructs containing at least 7.8 Kb of 5' flanking region. The GFP positive cells are dendritic in morphology representing early osteocytes in a mineralizing matrix. Subconfluent and mineralizing, stably transfected, 2T3/DMP1-GFP cells were subjected to fluid flow at defined levels of shear stress. In subconfluent cells, the three DMP1 cis-DNA regulatory regions are responsive to 1.6 Pascals with a lower response to 0.4 Pascals. At the highly dendritic mineralizing matrix stage, the -7892 to +4439 responded 7 to 8 fold to 1.6 Pascals of loading which is comparable to the endogenous DMP1 gene that is increased 5 fold. This DMP1 region, -7892 to +4439, driving GFP, was then used to generate a transgenic mouse model. GFP was shown to be highly selective for osteocytes and no expression was seen in osteoblasts. Differentiated bone marrow cells cultured from these mice showed GFP expression markedly increased in osteocytes within the mineralized matrix. Right ulnae from these mice were loaded for 1 bout of 60 cycles (2 Hz; peak force of 2.4 N) and the left ulna served as a control. After 24hrs, GFP expression was shown to increase in the loaded ulnae, distal to the mid-shaft. In summary, we have shown both *in vitro* and *in vivo* that the 12 Kb region (-7892 to +4439) of the DMP1 gene is capable of directing expression to osteocytes and that this region also responds to mechanical signals.

Deletion of Neuronal Nitric Oxide Synthase (NOS-1) α-isoform Induces a Higher Trabecular Peak Bone Mass and Modulates Bone Response to Unloading in Adult Male Mice. B. Boudignon*[1], L. Vico[1], N. Laroche*[1], D. Blottner*[2], M. Lafage-Proust[1]. [1]Lbto, INSERM 366, Saint-Etienne, France, [2]Anatomy, Benjamin Franklin University Hospital, Berlin, Germany.

In bone, mechanical strain signals through many second messengers including Nitric Oxyde (NO). NO is synthesized by 3 NO synthases (NOS) endothelial (3), inducible (2) and neuronal (1). NOS-2 knock-out inhibits osteogenic bone response to load after unloading. In this context, we studied the effects of NOS-1 alpha isoform knock-out on bone phenotype and response to unloading.

Twenty 4 month-old NOS I-alpha deficient male mice (NOS-$1^{-/-}$) (65.0 cM; AccID MGI:97368) and 20 wild type mice (WT, B6-129SF2/J) were divided into 2 groups: one control group (C) and one tail-suspended (Unload) for 21d. Cortical and trabecular bone mass and microarchitectural parameters were assessed with 3D microtomography (uCT40, Scanco), unloading effects were analysed on femur with sequential Bone Mineral Density measurements (BMD, Piximus, Lunar) and bone histomophometry of distal metaphysis made at the end of the experiment.

At baseline, NOS-$1^{-/-}$ mice displayed a trabecular bone mass 1.6 times higher (Figure) than WT ($p<0.01$), with plate-shaped trabeculae while WT's ones were more rod-like (SMI:1.58 +/- 0.15 vs 2.37 +/- 0.20, $p<0.05$). In contrast, cortical bone mass was similar between the 2 groups. After unloading, femoral BMD decreased by 14.5% in WT and by 17% in NOS-$1^{-/-}$ ($p< 0.01$). Trabecular bone mass was 30% and 38% lower in unloaded WT and NOS-$1^{-/-}$ compared to their respective C. Histomorphometric bone cell activities are shown in Table I.

	WT C	WT Unload	NOS-$1^{-/-}$ C	NOS-$1^{-/-}$ Unload
MAR, μm/d	1.4 +/- 0.2	1.2 +/- 0.2 [b]	1.3 +/- 0.1	1.3 +/- 0.1
MS/BS, %	63.0 +/- 6.8	50.5 +/- 8.1 [b]	38.4 +/- 8.6 [a]	62.5 +/- 4.1[b]
Oc.S/BS, %	20.6 +/- 3.9	27.4 +/- 8.0 [b]	15.6 +/- 3.1 [a]	25.1 +/- 3.2 [b]

a: significant vs WT-C, b significant vs respective C group, $p<0.05$.

In conclusion, these data show that NOS-1 alpha isoform plays a role in peak bone mass aquisition only in the trabecular envelope. Since it was shown that osteoclast resorption in NOS-$1^{-/-}$ mice is normal, the observed decrease in bone remodeling level is likely to involve the osteoblastic lineage which, moreover, responded to unloading with unexpected activity increase.

Absence of Both *BMP2* and *BMP4* during Skeletal Development Results in Severe Defects in Osteoblasts but not in Chondrocytes. K. Tsuji[1], A. Bandyopadhyay*[2], K. Cox[1], B. Harfe*[3], C. J. Tabin*[2], V. Rosen[1]. [1]Department of Tissue Growth and Repair, the Forsyth Institute, Boston, MA, USA, [2]Department of Genetics, Harvard Medical School, Boston, MA, USA, [3]Department of Molecular Genetics and Microbiology, University of Florida Colledge of Medicine, Gainesville, FL, USA.

BMP-2 and BMP-4 can induce both endochondral and membranous ossification when implanted into non-skeletal sites *in vivo* and are able to initiate the expression of osteoblast-related genes in undifferentiated mesenchymal cells *in vitro*. However, both *BMP2* and *BMP4* single knockout mice die before 11dpc, leaving the functions of these molecules during skeletal development to be established. In this study, we inactivated both *BMP2* and *BMP4* genes in the cranial and limb region by using double floxed mice with Cre recombinase driven by Prx-1 enhancer. X-ray and BMD (bone mineral density) data indicated that mineralized bone formation is severely decreased in homozygous conditional knockout *BMP2/BMP4* mice compared to control mice that do not carry the Cre recombinase at 1, 2 and 3 weeks after birth. Histological analyses of the long bones of these mice show abnormally thick perichondrium surrounding prehypertrophic- and hypertrophic-like chondrocytes, as well as the absence of osteoblasts and a bone marrow cavity. In addition to these defects, a large area of non-mineralized tissue occupies the posterior fontanel, indicating that membranous bone formation is also affected. These data demonstrate that *BMP2* and *BMP4* are required for osteoblastic differentiation and replacement of mineralized cartilage by bone but are less important for chondrocytic differentiation. They directly establish a link between these BMPs and bone formation.

Physiological Role of Combination of BMP2 and BMP6 in Bone Formation. F. Kugimiya*, S. Kamekura, H. Chikuda, K. Nakamura, H. Kawaguchi, U. Chung. Orthopaedic Surgery & Tissue Engineering, Univ. of Tokyo, Tokyo, Japan.

Pharmacologic actions of exogenously applied BMPs as potent bone anabolic agents have been demonstrated by a number of *in vitro* and *in vivo* studies. However, there is little evidence of the physiological roles of endogenous BMPs in bone formation, since mice deficient in BMPs and the receptors so far reported were normal or exhibited abnormalities in skeletal patterning or morphogenesis unless they died during embryonic development. During endochondral ossification, hypertrophic chondrocytes induce bone formation, and we have shown that BMP2 and BMP6 are the major BMPs expressed by the hypertrophic chondrocytes. Hence, to learn the physiological function of these BMPs, the present study investigated the skeletal abnormalities of mice deficient in BMP2 and/or BMP6. Since homozygous BMP2-deficient mice were embryonically lethal, heterozygous BMP2-deficient mice (BMP2+/-) and homozygous BMP6-deficient mice (BMP6-/-) were mated to create the double-deficient mice (BMP2+/-;BMP6-/-). Neither BMP2+/- nor BMP6-/- showed any skeletal abnormalities during observation periods up to 26 weeks of age. Alcian blue and alizarin red stainings showed no discernible difference in skeletal patterning or morphogenesis between BMP2+/-;BMP6-/- and wild-type (WT) embryos (E17.5); however, limbs and trunk of the mutant were 10-20% shorter than WT even after birth. Although BMP2+/-;BMP6-/- were healthy without major organ abnormalities, osteopenia developed postnatally and the bone volume determined by histomorphometric analysis of the proximal tibiae was decreased to 57% of the WT littermates at 8 weeks. Bone formation parameters (MAR & BFR/BS) of BMP2+/-;BMP6-/- were 40-50% lower than those of WT, while bone resorption parameters were comparable. When bone fracture was created at the midshaft of the tibia at 8 weeks, only BMP2+/-;BMP6-/-, but not BMP2+/- or BMP6-/- alone, showed impaired healing: both the volume and the mineral content of callus were about half those of WT littermates 3 weeks after the fracture. Histological analyses of the fracture site revealed that endochondral ossfication after chondrocyte hypertrophy was markedly impaired with intramembranous ossification unaffected. Finally, when hypertrophic chondrocytes derived from the rib cartilage were transplanted in the back muscle of nude mice, bone induction by BMP2+/-;BMP6-/- chondrocytes was markedly suppressed compared to that by WT chondrocytes. In summary, the double insufficiency of BMP2 and BMP6 impaired endochondral bone formation and osteoblast function without affecting skeletal morphogenesis. This is the first report clearly showing the physiological role of endogenous BMPs in bone formation.

BMP Type IA Receptor Signaling in Osteoblasts Regulates Bone Resorption and Osteoclast Functions. S. Harada[1], V. Kasparcova*[1], N. Kamiya*[2], M. W. Starbuck*[3], M. A. Gentile[1], T. Fukuda*[2], R. R. Behringer*[3], Y. Mishina*[2]. [1]Molecular Endocrinology/Bone Biology, Merck Research Laboratories, West Point, PA, USA, [2]Reproductive and Developmental Toxicology, National Institute of Environmental Health Science, Research Triangle Park, NC, USA, [3]Molecular Genetics, The University of Texas, MD Anderson Cancer Center, Houston, TX, USA.

Bone morphogenetic proteins (BMPs) function in developmental processes including skeletogenesis. However, despite the powerful osteogenic action of BMPs, the role for BMP signaling in bone remodeling is not well understood. We previously generated mice with osteoblast-specific disruption of *Bmpr1a*, which encodes type IA BMP receptor, via Cre-recombinase under the *OG2* promoter. Mutant mice initially exhibited smaller body size and lower bone volume due to decreased bone formation (up to 3-month old). However, surprisingly, when animals were aged (> 10-month old), significantly higher bone mineral density was observed at femur of mutant mice compared to litter-mate controls. Dynamic histomorphometric analysis of distal femur confirmed increased bone volume and documented suppressed bone turnover (bone formation rate) in aged-mutant mice, indicating that increased bone mass in mutant mice results from suppression of bone resorption. Following ovariectomy (OVX), more significant bone loss was observed in mutant mice, likely due to decreased osteoblast function which failed to compensate for OVX-induced bone resorption. To gain insight into the role of Bmpr1a in bone resorption, the impact of *Bmpr1a* ablation on genes associated with osteoclasts and osteoblasts were evaluated using organ culture of calvaria and tibia from aged-mice with floxed *Bmpr1a* alleles. BMP-4 treatment increased the expression of cathepsin K, matrix metalloproteinase-9, tartrate-resistant acid phosphatase and CLC-7 chloride channel, evaluated by real-time PCR analysis of RNA isolated from cultured bone samples. Interstingly, in aged calvaria, BMP-4 treatment showed no effets on genes associated with osteoblasts, such as osteocalcin or osterix. Ablation of *Bmpr1a* gene by adenoviral Cre-recombinase *in vitro* in cultured calvaria and tibia abolished the stimulatory effects of BMP-4 on the expression of all these genes that play essential roles for osteoclastic bone resorption. BMP-4 treatment showed no effects on the expression of receptor activator of NFκB ligand (RANKL) or osteoprotegerin, suggesting that BMP-4 effects are independent of RANKL/RANK signaling pathway. Taken together, these *in vivo* and *in vitro* results demonstrate essential and age-dependent roles for BMP signaling mediated by type IA BMP receptor in bone resorption and osteoclast function.

Cartilage-Specific Over-Expression of Smurf2 Induces an Osteoarthritic Phenotype in Mice. Q. Wu, M. J. Zuscik, E. M. Schwarz, M. K. Mulcahey*, T. O'Brien*, H. Drissi, J. E. Puzas, R. J. O'Keefe, R. N. Rosier. Orthopaedics, University of Rochester, Rochester, NY, USA.

Cartilage within diarthroidal joints is maintained by articular chondrocytes (ACs) which produce matrix and are prevented from undergoing terminal maturation. During osteoarthritis (OA), maturational constraints are lost and ACs partially recapitulate the differentiation process that occurs during normal endochondral ossification. Evidence in the literature suggests that this inappropriate maturation may occur in situations where TGF-β signaling is reduced, correlating with the known function of this pathway in the inhibition of chondrocyte maturation. An endogenous mechanism for the inhibition of TGF-β signaling involves Smad ubiquitin regulatory factor-2 (Smurf2), an E3 ubiquitin ligase that targets Smad2 for the proteasome. Since we have observed strong expression of Smurf2 protein in osteoarthritic but not in normal human cartilage, we hypothesize that Smurf2-induced loss of TGF-β signaling in ACs represents an underlying cause of OA. To test this hypothesis, we generated transgenic mice over-expressing Smurf2 under control of the type II collagen promoter. Functional up-regulation of Smurf2 was verified in sternal chondrocytes from transgenic mice i) by detecting loss of TGF-β signaling on the P3TP promoter-luciferase reporter, and ii) by detecting enhanced ubiquitination of Smad2. While there were no gross abnormalities, the articular cartilage from the knees of transgenic mice showed evidence of degeneration that was mild at 2 months of age and that progressed to a severe stage by 7 months. Specifically, between 2 and 5 months, transgenic mice showed reduced proteoglycan content that was accompanied by cloning and hypertrophy of the ACs. Degeneration was progressive during this period, culminating with mild fibrillation of the articular surface. By 7 months, radiographic evidence of a reduced joint space and osteophyte formation correlated with significant loss of cartilage, severe fibrillation and clefting, and reduced cellularity of the remaining articular surfaces. These changes occurred without synovial inflammation. *In situ* mRNA analysis of type II and type X collagen was also performed in 2 month old mice. A reduction in type II and an increase in type X collagen was observed, suggesting that ACs undergo hypertrophic differentiation in this model. Thus, *in vivo* over-expression of Smurf2 in cartilage leads to inappropriate maturation of ACs that is followed by development of an OA-like phenotype. These findings suggest that the up-regulation of Smurf2 seen in human OA may represent a mechanism driving the cellular and tissue phenotypes that are seen in diseased cartilage.

A New Smad Anchor for Receptor Activation (SARA) for BMP Signaling. W. Shi*, C. Sun*, J. Wang*, X. Cao. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

The cascade of phosphorylation is a pivotal event in TGFβ/BMP signaling. TGFβ specific Smads Anchor for Receptor Activation (SARA) binds to unphosphorylated R-Smads to facilitate their phosphorylation by activated TGFβ type I receptor (TβRI). Once Smad2/Smad3 are phosphorylated, phosphorylated TβRI can be dephosphorylated by Smad7 recruited GADD34/PP1c (catalytic subunit of the PP1 holoenzyme) complex. SARA facilitates the negative regulatory mechanism by controlling the subcellular localization of PP1c via its PP1c binding domain. However, SARA for BMP signaling remains to be identified and little is known of how phosphorylation of Smad1 by BMP receptors is controlled.

To characterize such a mechanism for BMP signaling, we screened a yeast two-hybrid human chondrocyte cDNA library, and identified a SARA-like molecule that controls subcellular localization of Smad1 and designated it as SARAb (SARA for BMP signaling). SARAb is another FYVE domain protein anchoring onto the cell membrane via PI3P-FYVE interaction. We examined whether it functions as a BMP specific SARA. Our co-immunoprecipitation assay demonstrated Smad1 was co-precipitated with SARAb. Mouse calvarial osteoblasts (MC-3T3 E1) were transfected with either HA-SARA or HA-SARAb, then stimulated with BMP for 5 hours. Cells were immunostained with either anti-HA or anti-phospho-Smad1. We found that SARAb, but not SARA, regulates phosphorylation and intracellular translocation of Smad1. PP1c was also co-precipitated with SARAb. Further mapping analysis of SARAb identifies a Smad binding domain (SBD), and a PP1c binding domain (PBD). Overexpression of mutant SARAb without PBD or knockdown of GADD34 by RNA interference causes hyperphosphorylation of BMPRI, enhanced BMP signaling, concomitant osteoblast differentiation, and mineralization nodule formation in culture of MC3T3-E1 cells, which can be inhibited by either overexpression mutant SARAb without SBD, or GADD34. Unlike in TGFβ signaling, the interaction between GADD34 and BMPRI is not mediated by inhibitory Smad6 or Smad7. Apparently, the extent of dephosphorylation of BMPRI largely depends on induction of GADD34 which is regulated by stresses such as hypoxia and starvation. This unique BMPRI dephosphorylation regulatory mechanism may be responsible for cell survival under stress conditions, like hypoxia in growth plate, by dampening BMP stimulation. In conclusion, we have identified SARAb for BMP signaling pathway. SARAb binds to Smad1 for its phosphorylation and to PP1c as a part of BMP negative feedback circuit. Identification of SARAb provides a mechanistic insight for BMP function in bone and cartilage, which could also potentially serve as a bone anabolic drug target for osteoporosis.

The Exported 18kDa Isoform of FGF2 Is a Critical Determinant of Bone Mass in Mice. L. Xiao[1], T. Naganawa[1], J. D. Coffin[2], T. Doetschman*[3], M. M. Hurley[1]. [1]Univ of Connecticut, Farmington, CT, USA, [2]Univ of Montana, Missoula, MT, USA, [3]Univ of Cincinnati, Cincinnati, OH, USA.

Fibroblast growth factor-2 (FGF2) has stimulatory effects on bone formation in vitro and in vivo. Although there are multiple nuclear isoforms of FGF2 and a low molecular weight (LMW, 18kDa) isoform that is exported from cells, the role of the individual isoforms in bone is not well defined. Previous studies showed that knockout of all isoforms of the Fgf2 gene (Fgf2 ALL-MW-/-) resulted in decreased bone mass in mice. Since the 18kDa isoform of FGF2 is exported, we tested its role in bone remodeling and the maintenance of bone mass by developing Col3.6-18kDaFgf2-IRES-GFPsaph mice in which a 3.6 kb fragment of type I collagen promoter (Col3.6) drives the expression of only the 18kDa isoform of FGF2 (18kDaFgf2) with green fluorescent protein-sapphire (GFPsaph). Vector mice (Col3.6-IRES-GFPsaph, VTg) were also developed. 18kDaTgFgf2 mice expressed high levels of Fgf2 mRNA and the 18kDa protein in type I collagen-producing tissues including bone, tendon and skin compared with VTg mice. Transgenic 18kDa FGF2 was not over-expressed in muscle, brain, heart, lung, liver, spleen or kidney. There was no difference in femur length, body weight, serum creatinine or hematocrit between 12-week-old 18kDaTgFgf2 and VTg mice. By DXA, tibial BMD and BMC were increased by 6.5 and 19 % respectively ($p< 0.01$), in 18kDaTgFgf2 compared with VTg mice. By micro-CT analysis, tibial cortical bone area, periosteal radius and endosteal radius were increased by 24, 17, and 29%, respectively ($p<0.001$), in 18kDaTgFgf2 mice. Histomorphometry revealed increased calvarial width of 18kDaTg Fgf2 mice vs. VTg (296±41 vs. 114±3, $p<0.01$). Marrow stromal cultures from 18kDaTgFgf2 mice produced more mineralized bone nodules than VTg marrow. Similar results were obtained in 2 independent lines of 18kDaTgFgf2 mice. To further examine the role of the 18kDa isoform in bone, Fgf2lmw-/- mice, which lacked only this isoform, were generated by targeted mutation of the ATG translational start site of 18kDa FGF2. DXA studies revealed a 10% reduction in femoral BMD in Fgf2lmw-/- mice and a marked reduction in mineralized nodules in marrow stromal cultures compared with wt littermates. These results are similar to the bone phenotype observed in Fgf2 ALL-MW-/- mice, and support an important functional role for the 18kDa isoform in bone. In summary, targeted over-expression of 18kDaFgf2 increased bone mass in vivo and increased mineralized bone nodule formation in vitro. Selective deletion of the 18kDa isoform resulted in decreased bone mass and ex vivo bone nodule formation. These results demonstrate that the exported 18kDa FGF2 isoform is a critical determinant of bone mass in mice.

Alendronate in the Treatment of Pediatric Osteogenesis Imperfecta. F. H. Glorieux[1], F. Rauch[1], L. M. Ward[1], P. Smith*[2], N. Verbruggen*[3], N. Heyden[3], A. Lombardi[3]. [1]Genetics Unit, Shriners Hospital for Children, Montreal, PQ, Canada, [2]Shriners Hospital for Children, Chicago, IL, USA, [3]Merck & Co Inc, Whitehouse Station, NJ, USA.

Osteogenesis imperfecta (OI) is a group of heritable disorders characterized by osteoporosis and bone brittleness, leading to chronic bone pain, severe skeletal deformities, short stature, and functional limitation. Currently, no medical treatment is approved for the treatment of OI. Although pamidronate has shown beneficial effects, it requires intravenous administration. We conducted a multicenter, double-blind, randomized, placebo-controlled study to examine the efficacy and safety of oral alendronate (ALN; manufactured by Merck & Co. Inc) in pediatric patients with moderate to severe OI. Lumbar spine areal bone mineral density (BMD) was the primary endpoint. The study was not powered to examine fracture differences. A total of 139 children (age 4-19 years) with type I, III, or IV OI were enrolled and randomized to either placebo (PBO, N=30) or ALN (N=109) for 2 years. ALN doses were 5 mg/day in children weighing < 40 kg, and 10 mg/day in those weighing ≥ 40 kg. Seventy patients took calcium, and 59 took vitamin D supplements. After 2 years of treatment, ALN significantly decreased urinary NTx by 62%, compared with a 32% reduction with PBO ($p<0.001$). ALN increased spine BMD by 53% vs. a 16% increase with PBO ($p<0.001$). The mean spine BMD Z-score increased significantly from -4.6 to -3.3 with ALN, while the change in the PBO group (from -4.6 to -4.5) was not significant. Positive trends (albeit not significant) were observed in bone pain and physical activity in ALN-treated patients. ALN was generally well tolerated, and the incidence of clinical or laboratory adverse experiences was very similar among treatment groups. Upper gastrointestinal adverse experiences occurred in 52% of ALN and 53% of PBO patients. There was no significant difference in the incidence of fractures between treatment groups. Histomorphometric analysis of transiliac bone biopsies revealed a significant increase of cortical width in the ALN (median +162 µm) but not in PBO patients. No evidence of a mineralization defect was found in either group. In summary, oral ALN treatment for 2 years in pediatric patients with OI significantly decreased bone turnover, increased spine BMD and cortical width, and was generally well tolerated.

A Lifestyle Intervention for Teen Girls Enhances Bone Mineral Density over Two Years. C. Ritenbaugh[1], L. DeBar*[1], M. Aickin*[1], P. Elmer[1], D. Elliott*[2], E. Orwoll[2]. [1]Kaiser Permanente Center for Health Research, Portland, OR, USA, [2]Oregon Health & Science University, Portland, OR, USA.

YOUTH is a lifestyle intervention for increasing bone mineral density (BMD) among teen girls (14-17 years of age); the primary endpoint is change in BMD by DEXA at two years. Higher-risk female adolescents (BMI 16-23) and their parent(s) were individually recruited among members of a large HMO in the Pacific Northwest. Eligible teens (N=228) were randomized into a lifestyle intervention or to a general health education control group. The intervention targets were: (1) improving diet (increasing consumption of fruits, vegetables, and high calcium foods and decreasing soft drink consumption), and (2) increasing high-impact physical activity and spinal motion.

Interim (1 yr) and final (2 yr) results of the intervention on spine, trochanter, and total hip BMD (Hologic 4500) are shown below for the 179 girls who provided complete data at all three time points. At baseline (mean ± S.D.): overall age = 15.6 ± 0.6 yrs; overall BMI = 20.6 ± 1.9; months since menarche = 33.3 ± 15.6. In both groups, 76% of girls self-identified as white. There were significant 1-yr and 2-yr differences in diet changes from baseline between the intervention group and control group (intervention: more fruits, vegetables, calcium, vitamin D; less soda), but no significant differences in high-impact or total activity levels or spinal motion. The table below shows adjusted mean changes (± S.E.) from baseline BMD values by group at one and two years, and the p-values for the differences between groups. The adjusted mean differences are estimated by conditional change regression (ANCOVA), adjusting for family history, BMD, time since menarche at baseline; BMI, height at measurement. Total body, femoral neck, and Ward's triangle BMD showed no differences between groups.

Year 01 - baseline	Change (control)	Change (intervention)	p
Spine L1-L4	.0171±.0025	.0306±.0025	.0002
Trochanter	.0025±.0025	.0118±.0026	.0099
Total hip	.0078±.0026	.0161±.0026	.0245
Year 02 - baseline			
Spine L1-L4	.0331±.0031	.0448±.0031	.0081
Trochanter	.0024±.0034	.0138±.0034	.0184
Total hip	.0154±.0035	.0215±.0035	.2186

Our findings show that teenage girls can enhance bone mineral density at predominantly trabecular bone sites through lifestyle dietary changes sustained over two years.

Funded by NICHHD grant HD037744.

PTH Can Improve the Disturbed Bone Growth in Achondroplastic Mice. K. Ueda*[1], Y. Yamanaka[1], D. Harada*[1], R. Nishimura[2], D. M. Ornitz*[3], Y. Seino[1], H. Tanaka[1]. [1]Pediatrics, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan, [2]Molecular and Cellular Biochemistry, Osaka University Graduate School of Dentistry, Osaka, Japan, [3]Molecular Biology and Pharmacology, Washington University Medical School, Saint Louis, MO, USA.

Achondroplasia (ACH) is caused by a constitutively activated mutation in FGFR3. The excessively activated FGFR3 inhibits the proliferation of chondrocytes, resulting in disturbing the growth of long bones. Recently, we have reported that the introduction of the mutated *FGFR3* into ATDC5, chondrogenic cell line, down-regulated PTHrP expression and induced apoptosis, and that replacement of PTHrP prevented the apoptotic changes.

To explore further mechanisms and new therapeutic applications, we performed organ culture experiments, using transgenic mice (AchTG) expressing ACH-type mutated *FGFR3* controlled by type II collagen gene. Wild-type (WT) female mice were mated with male AchTG.

At d.p.c.15, the fetal mouse femurs were dissected, transferred into serum-free medium and cultured for 4 days with/without 10^{-8}M PTH. AchTG femurs were significantly disturbed in longitudinal bone growth compared with WT ones after 4-day-culture (0.29 ± 0.10mm and 0.46 ± 0.06mm, respectively; $p<0.05$). PTH significantly increased bone growth of AchTG (0.50 ± 0.06mm; $p<0.01$ vs control), whereas WT did not show remarkable change of bone growth (0.55 ± 0.09mm; n.s.).

PTH is known to share its receptor with PTHrP, and increase chondrocyte proliferation and inhibit cell maturation. PTH widened proliferative zone but narrowed hypertrophic zone in the growth plate of AchTG.

In conclusion, constitutively active FGFR3 inhibited bone growth in organ culture experiments and that PTH rescued bone from the growth disturbance. PTH has a potential for the treatment of achondroplasia.

Mechanical Adaptation to Weight Gain in Late Adolescence: Do Fat Kids Have Weaker Bones? T. Lloyd[1], M. Petit[1], H. Lin*[1], C. Bentley*[1], T. Beck[2]. [1]Health Evaluation Sciences, Penn State College of Medicine, Hershey, PA, USA, [2]Radiology, Johns Hopkins Medical Institute, Baltimore, MD, USA.

The United States is in the midst of an obesity epidemic. Chronic weight gain often begins in childhood and adolescence but little is known about the effect of obesity on young adult bone strength. Using 6 years of longitudinal data from The Penn State Young Women's Health Study we explored the effects of weight gain in late adolescence on proximal femur geometry and strength. 71 participants remaining in the study until at least age 21 were classified as either weight-gainers (WG, n = 23) or stable weight (SW, n = 48). Using a random coefficients model, groups were partitioned by whether the age trend in weight slope was significantly positive. Annual hip DXA scans (Hologic QDR 2000) during ages 17-22 were analyzed using a hip structure analysis program to assess areal BMD (g/cm^2), subperiosteal width, cortical thickness, bone cross-sectional area (CSA) and section modulus (Z), at the proximal femoral shaft. Total body lean and fat mass were measured from DXA total body scans. Over ages 17-22, height remained stable in both groups. Weight remained static in the SW group but increased 14% in the WG group ($p < 0.05$). After controlling for age 17 baseline values, section moduli values were similar at age 22 but the WG group had thicker cortices, greater CSA and greater BMD. The SW group achieved similar Z values by subperiosteal expansion from 17-22y. When the bone strength index (SI = section modulus / height) was normalized to body weight, the ratio (shown in Figure) remained stable in the SW group but decreased significantly in the WG group. In contrast, the SI normalized to lean mass did not change in either group. These data are consistent with the hypothesis that bone adapts its strength primarily to muscle force, and not to static weight. Interestingly the greater BMD in the WG group did not translate to stronger bones, indeed their bones were relatively weaker relative to their body weight. Under trauma conditions where injury-producing forces are weight dependent (e.g., falls) bone strength would be lower in the obese. Whether the effect is mitigated by greater fat padding or actually results in higher traumatic fracture incidence in the obese is unknown.

Impact of Vitamin D Supplementation on Musculoskeletal Parameters in Adolescents: A Randomized Trial. G. El-Hajj Fuleihan[1], M. Nabulsi*[2], H. Tamim*[3], J. Maalouf*[1], M. Salamoun*[1], M. Choucair*[1], R. Veith[4]. [1]Calcium Metabolism and Osteoporosis Program, American University of Beirut Medical Center, Beirut, Lebanon, [2]Pediatrics Department, American University of Beirut Medical Center, Beirut, Lebanon, [3]Epidemiology and Population Health Department, American University of Beirut, Beirut, Lebanon, [4]Mt Sinai University, Toronto, ON, Canada.

Despite the high prevalence of hypovitaminosis D in children and adolescents worldwide, the real impact of such insufficiency on skeletal health is unclear.

We conducted a randomized double-blind placebo controlled trial to evaluate the safety and efficacy of vitamin D supplementation on bone mineral density (BMD) and content (BMC) in 362 children ages 10-17 yrs , N= 168 girls (34 pre-menarcheal), and 172 boys. They received oral vitamin D (vigantol oil) 1400 IU/week, 14000 IU/week, or placebo for one year. BMD/ BMC of the lumbar spine, total body, hip, forearm, and body composition were measured at baseline and one year. At one year, vitamin D levels stayed in the 15-17 ng/ml range in the placebo arms, increased to 17-20 ng/ml in the low dose arm and to 35-38 ng/ml in the high dose arm.

At entry girls had lower vitamin D levels than boys and they showed significant correlations between BMD/BMC and vitamin D levels, R =0.17-0.24 depending on the skeletal site (spine, forearm, femoral neck, total body). In the overall group of girls, and in the subgroup of pre-menarcheal girls there were significant changes in musculoskeletal variables in response to vitamin D supplementation (Table).

% Changes in Musculoskeletal Parameters with Treatment in Girls at 12 Months

Overall	Placebo	Low dose	High dose	p
Hip BMC	8 (8)	11 (9)	13 (11)	0.02
Lean Mass	6 (7)	9 (8)	9 (8)	0.05
Pre-menarcheal				
Spine BMD	8 (4)	15 (7)	12 (8)	0.04
Trochanter BMC	13 (11)	32 (16)	26 (21)	0.05
Lean Mass	11 (5)	17 (7)	18 (7)	0.04

Trends for increments were noted at the spine and trochanter BMC in the overall group, and at the spine BMC, total hip BMC/BMD, and total body BMC in the premenarcheal group (p=NS). In post-menarcheal girls, in the overall group of boys, and in the subgroups of early pubertal boys (Tanners I and II) and mid late pubertal boys (Tanner III-V), there was no significant effect of intervention on lean mass, BMD or BMC. The treatment was safe and well tolerated.

Low vitamin D levels are prevalent in healthy children and adolescents, more so in girls. The positive impact of vitamin D supplementation on BMD/BMC in girls and not boys may be explained by the higher prevalence of hypovitaminosis D in that gender, and may be partially mediated by increments in lean mass.

The Bone Mineral Density in Childhood Study (BMDCS): Baseline Results for 1554 Healthy Pediatric Volunteers. M. Horlick[1], J. M. Lappe[2], V. Gilsanz[3], H. J. Kalkwarf[4], B. S. Zemel[5], S. Mahboubi*[5], J. A. Shepherd[6], M. M. Frederick*[7], K. Winer[8]. [1]Pediatrics, Columbia University, New York, NY, USA, [2]Creighton University, Omaha, NE, USA, [3]Children's Hospital of Los Angeles, Los Angeles, CA, USA, [4]Children's Hospital Medical Center, Cincinnati, OH, USA, [5]Children's Hospital of Philadelphia, Philadelphia, PA, USA, [6]UCSF, San Francisco, CA, USA, [7]C-TASC, Baltimore, MD, USA, [8]NICHD, Rockville, MD, USA.

To establish reference standards for bone mineral density in children, 5 US clinical centers recruited 1554 healthy subjects (793 girls 6-15 y, 761 boys 6-16 y) for a longitudinal study with baseline and 3 annual follow-up visits. Height, weight, pubertal maturation and bone age were measured. BMD and BMC of total body (TB), lumbar spine (LS), total hip (TH), and forearm were obtained by dual energy x-ray absorptiometry (DXA, Hologic Delphi).

Preliminary sex-specific percentiles and z-scores for age for bone mineral density (BMD) and bone mineral content (BMC) for TB and LS were derived from the baseline data using LMS PRO software. Relationships between z-scores for BMD and BMC at different DXA sites were evaluated with Pearson correlation coefficients.

Curves from the cross-sectional data revealed earlier increase in BMD and BMC for girls than boys. In girls, TB BMD slope increased at about 10 y and leveled off at about 14 y. In boys, the slope increased at about 12 y and did not level off. LS BMD slope increased earlier, about 9 y in girls and 11 y in boys. The slope leveled at 13 - 14 y in girls, but not in boys. For both sexes, BMC slope increased slightly earlier than BMD, but the overall patterns were similar.

Correlations between z-scores for BMD and BMC at different sites were all significant (r: 0.53 - 0.93), and similar for girls and boys. The highest correlation for LS BMD z-score was with TB BMD, and the lowest was with ulna BMD. The highest correlation for TB BMC z-score was with LS BMC, and the lowest was with ulna BMC.

These are the first pediatric reference values for DXA bone results from a multiethnic population from across the US. Correlations between z-scores for different DXA sites could suggest appropriate combinations of scans for pediatric protocols. Use of uniform standards and protocols will link DXA values to pediatric clinical outcome, information that has been lacking to date. Follow-up visits will provide data on velocity of gain in BMC and on the effects of change in age, bone age, and pubertal status on bone measurements.

BMP4 Is Necessary for Bone Formation: Conditional BMP4Knock-out Using the 3.6kb and 2.3kb Collagen 1a1 Promoter-Cre and BMP4 Floxed Mice. D. Guo[1], S. Harris[1], W. Yang[1], M. Harris[1], J. Zhang[1], J. Feng[1], C. Anderson[2], B. Kream[3], A. Lichtler[3], B. Hogan[4], H. Kulessa[5]. [1]Oral biology, U of Missouri, Kansas City, MO, USA, [2]Pathology, Kansas U Medical School, Kansas City, KS, USA, [3]Genetics and Developmental Biology, U of Connecticut, Farmington, CT, USA, [4]Genetics, Duke U, Durham, NC, USA, [5]U of Vanderbilt, Nashville, TN, USA.

Bone morphogenetic protein 4 (BMP4) has multiple functions during embryonic and post natal development. A specific role in bone formation and osteoblast function is not known. BMP4 is abundantly expression in osteoblasts, osteoclasts, and osteocytes. However, the embryonic lethality of BMP4 knock-out mice at 8.5 dpc precluded analysis of BMP4 role in bone formation. Specific deletion of BMP4 gene was achieved by crossing collagen 1a1-Cre transgenic mice with BMP4 flox mice. Using the 3.6kb Col1a1-Cre, first, we deleted BMP4 in early spindle shaped osteoblasts, tendon, and components of the heart, kidney and skin. Using the 2.3kb Col1a1-Cre, we are deleting BMP4 at later stages of osteoblast development but with higher specificity. After crossing BMP4 floxed mice with 3.6kb Col1a1-Cre mice, less than expected new born mice (only 29 out of expected 50) were genotyped as conditional knock-out, indicating embryonic lethality. As assayed by histology, BMD, and X-ray, BMP4 conditional knock-out mice are defined as three types. Type I are arrested at 13.5 to 15.5 dpc, with asymmetric limb buds, absence of calvarias or mandible, and open circulation system. Type II conditional knock-out mice survive after birth, but show 30~50% ($p<0.001$) decrease of body size, weight, polydactyly, kinky tail, polycystic kidney, and severe osteopenia. Figure 1 shows an X-ray of Type II mutants. Type II mice do not live beyond about 35 days. Type III mice (50% of the surviving mice with BMP4 conditional knock-out) show a similar phenotype but less severe than type II. These mice have a reduce BMD and BV/TV, primarily in the vertebrae and other flat bones as compared to the long bones. There was no change in osteoclasts activity, as demonstrated by TRAP staining in Type II or III mutants. Dynamic measurements of bone formation rates in these Type II and III are now underway as well as analysis of the conditional BMP4 knock-out using the 2.3kb Col1a1-Cre mice. In summary BMP4 is necessary but not sufficient for bone formation in adult life.

Cyclic GMP-Dependent Protein Kinase II Is a Molecular Switch from Proliferation to Hypertrophic Differentiation of Chondrocytes through Attenuation of Sox9 Function. F. Kugimiya*[1], H. Chikuda[1], T. Ikeda[1], K. Nakamura[1], K. Komeda*[2], U. Chung[1], H. Kawaguchi[1]. [1]Orthopaedic Surgery & Tissue Engineering, University of Tokyo, Tokyo, Japan, [2]Tokyo Medical College, Tokyo, Japan.

The Komeda miniature rat Ishikawa (KMI) is a naturally occurring mutant caused by an autosomal recessive mutation *mri*, which exhibits severe longitudinal growth retardation. Our positional cloning analysis identified the *mri* mutation as a 5 kb deletion in the rat gene encoding cGMP-dependent protein kinase type II (*cGKII*), which resulted in a truncated product that lacks the kinase domain. KMI showed an expanded growth plate and impaired bone healing with abnormal accumulation of postmitotic but non-hypertrophic chondrocytes, demonstrating that the cGKII dysfunction impairs the synchronized switching from proliferation to hypertrophic differentiation of chondrocytes. *Ex vivo* culture of KMI chondrocytes reproduced the differentiation impairment, which was restored by introducing the adenovirus-mediated *cGKII* gene. Immunohistochemical analysis revealed that the expression of Sox9, a transcription factor that induces chondrogenesis from mesenchymal cells and prevents the hypertrophic differentiation, was not detected in the hypertrophic zone of wild-type rats, but persisted in the nuclei of the abnormal postmitotic chondrocytes of KMI. The Sox9 transduction increased the type II collagen (COL2) mRNA level in the culture of human hepatoma HuH-7 cells, and decreased the type X collagen (COL10) level in the three-dimensional culture of mouse chondrogenic ATDC5 cells. Co-transduction with cGKII attenuated both the COL2 induction and the COL10 suppression by Sox9, neither of which was seen by cGKII with the KMI mutation or lacking the entire kinase domain. The cGKII co-transduction stimulated the Sox9 phosphorylation and inhibited the Sox9 nuclear entry. To learn the functional relevance, we created two Sox9 mutants: one is resistant to phosphorylation ($Sox9^{S181A}$) and the other is forced to be localized in the nucleus (Sox9-NLS). Although both mutants regulated COL2 and COL10 levels similarly to the wild-type Sox9, cGKII could suppress only the $Sox9^{S181A}$ function but not the Sox9-NLS function, indicating that cGKII attenuates the Sox9 function by interfering with its nuclear entry independently of its direct phosphorylation. Finally, the impaired differentiation of cultured KMI chondrocytes was confirmed to be restored by the silencing of Sox9 through RNA interference. Hence, the present study is the first to shed light on a novel role of cGKII as a molecular switch, coupling the cessation of proliferation and the start of hypertrophic differentiation of chondrocytes through attenuation of Sox9 function.

Bidirectional Signaling by Ephrinb2-EphB4 Coordinates Osteoclast and Osteoblast Functions to Enhance Bone Formation. C. Zhao*[1], N. Irie*[1], K. Shimoda*[2], T. Miyamoto[3], T. Nishiwaki*[4], H. Ishikawa*[1], T. Suda*[3], K. Matsuo[1]. [1]Department of Microbiology and Immunology, School of Medicine, Keio University, Tokyo, Japan, [2]Laboratory Animal Center, School of Medicine, Keio University, Tokyo, Japan, [3]The Sakaguchi Laboratory of Developmental Biology, School of Medicine, Keio University, Tokyo, Japan, [4]Department of Orthopedic Surgery, School of Medicine, Keio University, Tokyo, Japan.

Bone homeostasis depends on the delicate balance between bone-forming osteoblasts and bone-resorbing osteoclasts. Several molecules are known to coordinate the function of osteoclasts with that of osteoblasts. However, no molecules that directly mediate osteoclast-osteoblast interactions by simultaneous signal transduction into both cell types have yet been identified. Interaction between ephrinB and EphB family proteins results in bidirectional signalling into both the ephrinB- and the EphB-expressing cells. Whereas activation of the receptor EphB by the ligand ephrinB is referred to as "forward signaling", activation of the ligand ephrinB by the receptor EphB is designated "reverse signaling". Here we show that ephrinB2 is expressed on differentiated osteoclasts, while its cognate receptor EphB4 is expressed on osteoblasts. Furthermore, using gain and loss-of-function experiments, we show that reverse signaling through ephrinB2 suppresses osteoclast differentiation, and forward signaling through EphB4 enhances osteoblast differentiation.

Reverse signaling down-regulates the essential osteoclastogenic transcription factors c-Fos and NFATc1, whereas forward signaling up-regulates osteoblastic transcription factors, such as *Runx2*, *Osterix* and *Dlx5* presumably through Erk1/2 activation. To further verify this interaction in vivo, we generated transgenic mice expressing EphB4 in osteoblasts. These mice show significantly increased bone mineral density compared to wild-type mice, suggesting that ephrinB2 and EphB4 interaction plays an important role in maintaining bone mass in vivo. In conclusion, our results demonstrate that bidirectional signaling by ephrinB2 and EphB4 functionally links osteoclasts and osteoblasts, suppressing bone resorption and simultaneously enhancing bone formation.

FIAT, a Novel Leucine Zipper Repressor of ATF4-mediated Transcription that Regulates Bone Mass Accrual in Transgenic Mice. V. W. C. Yu*, G. Ambartsoumian*, J. Prud'homme*, J. M. Moir*, R. St-Arnaud. Genetics Unit, Shriners Hospital for Children, Montreal, PQ, Canada.

We report the cloning and characterization of FIAT (Factor Inhibiting ATF4-mediated Transcription), a 66 kDa leucine zipper nuclear protein. FIAT interacted with ATF4 in yeast and mammalian cells and inhibited ATF4-mediated transcriptional activation of the osteocalcin gene promoter in cultured cells. Considering the recently reported role of ATF4 in the regulation of osteoblast function (Yang, X., et al. 2004. Cell 117: 387), we investigated a putative role of FIAT in bone forming cells in vivo. Transgenic mice specifically overexpressing FIAT in osteoblasts had reduced bone mineral density (21%). Histomorphometric measurements demonstrated a dramatic decrease in bone volume (70%), mineralized volume (45%), trabecular thickness (38%), and trabecular number (55%). This phenotype translated into decreased rigidity (20%) of long bones. Mineral homeostasis, osteoclast number and activity, and osteoblast proliferation and apoptosis were unchanged in transgenic animals. Expression of osteoblastic differentiation markers was largely unaffected but reduced BSP expression was measured. Mineral apposition rate was reduced by 46% in transgenic mice, suggesting that the lowered bone mass was due to a decline in osteoblast activity. This cell-autonomous decrease in osteoblast activity was confirmed by measuring reduced alkaline phosphatase activity and mineralization in primary osteoblast cultures. These results show that FIAT regulates bone mass accrual and establish FIAT as a novel transcriptional regulator of osteoblastic function.

C/EBP Homologous Protein (CHOP, Ddit3) Is Essential for Osteoblastic Function. R. C. Pereira[1], S. J. Marciniak*[2], D. Ron*[2], E. Canalis[1]. [1]Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA, [2]Skirball Institute, New York University School of Medicine, New York, NY, USA.

CCAAT/enhancer binding proteins (C/EBPs) are a family of transcription factors with important roles in cell differentiation and function. C/EBP homologous protein (CHOP, GADD153, Ddit3) was recently found to enhance BMP/Smad signaling, and as a consequence to induce osteoblast cell differentiation. But, the effects of CHOP on osteoblastic function are not known. To evaluate CHOP's role in skeletal cell function, we examined the skeletal phenotype of *chop* null mice and the function of *chop* null osteoblasts *in vitro.* Homozygous *chop* null mice back-crossed to a C57BL/6 genetic background five times were compared to wild type controls of identical genetic composition. *Chop* null mice exhibited a decrease in bone formation rate of 75%. The number of osteoblasts was not decreased, but the number of functional osteoblasts was, since the mineralizing surface was markedly reduced. *Chop* null mice exhibited a 30% reduction in eroded surface, indicating impaired osteoclastic/resorptive response and impaired bone remodeling. As CHOP has been implicated in the response of cells to client protein load in the endoplasmic reticulum (so-called ER stress), and as procollagen α_1 and α_2 chains are imported into the ER where they are post-translationally modified and then secreted, we hypothesized that impaired procollagen processing might be implicated in the bone phenotype of the *chop* mutant mice. We observed that whereas collagen synthesis rates were not decreased in cultured *chop* null osteoblasts, procollagen processing was severely affected compared with the wildtype cells. To estimate changes in procollagen processing, wild type and *chop* null osteoblasts were labeled with [^{3}H] proline and 'chased' in high proline containing medium. [^{3}H] hydroxyproline in the cell layer was separated by high performance liquid chromatography and measured by scintillation counting, and cell extracts were fractionated on 5% polyacrylamide/5M urea gels to visualize pro α1 and pro α2 type I collagen chains. This experiment demonstrated accumulation of newly synthesized procollagen in *chop* null osteoblasts. The half life of newly synthesized radiolabeled procollagen in the cell layer was extended from 14 min in wild type osteoblasts to ~60 min in *chop* null cells, confirming accumulation of newly synthesized procollagen in null cells and impaired export of procollagen from the cell to the extracellular space. In conclusion, CHOP is required for normal osteoblastic function and procollagen export from osteoblastic cells.

Conditional Disruption of Hypoxia Inducible Factor 1 α in Mouse Osteoblasts Reduces Bone Volume. L. Deng*[1], N. Akeno[1], A. Mukherjee*[1], M. Bouxsein[2], M. Faugere[3], R. S. Johnson*[4], T. L. Clemens[1]. [1]Department of Pathology, University of Alabama at Birmingham, Birmingham, AL, USA, [2]Department of Orthopedic Surgery, Beth Israel Deaconess Medical Center, Boston, MA, USA, [3]Department of Medicine, University of Kentuky, Lexington, KY, USA, [4]Department of Biology, University of California at San Diego, San Diego, CA, USA.

The ability of cells to sense and respond to changes in oxygen tension is critical for many developmental, physiological, and pathological processes. Osteoblasts are ideally positioned in bone to sense and respond to fluctuations in oxygen and nutrient supply. Osteoblasts respond to hypoxia by elevating the level of the hypoxia-inducible factor 1α (HIF-1α), which transactivates expression of angiogenic and nutrient sensitive genes whose products act in concert to facilitate the supply of metabolic energy. To investigate the role of HIF-1α in skeletal acquisition we conditionally disrupted this transcription factor in bone osteoblasts by Cre-mediated recombination. Transgenic mice expressing the Cre recombinase from the human osteocalcin promoter were crossed with mice homozygous for the floxed HIF-1α allele to obtain mice lacking HIF-1α in osteoblasts. Eight week-old mutant mice (N=6) were of normal size and weight. Micro CT measurements at the mid shaft of the femur revealed a significant decrease in cross sectional area in both sexes. Consistent with these changes we observed that bones dissected from HIF-1α mutants were more susceptible to breaking than controls. Histomorphometric analysis revealed a reduction in osteoblasts (678 ± 57 vs 440 ± 25) and a decrease in osteoid volume (2.74 ± 0.57 vs 1.43 ± 0.8) consistent with a role for HIF-1α in bone formation. Osteoclast number and erosion surface were significantly increased suggesting a state of uncoupled bone formation and resorption. To begin to examine the cellular mechanisms responsible for the changes in bone architecture in the HIF-1α deficient mice we determined the effect of loss of HIF-1α in vitro on osteoblast differentiation and mineralization. Primary calvarial osteoblasts from mice homozygous for the floxed HIF-1α allele were infected with adenoviral vectors expressing either Cre or GFP and allowed to differentiate in mineralizing medium. Cells deficient in HIF-1α showed a marked developmental delay associated with reduced expression of Runx-2 and osteocalcin and a reduction in calcified nodule formation. These results suggest that HIF-1α can function independent of angiogenic signals during skeletal development to promote the differentiation program of the osteoblast.

Osteoporosis as an Independent Risk Factor for Cardiovascular Events in Postmenopausal Women: Data from the Multiple Outcomes of Raloxifene Evaluation (MORE) Trial. C. Christiansen[1], L. Tanko*[1], D. A. Cox*[2], M. J. Geiger*[2], M. McNabb*[2], S. Cummings*[3]. [1]Center for Clinical and Basic Research, Ballerup, Denmark, [2]Eli Lilly and Company, Indianapolis, IN, USA, [3]University of California San Francisco, San Francisco, CA, USA.

Previous studies suggest an inverse association between bone mass and both cardiovascular (CV) mortality and the severity of peripheral atherosclerosis. The predictive value of osteoporosis for risk of CV events has not been addressed systematically. The objective of this analysis was to retrospectively assess the relationship between osteoporosis and CV risk in postmenopausal women in the MORE osteoporosis treatment trial assigned to placebo. MORE was a randomized, double-blind trial which enrolled 7705 postmenopausal women, 2576 taking placebo. For these analyses, osteoporosis (n=1289) was defined as having a baseline vertebral fracture or a total hip BMD t-score of -2.5 or less (based on Third National Health and Nutrition Examination Survey). Low bone density (n=1153) was defined as a t-score greater than -2.5 but less than or equal to -1 without baseline vertebral fracture. CV events (coronary events and stroke) were collected through 4-years as safety endpoints and subsequently adjudicated by a cardiologist. Proportional hazard models were unadjusted and adjusted for CV risk factors (age, smoking, diabetes, prior events, hypertension and hyperlipidemia) or for a composite CV risk score calculated for each woman. The incidence of CV events was significantly higher among women with osteoporosis [49 events (3.8%)] versus those with low bone density [10 events (0.9%)], both without and with adjustment for multiple CV risk factors or CV risk score (Figure). Coronary events and stroke were significantly higher in women with osteoporosis. Prevalent vertebral fracture [HR, 3.3; 95%CI, 1.5-7.1)] or low (t-score of -2.5 or less) total hip BMD [HR, 3.4; 95%CI, 1.4-8.0) were both associated with an increased incidence of CV events, independent of CV risk factors. We conclude that osteoporosis was a strong predictor of CV events independent of age and other traditional CV risk factors in postmenopausal women in the MORE trial, suggesting a possible pathophysiological link between these diseases that warrants further study.

Bone Mineral Density Predicts Incident Non-Spine Fractures in African-American Women. The Study of Osteoporotic Fractures. J. A. Cauley[1], L. Y. Lui[2], K. Ensrud[3], J. M. Zmuda[1], K. Stone[2], M. C. Hochberg*[4], S. R. Cummings[5]. [1]University of Pittsburgh, Pittsburgh, PA, USA, [2]UCSF, San Francisco, CA, USA, [3]U Minnesota, Minneapolis, MN, USA, [4]U Maryland, Baltimore, MD, USA, [5]California Pacific Medical Center, San Francisco, CA, USA.

Bone mineral density (BMD) measurements are powerful predictors of fracture risk in Caucasian women. To date, there have been no prospective studies of BMD and incident fractures in African-American women. To test the hypothesis that BMD predicts non-spine fractures in African-American women, we enrolled 651 women, mean age 75.4 years and followed them for an average of 5.2 years. Fifty-three African -American women experienced an incident non-spine fracture; all were confirmed by radiographic report. Hip BMD was measured by DXA (Hologic 2000 Bedford, MA). Femoral neck bone mineral apparent density (BMAD) was calculated to estimate volumetric density (BMAD = BMD/area^2). African-American women who fractured had a lower BMI (kg/m^2) (28.6 vs. 30.5, p = 0.05); were less likely to walk for exercise (25% vs. 37%, p = 0.06); were more likely to report osteoarthritis (34% vs. 20%, p = 0.02) and were more likely to use their arms to stand from a chair (25% vs. 16%, p = 0.09) as compared to African-American women who did not fracture. In age adjusted proportional hazards models, one standard deviation (SD) decrease in femoral neck BMD was associated with a 49% increased risk of fracture. (Relative risk = 1.49; 95% CI, 1.09 - 2.05) Similar results were obtained after adjusting for body weight and other risk factors. A one SD decrease in BMAD was associated with a 60% increased risk of fracture. (RR= 1.60; 1.16-2.22) We compared the incidence of non-spine fracture across tertile of BMD after 5.2 years of follow-up in African-American women to Caucasian women enrolled in SOF. (Table).

Tertile Femoral Neck BMD (g/cm^2)	Incidence Rates (per 1000 Person Years)	
	African-American	Caucasian
Low (≤ 0.599)	31.1	59.2
Med (0.5991 - 0.693)	22.6	35.8
High (≥ 0.6931)	12.0	25.1

In conclusion, Low BMD and BMAD predict fracture in older African-American women. The magnitude of the association is similar to that observed in Caucasians. Nevertheless, at every BMD level, the incidence of fracture is 40 to 50% lower among African-American women suggesting that other skeletal e.g. bone turnover and non-skeletal factors contribute to the lower incidence of fracture in African-American women.

Inhibition of GSK-3β by Lithium Chloride Reverses the Osteoporotic Phenotype Displayed by Lrp5 Deficient Mice and Increases Bone Density in Intact C57Bl6 and in Osteopenic SAMP6 Mice. P. Clément-Lacroix[1], M. Ai*[2], R. Chiusaroli*[3], F. Morvan*[3], S. Roman Roman[1], B. Vayssière*[1], C. Belleville*[1], M. Warman*[2], R. Baron[1], G. Rawadi*[1]. [1]Proskelia Pharmaceutical, Romainville, France, [2]Case Western Reserve University, Cleveland, OH, USA, [3]Yale University, Yale, CT, USA.

The importance of the Wnt signaling pathway in the regulation of bone mass has been recently underlined with the identification of mutations in the Wnt coreceptor low-density lipoprotein receptor-related protein 5 (Lrp5) gene causing either the osteoporosis-pseudoglioma (OPPG) or the hereditary high bone density (HBM) syndromes in human. The bone-related phenotypic modifications found in human and mice either lacking the LRP5 protein or displaying LRP5 gain-of-function mutations seem to be largely caused by an alteration of osteoblast function. A number of experimental data lead to speculate that pharmacological modulation of LRP5 signaling could positively affect bone mass and reduce the risk for developing clinically significant osteoporosis. In this study, we show that Primary calvarial osteoblasts derived from LRP5$^{-/-}$ mice display a delay in differentiation and exhibit a significant decrease in their responsiveness to BMP-2 compared to wild-type cells. Stimulation of LRP5$^{-/-}$ primary calvaria cells with Wnt3a fails to induce β-catenin nuclear translocation or TCF1-mediated transcriptional activity. In contrast, the GSK-3β inhibitor lithium chloride (LiCl) increases both β-catenin nuclear translocation and TCF1 activity. Since the inhibition of GSK-3β is a key event downstream of LRP5, we have examined whether LiCl treatment, acting downstream of the deleted receptor, could improve bone mass in LRP5$^{-/-}$ mice. We found that LiCl markedly increased bone volume, trabecular number, osteoblast number and bone formation rate in LRP5$^{-/-}$ animals. These data strongly suggest that the low bone mass in Lrp5-/- mice results from a defective canonical Wnt signalling. Furthermore, LiCl is able to significantly increase bone formation parameters in intact C57Bl6 and in osteopenic SAMP6 mice. Given that the serum levels of Li in treated animals are equivalent to the levels reported to inhibit GSK-3ß in humans, our results suggest that inhibiting this enzyme could constitute an efficient treatment for a number of osteopenic disorders including OPPG and senile osteoporosis.

Sex Steroid Hormones in Older Men: Cross-sectional and Longitudinal Associations with Bone Mineral Density (BMD). The Osteoporotic Fracture in Men Study (MrOS). J. Cauley[1], B. Taylor*[2], H. Fink*[2], K. Ensrud[2], D. Bauer[3], E. Barrett-Connor*[4], L. Marshall*[5], M. Nevitt[3], M. Stefanick*[6], E. Orwoll[5]. [1]U of Pitt, Pittsburgh, PA, USA, [2]U Minnesota, Minneapolis, MN, USA, [3]UCSF, San Francisco, CA, USA, [4]U California, San Diego, CA, USA, [5]Oregon Health & Science U, Portland, OR, USA, [6]Stanford U School of Medicine, Stanford, CA, USA.

Sex steroid hormones may be important determinants of BMD in older men, but there is limited information on whether they predict changes in BMD or whether declines in hormones are associated with faster rates of bone loss. To address this, we measured sex hormones in 2,619 randomly selected men aged 65+ enrolled in MrOS. A subset of 1,327 men returned for a follow-up clinic visit, an average of 1.8 years later. Estradiol, testosterone, SHBG, and albumin were measured in paired serum samples collected at baseline and follow-up visits using sensitive immunoassays; free steroid levels were calculated from mass action equations. BMD was measured by DXA (Hologic 4500 W). Linear regression models were used. Total hip and lumbar spine BMD were 5.3% and 7.0% higher, respectively, in men in the top quintile of total estradiol level compared to men in the lowest quintile, Table. The rate of hip bone loss was also higher in men with the lowest estradiol compared with men with the highest estradiol. During follow-up, estradiol levels declined in 65% of the men. Men who experienced the greatest declines in total estradiol lost more total hip BMD (-0.72%/yr) compared to men who experienced the greatest increase in estradiol (-0.22%/yr), p<0.002, independent of age, weight, baseline BMD, and baseline estradiol. Similar results were observed for free estradiol. Total and free testosterone were inversely related to hip BMD in age adjusted models, but this was not significant after adjusting for body weight. Men with the lowest (Quintile 1) free testosterone experienced greater rates of hip bone loss (-0.79%/yr) compared to men with the highest (Quintile 5) free testosterone (-0.41%/ yr) p=0.02. There was no relationship between change in testosterone and change in BMD. We conclude that estradiol is a major predictor of BMD and rates of bone loss in men. Higher serum estradiol levels in older men should preserve BMD and may prevent osteoporotic fractures.

	Baseline BMD g/cm^2		Change in

Bone Marrow Restricted Antigen Presentation by Dendritic Cells Induces T Cell Activation and T Cell TNF Production in Ovariectomized Mice. F. Grassi, J. K. Leavey, K. Dark*, W. Qian*, M. N. Weitzmann, R. Pacifici. Medicine, Emory University School of Medicine, Atlanta, GA, USA.

It has been reported that increased T cell TNF production resulting from enhanced T cell activation stimulates osteoclast (OC) formation and leads to bone loss in ovariectomized (ovx) mice. T cell activation is induced by ovx in all lymphoid organs through upregulation of antigen (Ag) presentation by macrophages, a population of antigen presenting cells (APC). However, since ovx increases OC formation only in the bone marrow (BM), a greater stimulation of Ag presentation and thus of T cell TNF production may specifically occur in the BM. Site-specific, Ag-dependent, T cell activation driven by dendritic cells (DC) is known to take place in the BM (Feuerer M et al. Nat Medicine 2003). DC are extremely powerful APC harbored in BM foci. The formation of foci of T cell activation through upregulation of DC Ag presentation may explain why osteoclasts form specifically in the BM but do not differentiate in the spleen or lymph nodes despite the presence of all the necessary precursors and cytokines. To investigate this hypothesis, BM DC (CD11c+ cells) were purified by positive immunomagnetic selection. Ovx increased by ~ 4 fold the antigen presentation activity of BM DC, as compared to BM DC from sham operated mice. This increased activity was further potentiated by a 20% increase in DC number. Attesting to specificity, ovx had no effect on the number or Ag presentation activity of splenic DC. Furthermore, ovx was found to increase the percentage of CD4+ T cells expressing the early activation marker CD25 in the BM but not in the spleen, demonstrating a local enrichment of activated T cells. Consistent with the fact that ovx upregulates Ag presentation by increasing MHCII expression, we found that ovx increased by 70 % the mRNA expression of the H-2b chain of the MHCII complex in BM DC, but not in splenic DC. Furthermore, the expression level of the key MHCII regulatory gene CIITA, which is known to be down-regulated when DC become activated, was 66% lower in BM DC from ovx than sham operated mice. In contrast sham and ovx splenic DC had similar CIITA mRNA levels. In summary, the data show that ovx is followed by a BM specific DC activation that leads to increased Ag presentation, T cell activation and T cell TNF production. These findings suggest that one of the mechanisms which restricts OC formation to the BM is the production of high levels of osteoclastogenic cytokines in discrete foci located in close proximity to osteoclast precursors and the endosteal bone surface. The data also demonstrate that DC represent a novel estrogen target that play a previously unrecognized role in the mechanism of ovx induced bone loss.

Osteopenia and Reduced Bone Formation Due to a Mutation in the Indian Hedgehog (IHH) Gene. L. Gennari[1], D. Merlotti[1], N. Giordano*[1], V. De Paola*[1], A. Calabrò*[1], G. Martini[1], A. Renieri*[2], R. Nuti[1]. [1]Dept. of Internal Medicine Endocrine Metabolic Sciences and Biochemistry, University of Siena, Siena, Italy, [2]Dept. of Molecular Biology, University of Siena, Siena, Italy.

Indian hedgehog (IHH), a member of the vertebrate hedgehog morphogen family, is a key signaling molecule that controls chondrocyte proliferation and differentiation. Recent in vitro and in vivo evidences support a direct role of IHH in the regulation osteoblast differentiation and bone formation. However, the consequences of IHH inactivation in bone homeostasis in man remain unknown. We report the skeletal phenotype of a family affected by brachydactyly type I (BDA-1) due to a mutation in the IHH gene. The proband was a 34 years old men admitted to our institute because of increasing low back pain. He was 160 cm tall (below the 3rd centile) and 58 kg in weight. At age 10 yrs he had his first fracture of a wrist after a mild fall. At age 12 he had a fracture of the humerus. Physical examination showed an upper lower segment ratio of 1.4 and brachydactyly. Skeletal x-ray examination showed signs of brachydactyly of the hands and feet, in accordance of the clinical diagnosis of BDA-1. His 66 yrs old mother and 11 yrs old daughter showed similar radiological manifestations of BDA-1. Moreover, the proband's mother also reported non-traumatic fractures of the vertebrae and the wrist, and a hip fracture. Linkage analysis showed segregation compatible with a locus at 2q35-q36 and sequence analysis of the IHH gene demonstrated the presence of a heterozygous codon 298 G/A transition in exon I, resulting in a substitution of asparagine for aspartic acid at residue 100, in all the three affected subjects.The mutation was not detected in other relatives as well as in 100 unrelated controls. DXA analysis of the proband showed marked osteopenia and reduced bone volume at the lumbar spine, proximal femur and total body, with long bones being the most severely affected. Similarly, reduced ultrasound parameters were observed at the calcaneous and the phalanxes. DXA analysis of the mother showed osteoporosis at both the spine and the hip. A DXA study on the father and on 6 male cousins was normal. Interestingly, the three affected BDA-1 subjects showed serum levels of bone formation markers (bone alkaline phosphatase and osteocalcin) at the lower values of the normal range, significantly lower than those observed in non affected family members. The markers of bone resorption (serum and urinary CTX) were in the normal range in the proband and his daughter, and slightly elevated in the mother. In summary we report the first evidence that mutations in the IHH gene in man, causing BDA-1, may be associated with low bone formation, osteopenia and increased fracture risk.

CREM/ICER Deficiency Blunts the Anabolic Effect of Intermittent PTH on Bone Mass. F. Liu*[1], S. Lee[1], D. J. Adams[2], G. A. Gronowicz[2], B. E. Kream[1]. [1]Endocrionology, University of Connecticut Health Center, Farmington, CT, USA, [2]Orthopaedic Surgery, University of Connecticut Health Center, Farmington, CT, USA.

The cAMP response element modulator (Crem) gene encodes a variety of transcriptional activators and inhibitors. We previously showed that osteoblasts express many Crem transcripts including the inducible cAMP early repressors (ICER), which are induced by PTH and act as potent transcriptional attenuators. To determine whether CREM/ICER factors play a role in the anabolic response of bone to intermittent PTH, Crem knockout (KO) mice, which are deficient in all CREM/ICER factors, and wild-type (WT) mice (11-12 week old males, n=20 per group) were given daily subcutaneous injections of vehicle or hPTH(1-34) (160 µg/kg) for 10 days. Skeletal parameters were assessed by DEXA, histomorphometry and microcomputed tomography (microCT). PTH significantly increased femoral bone mineral content and density by 12.5 and 7.6%, respectively, in WT mice but only by 2.3 and 3.5%, respectively, in KO mice. Similar results were seen in tibiae and vertebrae. MicroCT of femurs showed that PTH significantly increased cortical area by 11.5% in WT mice but only by 2.2% in KO mice. The increase in cortical area in WT mice was due to periosteal expansion. Histomorphometry showed that PTH significantly increased femoral trabecular bone volume and trabecular thickness by 28.3 and 27.3%, respectively, in WT mice but only by 11.9 and 14.0%, respectively, in KO mice. MicroCT corroborated these results. Interestingly, histomorphometry showed that PTH markedly increased the percent osteoblast surface (by about 2-fold) and the bone formation rate (by about 3-fold) in femurs of both WT and KO mice, indicating that the bone formation response to PTH was not altered by CREM/ICER deficiency. By contrast, PTH increased the percent osteoclast surface and osteoclast number by 88 and 71%, respectively, in WT mice but only by 49 and 21%, respectively, in KO mice. Moreover, PTH significantly increased calvarial porosity in KO but not WT mice. Since these data indicated that Crem KO mice might have a heightened osteoclastogenic response to PTH, ex vivo bone marrow cultures were established from WT and KO mice. PTH-induced (100 ng/ml) formation of TRAP-positive multinucleated cells (MNC) was about 2-fold greater in KO marrow, while MNC formation in response to M-CSF (30 ng/ml) and RANKL (30 ng/ml) was only 10-30% greater in KO marrow. There was no difference between WT and KO marrow in CFU-GM, the osteoclast precursor population. In conclusion, our data suggest that the Crem gene may specify anabolicity of intermittent PTH treatment by limiting PTH-induced osteoclastogenesis.

Elucidation of Osteoblastic versus Bone Marrow Cellular Compartments in the Anabolic Actions of PTH. A. J. Koh*[1], B. Demiralp*[2], E. L. Ealba*[1], A. Mattos*[1], L. K. McCauley[1]. [1]Perio/Prev/Geriatrics, University of Michigan, Ann Arbor, MI, USA, [2]Periodontology, Hacettepe University, Ankara, Turkey.

Mice with an ablation of c-*fos* do not respond to PTH in an anabolic manner whereas wildtype littermates do. It is difficult to conclude if the lack of PTH action is due to an osteoblast, c-*fos* transcriptional effect versus an osteoclast (OC) dependent effect associated with the osteopetrotic phenotype of c-*fos* knockout mice. The purpose of this study was to elucidate mechanisms for the altered PTH response in c-*fos* knockout mice. *In vitro* studies evaluated effects of PTH on osteoblast proliferation and differentiation in primary cells from c-*fos* wildtype (+/+), heterozygote (+/-) or null (-/-) mice. Primary cells induced to differentiate for 28d showed no difference in nodule formation (Von Kossa) or calcium incorporation amongst the genotypes, and all responded similarly to PTH which inhibited mineral formation. Interestingly, -/- cells exhibited increased cell viability over 8d compared to +/+ and +/- but responded similarly to PTH and to the induction of apoptosis. These *in vitro* data suggest knockout of c-*fos* may alter cell cycle regulation but there is no apparent alteration in the response to PTH. To focus on the dependence of OCs for the PTH anabolic response, an innovative model used transplanted vertebrae from test mice in recipient mice to rescue the hematopoietic component. Vertebral bodies (vossicles) were isolated from 4d -/-, +/- and +/+ mice, implanted into athymic mice, and vehicle or hPTH (1-34) (80µg/kg) administered s.c. daily for 3wks. Prior to sacrifice, a 2-4h BRdU injection was used to label proliferating cells. Vossicles were microradiographed and processed for histology. Qualitatively, PTH treated vossicles of all genotypes had thicker cortical bone and increased number and thickness of trabeculae. Quantitatively, bone mass was significantly increased by PTH compared to vehicle in mice from all genotypes. OCs (TRAP postive cells) were present in -/- vossicles after 3wks, confirming the rescue of OCs by host mice. BRdU staining revealed increased proliferation of bone marrow cells in PTH vossicles, while proliferation in vehicle-treated vossicles was limited to the lining of bony surfaces. Taken together, these results indicate that c-*fos* ablation is not critical for PTH effects in osteoblasts and while c-*fos* is necessary for OC formation *in vivo*, rescue of bone marrow cells containing OCs into c-*fos* deficient bones restores PTH's anabolic action. Therefore, cells in the bone marrow such as osteoclasts may be critical intermediaries of anabolic actions of PTH.

The Bone Anabolic Effects of Parathyroid Hormone (PTH) are Blunted by Deletion of the Wnt Antagonist Secreted Frizzled-Related Protein (sFRP)-1. P. V. N. Bodine, Y. P. Kharode, L. Seestaller-Wehr*, P. Green*, C. Milligan*, F. J. Bex. Women's Health Research Institute, Wyeth Research, Collegeville, PA, USA.

sFRP-1 is a secreted Wnt antagonist that when deleted in mice leads to increased trabecular bone formation in adult animals after 13 weeks of age. Treatment of mice with PTH also increases trabecular bone formation, and some of the anabolic actions of this hormone may result from altered expression of Wnt pathway components in bone. To test this hypothesis, we treated +/+ and -/- female sFRP-1 mice with 100 ug/kg/day, s.c., of hPTH 1-34 for 30 days and measured distal femur trabecular bone parameters by peripheral quantitative computed tomography and high-resolution microcomputed tomography. During the course of the 32-week study, volumetric bone mineral density (vBMD) declined 41% in vehicle treated +/+ mice, but increased 24% in vehicle treated -/- animals. At 8 weeks of age when vBMD was not altered by deletion of sFRP-1, treatment of +/+ and -/- mice with PTH increased vBMD by 147-163%, respectively. In contrast, at 24 weeks of age when vBMD was 75% higher in -/- mice, treatment with PTH increased vBMD 164% in +/+ animals, but only 58% in -/- mice. Moreover, at 36 weeks of age when vBMD was 117% higher in -/- mice, treatment with PTH increased vBMD 74% in +/+ animals, while no increase was observed in -/- mice. At each of these time points, PTH treatment increased vBMD to a similar level in +/+ and -/- mice, and this level declined with age. In addition, at 36 weeks of age, the vBMD level reached by PTH treatment of +/+ mice was the same as that achieved by deletion of sFRP-1. These results indicate that loss of sFRP-1 and PTH treatment increase vBMD to a similar extent in female mice, suggesting that there are overlapping mechanisms of action. As the effects of sFRP-1 deletion on vBMD increase, the ability of PTH to enhance vBMD declines. In contrast, PTH treatment of transgenic mice harboring the G171V gain-of-function mutation of human low-density lipoprotein receptor-related protein (LRP)-5, a Wnt co-receptor, leads to synergistic increases in trabecular vBMD when compared to non-transgenic control animals, suggesting that these mechanisms are complimentary. Thus, although these data support the concept that PTH and Wnt signaling may share common components to affect bone formation, they also suggest that the mechanisms of this signaling are complex and may extend beyond control of the canonical Wnt pathway.

Lrp5 Is not Essential for the Stimulatory Effect of PTH on Bone Formation in Mice. U. T. Iwaniec[1], G. Liu*[2], R. R. Arzaga*[1], L. M. Donovan*[1], R. Brommage[2], T. J. Wronski[1]. [1]Physiological Sciences, University of Florida, Gainesville, FL, USA, [2]Endocrinology, Lexicon Genetics, The Woodlands, TX, USA.

Lrp5 (low-density lipoprotein receptor-related protein 5), a key component of the Wnt signaling pathway, is involved in the regulation of osteoblastic proliferation, differentiation, and function. The purpose of this study was to evaluate the role of Lrp5 in mediating the bone anabolic effects of parathyroid hormone (PTH). Mice homozygous for the Lrp5 knockout (KO) allele were generated using retrovirus-mediated gene trapping. Eighteen-week-old male wildtype (WT, n = 10) and Lrp5 KO (n = 19) mice were treated sc with vehicle or 80 µg/kg human PTH (1-34) on alternate days for 6 weeks. Lumbar vertebrae (LV) were collected and processed undecalcified for quantitative bone histomorphometry (LV 3-4). Bone architecture of LV5 and the femoral midshaft were analyzed by microCT (Scanco µCT40). Data are expressed as mean ± SD and analyzed using a 2-way (genotype, treatment) ANOVA.

Cancellous bone volume in LV was lower in KO than WT mice (4.9 ± 2.9% versus 9.6 ± 3.7%, respectively, P<0.001). This 50% decrease in bone volume in Lrp5 KO mice determined by histomorphometry was confirmed by a similar decline measured by microCT. Femur cortical thickness was reduced by 10% (P < 0.006) in KO mice in comparison to WT mice. Osteoclast surface, an index of bone resorption, was similar in both genotypes. However, osteoblast surface was approximately 50% lower in the KO than in WT mice (P < 0.004), indicating that bone formation is decreased with Lrp5 deficiency. Treatment of mice with PTH for 6 weeks resulted in a 3 to 4-fold increase in osteoblast surface (P < 0.0001), a relatively modest 30 to 70% increase in osteoclast surface (P = 0.054), and a 13% increase in femur cortical thickness (P < 0.001), regardless of genotype. PTH treatment did not augment cancellous bone volume in either genotype. Our data confirm previous findings that loss of function of Lrp5 results in decreased cancellous and cortical bone mass due to decreased bone formation. Furthermore, we show that Lrp5 does not appear to be essential for the stimulatory effect of PTH on cancellous bone formation.

The Temporal Profile in Humans of the Subacute Skeletal Anabolic Response to Continuous Infusion of PTHrP and PTH. M. J. Horwitz[1], C. M. Gundberg[2], M. Tedesco*[1], S. Sereika*[1], A. Garcia-Ocana*[1], A. Bisello[1], G. Marshall*[1], C. J. Rosen[3], A. F. Stewart[1]. [1]U Pittsburgh, Pittsburgh, PA, USA, [2]Yale U, New Haven, CT, USA, [3]St. Joseph Hosp, Bangor, ME, USA.

While both PTH and PTHrP are skeletal anabolic agents in humans, the subacute (> 12-24 hours) temporal profile of the anabolic response is unknown. In young healthy adults, we explored the responses to continuous 46 hr infusions of either hPTH(1-34) or hPTHrP(1-36), in doses between 12 to 28 pmol/kg/hr. Plasma IGF-1, osteocalcin (OC), P1NP, and serum NTX were used to assess bone turnover.

Serum calcium increased over 48 hours from baseline (8.9 mg/dl) to a mean of 10.7 mg/dl for PTHrP and 11.5 mg/dl for PTH. There were no calcemic differences among individual doses of PTH or PTHrP.

As reported by others, sNTX, a resorption marker, increased following PTH, reaching a peak of +50% at 14 hours. In the PTHrP group, a group not previously studied with respect to resorption, sNTX increased by +20%, with a peak at 14 hours.

Plasma IGF-1, a putative mediator of PTH and PTHrP actions on osteoblasts and their precursors, rose rapidly (within 7 hours) and continued to increase over the 48 hours of the study, from a baseline of 188 ng/ml to a maximum of 232 ng/ml (p < 0.001). As observed previously in osteoblasts in vitro, as well as in 12-18 hour studies in humans, the formation marker OC initially decreased by approximately 20% (p < 0.001) in both the PTH and PTHrP groups in the first 14 hours. However, in contrast to prior 12-24 hour studies, OC then continuously rose (+40%, p < 0.0001) between 14 and 48 hours. The second formation marker, P1NP, declined continuously in both the PTH and PTHrP groups, reaching a nadir of -45% at 48 hours (p < 0.001). Interestingly, there was no dose response for either PTH or PTHrP for IGF-1, OC and P1NP, and there were no differences between the PTH and PTHrP groups.

In response to a two-day of infusion of PTH or PTHrP: 1) IGF-1 increases rapidly; 2) OC displays a biphasic response, initially declining, and then increasing continuously up to 48 hours; 3) P1NP, a marker of collagen-1 synthesis, declines continuously for 48 hours. While increases in P1NP and OC may reflect increases in bone formation under chronic, steady-state conditions, their acute responses to PTH and PTHrP in humans are negative. These human studies corroborate prior in vitro rodent osteoblast and calvariae studies with PTH causing acute declines in collagen and OC synthesis. The physiologic explanation for this apparent acute reduction in bone formation to PTH and PTHrP is uncertain, but we hypothesize that it may participate in the early calcemic response to acute increases in PTH. Finally, the suppression of bone formation in response to continuous PTH and PTHrP mirrors skeletal events in HHM.

Suppression of Runx2-Regulated Genes, but not Runx2 mRNA, Following Continuous but not Intermittent PTH Administration to Mice: *In Vivo* Evidence for PTH-stimulated Proteasomal Degradation of Runx2 and a Mechanistic Explanation for why Continuous PTH does not Attenuate Osteoblast Apoptosis. A. A. Ali, I. Gubrij, X. Liu*, Q. Fu, X. D. Chen, C. A. O'Brien, S. Manolagas, T. Bellido, R. L. Jilka. Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Intermittent PTH causes bone anabolism at least in part by attenuation of osteoblast apoptosis, whereas continuous administration does not affect osteoblast lifespan. *In vitro* studies have indicated that PTH-induced survival signaling is short-lived because the hormone also stimulates Smurf1-mediated proteasomal proteolysis of Runx2 - a transcription factor needed for increased synthesis of survival genes like Bcl-2. Here, we sought evidence for a PTH-induced reduction in functional Runx2 by quantifying transcript levels of 4 osteoblast/osteocyte-specific genes that strongly depend on Runx2 for transcription: osteocalcin (OCN), bone sialoprotein (BSP), dentin matrix protein 1 (Dmp1) and sclerostin (SOST). Addition of PTH to osteoblastic OB-6 cells caused a reduction in all 4 transcripts (determined by TaqMan PCR), which was first significant at 3-6 hours, and reached <10% of basal levels by 24 hours. Runx2 transcripts did not change, but the decline in target gene transcripts coincided with a 50% reduction in Runx2 protein. More important, infusion of female adult Swiss Webster mice with PTH to raise the circulating level from 10 pg/ml to 500 pg/ml also caused a 2-3 fold reduction in the level of all 4 transcripts in tibia and vertebrae after 16 h of treatment. By 48 h, transcript levels had declined by 10-fold as compared to contemporaneous vehicle controls. Again, Runx2 transcripts were not affected. The reduction in OCN mRNA corresponded with a 50% reduction in circulating OCN protein. By 96 h however, OCN, BSP and Dmp1 transcripts returned to levels at or above vehicle controls, corresponding with an increase in osteoblast number. SOST transcripts remained low at 96 h, perhaps because it is highly expressed in osteocytes as compared to osteoblasts. In contrast to the strong suppressive effects of continuous PTH, an injection of 100 ng/g of PTH did not significantly decrease these Runx2-regulated transcripts at 1, 2, 4 or 16 h. These findings support the hypothesis that continuous elevation of PTH is unable to attenuate osteoblast apoptosis because of a sustained decrease in functional Runx2, whereas intermittent administration of PTH allows repeated bursts of anti-apoptosis signaling.

A Prospective Study of DXA and QCT at the Hip and Spine Predicting Clinical Fractures in Men: the MROS Study. D. M. Black[1], L. Palermo[1], T. F. Lang[1], B. Chan[2], S. R. Cummings[3], E. S. Orwoll[2]. [1]U of CA, SF, CA, USA, [2]OR Health Sci. U, Portland, OR, USA, [3]CA Pac. Med. Ctr., SF, CA, USA.

QCT can assess several characteristics of bone density and size but the relationship of QCT of the hip and spine to risk of fractures has not been prospectively studied nor compared to DXA BMD. Using data from the MROS study, we examined this question with the hypothesis that QCT would better predict non-spine fracture than DXA.

The MROS study is a prospective cohort study of 5995 men conducted at 6 clinical sites in the U.S. A total of 3486 men had either hip or spine QCT; for this analysis, 2959 had usable hip QCT data and 3250 had usable spine QCT. The baseline visit was conducted in 2000-2002 and at the time of this analysis the mean follow-up was 2.8 years. There were a total of 120 men (12 per 1000 person years) with one or more fully adjudicated clinical non-spine fractures. We analyzed the DXA BMD, QCT volumetric BMD in the cortical and trabecular compartments at the spine and total femur and cortical volume from QCT at the hip as predictors of non-spine fracture risk. We used age-adjusted proportional hazards models and report the relative risk per standard deviation decrease in BMD/volume (RR/SD). Variations in some QCT parameters across sites were adjusted for by including clinical center in all multivariable models.

Several QCT parameters of bone density along with cortical bone volume were significantly associated with risk of non-spine fractures:

QCT and DXA for the Prediction of Non-Spine Fractures

	Spine		Total Femur				
	DXA	QCT BMD (trabecular)	DXA	QCT BMD (integral)	QCT BMD (cortical)	QCT volume (cortical)	QCT BMD (trabecular)
RR/SD	1.6	1.6	1.8	1.7	1.4	2.0	1.6
95% CI	(1.3, 2.0)	(1.3,2.1)	(1.5,2.1)	(1.4,2.2)	(1.1,1.8)	(1.5,2.7)	(1.3,2.0)
p	<.0001	<.0001	<.0001	<.0001	.002	<.0001	<.0001

The results show that QCT measurements at the hip and spine are significant predictors of non-spine fractures. QCT had similar predictive value as corresponding DXA. QCT measurements in subregions of the hip were similarly or less predictive than QCT of the total femur. QCT parameters of bone size (cross sectional area of femoral neck and vertebra) were not significantly associated with risk of non-spine fractures. Multivariate analyses including both DXA BMD and QCT BMD or cortical volume showed that DXA dominated prediction and QCT parameters were greatly attenuated.

We conclude that QCT-assessed volumetric BMD of the hip and spine and QCT cortical volume significantly predict non-spine fracture risk in men. However, in this study QCT BMD was not a better predictor than DXA BMD and the addition of QCT BMD to DXA did not substantially improve prediction of non-spine fractures in men.

Type I Collagen C-telopeptide Isomerization Predicts the Long-term Risk of Non-vertebral Facture in Postmenopausal Women, Independently of Bone Mineral Density and Bone Turnover: A Non Invasive Index of Bone Collagen Quality. P. Garnero[1], P. Qvist*[2], F. Munoz*[3], E. Sornay-Rendu*[3], C. Christiansen[2], P. Delmas[3]. [1]Synarc, Inserm Unit 403, Lyon, France, [2]Nordic Bioscience, Herlev, Denmark, [3]Inserm Unit 403, Lyon, France.

Bone strength depends on its mass and architecture, but also on the material properties of its matrix. In vitro studies have suggested that the extent of post-translational modifications of collagen is associated with mechanical properties of cortical bone.

Aim: To investigate the relationships between type I collagen C-telopeptide isomerization - an index of the overall extent of spontaneous post-translational modifications of bone collagen- and the risk of fracture in postmenopausal women.

Methods: We measured native (α CTX) and age-related β isomerized (β) type I collagen C-telopeptide fragments (CTX) in the baseline fasting second morning void urine of 283 healthy premenopausal (pre MP) women (mean age: 40 from 30-57 yr) and 671 postmenopausal women (mean age 62.2 ± 9 years) from the OFELY cohort using new highly specific two site ELISAs (α-α and β-β Crosslaps, Nordic Biosciences). During a median 9.1 (IQ:2.9) yr follow-up, 158 incident fractures including 50 vertebral and 108 non-vertebral fractures were recorded in 116 women among the postmenopausal cohort.

Results:

	Hazard ratio* (95% CI) for α/β CTX > upper limit of pre MP	
	All w. with Fractures (n=116)	W. with Non-Vertebral Fractures only(n=78)
Unadjusted	1.70 (1.05-2.75)	1.84 (1.07-3.14)
Adj. for bone turnover	1.57 (0.96-2.57)	2.09 (1.23-3.58)
Adj. for hip BMD	1.39 (0.85-2.30)	1.84 (1.07-3.14)
Adj. for turnover and BMD	1.34 (0.81-2.23)	1.75 (1.04-3.041)

* adjusted for age

After adjustment for age, postmenopausal women with a urinary α/β CTX ratio above the upper limit of the premenopausal range (97.5 percentile of pre MP; 20% of postmenopausal women) had an increased risk of fracture. For non-vertebral fractures, the odds-ratio remained significant after adjustment for the overall bone turnover (assessed by serum bone alkaline phosphatase) and hip BMD.

Conclusion: Abnormally high urinary ratio between native and β isomerized CTX predicts the long-term risk of non-vertebral fracture in postmenopausal women independently of BMD and bone turnover. The measurement of urinary α/β CTX may provide a non invasive biological index of bone collagen quality.

In vivo **Monitoring of Local Bone Formation Activity by Quantitative Near-Infrared Fluorescence Imaging (NIRF).** H. Gremlich*, R. Kneuer*, S. Kerrad*, M. Merdes*, A. Suter*, M. Kneissel. Novartis Institutes for BioMedical Research, Basel, Switzerland.

Detection of bone formation rates by histomorphometric evaluation of fluorochrome markers in bone is slow. It takes months from the actual *in vivo* experiment to the final readout. We tested whether we can monitor local bone forming activity *in vivo* by near-infrared fluorescence imaging (NIRF), using a near-infrared fluorescent bisphosphonate derivative homing to bone and binding to hydroxyapatite, as suggested previously [1]. In the cited study, a specific uptake of near-infrared labeled bisphosphonate into skeletal structures was demonstrated. It was hypothesized, that the bisphosphonate is taken up preferentially at sites of active bone turnover, where matrix, laid down by osteoblasts, is mineralizing. If correct, the use of such a labeled bisphosphonate should make it possible to quantify bone formation activity by NIRF.

In a 1st experiment we treated 3-month-old OF1/IC mice (n=3/group) with 0.1 or 1 mg/kg of Cy5.5 labeled pamidronate or vehicle intravenously for 1 to 5 days. NIRF images of the calvaria of the anaesthetized mice were recorded 0.5, 1, 2, 4 and 24 hours after the last administration of the near-infrared fluorescent bisphosphonate derivative using a Siemens bonSAI small animal imager prototype. Fluorescent signals could be detected in the calvaria of mice treated with labeled bisphosphonate in a dose- and application number-dependent manner but not in vehicle treated controls. Standard deviation within groups was on the average 6% of the mean value. The fluorescent signals reached 4 hours after the bisphosphonate application a steady state level that remained constant over the 1 day monitoring period. Histological examination using fluorescence imaging confirmed the presence of Cy5.5 signal on calvaria microtome sections of animals treated with the labeled bisphosphonate. In a 2nd experiment 4-month-old OF1/IC mice (n=6/group) were administered hPTH (30, 100, 300 nM), BMP-2 (2400 ng/mL, 7200 ng/mL) or vehicle (PBS + 0.1 BSA) twice daily subcutaneously onto the calvaria for 5 or 7 days. The mice were administered intravenously 0.1 mg/kg of the Cy5.5 labeled bisphosphonate or control on day 7 and 8. A dose-dependent increase of NIRF signal was observed upon hPTH (5 days: 1.8-, 2.5-, 3.2-fold; 7 days: 1.9-, 2.7-, 5.7-fold) and BMP-2 (5 days: 2.6-, 2.8-fold; 7 days: 5.7-, 7-fold) treatment 4 and 24 hours after the last application of the labeled bisphosphonate.

These results confirm that homing of fluorescent bisphosphonate into skeletal structures can be monitored by NIRF. Furthermore they demonstrate that bone formation responses can be quantified rapidly *in vivo* by the use of this technology.

Teriparatide Prevents the Fracture Risk Associated With Increasing Number and Severity of Osteoporotic Fractures. J. H. Krege*[1], G. C. Crans*[1], J. C. Gallagher[2], H. K. Genant[3]. [1]Eli Lilly and Company, Indianapolis, IN, USA, [2]Bone Metabolism Section, Creighton University Medical Center, Omaha, NE, USA, [3]Osteoporosis and Arthritis Research Group, University of California, San Francisco, CA, USA.

The relationship between number and severity of prior fractures and risk of new fractures was evaluated in 931 postmenopausal women with prevalent vertebral fractures (VFx) who were randomized to daily placebo or teriparatide 20 μg in the Fracture Prevention Trial (Neer et al. NEJM 2001). Spine radiographs were evaluated using a visual semiquantitative scoring system (Genant et al. JBMR 1993) at baseline and after a median observation of 21 months. The number of prior nonvertebral fragility fractures (NVFx) was assessed at baseline and new nonvertebral fragility fractures were confirmed by radiographs or radiologic reports. For each treatment group, the relationship between each baseline covariate and fracture risk was assessed using the Cochran-Armitage trend test; treatment group slopes were compared using the bootstrap technique. In the placebo group, both increasing number and severity of prevalent vertebral fractures were associated with a significant increase in incident vertebral fracture risk. In the placebo group, increasing number of prior nonvertebral fragility fractures was associated with a significant increase in new nonvertebral fragility fracture risk. In the teriparatide group, neither increasing number nor severity of prevalent vertebral fractures was significantly associated with increased risk for new vertebral fractures. Additionally, increasing number of prior nonvertebral fragility fractures was not significantly associated with an increased risk for new nonvertebral fragility fractures. In conclusion, in placebo patients, the number and severity of prior fractures predicted risk for new fractures. This relationship was not observed in women treated with teriparatide.

	New VFx (%)	
Prevalent VFx number	Placebo	Teriparatide 20 μg
1	6.8*	3.4
2	15.7*	5.8
≥3	22.6*	7.2
Prevalent VFx severity		
Mild	9.6*	3.5
Moderate	12.9*	6.4
Severe	28.4*	5.8
	New NVFx (%)	
Prior NVFx number	Placebo	Teriparatide 20 μg
0	3.6*	2.7
1	8.2*	0
≥2	18.0*	3.9

*P<0.001 for association between increase in baseline variable and increasing new fracture risk; slope significantly greater than in teriparatide group. (bootstrap technique).

The RANKL Antagonist OPG-Fc Causes Significant Increases in Cortical Bone Mineral Area, Content and Density in Adult Cynomolgus Monkeys. P. J. Kostenuik[1], C. Paul*[2], S. Smith[3], F. Asuncion*[1], J. Atkinson[2]. [1]Metabolic Disorders, Amgen, Inc., Thousand Oaks, CA, USA, [2]Toxicology, Amgen, Inc., Thousand Oaks, CA, USA, [3]CTBR, Senneville, PQ, Canada.

OPG-Fc is a RANKL antagonist that blocks osteoclast differentiation, activation and survival. OPG-Fc leads to rapid, profound and sustained suppression of bone resorption and increased bone mineral density (BMD) in rodents, monkeys and humans. Cortical bone contributes significantly to overall skeletal strength, but this bone compartment tends to be less responsive to antiresorptive therapy compared to the more dynamic trabecular compartment. We therefore tested the effects of OPG-Fc on cortical bone area, bone mineral content (BMC), and density (BMD) in 2-3 year old intact female cynomolgus monkeys. OPG-Fc was administered once weekly for 6 months at 15 mg/kg SC (n = 8) or IV (n = 5). Vehicle (PBS) was administered weekly (SC) to control animals (n = 5). The distal radius and proximal tibia were analyzed at baseline and at 6 months by peripheral quantitative computed tomography (pQCT). Serum was obtained for biochemical markers of bone turnover. All measured pharmacologic responses to IV and SC administration of OPG-Fc were very similar, so data from these groups were merged for analyses.

Bone resorption was dramatically suppressed by OPG-Fc, as evidenced by a ~90% suppression of urine N-Telopeptide (NTx) versus PBS controls at month 6. This antiresorptive response was associated with significant improvements in total, trabecular and cortical BMC and BMD at the distal radius and at the proximal tibia. The following comparisons were all statistically significant ($p<0.05$) versus PBS controls after 6 months of treatment: OPG-Fc increased cortical thickness by 251% and 39% in the distal radius and proximal tibia, respectively. OPG-Fc increased cortical bone area by 223% and 49% in the distal radius and proximal tibia, respectively. The radius of OPG-treated animals had a 20% increase in periosteal circumference and a 40% reduction in endosteal circumference. Cortical BMC was increased by 269% in the distal radius, and by 67% at the proximal tibia. OPG-Fc treatment also significantly improved BMD at each of these sites, as well as at the midshaft of the radius and tibia. These data demonstrate that OPG-Fc treatment of intact female cynomolgus monkeys results in the significant expansion of cortical bone. Increases in cortical bone volume were associated with proportional increases in bone mineral content and improvements in BMD. The expansion of periosteal circumference at cortical sites suggests that osteoblast activity is maintained during OPG-Fc therapy despite the significant suppression of bone resorption.

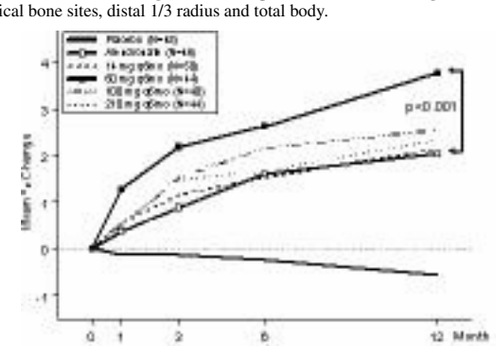
AMG 162 Increases Bone Mineral Density (BMD) within 1 Month in Postmenopausal Women with Low BMD. M. R. McClung[1], E. M. Lewiecki[2], M. A. Bolognese*[3], G. Woodson*[4], A. Moffett*[5], M. Peacock*[6], P. D. Miller*[7], S. Lederman*[8], C. H. Chesnut*[9], R. Murphy*[10], D. L. Holloway[10], P. J. Bekker[10]. [1]Oregon Osteo Ctr, Portland, OR, USA, [2]New Mexico Clin Research & Osteo Ctr, Albuquerque, NM, USA, [3]Bethesda Hlth Research Ctr, Bethesda, MD, USA, [4]Atlanta Research Ctr, Decatur, GA, USA, [5]OBGYN Associates of Mid Florida PA, Leesburg, FL, USA, [6]Indiana Univ School Medicine, Indianapolis, IN, USA, [7]Colorado Ctr for Bone Research, Lakewood, CO, USA, [8]Radiant Research, Lake Worth, FL, USA, [9]Univ Washington Med Ctr, Seattle, WA, USA, [10]Amgen Inc, Thousand Oaks, CA, USA.

AMG 162, a high-affinity, high-specificity, fully human monoclonal antibody to receptor activator of NF kappa B ligand (RANKL), inhibits osteoclastic bone resorption. The objectives of this randomized, dose-ranging study were to evaluate the efficacy and safety of AMG 162 in postmenopausal women with low lumbar spine BMD (T-score ≤-1.8). Four hundred eleven women were randomized to placebo or 6, 14, or 30 mg 3-monthly or 14, 60, 100, or 210 mg 6-monthly (q6mo) or 70 mg/wk alendronate. BMD (DXA), bone turnover markers, and safety measurements have been followed for 12 months.

Baseline age and lumbar spine BMD T-score (mean [SD]) were 63 (8) years and -2.2 (0.8), respectively. At month 12, AMG 162 increased lumbar spine BMD 4% to 7% in all groups (alendronate 5%). Total hip BMD change for the 60-mg, q6mo AMG 162 group was greater than alendronate ($p < 0.001$) (Figure). AMG 162 had a positive effect on mainly cortical bone sites, distal 1/3 radius and total body.



AMG 162 given 3-monthly also was effective. A rapid (72 hours), dose-dependent decrease of serum C-telopeptide and urine N-telopeptide/creatinine occurred with AMG 162. AMG 162 was well tolerated. The most common adverse event in any group was dyspepsia (4%, 5%, and 20% in the placebo, AMG 162, and alendronate groups, respectively). One (0.3%) subject (14 mg AMG 162) had a transient, asymptomatic decrease in albumin-adjusted serum calcium below 8 mg/dL (7.8 mg/dL at month 2). No other clinically meaningful laboratory changes occurred. Non-neutralizing anti-AMG 162 antibodies occurred at month 1 for 1 (0.3%) subject, but did not persist. Two fractures (traumatic vertebral and ankle) occurred in the AMG 162 groups.

In summary, AMG 162 increased BMD within 1 month in postmenopausal women and appeared to be more effective than alendronate at cortical bone sites.

New Insights into Bone Extracellular Matrix Assembly from Dynamic Computational Imaging in Living Osteoblasts. P. Sivakumar[1], B. J. Rongish*[2], A. Czirok*[2], V. P. Divakara*[1], S. L. Dallas[1]. [1]Univ. of Missouri, Kansas City, MO, USA, [2]Univ. of Kansas Medical Center, Kansas City, KS, USA.

Bone extracellular matrix (ECM) has been classically viewed as a static scaffold that supports cells and tissues. However, using dynamic imaging in living osteoblast cultures we have shown that the ECM is highly elastic and undergoes large dynamic movements associated with cell motility. We have also shown that fibronectin is a key regulator for assembly of multiple bone ECM proteins. To gain further insights into the kinetics of bone ECM assembly and the role of fibronectin, we have performed time lapse imaging in living osteoblasts using fluorescent probes for fibronectin and other bone ECM proteins and have developed computational techniques to correlate cell and fibril movement. Time lapse imaging revealed that fibronectin was initially incorporated onto the cell surface as punctate spots, resembling focal adhesions, which then coalesced progressively to form fibrils. Individual fibrils received contributions from cells that could be quite distant (up to 100µm) from the forming fibril. Pulse-chase dynamic imaging using green followed by red fluorescent fibronectin showed that newly incorporated fibronectin did not assemble onto existing fibrils. Instead it was localized in focal spots on the cell surface which then redistributed over the next 24 hours to become colocalized with preexisting fibronectin fibrils. This reorganization was inhibited by jasplakinolide, an actin destabilizing agent, suggesting that cell motility is critical for reorganization of newly incorporated fibronectin. Next we performed dual imaging of fibronectin and latent TGF beta binding protein-1, an ECM glycoprotein responsible for storage of TGFβ in bone. Time lapse movies in living osteoblasts revealed a surprising amount of cell and fibril movement even after 12 days in culture, resulting in continual stretching and contracting of fibrils. Cells appeared to actively contribute to ECM assembly by adding "packets" of ECM material onto growing fibrils. In addition there were many examples where fibrillar material appeared to be exchanged between fibrils, suggesting a novel mechanism for ECM reorganization. Image analysis showed that individual fibrils could stretch up to twice their length and contract as much as 75%. Occasionally fibrils were seen to break and recoil, suggesting that they exist in a highly stretched state. Analysis of cell and fibril movement by vector displacement mapping showed that the movement of cells and fibrils was correlated in magnitude and direction. These data suggest a major role for cell motility in assembly of bone ECM proteins and suggest novel cell mediated mechanisms for ECM reorganization.

Glucocorticoids Induce Osteocyte Death by Blocking Focal Adhesion Kinase Survival: Evidence for Inside-Out Signaling Leading to Cell Detachment-Induced Apoptosis (Anoikis). L. I. Plotkin, L. Dominguez, K. Vyas*, J. I. Aguirre, S. C. Manolagas, T. Bellido. Endocrinology, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. Arkansas for Med. Sci., Little Rock, AR, USA.

Premature apoptosis of osteocytes by direct actions on these cells contributes to the bone fragility syndrome that characterizes glucocorticoid (GC)-induced osteoporosis. However, the mechanism of this phenomenon remains unknown. The GC dexamethasone (dex) induces apoptosis of osteocytic MLO-Y4 cells, which is prevented by caspase 3 inhibitors. We now report that dex-induced apoptosis is abolished by the GC receptor antagonist RU486, it is not affected by inhibitors of protein or RNA synthesis and it is preceded by changes in cell shape leading to detachment. Thus, dex increased the percentage of cells exhibiting 3 or less cytoplasmic projections at expenses of a decrease in cells with more than 4 projections. Both cell survival and shape are controlled by the focal adhesions, sites at the plasma membrane in which integrins assemble with cytoskeletal and signaling molecules such as the focal adhesion kinase (FAK). FAK promotes attachment and survival, whereas the related protein proline-rich tyrosine kinase 2 (Pyk2) has the opposite effects. We found that cells overexpressing FAK were protected from dex-induced apoptosis. On the other hand, cells overexpressing Pyk2 were as responsive to dex as vector transfected cells. However, cells expressing either a kinase-deficient (Lys457Ala) or an authophosphorylation-defective (Tyr402Phe) Pyk2 were refractory to dex-induced apoptosis. Consistent with this, dex induced rapid Pyk2 phosphorylation in Tyr402; and knockdown Pyk2 expression with small interference RNA abolished the proapoptotic effect as well as the changes in cell shape induced by dex, whereas transfection with human Pyk2 rescued both responses. Furthermore, the proapoptotic effect of dex was abolished by inhibiting JNK activity - a known mediator of Pyk2 actions - with SP600125; but it was not affected by inhibiting other kinases involved in apoptosis regulation, such as p38, ERKs, Src, or PI3K. Moreover, inhibition of JNK activity also abolished the effect of dex on cell shape. In sharp contrast, although inhibition of caspase 3 with DEVD abolished dex-induced apoptosis, it did not reverse its effect on cell shape, indicating that changes in cellular morphology precede caspase 3 induction and apoptosis. We conclude that GC promote osteocyte apoptosis via a receptor-mediated mechanism that do not require gene transcription and that is mediated by Pyk2 and JNK, followed by inside-out signaling which favors cell detachment-induced apoptosis or anoikis.

Osteocrin, a Local Mediator of the Natriuretic System. G. P. Thomas, K. Sellin*, M. Bessette*, F. Lafreniere*, C. Lanctot*, P. Moffatt*. Phenogene Therapeutics, Montreal, PQ, Canada.

The natriuretic system, important in regulation of vascular tone and cardiovascular homeostasis, also acts on the skeleton. Control is exerted through 3 peptides, ANP, BNP and CNP, and 3 receptors, GC-A and GC-B which are guanylate cyclases producing cGMP, and NPR-C the clearance receptor. CNP- and BNP-transgenic mice and NPR-C knockout mice have elongated bones and marked kyphoses whereas CNP-knockout mice exhibit dwarfism. We previously identified an osteoblast lineage protein, osteocrin (Ostn) which has no clear homology with any other protein group except for limited C-terminal homology with the natriuretic peptides.

Thus, we hypothesised that Ostn could interact with members of the natriuretic receptor family thereby modulating natriuretic peptide actions on the skeleton. To investigate Ostn binding to the natriuretic receptors we generated a fusion protein consisting of an N-terminal secreted placental alkaline phosphatase moiety linked to mouse Ostn (PLAP-Ostn). Binding studies showed that PLAP-Ostn binds specifically and saturatably to the NPR-C receptor with no binding to the GC-A or GC-B receptors. Further, PLAP-Ostn can be competed off NPR-C with either cold ANP or cold mn306C, a synthetic C-terminal Ostn peptide. We then investigated the ability of Ostn to augment the activity of natriuretic peptides. Overexpression of NPR-C in HEK293 cells (which express endogenous GC-A) inhibited ANP-stimulated increases in intracellular cGMP production. However, when cells overexpressing NPR-C were co-treated with ANP and Ostn or mn306C, the effects of ANP activity were greatly increased. These results suggest that Ostn can modulate the hormonal response of cells to natriuretic peptides by limiting their clearance through NPR-C. To investigate the role of Ostn *in vivo* we generated transgenic mice overexpressing Ostn in osteoblastic cells using the collagen type I 3.6kb promoter. These mice displayed elongated bones and a marked kyphosis. Further, cGMP levels were elevated in the bones of the transgenic mice suggesting elevated natriuretic peptide activity contributed to the increased bone length.

Thus we have demonstrated that Ostn is a naturally occurring antagonist of the NPR-C clearance receptor and may act to locally modulate the actions of the natriuretic system in the skeletal compartment. Interestingly, we and another group have also observed Ostn expression in other mesenchymal tissues such as tendons, ligaments and muscle suggesting Ostn may play a more general role in mediating the local actions of the natriuretic system in mesenchyme tissue.

Mechanical Stress Dependent Remodeling of the Periodontal Ligament Is Defective in Periostin Deficient Mice; Mechanotransduction through Periostin Protein. I. Kii*[1], N. Amizuka[2], S. Kitajima*[3], M. Li*[2], K. Takeuchi*[2], T. Maeda*[2], J. Kanno*[3], T. Inoue*[3], Y. Saga*[4], A. Kudo[1]. [1]Department of Biological Information, Tokyo Institute of Technology, Yokohama, Japan, [2]Department of Oral Biological Science, Niigata University Graduate School of Medical and Dental Science, Niigata, Japan, [3]Division of Toxicology, National Institute of Health Science, Tokyo, Japan, [4]National Institute of Genetics, Division of Mammalian Development, Mishima, Japan.

The secreted matricellular protein, periostin is specifically expressed in the periodontal ligament and the periosteum in adult mice, and is postulated as a cell spreading factor to matrix. The periodontal ligament is involved in the tooth eruption and the orthodontic tooth movement. To investigate the function of periostin in the periodontal ligament, we generated periostin-/- mice and found that -/- mice are born and grow normally, however, during aging from 6 to 12 weeks old -/- mice showed abnormal incisors, disorganized ameloblastic layer and deformed enamel matrix because of disappearance of the shear zone in the incisor periodontal ligament. Electron microscopic analysis of the periodontal ligament in -/- mice showed no matrix remodeling but accumulated matrix fiber with type I collagen. Excision of incisors demonstrated that in -/- mice, no tooth eruption was observed. Moreover, the experimental molar movement revealed that at the compressed side of the periodontal ligament in -/- mice, hyalinized extracellular matrix induced by compression largely remained, although it was removed from +/+ mice. The results suggested that periostin functions in remodeling of the periodontal ligament, specifically in matrix degradation and metabolism in response to compressive mechanical stress. In in-vitro analyses using the purified periostin protein, we revealed that periostin bound to type I collagen mediated with the cysteine-rich N-terminal region of periostin, and matrix-free periostin was endocytosed into 10T1/2 cells to give rise to phosphorylation of ERK. We speculate that mechanical stress unfasten the periostin cysteine-rich domain binding to collagen matrix, then periostin is endocytosed and acts on the hyalinized matrix degeneration through the MAPK activation. Taken together, periostin functions as a mechanosensor in the remodeling of periodontal ligament.

Insertional Mutagenesis of Osteopotentia, a Novel Transmembrane Protein Essential for Skeletal Integrity. M. L. Sohaskey*[1], Y. Jiang[2], J. Zhao[2], A. Mohr*[2], F. Roemer*[2], H. K. Genant[2], W. C. Skarnes*[1]. [1]Molecular and Cell Biology, University of California, Berkeley, CA, USA, [2]Osteoporosis and Arthritis Research Group, University of California, San Francisco, CA, USA.

Strict coordination of bone remodeling processes is essential for skeletal integrity and homeostasis. Deregulation of these processes leads to pathophysiological changes and metabolic bone disease. In an insertional mutagenesis screen for critical regulators of mammalian development and physiology, we identified *Osteopotentia* (*Opt*), a gene encoding a novel transmembrane protein. We have investigated the consequences of *Opt* mutation for postnatal skeletal development using a combination of genetic, biochemical, histological and radiological approaches. Mice homozygous for an insertional mutation in the *Opt* gene die predominantly at birth of undetermined causes. A subset of these mice, however, survive for up to twenty days and develop striking skeletal abnormalities similar to those seen in humans and genetically engineered mouse models having severe forms of the brittle bone disease osteogenesis imperfecta. Abnormalities include inflammation and hemorrhaging around limbs, bowing deformities of the long bones, and poorly healed fractures evidenced by the formation of hypertrophic calluses on long bones and ribs. Histological analyses reveal a marked decrease in the amount of trabecular and cortical bone in surviving *Opt* homozygous mutant mice relative to normal littermates. Likewise, quantitative dual-energy x-ray absorptiometry (DEXA) and micro-CT imaging demonstrate a significant reduction in total bone mineral density as well as 3D trabecular bone volume fraction, number and thickness, with an increase in 3D trabecular spacing. Biochemical assessment of serum and urine parameters reveals that *Opt* homozygous mutants are hypercalciuric and hypophosphaturic, despite having normal serum calcium and phosphate levels. Finally, decreased levels of osteocalcin mRNA and protein in bone and serum, respectively, suggest that *Opt* homozygous mutants may manifest a defect in osteoblast differentiation and/or activity. Overall, elucidation of the physiological role played by Opt will be important in determining how mutagenesis of this novel gene results in severely compromised skeletal integrity in the mouse. Our studies may thus provide mechanistic insight into the etiology of recessively inherited forms of osteogenesis imperfecta demonstrating no genetic linkage to either type I procollagen locus. Moreover, our results may have important therapeutic implications for the clinical understanding, prevention and treatment of idiopathic hypercalciuria.

Biglycan and Decorin Are Essential for Post-Natal Fronto-Nasal Craniofacial Growth and Development. S. Wadhwa, M. Embree*, Y. Bi*, M. Young. Csdb, NIDCR/NIH, Bethesda, MD, USA.

Biglycan (BGN) and decorin (DCN) are members of a family of proteins known as SLRPs (Small leucine rich proteoglycans). They are believed to have similar physiologic roles important for growth factor binding and function. Thus, the absence of one SLRP may be compensated for by the presence of another. The objective of this study was to determine whether BGN and /or DCN play a role in craniofacial growth and development by characterizing their expression at various stages of development, and examining the phenotype of mice deficient in one or both small proteoglycan. At embryonic day (ED) 18.5 biglycan and decorin were found to be abuduntantly expressed in the craniofacial complex. ED 18.5 day embryos deficient for biglycan and decorin had no craniofacial abnormalities compared to wildtype (WT) littermates. However, ED 18.5 double knock out (DKO) embryos were severely hypomineralized in the frontal bone compared to the control littermates. In the adult mice, biglycan and decorin were also found to be expressed throughout the craniofacial complex. In particular, in the calvarial sutures, biglycan appeared in the fusing bone fronts while decorin was highly expressed in the dura underlying the fusing sutures. Adult 60 day-old mice deficient in either biglycan or decorin did not have a craniofacial phenotype. However, the DKO mice had a severe phenotype. The DKO skulls were 40 % smaller in the anterior-posterior direction compared to WT. In normal mice, the posterior frontal suture normally fuses within 25-45 days after birth. Analysis of 60 day-old DKO mice showed that the posterior frontal sutures were completely patent and lacked symmetry compared to WT controls. In addition there was also disorganization in the olfactory structures. In particular there was hypoplasia of the olfactory epithelia and irregular shape of the nasal bones. In order to determine the molecular basis for the craniofacial defects in the DKO mice, we examined the expression of several genes previously shown to control olfactory and/or calvarial suture development. In these experiments bone marrow stromal cells were isolated from normal and DKO mice, treated with TGF-beta and mRNA expression profiles measured by semi-quantitative RT PCR. One factor, DLX5, was significantly reduced and dysregulated by TGF-beta, a factor that is overactive in the DKO cells. We conclude that biglycan and decorin potentially control postnatal frontonasal craniofacial growth and organization through a molecular link to DLX5 signaling pathways.

Van Buchem Disease Mouse Models and Genomic Comparisons Reveal a Bone-specific Enhancer Regulating Sclerosteosis Causing Gene SOST. M. Kneissel[1], H. J. Keller*[1], M. Baptist*[1], E. M. Rubin*[2], G. G. Loots[3]. [1]Bone Metabolism, Novartis Institutes for BioMedical Research, Basel, Switzerland, [2]JGI, Walnut Creek, CA, USA, [3]Genomics Division, LLNL, Livermore, CA, USA.

Sclerosteosis is a generalized progressive bone overgrowth disorder due to the loss of function of the SOST gene product sclerostin (SOST). Affected patients display increased bone formation, while bone resorption is undisturbed. Van Buchem disease (VB) is a very similar skeletal abnormality associated with a ~52kb noncoding deletion downstream of the SOST transcript. It has been proposed that VB is caused by misregulating SOST transcriptional activity. We have tested this hypothesis by analyzing the expression pattern of human SOST in transgenic mice carrying either normal alleles (hSOSTwt) or genetically modified VB alleles (hSOSTvbd) cloned from human BACs. Several independent lines of transgenic hSOSTwt and hSOSTvbd animals were obtained and characterized. Similar to the endogenous murine SOST expression, human SOST transcripts were robustly expressed in bone of adult hSOSTwt but not of hSOSTvbd mice. DEXA, microCT and histomorphometric analysis of the skeleton of 5-month-old animals revealed that increased doses of human SOST resulted in osteopenia and reduced bone formation rates in the axial and appendicular skeleton in hSOSTwt but not in hSOSTvbd mice, whose bone mass and structure were indistinguishable from wild-type control mice. In contrast, elevated embryonic SOST expression resulted in dose-dependent digit abnormalities in both hSOSTwt and hSOSTvbd transgenic mice, suggesting the presence of different tissue specific enhancers. To search for regulatory elements within the 52kb VB deletion that drive bone-specific sost expression a cross-species human-mouse sequence comparison was performed for conserved sequences. The seven most highly conserved sequences (>200bp length; >80% identity; CNS2-8) were tested for the ability to stimulate the SV40 promoter in an osteoblastic and a control kidney cell line, both expressing high levels of endogenous SOST. Only CNS5 significantly activated transcription in the osteoblastic but not in the kidney cells. Furthermore, CNS5 was also able to stimulate the human SOST promoter (2kb upstream sequence) and to drive bone-specific reporter gene expression in transient transgenic mice. Thus, we have identified an enhancer element within the VB deletion that drives SOST expression in the mouse skeleton.

Congenic Mice with Low Serum IGF-I Have An Impaired Osteoblast Differentiation Program as well as Increased Body and Marrow Adiposity. C. Ackert-Bicknell[1], M. C. Horowitz[2], T. Nelson*[2], K. L. Shultz[1], V. E. Guido*[1], L. R. Donahue[1], M. L. Bouxsein[3], M. L. Adamo[4], W. G. Beamer[1], C. J. Rosen[1]. [1]The Jackson Laboratory, Bar Harbor, ME, USA, [2]Yale University School of Medicine, New Haven, CT, USA, [3]Beth Israel Medical Center, Boston, MA, USA, [4]University of Texas Health Center, San Antonio, TX, USA.

We previously reported 4 Quantitative Trait Loci (QTLs) for serum IGF-I on Chr 1, 6, 10 and 15. The B6.C3H-6T (6T) congenic strain is a C57BL/6J (B6) mouse carrying a portion of the C3H/HeJ (C3H) from Chr 6 (*D6Mit93* to *D6Mit150*). It has reduced serum IGF-I, a smaller periosteal circumference, shorter femurs and reduced BMD compared to B6. The 6T strain also has a lower bone formation rate and nearly a 50% reduction of IGF-I mRNA in adult bone ($p<0.05$). In order to further understand this skeletal phenotype, we investigated osteoblast (OB) precursor number and their differentiation in bone marrow stromal cell (BMSC) cultures from B6 and 6T mice as well performing candidate gene analysis. Adherent BMSC were cultured with guinea pig BM feeder cells in α-MEM with 10%FCS and ascorbate. OB progenitor colonies were stained with alkaline phosphatase (CFU-AP+) and counter stained with crystal violet (CFU-F). At 7, 10 and 15 days, 6T BM revealed there were less CFU-Fs ($p<0.007$) and less CFU-AP+ colonies ($p<0.0001$) than B6. We then assessed Runx2 expression, by Quantitative Real Time PCR (QPCR), using a Global Pattern Recognition algorithm to assess statistical significance. Runx2 mRNA was decreased in femur (-1.52 fold in 6T vs B6) from 8 wk old females as well as BMSC cultures (-1.32 fold in 6T vs B6). Co culture of stromal cells with BM or spleen cells reveal no strain differences in the generation of osteoclast-like cells (by TRAP). 6T females weigh less ($p=0.006$) than B6 at 16 weeks, but have higher percent body fat (B6:17.5 ± 0.50; 6T: 20.5±1.0 $p=0.02$). These mice also have significantly more marrow fat than B6 by Oil Red 0 staining ($p=0.05$). The 6T congenic region is very large (25cM) and contains > 500 genes. To quickly narrow this list, we used block haplotyping with SNPs and SSLPs makers to excluded genomic regions where B6 was identical to C3H. Further power was added to this analysis by adding the A/J strain, which does not have a serum IGF-1 phenotype mapped to Chr 6. We were able to narrow our region to two haplotype blocks (<2cM) on distal Chr 6, containing 11 known genes and 39 novel or predicted genes. By QPCR we have identified two potentially important candidate genes on Chr 6 involved in OB differentiation. In conclusion, 6T mice have increased body and marrow adiposity, along with impaired OB differentiation and reduced BMD due to allelic differences in a gene on Chr 6 that suppresses skeletal IGF-I and impacts OB differentiation.

Genetic Association Studies of the Human Arachidonate Lipoxygenase Genes, *ALOX12* and *ALOX15*, with Peak Bone Mineral Density. S. Ichikawa*[1], D. L. Koller[2], M. L. Johnson*[1], D. Lai*[2], R. F. Klein[3], E. S. Orwoll*[3], S. L. Hui[1], C. C. Johnston[1], T. M. Foroud[2], M. Peacock[1], M. J. Econs[1]. [1]Medicine, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA, [3]Bone and Mineral Research Unit, Oregon Health & Science University, Portland, OR, USA.

The arachidonate 15-lipoxygenase (*Alox15*) gene was recently identified as a negative regulator of peak bone mineral density (BMD) in mice. At the protein level, mouse Alox15 has the highest identity to its human homolog ALOX15 (73%), followed by arachidonate 12-lipoxygenase (ALOX12) (57%). However, mouse Alox15 is functionally more similar to human ALOX12 as both enzymes preferentially oxygenate arachidonic acid at carbon-12, instead of carbon-15. To determine the contribution of the lipoxygenase genes to peak BMD variation in normal subjects, we performed population- and family-based genetic association studies in Caucasian sibpairs ascertained in Indiana. Analysis of genome screen marker data from this sample demonstrated minimal inflation of the false positive rate of association tests due to population stratification (JBMR, in press). BMD was measured at proximal femur and lumbar spine in 190 men, aged 20-61 and 588 women, aged 21-52. We tested five and seven single nucleotide polymorphisms (SNPs) distributed across *ALOX15* and *ALOX12*, respectively. SNP genotyping was performed using matrix-assisted laser disorption/ionization time-of-flight (MALDI-TOF) mass spectrometry of allele-specific primer extension products. No statistically significant association was found between the five *ALOX15* SNPs and peak BMD variation. In contrast, moderate evidence for association was found with six SNPs in the *ALOX12* gene. Five allelic variations in the 5' region were significantly associated with spine BMD in both men and women ($p=0.0041$-0.057). These genetic variations may account for 0.5-2.8% and 0.5% of BMD variation in men and women, respectively. The most common haplotype, composed of these 5 SNPs, was also associated with spine BMD in men ($p=0.019$). Of note, there were two nonsynonymous SNPs in exons 6 and 8 of *ALOX12*, which change encoded residues, Arg261Gln and Ser322Asn, respectively. Further, genetic variation with the highest association, accounting for 2.8% of the variation in men, was located within 300 bp upstream of the gene, suggesting that the regulatory element in the promoter region may influence *ALOX12* expression. In light of the recent finding in mice, association between *ALOX12* alleles and peak BMD variation suggests a role for this gene or another in linkage disequilibrium with *ALOX12*, in the development of peak BMD in men and women.

Bone Formation Phenotype in Cathepsin K Null Mice. B. Pennypacker, D. B. Kimmel. Bone Biology and Osteoporosis, Merck Research Laboratories, West Point, PA, USA.

Cathepsin K (CatK), a cysteine protease that degrades Type I collagen, is highly and selectively expressed in osteoclasts. Adult CatK null mice have osteopetrosis with hypofunctional osteoclasts that appear to have reduced ability to degrade bone matrix. Bone strength of CatK null mice is increased in proportion to the increased bone mass. The purpose of this study is to evaluate bone formation in CatK null mice.

Fifty mice of both genders, including wild type homo- and heterozygotes, aged 4.5 months were necropsied after *in vivo* dual calcein labeling. Right femora were fixed in 70% ethanol. The distal femur was embedded non-decalcified in methyl methacrylate. Bone volume (BV/TV, %), trabecular thickness, trabecular number, mineral apposition rate (MAR, μm/d), mineralizing surface (MS/BS, %), and bone formation rate were determined in 6μm, unstained sections of cancellous bone. Data were analyzed by two-factor ANOVA (gender/genotype) plus Neuman-Keuls post-hoc testing within gender.

Bone volume, reflected as both increased thickness and number of trabeculae, was influenced positively by genotype ($P<.001$). Both osteoblast activity (MAR) and extent of formation surface (MS/BS) were also influenced positively by genotype ($P<.001$). Both were also increased in female as comapred to male mice.

The osteopetrosis seen in cancellous bone of adult CatK null mice was accompanied by an unexpectedly high rate of bone formation. Based on ultrastructure and the increased bone mass, it has previously been inferred that osteoclasts in CatK null mice are hypofunctional. Usually, when resorption is inhibited, bone formation is similarly reduced due to coupling. The CatK null mouse disobeys this paradigm, since bone resorption rate is decreased while bone formation rate remains high. This finding may suggest that CatK plays a role in the coupling of resorption and formation that is usually present in adult bone tissue.

Bone Formation and Bone Volume

Congenic Mice from Chromosome 1 Reveal Sex-Specific Differences in Vertebral Trabecular Bone Volume Fraction and Microarchitecture. J. Swenson*[1], K. L. Shultz[2], C. J. Rosen[2], L. Donahue[2], W. J. Beamer[2], M. L. Bouxsein[1]. [1]Beth Israel Deaconess Medical Center & Harvard Medical School, Boston, MA, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

Low BMD is among the strongest risk factors for osteoporotic fracture, and growing evidence indicates that a large portion of the variability in adult BMD is genetically determined. Identification of genes that regulate bone density may improve diagnosis and promote development of novel interventions. We and others have used inbred strains of mice to established heritability and identify quantitative trait loci (QTL) for several skeletal features. Specifically, we used genome-wide analysis of an F2 intercross of C57BL/6J (B6) and C3H/HeJ (C3H) mice to identify QTL associated with several traits (1), including two QTL on Chr 1 that were associated with vertebral trabecular bone volume fraction (BV/TV) (3). To further evaluate the influence of these QTL, we generated a congenic mouse strain wherein the initial QTL chromosomal region from C3H was introgressed into the B6 background for 10 generations, and then nested sublines were created by genetic decomposition of this region (2). To test the effect of the Chr1 QTL on vertebral trabecular bone, we used microCT to compare trabecular BV/TV and microarchitecture in L5 vertebrae from 4-month old B6 controls (n=24 F, 21 M) and 8 Chr1 congenic sublines (n=7-10 per subline and sex). Analysis of the congenic sublines revealed that compared to B6 controls, BV/TV was about 10% lower in M and F mice carrying a proximal portion of Chr 1 (25 to 62 centiMorgans (cM) distal to the centromere, $p=0.0008$ to 0.04). This decreased BV/TV was accompanied by a lower trabecular thickness in F (-6.5%, $p=0.01$), and a lower trabecular number in M (-7%, $p=0.003$). In comparison, F congenic mice carrying a distal portion of Chr 1 (71 to 109 cM) had 28% higher BV/TV than B6 controls ($p<0.0001$). This increased BV/TV was accompanied by an increased number of trabeculae (+24%, $p<0.0001$), but no change in the mean trabecular thickness, and persisted after adjusting for the higher body weight observed in mice from this subline. In contrast, male congenic mice carrying a distal portion of Chr 1 exhibited lower BV/TV than B6 controls (-15%, $p=0.007$), primarily attributable to a decline in trabecular thickness (-10%, $p=0.008$). In summary, decomposition of QTL regions by congenic sublines can be used to verify QTL, and to refine their genomic locations. Interestingly, male and female mice show different regulation of vertebral trabecular bone, providing strong rationale for further study of genetic and hormonal contributions to trabecular bone mass and microarchitecture.

Sex Differences in Skeletal Development Are Independent of the Complement of Sex Chromosomes. R. F. Klein[1], D. C. Dinulescu*[1], D. A. Olson*[1], E. A. Larson*[1], L. Lambert[1], T. Yang*[2], R. Bijlani*[2], A. P. Arnold*[2], E. S. Orwoll[1]. [1]Bone and Mineral Unit, Oregon Health & Science University, Portland, OR, USA, [2]Department of Physiological Science, University of California, Los Angeles, CA, USA.

Sex exerts a profound effect on the skeleton, especially peak bone size and mass. Since the male phenotype is associated with considerable fracture risk reduction, an understanding of the genetic basis for the male-female divergence in bone development is of significant interest. The aim of this study was to determine if sex differences in skeletal development are the result of gonadal hormones, or alternatively the result of an effect of genes encoded on the sex chromosomes. We examined 20-wk-old mice that were normal males or females, as well as mice in which the testis-determining gene (Sry) had been deleted from the Y chromosome and inserted as a transgene on an autosome to produce XX-Sry+ animals that possessed testes, or XY-Sry- animals that possessed ovaries. In addition, all animals in each group underwent gonadectomy (GDX) or sham operation at 4 weeks of age (n= 12-20 per group). Thus, this model allowed assessment of the role of sex chromosome genes, independent of gonadal hormones, in the ontogeny of sex differences in the mouse skeleton. Whole body bone density and body composition was assessed by DEXA, femoral bone geometry was determined with microCT, and biomechanical properties of the femoral shaft were determined by 3-point bending. As expected sex differences ($p < 0.05$) were observed in body weight, lean body mass (LBM), femoral shaft geometry (marrow area, cortical area and thickness) and bone strength parameters (ultimate failure load, stiffness and modulus). For each of these differences, mice possessing testes were invariably more masculine in their skeletal morphology, independent of their sex chromosome chromosomes (XX vs. XY), than mice with ovaries. In all 4 groups of mice, GDX resulted in greater femoral length, and reduced bone density and strength measures (failure load and modulus). There was no evidence that sex chromosomes affected the response to gonadectomy. These data strongly suggest that sex differences in skeletal development are under the control of gonadal steroids rather than genes located on sex chromosomes. The origins of sex differences in skeletal traits should be sought in physiological pathways related to gonadal hormone action.

cAMP/PKA Transactivation of Murine 1-hydroxylase in Renal Proximal Tubular Cells Requires Enhanced C/EBPβ Transcriptional Activity at a C/EBPβ Binding Site, a Process Antagonized by Ligand-activated VDR. T. Sato*, J. Yang*, L. Esteban*, A. Dusso. Internal Medicine/Renal, Washington University, St. Louis, MO, USA.

1-hydroxylase catalizes the main step in vitamin D activation to 1,25-dihydroxyvitamin D (1,25D), a potent calcitropic hormone. To maintain calcium homeostasis, renal 1-hydroxylase is induced by PTH and inhibited by 1,25D. PTH transactivates the1-hydroxylase gene through a cAMP/PKA mediated mechanism, which is inhibited by 1,25D. To delineate the mechanisms underlying the transactivation of 1-hydroxylase by cAMP and its inhibition by 1,25D, the murine renal proximal tubule cell line MCT was transfected with luciferase reporter contructs driven by the whole murine 1-hydroxylase promoter [-1652+22], which contains three putative cAMP responsive sequences (CRE), as well as 5'-deletion contructs. Surprinsingly, the response to 1mM dibutyryl cAMP in inducing 1-hydroxylase promoter activity mapped to a CRE-less minimal promoter [-85+22] that contains a putative C/EBPβ-binding site. Mutations of three base pairs in the core C/EBPβ binding site eliminated cAMP transactivation of the minimal promoter. Furthermore, neither ectopic CRE-binding protein (CREB) expression nor the expression of a dominant-negative CREB isoform affected cAMP induction of either whole or minimal [-85+22] promoter activity. Consistent with a C/EBPβ-mediated transactivation, ectopic C/EBPβ expression enhanced both basal- and cAMP-induced minimal promoter activity. Both C/EBPβ actions were inhibited by simultaneous co-expression of C/EBPβ and its dominant negative isoform, which lacks C/EBPβ transactivation domain. Studies using the specific inhibitors for PKA (H89) and MAPK (U0126) before cAMP treatment demonstrated that cAMP activation of PKA is mandatory for cAMP induction of de novo C/EBPβ expression, whereas both PKA and MAPK activate C/EBPβ nuclear translocation and transactivating potential in response to cAMP treatment. The finding that cAMP transactivation of 1-hydroxylase in MCT cells requires C/EBPβ activation and binding to a C/EBPβ site in the minimal promoter led us to examine whether 1,25D-inhibition of cAMP-transactivation of 1-hydroxylase involved a direct antagonism on C/EBPβ transactivating potential. Ectopic expression of VDR, in a ligand-dependent fashion, inhibited both cAMP induction of minimal promoter activity and the cooperative enhancement by ectopic C/EBPβ of the response to cAMP. These studies reveal a novel cross talk between C/EBPβ and the vitamin D endocrine system. cAMP/PKA transactivation of 1-hydroxylase requires enhanced C/EBPβ transcriptional activity at a C/EBPβ binding site, a process directly inhibited by ligand activated VDR.

Estrogenic Control of the MHC Class II Transactivator in Vivo through Chromatin Remodelling. E. Benasciutti*[1], L. Oliva*[1], W. Reith*[2], S. Cenci[1]. [1]Dibit, San Raffaele Scientific Institute, Milano, Italy, [2]University of Geneva Medical School, Geneva, Switzerland.

Estrogen (E) withdrawal has been reported to induce osteoclastic bone resorption and bone waste through enhanced MHC class II expression by bone marrow macrophages (BMM), resulting in enhanced T cell activation and production of inflammatory cytokines. An increased induction of the MHC class II transactivator (CIITA), the molecular switch of MHCII genes, has been proposed to underlie such effects. We thus investigated the nature of the suppressive effect of E on CIITA gene expression.

We adopted chromatin immunoprecipitation (ChIP) and real-time PCR on cross-linked samples from primary purified BMM from ovariectomized mice and sham-operated controls to analyze histone modifications and recruitment of cofactors at the CIITA regulatory region. The analysis of global post-translational modifications at the amino-terminal tails of histones H3 and H4 on CIITA promoter IV (pIV), the main promoter responsible for CIITA induction, revealed a selective and profound hyperacetylation of histone H3 in E deficiency. A wider analysis showed that histone acetylation is increased by E withdrawal in the whole CIITA regulatory region. The analysis of key modifications of single aminoacid residues within H3 tail revealed that E in vivo specifically represses acetylation of lysine 9 and methylation of lysine 4, two modifications known to potently activate transcription. ChIP analysis was also adopted to identify the cofactors involved in the observed modifications. We found that E deficiency greatly increases recruitment of the key histone acetyl transferase CREB binding protein (CBP) to the CIITA promoter.

Furthermore, we aimed at defining the in vivo role of pIV in mediating the suppressive effect of E on CIITA expression by utilizing CIITA pIV deficient mice. In primary wild-type BMM E suppressed by over 70% CIITA mRNA induction by IFNγ in vitro (as assessed by real time RT-PCR). Conversely, E failed to suppress CIITA induction in pIV deficient BMM, indicating a key role of pIV in mediating the suppressive effect of E in vivo on CIITA expression.

Taken together, our data describe a pattern of histone modifications and cofactor recruitment underlying the control exerted by E on CIITA transcription and MHCII expression. The data provide insights towards a better understanding of the molecular interplay between E, inflammation, and bone homeostasis.

The Importance of Nuclear Localization in Ligand-Mediated Protection of the Vitamin D Receptor (VDR) from Ubiquitination and Proteasome-Mediated Degradation. S. Peleg[1], J. Hsieh[2], M. R. Haussler[2], C. V. Nguyen*[1]. [1]Endocrine Neoplasia & HD, M. D. Anderson Cancer Center, Houston, TX, USA, [2]Biochemistry, University of Arizona, Tucson, AZ, USA.

Recent studies from our laboratory have shown that susceptibility of the VDR to proteasome-mediated degradation depends on the cell type and on ligand structure. We found that in intestinal-derived Caco-2 cells the predominant form of VDR was resistant to proteasome degradation and shuttled between the chromatin and the cytoplasm in a ligand-independent fashion. In these cells, 1,25(OH)2D3 (1,25D3) but not the selective agonist Ro-26-9228 could induce the accumulation of a distinct proteasome-sensitive transcriptionally-active form of the VDR in the chromatin. In contrast, in the osteoblastic cells hFOB, the VDR was localized in the cytoplasm in the absence of ligand, but rapidly accumulated in the chromatin upon treatment with either 1,25D3 or the analog Ro-26-9228. Further studies suggested that ligand treatment caused the accumulation of a proteasome-sensitive VDR, which is the predominant form in hFOB cells. These results also suggested a linkage between nuclear import and ligand-dependent stabilization of the VDR against proteasome-mediated degradation. To further explore this possibility we used COS-1 cells transfected with hVDR and histidine-tagged ubiquitin expression vectors to determine which residues are necessary for VDR ubiquitination and what is the role of nuclear translocation in ligand-mediated protection of the VDR from degradation. We found that WT VDR was polyubiquitinated in the absence of ligand and that 1,25D3 diminished this modification. The analog Ro-26-9228 had no inhibitory effect on VDR ubiquitination. Deletion (410-427) or point mutations (V421M/F422A) in AF2 core diminished 1,25D3's ability to protect the VDR from ubiquitination. Deletion of residues 403-427 abolished VDR's ubiquitination, suggesting that ubiquitination signal may reside between residues 403-410. Mutations in the nuclear localization signal (R49W/R50G or K53Q/R54G/K55E) abolished the ability of 1,25D3 to protect the VDR from ubiquitination. Because neither the nuclear localization signal nor the AF-2 residues are required for high affinity binding of 1,25D3 to VDR, but both are necessary for ligand-dependent nuclear import of VDR, we concluded that C-terminal/AF-2 or DNA-binding domain mutations that diminish nuclear import of the VDR also cause a loss in the ability of 1,25D3 to prevent ubiquitination and proteasome-mediated degradation. These results also provide a foundation to the hypothesis that effective nuclear import machinery is essential to maintain transcriptionally active pool of the VDR.

The Human TRPV6 Distal Promoter Contains Functional Vitamin D Receptor Binding Sites that Mediate 1,25-Dihydroxyvitamin D3 Response in Intestinal Cells. M. Watanuki, S. Kim, N. K. Shevde, J. W. Pike. Biochemistry, University of Wisconsin- Madison, Madison, WI, USA.

Transient receptor potential vanilloid type 5 and 6 (TRPV5 and TRPV6) are members of a large superfamily of non voltage-gated cation channels that function as sensory detectors for environmental stimuli. TRPV6 (CaT1/ECAC2) encodes an epithelial calcium channel that is highly expressed in calcium transporting tissues such as the intestine. In this tissue, TRPV6 is localized to the apical membranes of mucosal epithelia where it is believed to mediate the uptake of calcium from the gut lumen, the rate limiting step in trans-epithelial calcium absorption. Indeed, recent studies reveal that this channel protein is regulated physiologically by 1,25-dihydroxyvitamin D3. The molecular basis for this regulation has yet to be defined, however. To explore this, we first established a model system in which 1,25(OH)2D3 induced TRPF6 mRNA expression in a typical time- and dose-dependent manner using cultured human intestinal Caco-2 cells. Next, we scanned the TRPV6 promoter for functional, 1,25(OH)2D3-induced VDR/RXR binding sites in intact cells using chromatin immunoprecipitation (ChIP) methods. We identified at least two such sites or VDREs located approximately 2.1 kb and 4.3 kb upstream of the start site of transcription. Small 200-400 bp fragments encompassing these two regions were then amplified from human genomic DNA, cloned into the luciferase expression vector pTK-luc and shown to mediate 1,25(OH)2D3-response in transfected Caco2 cells. Sequence analysis of these DNA fragments together with point mutagenesis in the pTK-luc/TRPV6 gene chimeras that resulted in abrogation of hormonal response verified the location of the two VDREs. These sites also bound the VDR/RXR heterodimer with high affinity, as assessed using DNA bandshift analysis. To confirm the functional nature of these elements in intact cells, we utilized ChIP to show that 1,25(OH)2D3-induced localization of the VDR/RXR heterodimer to this region of the TRPV6 gene also coincided with the time-dependent recruitment of the p160 coactivators SRC-1, SRC-2 and SRC-3 as well as selective acetylation of histone 4. These studies define two regions within the TRPV6 gene that contain regulatory sequences capable of mediating 1,25(OH)2D3's actions on TRPV6 gene expression. Interaction of both VDR and RXR at these sites leads to chromatin remodeling processes that are directly associated with increases in gene expression.

Estrogen and Vitamin D Utilize Common Transcriptional Machinery to Exert Transcriptional Inhibition. T. Okazaki, T. Fujita*. Division of Endocrinology and Nephrology, University of Tokyo, School of Medicine, Tokyo, Japan.

Expression of PTHrP gene is repressed by $1,25(OH)_2$ vitaminD_3 (abbreviated as vit.D) in various cell lines. On the assumption that the mechanism of gene inhibition by the liganded nuclear hormone receptors is conserved, we examined whether other nuclear hormones affect PTHrP gene expression. Here, by using RT-PCR, we report that 17β estradiol, like vit.D, inhibits PTHrP gene transcription, while dexamethasone, triiodothyronine and dihydrotestosterone were all transcriptionally inert in human breast cancer MCF7 cells. Both types of inhibition were recognized as early as 1h after administration of 10 nM of each hormone, which lasted 40h. Chromatin immunoprecipitation (ChIP) assay revealed that each hormone, respectively, recruited HDAC2 (histone deacetylase2) as well as DNA-dependent protein kinase (DNA-PK) to the chromatinized nVDREm, a half site of DR-3 type DNA element in the PTHrP promoter region. In both, recruitment of HDAC2, which first emerged 15 min after each hormone treatment and exhibited a cyclic occupancy pattern thereafter, displayed mirror image of histone acetylation around the nVDREm during the same time course. On the other hand, DNA-PK remained linked to the nVDREm region for 40h since its first appearance 15min after hormone treatment. The behavior of p300 histone acetyltransferase resembled that of acetylated histone3, while mSin3A was recruited in a way similar to HDAC2. The DNA spanning more upstream region of the PTHrP gene did not produce these patterns. Further, we found that transcriptional repression of the PTHrP gene by each hormone was abrogated after treatment of the cells with inhibitors of either HDAC or DNA-PK. We also observed that the mechanism of transcriptional repression is quite different from that of stimulation; we employed oligonucleotides surrounding the positive VDRE region in the 24,25vitamin D hydroxylase promoter or positive ERE in the PS2 promoter in ChIP assay using MCF7 chromatin. In these experiments, only cyclic acetylation of the histone surrounding nVDREm was recognized; neither HDAC2 nor DNA-PK gathered around these DNA after the treatment of each hormone. Finally, while VDR was consistently recruited to the nVDREm region irrespective of the presence of vit.D, the initial absence of the estrogen receptor (ER)α around the nVDREm region was followed by the periodical recruitment after 17β estradiol administration to the cells. In agreement with this finding, gel shift assay using appropriate antibodies showed that nVDREm binds directly to VDR, but not ERα. Taken together, we raise a possibility that estrogen and vit.D utilize some transcriptional machinery in common to exert nVDREm-mediated gene inhibition.

Docking Genomic and Non-Genomic Agonists to the Vitamin D Receptor Ligand Binding Domain: Discovery of a Novel Alternative Ligand Binding Site and Functional Validation. M. T. Mizwicki*, C. M. Bula*, J. E. Bishop, L. P. Zanello, A. W. Norman. Dept. Biochem., Univ. California, Riverside, CA, USA.

$1\alpha,25(OH)_2$-vitamin D_3 (1,25D) is known to activate genomic and non-genomic cellular signaling. While novel membrane receptors may exist that serve to bind and initiate rapid, non-genomic responses (RR), increasing evidence in the vitamin D receptor (VDR) and estrogen receptor (ER) fields suggests that the traditional nuclear receptor (NR) may also function as a RR receptor. To elucidate a mechanism describing how the VDR can function in both genomic and RR signaling we developed a molecular modeling protocol designed around the sterol structural attributes shown to be required in rapid opening of osteoblast chloride channels; these include a 3β-OH, 25-OH, and 6-*s-cis* sterol configuration. Docking the 6-*s-cis* locked, chloride channel agonist, $1\alpha,25(OH)_2$-lumisterol (JN) to the VDR LBD resulted in the discovery of an alternative ligand binding site (A-pocket). Calculated interaction energies (I_E) for JN, $25(OH)D_3$ (25D), and 1,25D docked in the partially overlapping x-ray, genomic pocket (G-pocket), or the proposed A-pocket provide a plausible molecular mechanism consistent with 1,25D, JN, and 25D chloride channel agonism as well as antagonism of the 1,25D response by $1\beta,25(OH)_2D_3$. Similarly, docking the RR specific ER agonist, 4-estren-3α,17β-diol (EST), indicates that ERα may also contain an A-pocket that EST prefers, possibly explaining its ER dependent RR effects in bone. Functional validation of the VDR A-pocket was obtained from assaying three vitamin D sterols that have different A-ring chemistries [3-deoxy-1,25D, 25D, and 1,25D] with VDR point mutants made in the overlapping region of the two pockets: Y143A, S237A, R274A, S278A, and Y143F/ S278A. Results show the ligands genomic responses (EC_{50}s) and VDR affinities are affected in a differential manner, consistent with the existence of the A-pocket. Of 20 analogs docked in the VDRwt A-pocket, 23S,25R-$1\alpha,25(OH)_2D_3$-26,23-lactone (BS) and 21-(3'-hydroxy-3'-methylbutyl)-$1\alpha,25(OH)_2D_3$ (KH) have the best I_E, 10 kcal/mol better than any other vitamin D sterol tested. Since ligands in the A-pocket do not directly contact helix-12, the presence of an A-pocket provides the first molecular evidence that explains why BS and KH have different protease sensitivity profiles than 1,25D. In summary, we propose that VDR and 1,25D both exist in multiple conformations that follow the standard laws of statistical distribution. The differential ligand affinities for the G- and A-pocket provide an explanation for how the VDR can function as a RR receptor as well as explain puzzling VDR/ vitamin D sterol structure/ function results.

Resveratrol Prevents Osteoclast Formation, Promotes Osteoblast Differentiation Markers and Inhibits Proliferation of Myeloma Cells. P. Boissy*[1], T. L. Andersen*[1], B. M. Abdallah*[2], M. Kassem[2], T. Plesner*[1], J. M. Delaisse[1]. [1]Clinical Research Unit (KFE) and Division of Hematology, Vejle Hospital, Vejle, Denmark, [2]Endocrinology and Metabolism, Odense University Hospital, Odense, Denmark.

A typical multiple myeloma patient shows proliferation of clonal plasma cells in the bone marrow, massive bone destruction, and reduced bone formation. It is a challenging task for the clinician to act simultaneously at each of these 3 different levels. We report here that each of these 3 processes are reversed by resveratrol (3, 4', 5 trihydroxystilbene), a natural compound that has recently drawn the attention because of its antitumor effects in various experimental systems.

First, resveratrol was tested on the proliferation of 2 human myeloma cell lines, RPMI 8226 and OPM2. After a 3-day culture, cell-numbers showed a 4- to 5-fold increase which was dose-dependently inhibited by resveratrol. Full inhibition was obtained at 100microM. Second, the effect of resveratrol on osteoclasts was investigated. CD14-positive cells isolated from human PBMCs differentiated into osteoclasts after a culture of 7 days in the presence of M-CSF and RANKL. Upon addition of resveratrol (1 to 100microM), the number of TRAP+ multinucleated cells and the level of TRAP activity released in the medium were strongly reduced, and instead, elongated mononucleated cells were seen. Almost full effects were obtained at 25 microM. Accordingly, pit formation was abrogated. When added at different time points before and during cell fusion (day 0-3 or day 3-6), resveratrol retained its inhibitory activity. When added for only 2 days to multinucleated osteoclasts cultured on dentine slices, pit formation was strongly impaired and osteoclast morphology was dramatically affected.

Finally, we analyzed the effect of resveratrol on the induction of osteoblast markers in telomerized human bone marrow stem cells (hMSC-TERT) known to differentiate into osteoblasts. A 3-day-culture in the presence of resveratrol led to an up-regulation of the expression level of osteocalcin and the nuclear receptor of calcitriol (VDR), as evaluated by Q-PCR. Moreover, resveratrol synergized the calcitriol-induced osteocalcin induction in hMSC-TERT.

In conclusion, we demonstrate that a single compound, resveratrol, inhibits bone resorption, promotes osteoblast differentiation markers, and prevents myeloma cell proliferation. We are presently elucidating its molecular mechanism of action, and thereby hope to understand why a single compound antagonizes 3 distinct processes that all cooperate in promoting myeloma development.

Lysophosphatidic Acid: A New Link between Breast Cancer and Bone Metastasis. A. Boucharaba*[1], C. Serre*[1], J. Saulnier Blache*[2], J. Bordet*[3], J. Guglielmi*[1], P. Clezardin[1], O. Peyruchaud*[1]. [1]INSERM U-403, Lyon, France, [2]INSERM U-586, Toulouse, France, [3]EA3735, Lyon, France.

Bone is a very common metastatic site for breast cancer. Current treatments of bone metastatic patients with bone resorption inhibitors (*e.g.* bisphosphonates) are only palliative and do not provide a life-prolonging benefit. This indicates that in addition to the vicious circle established between tumor cells and osteoclats, there exists at the bone site unidentified factors that stimulate skeletal tumor growth independently of bone-derived growth factors released from the bone matrix. Lysophosphatidic acid (LPA) is a naturally occurring lipid which interacts with cell surface G-protein couple receptors (LPA1, 2 and 3). LPA exhibits growth factor-like activities for breast cancer cells *in vitro* but its role *in vivo* is unknown. To address this question we engineered human MDA-BO2 breast cancer cells (a bone metastatic cell line) to over-express LPA1 using the tet-Off expression-regulated system. We found that LPA1 over-expression (1) specifically sensitized these cells to the mitogenic action of LPA *in vitro*, (2) enhanced the subcutaneous tumor growth in animals, and (3) increased 2 to 3-fold the extent of osteolytic lesions and (4) skeletal tumor burden in an experimental model of bone metastasis. MDA-BO2 cells did not produce LPA nor did they express autotaxin (a LPA-producing enzyme). Instead, these cells induced platelet aggregation and the release of LPA from activated platelets. In turn, platelet-derived LPA stimulated both the proliferation of tumor cells *in vitro* and the production by these cells of IL-6 and IL-8, two potent bone resorption stimulators. *In vivo*, a specific platelet aggregation inhibitor (eptifibatide) inhibited by 50% both bone destruction and skeletal growth of parental MDA-BO2 cells. In addition, it abolished the increased extent of osteolytic lesions caused by LPA1 over-expressing cells. Overall, our data indicated that in addition to the vicious circle coming from the reciprocal interaction between breast cancer cells and osteoclasts, the development of bone metastasis is supported by a second vicious circle wherein bone-residing cells stimulate LPA production by blood platelets which, in turn, enhances tumor growth and cytokine-mediated bone resorption.

Adrenomedullin Is Made by Prostate Cancers and Increases Both Osteolytic and Osteoblastic Bone Metastases. K. S. Mohammad[1], Z. Wang*[2], A. Martinez*[3], E. Corey*[4], R. L. Vessella[4], T. A. Guise[1], J. M. Chirgwin[1]. [1]U Virginia, Charlottesville, VA, USA, [2]Northwestern U, Chicago, IL, USA, [3]Natl Cancer Inst, Bethesda, MD, USA, [4]U Washington, Seattle, WA, USA.

Adrenomedullin (AM) is a polypeptide produced by many cancers. It stimulates angiogenesis and tumor cell growth. AM potently enhances osteoblast proliferation in vitro and new bone formation in vivo. We hypothesized that AM is secreted by prostate cancers and stimulates bone metastasis by enhancing osteoblast proliferation.

AM dose-dependently increased osteoblast number and new bone area ($p<0.05$) in ex vivo organ cultures of neonatal mouse calvariae, with significant effects at 10pM. To test the role of AM in bone metastases, we carried out a gain-of-function experiment in prostate cancer by stable expression of AM cDNA in PC-3 prostate cancer. Mice bearing PC-3 clones which overexpressed AM by 10-fold had accelerated bone metastases ($p<0.05$) and significantly reduced survival compared to mice bearing empty vector PC-3 cells. Mice bearing AM-overexpressing tumors showed extensive bone destruction but also many areas of new bone formation by x-ray and histology. The AM-overexpressing cells grew more slowly than control cells as subcutaneous tumors, indicating that the effect of AM was specific to bone.

To test whether prostate cancers generally express AM, we surveyed human prostate cancer cell lines for AM mRNA. LNCaP, C4-2B, and DU145 cells made moderate levels of message, while parental PC-3 cells made higher amounts. RNA was also isolated from LuCaP23.1 xenografts (established from a metastasis). It causes a strong osteoblastic response 15 weeks after inoculation into the tibiae of nude mice. When analyzed by RT-PCR, the LuCaP23.1 tumor expressed AM mRNA in substantially greater amount than the other prostate cancer lines, suggesting that AM may be responsible for the osteoblastic responses caused by these tumors.

We have also carried out a loss-of function experiment with AM in bone metastasis. In a mouse model of bone metastasis, clonal variant lung adenocarcinoma A549 cells with 50% decreased AM secretion caused fewer osteolytic metastases ($p<0.05$) and improved survival compared to animals receiving parental A549 cells.

Secretion of AM by tumor lines such as PC-3 and A549, which cause osteolysis, appears to increase the severity of osteolytic bone destruction, perhaps by stimulating osteoblast proliferation and the number of RANK ligand-positive cells. AM may also function as an osteoblastic factor, a role supported by its high expression in LuCaP23.1 tumors. The data identify AM as an important contributor to the pathophysiology of bone metastases.

Use of Bisphosphonate Analogs of Risedronate to Elucidate Antitumor Mechanisms of Bisphosphonates *In Vivo*. P. G. Fournier*[1], M. W. Lundy*[2], F. H. Ebetino*[2], P. Clézardin[1]. [1]INSERM U403, Lyon, France, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

Bisphosphonates (BPs) exhibit antitumor activity *in vitro* and reduce skeletal tumor growth in experimental models of bone metastasis. However, because of their high bone affinity and rapid uptake in bone, it is likely that the antitumor activity of BPs is mainly mediated through inhibition of bone resorption which, in turn, deprives tumor cells of bone-derived growth factors released from the bone matrix. Conversely, a BP having a lower bone affinity could act to a higher degree directly on tumor cells because of its more rapid release from bone mineral. To address this question, we compared the antitumor potency of risedronate (RIS) with that of NE-10790 and NE-58051. NE-10790 is a phosphonocarboxylate analog of RIS which had a 15-fold lower bone affinity compared to RIS. NE-58051 is a pyridyl BP which differs from RIS only in the length of the R2 chain but exhibited similar bone affinity compared to RIS. *In vitro*, RIS, NE-10790 and NE-58051 inhibited to a similar extent the proliferation of GFP-expressing B02 breast cancer cells. *In vivo*, a continuous treatment of mice with RIS (0.05 to 0.15 mg/kg/day) dose-dependently inhibited bone destruction caused by GFP-expressing B02 cells (as judged by radiography, microCT and histomorphometry). The highest dose of RIS (0.15 mg/kg/day) also substantially reduced skeletal tumor burden (as judged by external fluorescence imaging and histomorphometry). NE-58051 (0.15 mg/kg/day) and NE-10790 (0.15 mg/kg/day) did not inhibit bone destruction. This lack of inhibitory effect of NE-58051 and NE-10790 on bone destruction was consistent with the observation that these analogs were 8,000 to 10,000-fold less potent than RIS in preventing ovariectomy-induced bone loss in rats. However, as opposed to NE-58051, a daily dose (0.15 mg/kg) of NE-10790 that did not inhibit bone resorption did drastically reduce skeletal tumor burden (75% reduction). A higher dose (37,000 mg/kg/day) of NE-10790 reduced skeletal tumor burden similarly, but also decreased bone destruction. Moreover, using a daily dose of 0.15 mg/kg, RIS, NE-58051 and NE-10790 did not inhibit the subcutaneous growth of B02 cells nor did they inhibit B16F10 melanoma lung metastasis in animals. As exemplified with NE-10790, low bone affinity BPs are rapidly released from bone and act directly on tumor cells to inhibit their growth. Conversely, as exemplified with NE-58051, high bone affinity antiresorptive BPs mainly reduce skeletal tumor growth through inhibition of bone resorption. Overall, our findings strongly suggest that BPs exhibit *in vivo* antitumor activity in bone through two distinct mechanisms.

RANK Ligand Directly Induces Osteoclastogenic, Angiogenic, Chemoattractive and Invasive Factors on RANK-expressing Human Cancer Cells MDA-MB-231 and PC3. M. Tometsko*[1], A. Armstrong*[1], R. Miller*[1], J. Jones*[1], M. Chaisson*[1], D. Branstetter*[2], W. Dougall[1]. [1]Cancer Biology, Amgen Washington, Seattle, WA, USA, [2]Pathology, Amgen Washington, Seattle, WA, USA.

RANK and RANKL are the key regulators of osteoclast differentiation, activation and survival. Blockade of RANKL in animal models of breast and prostate cancer metastases inhibits tumor-induced osteolysis and prevents the progression of skeletal tumor burden (Morony et al., 2001; Zhang et al., 2003). RANK and RANKL knockout mice also have a defect in mammary lobulo-alveolar formation during pregnancy suggesting that RANK and RANKL may function on breast carcinomas. In this study we have demonstrated that RANK is expressed on the breast cancer cell line MDA-231 and the prostate cancer cell line PC3. While neither cell line expresses RANKL in vitro, it is probable that the locally increased RANKL within the bone microenvironment could activate tumor cell-expressed RANK in a paracrine manner. RANKL treatment of both MDA-231 and PC3 cells led to the acute activation of signal transduction pathways including p38 MAPK, p42/44 MAPK, NF-kB, and this activation can be blocked by OPG. Global gene expression analysis indicates that RANKL treatment of MDA-231 cells leads to the upregulation of 194 mRNAs greater than 2-fold. The transcriptional profile induced by RANKL on human tumor cells includes osteotropic factors (IL-1, IL-6, CSF-1), angiogenic factors (IL-8, CXCL-2), metalloproteinases (MMP1, MMP9, MMP13), and chemoattractants (CXCL-1,2,3,5 and 6). In addition, RANKL treatment of MDA-231 significantly decreased the expression of thrombospondin-1 and TIMP-4. Interestingly, of all the mRNA changes induced by RANKL in MDA-231 cells, COX-2 mRNA was induced to the greatest extent; activation of this pathway in tumor cells by RANKL was confirmed by PGE2 ELISA.

Local increases of RANKL result from the interaction of tumor and bone. These studies suggest that the locally increased RANKL can activate RANK positive breast or prostate tumors within the bone and can influence tumor cell homing and invasion and result in the secretion of angiogenic and osteolytic factors. These data indicate that RANKL regulates the osteolytic tumor-bone "vicious cycle" in at least three different ways: 1). release of growth factors from bone matrix; 2). production of growth factors, chemokines and cytokines by the activated osteoclasts; and 3). direct RANKL-mediated induction of angiogenic, invasion, chemoattractant and osteotropic factors by RANK positive tumor cells. Current studies are underway using an experimental metastasis animal model to test whether RANKL inhibition will target tumor cells directly.

Targeting EGF-R, VEGF-R, and the Osteoclast in Renal Cell Carcinoma Bone Metastasis. M. Doucet*[1], R. Langley*[2], K. Weber[1]. [1]Orthopaedic Surgery, Johns Hopkins University School of Medicine, Baltimore, MD, USA, [2]Cancer Biology, University of Texas M.D. Anderson Cancer Center, Houston, TX, USA.

Metastatic renal cell carcinoma (RCC) to the skeleton is clinically challenging as there is no reliable, effective method of treatment. The tumors are relatively radio- and chemoresistant. The goal of our study was to find an effective combination of agents to decrease the growth of RCC in the bone and inhibit bone destruction. We hypothesized that a combination of pegylated interferon-*a* (PEG-IFN-*a*), Zometa, and blockade of the epidermal growth factor receptor (EGF-R) and vascular endothelial growth factor receptor (VEGF-R) pathways would be effective in an established animal model.

Proliferation studies and western blotting were performed using mouse-derived bone endothelial cells and human bone-derived metastatic RCC cells. The cells were stimulated by the addition of TGF-*a* (40 ng/ml) with or without the addition of various inhibitory agents. In a nude mouse intratibial injection model, mice were treated with AEE788, PEG-IFN-*a,* and Zometa in various combinations and compared with control mice. Tumor incidence, tumor weight, radiographic lysis, and immunohistochemical staining were evaluated at 12 weeks.

Proliferation studies revealed that AEE788, an EGF-R/VEGF-R inhibitor, was effective in inhibiting cell proliferation of both RBM1-IT4 and bone endothelial cells in a dose-response fashion ($p<0.01$). PEG-IFN-*a* was also effective, but comparatively higher doses were required. Zometa had no effect on cell proliferation. On western blotting, AEE788 effectively inhibited EGF-R phosphorylation of RBM1-IT4 cells (90%) more than bone endothelial cells (28%) at the same dose. Downstream signaling through AKT was also inhibited. There was a significant decrease in tumor incidence and tumor weight in the 4 groups of mice treated with AEE788 alone or in combination with Zometa or PEG-IFN-*a* ($p<0.05$). PEG-IFN-*a* was not effective alone but was synergistic with AEE788. Bone destruction was decreased in all groups except mice treated with PEG-IFN-*a* alone ($p<0.05$). Immunohistochemistry revealed decreased staining of activated EGF-R, activated VEGF-R, and TGF-*a* in all groups that included treatment with AEE788 ($p<0.001$). VEGF was decreased in all groups except Zometa alone ($p<0.001$). Basic fibroblast growth factor (bFGF) was decreased in mice treated with AEE788/Zometa and PEG-IFN-*a*/Zometa ($p<0.01$).

The targeting of multiple growth factor receptors and the inhibition of osteoclastic resorption is effective in the treatment of metastatic RCC to bone in a nude mouse model.

Teriparatide Suppresses Activation of Aortic Msx2 /Wnt Gene Regulatory Programs *In Vitro* and *In Vivo*. J. S. Shao, S. L. Cheng, N. Charlton-Kachigian*, A. P. Loewy*, D. A. Towler. Dept. of Internal Medicine, Washington University School of Medicine, St. Louis, MO, USA.

In a murine model of diabetic vascular calcification, an aortic BMP2-Msx2 gene regulatory program is activated that recruits aortic adventitial and valvular myofibroblasts to the osteogenic lineage. In these LDLR receptor-deficient mice, male animals are susceptible, while females are resistant. Consistent with an active role for BMP2 in this process, BMP2 synergizes with Msx2 to re-program cell fate and drive mineralization in vitro. Moreover, mice transgenic for BMP2 driven by the vascular smooth muscle cell (VSMC) SM22 promoter exhibit more extensive cardiac valve calcification, and female SM22-BMP2tg+; LDLR+/- mice become susceptible to disease. To better understand the mechanisms controlling vascular osteogenic differentiation, we studied effects of BMP2 in cultured primary aortic myofibroblasts. Since PTHrP had been demonstrated to suppress VSMC calcification in vitro, we examined the response to teriparatide in this system as well. BMP2 treatment (100 ng/ml) markedly induced Msx2 expression (40-fold) in aortic myofibroblasts at 72 hours. By contrast, a 90 min exposure to teriparatide (100 nM) on day 1 suppressed basal Msx2 expression by 50% ($p < 0.05$) - with no effect on endogenous BMP2-- and teriparatide treatment completely abrogated Msx2 induction by BMP2. A downstream component of Msx2 actions in aortic myofibroblasts is upregulation of Wnt3a and Wnt7a with paracrine activation of Wnt signaling; recombinant Dkk1 inhibits Msx2 reprogramming of cell fate. Consistent with its effects on Msx2 expression, teriparatide significantly inhibited Wnt3a and Wnt7a by ca. 90% either in the presence or absence of BMP2, but had no effect on Dkk1 expression. To confirm the physiological relevance of this in vitro observation, we studied the effects of teriparatide on calcific vasculopathy and Msx2/Wnt activity in vivo. Male LDLR-/- mice (n= 5 to 6 animals per arm) were fed high fat diets and treated with either vehicle or teriparatide (400 ng/gm s.c. 5 days a week, 4 weeks). Teriparatide inhibited cardiac valve calcification in male LDLR-/- mice (area of valve calcification by Alizarin red decreased from 8.3 +/- 1.5% to 1.4 +/- 0.5%; $p < 0.001$). Fluorescence RT-PCR analysis of aortic mRNA accumulation revealed that teriparatide concomitantly reduced aortic expression of Msx2, Wnt3a, and Wnt7a by ca. 60% ($p < 0.05$), but did not alter BMP2 or Dkk1. Thus, in vitro and in vivo, teriparatide suppresses the Msx2/Wnt gene expression program that recruits aortic myofibroblasts to the osteogenic lineage. This activity may contribute to beneficial effects of teriparatide in prevention of diabetic vascular calcification in our murine model.

The Effect of 1 year of Alendronate following 1 Year of PTH 1-84: Second Year Results from the PTH and Alendronate (PaTH) Trial. D. M. Black[1], C. J. Rosen[2], L. Palermo[1], T. Hue[1], K. E. Ensrud[3], S. L. Greenspan[4], T. F. Lang[1], J. A. McGowan[5], J. P. Bilezikian[6]. [1]U of CA, SF, CA, USA, [2]ME Ctr. for Osteo. Res., Bangor, ME, USA, [3]U of MN & MVAMC, Minn, MN, USA, [4]U of Pitt, Pitt, PA, USA, [5]NIAMS, NIH, Bethesda, MD, USA, [6]Columbia U, New York, NY, USA.

Since PTH use is limited to no more than two years, a key question to address is whether it should be followed by antiresorptive agent. We have previously reported the results of a trial comparing 1 year of therapy with either PTH(1-84) alone, alendronate alone or the two in combination. (Black et al., NEJM, 2004). This randomized trial was designed also to evaluate the results of a second year in which PTH(1-84) was discontinued and either followed by no therapy or with the antiresorptive alendronate (ALN). We tested the hypothesis that antiresorptive therapy is required to maintain the densitometric gains in bone mineral density after 1 year of PTH(1-84).

The 119 women who received PTH 1-84 (100 mcg) monotherapy in the first year were randomized to 1 additional year with either placebo (n=60) or alendronate (n=59)(10 mg/day) in a protocol that continued to be double-blinded. PTH was stopped in all subjects after the first year. The main endpoints were spine and hip BMD by DXA and by QCT, the latter in a subset (approximately 75%) of participants. Bone markers were measured but results are not yet available.

During the first year of study among those treated with PTH 1-84 alone, there was a 6.2% mean increase in DXA spine BMD and a 29% increase in trabecular spine BMD (QCT). Comparable increases at the (total) hip were 0.3% by DXA and 8.6% for trabecular hip BMD. The second year, post-PTH changes, in the ALN and placebo groups are described in the table below:

Mean Percent Changes: 1 year of PTH(1-84) followed by 1 year of ALN or PBO

	Changes within 2nd year Treatment in year 2			Changes over 2 years Treatment in year 2		
Endpoint	**ALN**	**PBO**	**Difference**	**ALN**	**PBO**	**Difference**

*p<0.01 vs. year 1 value; ***p<0.01 between groups; ^p<0.01 vs. baseline value

Following PTH, there were significant gains in the group treated with ALN while there were losses in those on PBO. Changes in other QCT-assessed parameters such as cortical BMD showed similar trends as the results in the table but did not achieve significance.

There were striking differences following PTH in those on alendronate compared to those on placebo, particularly for trabecular bone. These data suggest that BMD gains after 1 year of PTH(1-84) are quickly lost in the next year if PTH is not followed by an antiresorptive agent. The results have clear implications for therapeutic choices after PTH therapy is stopped.

A Genetic Evidence of Direct VDR function in Osteoblasts -Generation and Analysis of Osteoblast-specific VDRKO Mice. Y. Yamamoto*[1], T. Yoshizawa[2], T. Fukuda*[1], H. Kawano[3], T. Nakamura*[1], T. Yamada[3], G Karsenty[4], S. Kato[1]. [1]Institute of Molecular and Cellular Biosciences, The University of Tokyo, Tokyo, Japan, [2]Niigata University Graduate School of Medical and Dental Sciences, Niigata, Japan, [3]Department of Orthopedic Surgery, Faculty of Medicine, The University of Tokyo, Tokyo, Japan, [4]Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA.

1α,25-Dihydroxyvitamin D_3[V.D], an active form of vitamin D, is a primary regulator in many biological phenomena such as calcium homeostasis and bone formation. Such V.D actions are thought to be mediated through transcriptional controls by the V.D receptor (VDR), a member of the nuclear hormone receptor superfamily. To investigate the physiological roles of VDR, we had generated VDR deficient mice by a conventional gene targeting, and found that $VDR^{-/-}$ knockout (VDRKO) mice showed features typical of vitamin D-dependent type II rickets, but only after weaning (Yoshizawa *et al. Nature Genet.* 1997). However, it is impossible to account for all these phenotypes only by direct VDR functions, considering from the facts that the observed impaired bone formation in the VDRKO mice may be caused, at least in part, by secondary hyperparathyroidism. Taking possible parathyroid hormone (PTH) actions in VDR KO mice, the direct function of VDR in bone thus still remains to be defined. To assess such VDR function in bone formation and remodeling, a conditional gene inactivation scheme was undertaken using the Cre/loxP system.

Mice with loxP sites in both sides of the VDR gene exon2 ($VDR^{L2/L2}$) were generated, and crossed with transgenic mice with the Cre recombinase under the mouse α1(I)-collagen promoter (Dacquin *et al. Dev.Dyn.* 2002), which is presumed to be functional only in osteoblasts.

Serum calcium, phosphate, PTH and V.D levels were normal in osteoblast-spcific VDRKO (Ob-VDRKO) mice, and the growth curve appeared normal without any overt rachitic abnormality. However, to our surprise, clear increases in bone mass as well as bone mineral density were found in 16-week-old Ob-VDRKO mice. Reflecting such bone phenotypes, decreased trabecular bone formation and increased cortical bone formation were seen in Ob-VDRKO

mice. Trabecular bone resorption and the level of urinary deoxypyridinoline, a marker of bone resorption, were also decreased. Thus, the present study suggests that VDR directly functions in bone, at least in osteoblasts, to control bone remodeling and formation, without indirect VDR functions like secondary hyperparathyroidism. It also establishes that VDR is a global regulator for normal bone remodeling and formation though its direct function in bone and indirect functions in the other tissues.

Fracture Risk After Estrogen Plus Progestin Discontinuation: The Women's Health Initiative. R. D. Jackson, N. B. Watts, P. Caralis*, J. A. Cauley, Z. Chen, N. Greep, A. Z. LaCroix, C. E. Lewis, C. P. Mouton*, J. M. Neuner, M. J. O'Sullivan*, J. A. Robbins, A. Sato*, M. L. Stefanick. The Ohio State University, Columbus, OH, USA.

After publication of the Women's Health Initiative (WHI) results on the overall balance of risks and benefit of estrogen plus progestin (E+P), it was estimated that 56% of women taking E+P attempted to discontinue hormone therapy (HT). Previous observational studies and clinical trials (CT) suggested that there might be accelerated bone loss after HT discontinuation and recent epidemiologic data suggest that women have an increased risk of hip fracture within 5 years of stopping HT relative to women who never used HT. The purpose of this report of fracture data during the early follow-up of the WHI after study drug was stopped, is to prospectively determine the overall effect of discontinuation of E+P on fracture risk. Out of the 16,608 women who were initially randomized in the E+P trial, 15,694 women were in the post-treatment phase of WHI E+P. After exclusions for prior fracture and drop in/drop-out that had occurred during the CT, 10,095 women were included in the analyses (5166 women from the former placebo group, 4929 women from the former E+P group; mean age 63 yrs; 85% White). Six-month interval fracture history (hip and total fractures) was collected by standardized questionnaire and locally adjudicated based on review of radiology reports; all hip fractures were centrally confirmed. In the first 16.12 (SD 2.53) months after study medication was stopped, fractures occurred in 96 women in the former E+P group (1.33 fractures per 1000 pt-yrs) and 130 women in the former placebo group (1.76 fractures per 1000 pt-yrs) [hazard ratio (HR) 0.76; 95% CI 0.58-0.99]. During this interval, hip fractures occurred in 12 former E+P patients (0.15 fractures per 1,000 pt-years) and 20 former placebo patients (0.24 fractures per 1000 pt-yrs) (HR 0.63; 95% CI 0.31-1.29). These results did not differ after exclusion for use of defined osteoporosis medication during the follow up and exclusion of women who were non-adherent to study medication during the CT. In summary, through 16 months of follow up after discontinuation of combination E+P, there was maintenance of overall facture benefit and no increased risk of hip fracture. Longer follow up will be required to determine when loss of protection occurs.

Distinct Y-Receptor Effects on Leptin Antiosteogenic and Adipogenic Pathways. S. J. Allison*[1], P. A. Baldock[1], A. Sainsbury*[2], R. F. Enriquez*[1], M. Couzens*[2], H. Herzog*[2], E. M. Gardiner[1]. [1]Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia, [2]Neurobiology Program, Garvan Institute of Medical Research, Sydney, Australia.

The neuropeptide Y (NPY) Y2 receptor and the adipocyte-derived hormone, leptin, regulate cancellous bone formation in the mouse by central mechanisms, with increased cancellous bone volume in Y2-deleted and in leptin-deficient obese (*ob/ob*) mice. Understanding the mechanisms involved is important for development of anabolic strategies using these pathways. Leptin and NPY are known to interact in the hypothalamus to regulate energy homeostasis, with deletion of Y1 or Y2 but not Y4 receptors reducing peripheral fat mass in *ob/ob* mice. We therefore proposed that these pathways also interact to regulate marrow fat content and bone formation. To this end, adipocyte and bone formation were determined in distal femora of Y1, Y2, Y4, *ob/ob*, Y1ob, Y2ob and Y4ob deleted and wildtype mice. Values are given: mean ± SEM.

BV/TV [%] was increased in Y1 KO (13.4 ± 1.8), Y2 KO (12.4 ± 1.7) and *ob/ob* (10.3 ± 1.0) mice relative to wildtype (5.3 ± 0.5) and Y4 KO (8.3 ± 1.1). Interestingly, double deficiency of leptin and Y2 in Y2ob did not change BV/TV from Y2 KO (12.4 ± 1.6 vs 12.4 ± 1.7 in Y2 KO). However, BV/TV was reduced in Y1ob (8.5 ± 1.4) compared to Y1 KO. BV/TV of Y4ob (10.2 ± 1.2) was not different from Y4 KO or *ob/ob*. The high bone mass in Y2ob was associated with a significant 43% elevation in mineral apposition rate above wildtype, not seen in Y1ob.

Marrow adipocyte number was increased 80-fold in *ob/ob* mice (268 ± 63 vs 3.3 ± 1.2 in wildtype). While marrow adipocyte number in Y1 KO, Y2 KO or Y4 KO was not significantly different from wildtype, deletion of either Y1 or Y2, but not Y4 receptors in *ob/ob* mice significantly decreased adipocyte number from *ob/ob*, with the effect most pronounced in Y2ob (76 ± 23 vs 268 ± 63 in *ob/ob*). Interestingly, while adipocyte size (μm^2) tended to be larger in genotypes lacking leptin compared with single Y KO and wildtype mice (787 ± 185), Y4 KO adipocytes were large and comparable to *ob/ob* (1176 ± 140 vs 1326 ± 50 in *ob/ob*).

Thus, deletion of Y1 attenuated the high bone phenotype of *ob/ob* mice, suggesting functional interaction between Y1 and leptin in their antiosteogenic responses. Roles for Y2 and Y4 in leptin antiosteogenic action were not evident in these models. Moreover, Y1 and Y2 but not Y4 receptors mediated the effects of leptin deficiency on marrow fat, to an even greater extent than effects seen in peripheral fat. Effects of Y4 on marrow fat appeared to be independent of leptin. These studies provide evidence that leptin and specific Y-receptor pathways interact by distinct mechanisms in the regulation of bone formation and marrow adipogenesis.

A Novel *COL1A1* Mutation Causes Autosomal Dominant Infantile Cortical Hyperostosis (Caffey Disease). R. C. Gensure[1], O. Mäkitie*[2], C. Barclay*[2], C. Chan*[2], S. DePalmer*[3], M. Bastepe[4], H. Abuzahra*[4], R. Couper*[5], J. Seidman*[3], W. G. Cole*[2], H. Jüppner[4]. [1]Department of Pediatrics, Tulane University, New Orleans, LA, USA, [2]Division of Orthopaedics, The Hospital for Sick Children, Toronto, ON, Canada, [3]Department of Genetics, Harvard Medical School and Howard Hughes Medical Institute, Boston, MA, USA, [4]Endocrine Unit, Department of Medicine, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA, [5]Department of Paediatrics, University of Adelaide, Women's & Children's Hospital, North Adelaide, Australia.

Infantile cortical hyperostosis (Caffey disease) is an autosomal dominant disorder characterized by episodes of localized rapid subperiosteal bone formation, which are usually limited to the first 2 years of life. We performed a genome-wide screen for genetic linkage in an affected family and mapped the genetic locus of Caffey disease to chromosome 17q21 (2-point LOD score: 6.78). Candidate genes within the linked region were sequenced after PCR amplification of genomic DNA. Affected individuals and obligate carriers were heterozygous for a missense mutation (3041C>T) in exon 42 of *COL1A1*, which was predicted to alter the amino acid sequence (R836C) of the triple helical domain of the α1(I) chain of type I collagen. The same mutation was identified in the affected members of an unrelated family with Caffey disease, and it occurred, most likely as a *de-novo* mutation, in identical twins each affected by this disorder. The mutation was not found in a single sporadic case, and it was not present in >300 chromosomes from healthy individuals. Dermal fibroblast cultures from an affected individual retained abnormal disulfide-bonded dimeric α1(I) chains, designated ß11', within the cell layer. Two-dimensional SDS-PAGE analysis showed that these ß11' dimers dissociated after reduction of disulfide bonds into a α1(I) chain and a α1(I)' chain that was likely to comprise the R836C mutation. Consistent with a change in collagen type I that impairs its secretion, electron microscopic analysis revealed a mildly dilated rough endoplasmic reticulum. Mutations in *COL1A1* have been previously shown to cause Ehlers-Danlos syndrome type III and osteogenesis imperfecta; we therefore re-examined our Caffey patients for features of these disorders. Individuals with R836C mutation showed increased joint laxity, noticeably soft skin, frequent inguinal hernias and increased fracture rates. Our findings extend the spectrum of *COL1A1*-related diseases to include a hyperostotic disorder. Further definition of the mechanisms leading to Caffey disease may provide new approaches for treating disorders associated with abnormal bone turnover.

Sequential Roles of Hedgehog and Wnt Signaling in Osteoblast Development. F. Long, H. Hu*. Washington University, St. Louis, MO, USA.

Signals that govern development of the osteoblast lineage are not well understood. Indian hedgehog (Ihh), a member of the Hedgehog family of proteins, is essential for osteogenesis in the endochondral skeleton during embryogenesis. The canonical pathway of Wnt signaling has been previously implicated by studies of LRP5, a co-receptor for Wnt proteins, in postnatal bone mass homeostasis; our recent genetic studies in the mouse have demonstrated that β-catenin, a central player in the canonical Wnt pathway, is indispensable for osteoblast differentiation in the embryo (Hilton and Long, abstract submitted to 26th ASBMR). Here we present evidence that Hedgehog and Wnt signaling function sequentially in development of the osteoblast lineage. Tcf1, the predominant member of the Lef/Tcf family that mediates canonical Wnt signaling in the perichondrium of wild type long bones, is undetectable in the perichondrium of Ihh null embryos. Consistent with defective canonical Wnt signaling in the perichondrium, Dkk1, a transcriptional target of the pathway and normally expressed in the developing perichondrium, is absent in the Ihh null embryo. Furthermore, nuclear accumulation of β-catenin normally detected in cells within the osteogenic region of the perichondrium, is abolished in the Ihh mutant. Functional studies in the C3H10T1/2 cells demonstrate that osteogenesis induced by Hedgehog signaling is mediated at least in part by Wnt/Tcf signaling as Hh-induced expression of osteoblast markers is partially inhibited by either Dkk1 or a dominant negative form of Tcf4. Whereas Hh signaling induces expression of Osx, activation of the Wnt pathway by a dominant active form of β-catenin does not alter Osx expression. Finally Hh signaling induces expression of several Wnt molecules in C3H10T1/2 cells. These data support a model in which Hh signaling directs osteoprogenitors along the osteoblast lineage and subsequently induces either directly or indirectly expression of Wnts, which further promotes osteoblast development.

An Evolutionarily Conserved CREB-binding Enhancer, in an Unusually Remote Location 74 kb Upstream from the Initiation Site, Confers the Stromal/Osteoblast-Specific Control of RANKL Transcription by PTH, 1,25(OH)$_2$D$_3$, and gp130 Cytokines. Q. Fu, I. P. Foote*, S. C. Manolagas, C. A. O'Brien. Div. of Endo/Metab, Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. of Arkansas for Med. Sciences, Little Rock, AR, USA.

RANKL is highly expressed only in bone and lymphocyte-containing tissues, and stimulation of RANKL by PTH, 1,25(OH)$_2$D$_3$ and the gp130 cytokines seems to be limited to stromal/osteoblastic cells. Based on evidence that all these agents require protein kinase A (PKA)-mediated activation of the CREB transcription factor to elevate RANKL, we searched for the molecular basis of the cell type-specificity and hormonal responsiveness of this gene. Injections of dibutyryl-cAMP (db-cAMP) into mice elevated RANKL mRNA in bone, but not in spleen, kidney, liver, or lung, whereas a control mRNA, IL-6, was elevated in all these tissues. Therefore, restricted receptor expression alone does not account for cell type-specific regulation of RANKL by cAMP. Next, we sought evidence for cell type-specific transcription by determining the activity of RANKL promoter-reporter constructs in cell lines that express or do not express RANKL. Constructs containing up to 2 kb of the murine RANKL 5'-flanking region were not regulated by db-cAMP and had similar activity in stromal/osteoblastic and hepatocytic cell lines. However, a construct containing 120 kb of 5'-flanking region was stimulated by db-cAMP in the stromal/osteoblastic, but not a hepatocytic, cell line. Deletion analysis of this fragment revealed that an 8 kb region located 74 kb upstream of the transcription start site was required for full responsiveness to cAMP. Comparison of mouse, rat, chimp, and human genome sequences in this region identified a highly conserved non-coding sequence (CNS). Deletion of this CNS from the 120 kb construct significantly reduced cAMP-responsiveness, as well as responsiveness to PTH, 1,25(OH)$_2$D$_3$, or oncostatin M. Moreover, this CNS was sufficient to confer cAMP-responsiveness to a minimal RANKL promoter in a cell type-specific manner. Furthermore, the CNS contained 2 sequences resembling cAMP-response elements (CREs) that are evolutionarily conserved. CREB protein binding to the CNS was confirmed by chromatin immunoprecipitation assay, and mutation of the CRE-like sites abolished cAMP-regulation of RANKL promoter activity. These observations establish that the cAMP responsiveness of the RANKL gene is due to a distant regulatory region that responds to CREB activation in a cell type-specific manner and that this site plays a central role in the regulation of RANKL expression by all major hormones and cytokines that stimulate bone resorption.

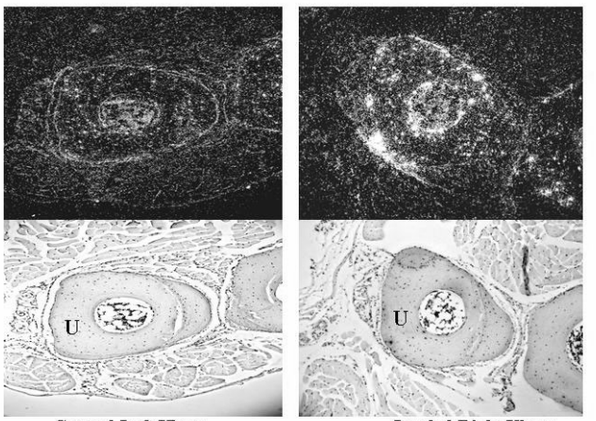
Mapping Expression Patterns of Mechanically Responsive Genes, DMP1 and MEPE, in Osteocytes Using the Mouse Ulnae: Correlation to Predicted Local Strain. S. E. Harris[1], J. Gluhak-Heinrich*[2], M. A. Harris[3], W. M. Yang[1], L. F. Bonewald[1], A. G. Robling*[4], C. H. Turner[5]. [1]Oral Biology, U. of Missouri at Kansas City, Kansas City, MO, USA, [2]Orthodontics, U. of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [3]Periodontics, U. of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [4]Orthopedics, Indiana University School of Medicine, Indianapolis, IN, USA, [5]Orthopedics, Indiana University School of Medicine, Indianapolis, IN, USA.

Axial loading of the mouse ulna is a useful model for studying bone formation in response to mechanical loading. New periosteal bone formation occurs in the ulna at 12-20days after a single 30 second bout of dynamic loading of 2.4N, 60 cycles, 2Hz. Ulnae from 4 month old loaded C57BL/6 mice were prepared for in situ hybridization and for total diaphyseal RNA at 1, 2, 4, and 24hrs after loading. From microarray analysis using 5K oligonucleotide arrays, combined with Northern analysis, we identified a series of matrix and cytoskeleton related genes thought to be involved in osteocyte function. These include cdc 42, CD44, OPN, DMP1, MEPE and others. From these data we built a pathway model (GenMapp.org) to describe this selective response. We have developed an efficient in situ hybridization procedure to evaluate expression of the osteocyte specific genes, DMP1 and MEPE, along the axis of the ulna using serial cross sections. We found dramatic increases in DMP1 and MEPE expression, specific to osteocytes 24hrs after loading. The expression of both of these genes was highest 2 mm distal to the mid-shaft and highest in osteocytes closer to the periosteal and endosteal surface. An example for DMP1 expression in the ulnae is shown in Figure 1. The expression patterns of DMP1 and MEPE were then mapped, both axially and laterally to develop a 3D model of expression within the ulna. These data were then compared with estimated mechanical strain maps. Gene expression in osteocytes consistently correlated with predicted local strains. Since both MEPE and DMP1 are thought to regulate mineralization processes within the lacunocanalicular system, we conclude that the osteocyte is altering it local environment in a spatially restricted manner that correlates to strain.



Control-Left Ulnae **Loaded-Right Ulnae**

Gap Junctions Regulate Extracellular Signal-Regulated Kinase (ERK) Signaling to Affect Osteoblast Gene Transcription. J. P. Stains, R. Civitelli. Bone and Mineral Diseases, Washington University in St. Louis, St. Louis, MO, USA.

ROS 17/2.8 cells are highly coupled by gap junctions formed by connexin43 (Cx43). Overexpression of connexin45 (Cx45), which has been shown to act in a dominant negative fashion with respect to Cx43 function, decreases chemical and electrical coupling in these cells. We have recently demonstrated that Cx45 overexpression reduces gene transcription by diminishing recruitment of the transactivator Sp1 to connexin response elements (CxREs) in the promoters of the osteocalcin and α1 (I) collagen genes. We now find that an identical mechanism accounts for the decreased osteocalcin gene transcription in Cx43 "knockout" calvaria cells, thus pointing to a direct role of Cx43 in gene transcriptional regulation. Furthermore, we demonstrate that transcription of a luciferase reporter driven by the osteocalcin CxRE is regulated by extracellular signal-regulated protein kinase (ERK) activity in ROS 17/2.8 cells. Overexpression of upstream activators of ERK, including constitutively active MEK, Raf, or Ras can increase transcriptional activity of the CxRE-luciferase reporter at least 2.5-fold in all cases. Accordingly, the MEK1/2 inhibitor, U0126 can decrease transcription 3-fold from the osteocalcin CxRE. Importantly, immunoblotting performed using phospho-Raf and -ERK antibodies reveal that overexpression of Cx45 in ROS 17/2.8 cells results in reduced amounts of active Raf and ERK. Cell exposure to the gap junction inhibitor, oleamide, mimics the effects of Cx45 overexpression on both CxRE-mediated transcription and ERK activation. We hypothesize that this attenuation of signal transduction is a consequence of decreased signal propagation caused by perturbation of intercellular communication via gap junctions. Consistent with this notion, disruption of ERK activation by either Cx45 overexpression or by treatment with U0126 results in decreased Sp1 phosphorylation, by immunoblotting, and diminished recruitment of Sp1 to CxREs, by chromatin immunoprecipitations. Therefore, Cx43 control of gene transcription is effected by modulation of Ras/Raf/MEK/ERK signaling and consequent regulation of Sp1 recruitment on CxREs. These data demonstrate that Ras/Raf/MEK/ERK signaling is required for the optimal elaboration of transcription from the osteocalcin CxRE and establish a paradigm by which intercellular communication via gap junctions composed of Cx43 can modulate nuclear function.

Expression of the Trps1 Transcription Factor and Its Regulation of Runx2. D. Napierala*[1], R. Morello*[2], G. Zhou[2], Q. Zheng*[2], T. Bertin*[2], R. Shivdasani*[3], B. Lee[1]. [1]Howard Hughes Medical Institute, Houston, TX, USA, [2]Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA, [3]Dana-Farber Cancer Institute and Harvard Medical School, Boston, MA, USA.

Trps1 is a GATA-type transcription factor that contains nine zinc-finger domains. Unlike other GATA transcription factors, Trps1 acts as a transcriptional repressor and this activity maps to the C-terminal Ikaros-type zinc-finger domain. Mutations involving *Trps1* gene cause dominantly inherited craniofacial and skeletal dysplasia tricho-rhino-phalangeal syndrome (TRPS). Loss of function mutations in GATA and Ikaros domains cause milder type I TRPS phenotype, more severe type III TRPS is caused by missense mutations in GATA domain, while type II TRPS is caused by deletion of the gene as a part of a larger continuous gene deletion syndrome (Langer-Geideon syndrome). To analyze the expression pattern of *Trps1* during embryonic development, we performed RNA *in situ* hybridization on E12.5, 14.5 17.5 and P1 mouse sections. At E12.5, *Trps1* is highly expressed in mesenchymal condensations destined for chondrogenic lineages, then expression becomes intense in joint mesenchyme and perichondrial cells. After establishment of endochondral ossification, *Trps1* expression is restricted to prehypertrophic chondrocytes and perichondrium. Interestingly, *Trps1* high expression is observed in skeletal regions where *Runx2*

expression is not usually found. *Runx2* is a key transcription factor involved in osteoblast differentiation and chondrocyte maturation. To test the potential interaction of *Trps1* and *Runx2*, we performed cotransfection studies in ROS17 and COS7 cell lines. In COS7 cells, *Trps1* strongly represses *Runx2* transactivation of the target 6xOSE reporter derived from the osteocalcin promoter, which responds only to *Runx2* transactivation. The 6xOSE reporter is also down regulated in the presence of *Trps1* in ROS17 cells expressing high levels of endogenous *Runx2*. Analysis of transcriptional activity of *Runx2* deletion mutants as well as chimeric Runx2 runt domain-Vp16 fusion protein demonstrated that runt domain mediates the Trps1 repression effect on Runx2 activity. Moreover, the bone-related promoter of *Runx2* contains several potential GATA consensus sequences. *In vitro* analyses showed that *Trps1* forms complexes with each of these elements in COS7 but not in ROS17 cell lines. Our data suggest that *Trps1* can inhibit expression of the *Runx2* gene as well as *Runx2* protein function.

Dlx5 Specifically Regulates Runx2-type II Expression by Binding with the Homeodomain Response Elements in the Distal Promoter. M. Lee*[1], H. Park*[1], S. Bae[2], J. Cho*[1], H. Ryoo[1]. [1]Dept. of Biochemistry, School of Dentistry, Kyungpook National University, Daegu, Republic of Korea, [2]Dept. of Biochemistry, School of Medicine, Chungbuk National University, Cheongju, Republic of Korea.

Dlx5 is a key mediator of BMP-2-induced osteoblast differentiation that triggers osteogenic master gene, Runx2, and ultimately results in the bone marker gene expression in BMP-induced osteogenic transdifferentiation. However, little is known about the molecular mechanisms by which Dlx5 regulates Runx2 expression in response to BMP-2 signaling. Two major isoforms of Runx2 have been reported, and are caused by different promoter usage. One of these isoforms, denoted as Runx2-typeI/p56 (starting with the sequence MRIPV), use the proximal promoter and the other, denoted as Runx2-type II/p57 (starting with the sequence MASNS), use the distal promoter. In this study, we found that Dlx5 overexpression strongly stimulated Runx2 expression and the bone specific Runx2-typeII expression was specifically stimulated either by BMP treatment or by Dlx5 overexpression. As Runx2 isoforms are distinctly regulated by two different promoters, we first tested Dlx5 responsiveness of each promoter-reporter constructs. The promoter activity of Runx2-typeII was strongly stimulated by Dlx5 overexpression while that of Runx2-type I by Dlx5 was marginally stimulated. The different responsiveness of the two promoters was highly correlated with the higher expression of Runx2-II by BMP-2 signalling. To identify Dlx5 response elements in Runx2-II promoter, serial promoter deletion constructs were generated. Cotransfection of the Dlx5 expression vector and the promoter deletion constructs indicated that Dlx5 response element is between -1kb and -0.45kb of Runx2-II transcription start site. There were 3 putative homeodomain binding consensus sequences between -1kb and -0.45kb in the Runx2-II promoter. We found that all 3 putative binding sites effectively interact with Dlx5 by gel mobility shift assay. The site-directed mutagenesis of each binding site or combinations of two or three of those sites indicated that all three elements are responsible for the regulation. These results indicate that Dlx5 is a key mediator of BMP-2-induced osteoblast differentiation that triggers osteogenic master gene, Runx2 (more specifically type-II isoform), and ultimately results in the BMP-induced osteogenic transdifferentiation.

Expedited Cataract Surgery can Reduce Recurrent Falls and Fractures - A Randomised Controlled Trial. T. Masud[1], R. Harwood*[1], A. Foss*[2], F. Osborn*[2], R. Gregson*[2], A. Zaman*[2]. [1]Medicine, Nottingham City Hospital, Nottingham, United Kingdom, [2]Opthalmology, Queens Medical Centre, Nottingham, United Kingdom.

Epidemiological evidence suggests that poor vision increases the risk of falls and fractures. Cataract is the commonest cause of visual impairment. We aimed to determine if expedited cataract surgery would reduce the risk of falling by more than 30% (primary outcome) and fractures (secondary outcome).

306 women over 70 years with bilateral cataracts were randomised to expedited (approximately 4 weeks) or routine (12 months wait) first eye cataract surgery by phakoemulsification with intra-ocular lens implantation. Falls and fractures were ascertained by diary, with follow-up by telephone at 3 and 9 months, and by interview at 6 and 12 months. Health status parameters were also measured at baseline and 6 months.

Visual function improved in the operated group (spectacle corrected binocular vision improved by 0.25 log MAR units and proportion with visual acuity worse than 6/12 decreased from 24% to 8%). Falls were recorded in 76 participants (49%) randomised to expedited surgery, with 28 (18%) falling more than once. 69 (45%) patients in the control group fell at least once, and 38 (25%) fell more than once. Hazard ratio for first falls was 0.95 (95%CI 0.69-1.35; p=0.77), and for second (recurrent) falls was 0.60 (95%CI 0.36-0.98; p=0.04). Measurements of activity, anxiety, depression, confidence, vuisual disability and handicap all improved in the operated group. Four particpants in the operated group had fractures (3%), compared with 12 (8%) in the control group (p=0.04).

In conclusion, first eye catarct surgery improves visual function and health status , and to our knowledge this is the first randomised controlled trial which has shown that recurrent falling (though not first fall) and fractures can be reduced by intervention to improve impaired visual function.

Falls and Physical Performance Changes in Older Adults with Diabetes and Pre-diabetes. A. V. Schwartz[1], E. Vittinghoff*[1], D. E. Sellmeyer*[1], N. De Rekeneire*[2], K. R. Feingold*[1], M. C. Nevitt[1], E. S. Strotmeyer[3], H. E. Resnick*[4], R. I. Shorr*[5], J. A. Cauley[3], S. R. Cummings[6], T. B. Harris*[2]. [1]University of California, San Francisco, CA, USA, [2]National Institute on Aging, Bethesda, MD, USA, [3]University of Pittsburgh, Pittsburgh, PA, USA, [4]Medstar Research Institute, Hyattsville, MD, USA, [5]University of Tennessee, Memphis, TN, USA, [6]California Pacific Medical Center, San Francisco, CA, USA.

Type 2 diabetes (DM) is associated with elevated fracture risk despite higher bone mineral density (BMD). Falls may be a contributing factor. To determine if falls and decline in physical performance are associated with DM or impaired glucose metabolism (IG), we analyzed data from the Health, Aging and Body Composition study of 3,075 white and black, well-functioning men and women age 70-79 years. Participants reported falls in the previous year at each annual clinic visit. Physical performance was measured at the baseline, year three and year five visits. Of 2940 participants with baseline data on diabetes, 719 (24%) participants had DM, defined by self-report, use of hypoglycemic medication, or an elevated fasting glucose (FG≥ 126 mg/dl) or 2-hour glucose (OGTT≥ 200 mg/dl); 658 (22%) had IG; and 1,563 had normal glucose homeostasis (NG), defined as FG<110 mg/dl and OGTT<140 mg/dl. At the year five visit, 862 (33%) had DM, 1,066 (41%) had IG, and 695 had NG.

Falling and performance measures were evaluated over five years of follow-up using ordinal logistic (falls), linear mixed (walks and chair stands), and gamma-frailty (standing balance) models adjusted for age, gender and race. Those with DM fell more frequently compared with NG participants (OR = 1.40; 95% CI 1.17, 1.67) but those with IG did not (OR = 0.95; 95% CI 0.81, 1.12). DM participants had poorer baseline performance on the 6m usual walk (longer time), chair stands (fewer per minute), and standing balance (shorter time held) compared with NG participants and had bigger declines over follow-up in the 6m usual and narrow walks (Table) and standing balance (RH = 1.27; 95% CI 1.06, 1.53, for decline in performance). IG and NG participants did not differ at baseline or in rate of decline.

Difference in change in performance over 5 years, adjusted for age, gender and race

Performance test	DM vs NG		IG vs NG	
	Coefficient	(95% CI)	Coefficient	(95% CI)
6m usual walk (sec)	0.16*	(0.04, 0.28)	0.03	(-0.08, 0.15)
6m narrow walk (sec)	0.35*	(0.15, 0.54)	0.16	(-0.02, 0.34)
Chair stands (per min)	-0.56	(-1.19, 0.07)	-0.21	(-0.82, 0.41)

* p<0.05

Older adults with diabetes have an increased risk of falls and of declines in gait and balance, factors that may contribute to their higher fracture rate.

Rib Fractures Predict Incident Limb Fracture: Results from the European Prospective Osteoporosis Study. A. A. Ismail*[1], A. J. Silman*[2], J. Reeve[3], S. Kaptoge*[3], T. W. O'Neill[2]. [1]Department of Rheumatology, Stepping Hill Hospital, Stockport, United Kingdom, [2]ARC Epidemiology Unit, University of Manchester, Manchester, United Kingdom, [3]University Department of Medicine, Strangeways Research Laboratory, Cambridge, United Kingdom.

Population studies suggest that rib fractures are associated with a reduction in bone mass. While much is known about the predictive risk of hip, spine and distal forearm fracture on the risk of future fracture, little is known about the impact of rib fracture. The aim of this study was to determine the predictive risk of rib fracture on future risk of limb fracture.

Men and women aged 50 years and over were recruited from population registers in 31 European centres for participation in a screening survey of osteoporosis (European Prospective Osteoporosis Study). Subjects were invited to complete an interview administered questionnaire which included questions about previous fractures including rib fracture, the age of their first fracture and the level of trauma. Lateral spine radiographs were performed and the presence of vertebral deformity was determined morphometrically. The subjects were followed prospectively by annual postal questionnaire to determine the occurrence of clinical fractures. Poisson regression was used to assess the predictive risk of recalled history of low trauma rib fracture on future limb fracture.

6,344 men, mean age 64.2 years, and 6,788 women, mean age 63.6 years were followed for a median of 3 years (range 0.4-5.9 years). 135 men (2.3%) and 101 women (1.6%) reported a previous low trauma rib fracture. In total, 138 men and 391 women sustained a limb fracture during follow-up. In women, after age adjustment, those with a recalled history of low trauma rib fracture had an increased risk of sustaining 'any' limb fracture (Relative Risk [RR]=2.3;95%Confidence Intervals [CI] 1.3, 4.0). When stratified by fracture type the predictive risk was more marked for hip (RR=7.8;95%CI 2.3, 25.9) and humerus fracture (RR=4.5;95%CI 1.4, 14.7). Additional adjustment for prevalent vertebral deformity and previous low trauma fractures slightly reduced the strength of the association between rib fracture and subsequent limb fracture. In men, after age adjustment, there was a small though not significant association between recalled history of rib fracture and future limb fracture.

Our data highlight the importance of rib fracture as a marker of bone fragility in women. Treatment of osteoporosis in women with low trauma rib fracture may help reduce the morbidity related to limb fracture in later life.

Asymptomatic Vertebral Deformity as Major Risk Factor for Subsequent Fractures and Mortality: A 14-year Prospective Study. C. Pongchaiyakul, N. D. Nguyen, J. R. Center, J. A. Eisman, T. V. Nguyen. Bone and Mineral Program, Garvan Institute of Medical Research, Sydney, Australia.

In the elderly, vertebral deformity silently affects at least 20% of the population and is associated with considerable disability and increased mortality. However, it is unclear how the three events of vertebral deformity, fracture, and mortality are linked with each other and with bone mineral density (BMD). The present study examined the association between asymptomatic vertebral deformity, osteoporotic fractures and risk of mortality in a sample of elderly men and women.

In 1992, radiographs (X-ray) at the lumbar spine were performed on 300 individuals (113 men and 187 women) aged 60 or above (as at mid-1989), who were randomly selected from the Dubbo Osteoporosis Epidemiology Study (DOES). The presence of vertebral deformity was defined as a reduction of at least 3 standard deviations (SD) from same-sex normals for each vertebrae. Baseline lumbar spine and femoral neck bone mineral density (BMD) was measured by dual energy x-ray absorptometry (GE Lunar DPX-L, WI, USA). Incidence of mortality and atraumatic fractures was ascertained during the study period of 1989 and 2003.

At baseline, the prevalence of asymptomatic vertebral deformity was 30.7% in men and 16.7% in women. During the follow-up period, subjects with vertebral deformity had a significantly higher risk of all types of osteoporotic fractures than those without vertebral deformity (44% vs. 29%; relative risk (*RR*), 2.1 [95%CI, 1.2 to 3.7]), particularly symptomatic vertebral fracture (*RR,* 7.4 [3.0 to 17.7]). Mortality rate was highest after a symptomatic fracture among those with vertebral deformity (*RR*, 9.6 [3.0 to 30.6]). These associations remained virtually unchanged after adjusting for age, BMD and gender. In conclusion, vertebral deformity was a strong predictor of subsequent risk of fractures, particularly symptomatic vertebral fracture, and of fracture-associated mortality in both elderly men and women. Vertebral deformity should be considered a primary risk factor for mortality as well as fracture.

The Near Absence of Osteoporosis Treatment in Older Men with Fractures. A. C. Feldstein*[1], G. Nichols*[1], E. Orwoll*[2], P. J. Elmer*[1], D. H. Smith*[1], M. Herson*[3], M. Aickin*[1]. [1]Center for Health Research, Kaiser Permanente Northwest, Portland, OR, USA, [2]Bone and Mineral Unit, Oregon Health & Sciences University, Portland, OR, USA, [3]Northwest Permanente, Portland, OR, USA.

Background; The burden of osteoporotic fractures in older men is significant, and treatment rates for secondary prevention are low. The study objectives were to 1) Characterize older men with fractures associated with osteoporosis, 2) Determine if treatment rates for osteoporosis are improving, and 3) Identify patient, healthcare benefit and utilization, and clinician characteristics that are significantly associated with treatment.

Methods: *Design*. Retrospective cohort study used multiple logistic regression to evaluate pre-fracture factors for their association with osteoporosis treatment in the 6-month post-fracture period.

Setting. A non-profit health maintenance organization in the United States.

Participants. 1,171 men aged 65 or older with any new fracture associated with osteoporosis between January 1, 1998, and June 30, 2001.

Main Outcome Measure. Pharmacologic treatment for osteoporosis in the 6 months after the index fracture.

Results: Average age was 76.7 years; 3.3% had a diagnosis of osteoporosis and 15.2% a diagnosis or medication associated with secondary osteoporosis. Only 7.1% of the study population received a medication for osteoporosis following the index fracture, and treatment rates did not improve over time. In the multivariate model, a higher value on the Charlson Comorbidity Index (odds ratio 1.26, 95% confidence interval 1.05-1.51), having an osteoporosis diagnosis (odds ratio 8.11, 95% confidence interval 3.08-21.3), chronic steroid use (odds ratio 5.37, 95% confidence interval 2.37-12.2), and a vertebral fracture (odds ratio 16.6, 95% confidence interval 7.8-31.4) were significantly associated with drug treatment. Bone mineral density measurement was rare (n=13, 1.1%).

Conclusions: There is under-ascertainment of osteoporosis and modifiable secondary causes in older men with fractures. Fracture does not prompt sufficient bone mineral density measurement or treatment. Information systems merging diagnostic and treatment information can help delineate gaps in patient management. Interventions showing promise in other conditions should be evaluated to improve care for osteoporosis.

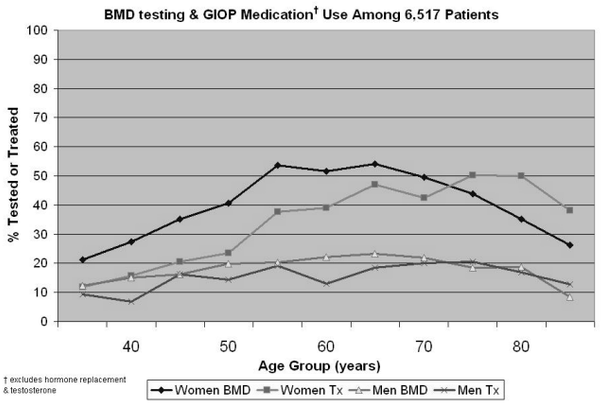
Screening and Treatment of Glucocorticoid Induced Osteoporosis among 6517 Adults. J. R. Curtis*[1], J. Allison*[1], A. Becker*[1], L. Casebeer*[1], V. George*[1], S. H. Kovac*[2], C. Spettell*[3], A. Westfall*[1], N. Weissman*[1], S. Wilkie*[3], K. G. Saag[1]. [1]Division of Rheumatology, University of Alabama Birmingham, Birmingham, AL, USA, [2]Durham VA Medical Center, Durham, NC, USA, [3]Aetna Integrated Informatics, Inc., Blue Bell, PA, USA.

Aim: Despite a significant associated fracture risk, previous population-based studies document low screening and treatment rates for glucocorticoid induced osteoporosis (GIOP). We determined updated rates and predictors of BMD measurement and anti-osteoporotic prescriptions among chronic glucocorticoid (GC) users.

Methods: Using data from a national managed care organization (MCO), adults receiving 60+ days of GCs from Jul '01-Dec '02 were identified. Linked MCO databases identified both BMD tests and prescription medications used to prevent or treat GIOP, including hormone replacement therapy (HRT), testosterone (T), and GIOP-specific therapies. Multivariate logistic regression, adjusted for case mix, was employed to examine potential effects of physician specialty.

Results: 6,517 GC patients treated by 2,138 physicians were identified and were: 34% male, mean age = 50 (SD = 14) yrs, 16 (13) mg/day of prednisone for 9.8 (7.3) months. GC associated conditions included RA (37%), SLE (13%), COPD (11%), asthma (12%) and IBD (9%).

Overall rates of BMD testing and any GIOP prescription medication including HRT & T were 33% and 37%, respectively. HRT use was 12% among women < 50, 35% among women 50-70, and 23% among women >70. Testosterone was used by 3% of men. BMD testing and GIOP-specific medications (excluding HRT & T) were significantly greater among women ≥50 (50% & 42%) compared to men (18% & 15%) and women <50 (31% & 18%) [see Figure].



After adjusting for physician case mix, BMD testing differed significantly by specialty (internal medicine referent): nephrology (OR = 1.5; 95% CI 1.1-1.9), rheumatology (OR = 1.7; 1.4-2.0). GIOP medication use also differed by specialty (internal medicine referent): rheumatology (OR = 1.3; 1.1-1.5), gastroenterology (OR = 0.6; 0.4-0.8), and family medicine (OR = 0.7; 0.5-1.0).

Conclusions: Even among high risk patients, both BMD screening and GIOP treatment rates remain low, particularly for pre-menopausal women and men of all ages. Significant practice pattern variations among specialties persist. Developing interventions to improve GIOP management remains a high priority.

Disruption of Endogenous Glucocorticoid Signaling in Col2.3-HSD2 Transgenic Mice Results in Decreased Cortical Bone Mass and Impaired Ex Vivo Osteogenic Differentiation. L. B. Sher[1], J. R. Harrison[2], D. J. Adams*[3], B. E. Kream[1]. [1]Medicine, UCONN Health Center, Farmington, CT, USA, [2]Orthodontics, UCONN Health Center, Farmington, CT, USA, [3]Orthopaedic Surgery, UCONN Health Center, Farmington, CT, USA.

In contrast to the well known catabolic effects of excess glucocorticoids (GC) on bone mass, disruption of GC signaling in mature osteoblasts in Col2.3-11ß-hydroxysteroid dehydrogenase (Col2.3-HSD2) transgenic mice revealed an anabolic role for endogenous GC on bone. We previously showed trabecular bone volume of vertebrae was reduced and mineralization was impaired in female Col2.3-HSD2 mice. In the present study, we compared femoral cortical bone morphometric parameters in Col2.3-HSD2 mice versus wild type (WT) controls and the differentiation of Col2.3-HSD2 versus WT osteoblasts ex vivo. Cortical bone morphometric parameters were measured in 7-week-old mice using X-ray microcomputed tomography. Cortical thickness and cross-sectional area were significantly reduced in Col2.3-HSD2 males and females, while femur length was unchanged. In females, this was due to a decrease in periosteal diameter. This cortical bone phenotype was seen in two Col2.3-HSD2 lines. For cell culture, hemizygous Col2.3-HSD2 mice were crossed to mice homozygous for a Col2.3-driven green fluorescent protein transgene (GFP) that serves as a marker of late-stage osteoblast differentiation. All progeny contained Col2.3-GFP; approximately half contained the Col2.3-HSD2 transgene (Col2.3-HSD2/GFP) while the remaining progeny (WT/GFP) served as controls. Primary calvarial osteoblasts and bone marrow stromal cells were isolated from 6- to 8-week-old male and female progeny and differentiated in culture with ascorbate and ß-glycerophosphate. At day 21 (calvarial osteoblasts) and day 28 (stromal cells), plates were imaged for GFP fluorescence, alkaline phosphatase and von Kossa (mineralization) staining. Bone markers were assessed by Northern blotting. Col1a1, bone sialoprotein, osteocalcin and GFP expression were reduced in Col2.3-HSD2/GFP cultures. The amount of alkaline phosphatase staining per well was unchanged in Col2.3-HSD2/GFP primary calvarial osteoblast cultures, but was significantly decreased in stromal cultures. Both primary calvarial osteoblasts and stromal cultures from male and female Col2.3-HSD2/GFP mice showed decreased mineralization compared to WT/GFP cultures. Overall, cortical bone parameters in females and female-derived cell cultures appeared more affected than males. These data show that disruption of glucocorticoid signaling *in vivo* leads to a decrease in cortical bone mass. This may be due at least in part to impairment of osteoblast differentiation.

Estrogen Represses Hematopoietic Stem Cell Proliferation, Thymopoiesis, Thymic Output, and T Cell Peripheral Expansion through IL-7. M. Ryan, F. Grassi, W. Qian, M. N. Weitzmann, R. Pacifici. Division of Endocrinology, Metabolism, and Lipids, Emory University, Atlanta, GA, USA.

Ovariectomy (ovx) leads to bone loss through an expansion of the pool of TNF producing T cells resulting in TNF potentiation of RANKL induced osteoclastogenesis. Bone loss following ovx is prevented by neutralization of IL-7, an estrogen regulated factor required for T lymphopoiesis and T cell homeostasis. To determine how ovx leads to the expansion of T cells critical for bone loss through IL-7, mice were ovx or sham operated and treated with neutralizing IL-7 antibody or irrelevant antibody for 2 weeks. Bone marrow (BM) hematopoietic stem cells (HSC) and common lymphoid progenitors (CLP), thymic T cell differentiation, thymic output, and T cell peripheral expansion was then measured. Ovx increased the proliferation of early T cell precursors and the number of naïve T cells in the thymus by ~ 2-fold while IL-7 neutralization in vivo completely prevented these effects, demonstrating that ovx upregulates thymopoiesis through IL-7. We then examined if increased seeding of BM lymphoid progenitors contributes to the ovx-induced stimulation of thymopoiesis. We found that ovx induced, and IL-7 neutralization prevented, a 2-fold increase in the number of HSC and CLP in the BM, thus unveiling a novel IL-7 mediated effect of ovx on progenitor expansion and differentiation. Measurements of T cell receptor excision circles (TREC), a specific marker of recent thymic emigrants, revealed that ovx decreases TREC by 2-fold in the thymus while it increased TREC in the spleen, suggesting increased export of naïve T cells into the periphery. In addition, in vivo FITC thymic labeling showed a 2-fold increase in the total number of FITC labeled naive T cells in the spleen following ovx, confirming enhanced thymic export of T cells induced by estrogen deficiency. The ovx induced changes in TREC expression and FITC labeling were prevented by IL-7 neutralization establishing that thymic output was regulated through IL-7. Furthermore, ovx also increases the proliferation of naïve and memory T cells in the spleen and the BM in an IL-7 dependent manner. In summary these findings demonstrate for the first time that ovx stimulates the proliferation of HSC, the influx of early lymphoid precursors to the thymus, thymopoiesis, thymic output and mature T cell peripheral expansion through an IL-7 dependent mechanism. Thus IL-7 is a newly recognized key "upstream" target through which estrogen regulates multiple aspects of T cell differentiation critical for bone homeostasis and ovx induced bone loss.

Osteoblast-targeted Overexpression of ERRα Decreases Bone Formation in Transgenic Mice. B. Horard*[1], P. Clément-Lacroix[2], F. Morvan[3], R. Chiusaroli[3], C. Belleville*[2], R. Galien*[2], R. Baron[2], M. Resche-Rigon[2], J. Vanacker*[4]. [1]Lbmc, ENS, Lyon, France, [2]ProSkelia Pharmaceuticals, Romainville, France, [3]Orthopaedics and Cell Biology, Yale University School of Medicine, New Haven, CT, USA, [4]Crlc, INSERM, Montpellier, France.

Estrogen-Receptor Related receptors (ERRs) constitute a subfamily of orphan receptors closely related to the Estrogen Receptors (ER) that interfere with estrogen signaling though their activities are not regulated by natural estrogens. ERRα has been suggested to play a role in bone development and/or homeostasis. This receptor is indeed expressed in ossification zones during mouse development, but also in osteoblasts of adult long bones. In addition, ERRα stimulates osteoblastic proliferation and differentiation *ex vivo*, and upregulates the expression of osteopontin. To investigate the *in vivo* functions of ERRα in bone, we have established mouse transgenic lines overexpressing the receptor specifically in osteoblasts through the osteocalcin promoter. Detailed analysis of bone remodeling activity in these mice at various time points after birth including pQCT, μCT, dynamic histomorphometry, and bone markers, revealed a specific role of ERRα in bone formation. Overexpression of ERRα in osteoblasts did not affect longitudinal growth. In contrast, sexually immature mice overexpressing wild-type ERRα display significantly reduced trabecular bone mineral density, and trabecular bone volume (-12% and -16.7% respectively) compared to WT controls), associated with decreased trabecular thickness and number. Cortical thickness was significantly reduced as well. More importantly, while the osteoclast number was not affected in transgenic mice, the parameters of bone formation were all significantly decreased in ERRα tg mice (30%, 20%, and 22% decrease in osteoid surface, osteoblast surface and osteoblast number respectively). The phenotype was less markedly altered in adult (12 week-old) transgenic animals. The trabecular bone mass was still reduced in older tg mice (-9.8% and -7.5% for trabecular BMD and BV/TV, respectively) but the parameters of bone formation, as well as the bone turnover were normalized compared to control animals. Finally overexpression of ERRα in osteoblast did not prevent bone loss associated with gonadectomy. These data confirm that ERRα may affect bone homeostasis and suggest that it functions as an inhibitor of bone formation.

Estrens Are Non-selective Ligands of the Androgen Receptor, Protecting Bone in Estrogen Receptor α-deleted Male Mice Whilst Also Affecting Reproductive Organs. S. H. Windahl[1], R. Chiusaroli[1], P. Clément-Lacroix[2], D. Minet*[2], R. Galien*[2], W. C. Horne[1], M. Resche-Rigon[2], R. Baron[1]. [1]Orthopaedics and Cell Biology, Yale University School of Medicine, New Haven, CT, USA, [2]ProSkelia Pharmaceuticals, Romainville, France.

Bone can be maintained in vivo by estrogens acting on the estrogen receptors (ERs) and by androgens acting on the androgen receptor (AR). Given a recent report that 4-estren-3α, 17β-diol (estren-α) acts via both receptors, the present study was designed to 1) compare the abilities of estren-α and its isomer estren-β (4-estren-3β, 17β-diol) to prevent orchidectomy (orx)-induced bone loss in adult male mice, 2) examine the safety profile of these compounds on reproductive organs and 3) determine which receptor/s was/were utilized by these compounds in vivo (ER vs. AR).

We and others have previously shown that ERα is the only receptor that can be activated by 17β-estradiol in the male mouse. In order to study the possible activation of AR and/or other steroid receptors by the estrens in vivo, we examined the response of bone and seminal vesicles in ERα-deficient ($ERα^{-/-}$) orx mice to hormone treatment with or without anti-androgen treatment. Twelve week-old orx male $ERα^{-/-}$ mice were implanted with slow-release pellets delivering either 1) vehicle, 2) estren-α (5mg/kg/d), 3) estren-β (5mg/kg/d) or 4) 5α-dihydrotestosterone (DHT, 2.5mg/kg/d), with or without daily injections with the pure anti-androgen RU58642 (30mg/kg/d) in all cases but vehicle.

After 4 weeks of treatment, detailed histomorphometric analysis showed that both of the estrens and DHT prevented orx-induced cancellous bone loss by affecting osteoblast and osteoclast numbers and bone formation rate. The effect could be reversed by simultaneous delivery of RU58642, indicating that in the absence of ERα, the estrens signal only through the AR in male rodent bone. Interestingly, both estrens had deleterious effects on the seminal vesicles, similar to DHT, suggesting that in the absence of ERα signaling, these compounds are not selective in their effect on bone versus reproductive organs. Again, these effects were totally abolished by co-administration of RU58642, showing that in the absence of ERα signaling, estrens exert their effects on the seminal vesicles, as on bone, via the AR. Both estrens were found to be ligands for the AR and to display full agonist activity on the AR, with strong stimulation of androgen response element-dependent transcription from the probasin promoter. In conclusion, estren-β and estren-α can activate both ERα and AR in vivo and are thereby capable of efficiently preventing bone loss in orx $ERα^{-/-}$ males. However, neither estren demonstrated a good safety profile on reproductive organs.

Estren, but not Estradiol, DHT or 19-Nortestosterone, Induces Osteoblast Commitment and Differentiation by Stimulating Smad1/5/8 Phosphorylation and Transcription. S. Kousteni, L. Han, M. Almeida, A. D. Warren*, V. G. Lowe*, T. Bellido, S. C. Manolagas. Div. Endocrinol., Center for Osteoporosis and Metabolic Bone Diseases, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. Arkansas Med. Sci., Little Rock, AR, USA.

4-Estren-3α, 17β-diol (estren), a synthetic compound that mimics nongenotropic effects of both estrogen and androgen with minimal effects on classical transcription, exerts bone anabolic effects as opposed to the anti-remodeling/anti-catabolic effects of estrogens and androgens. We searched for mechanism(s) responsible for this unique biologic profile. Estren dose dependently (10^{-12} to 10^{-6} M) induced lineage commitment and differentiation towards osteoblasts in two bipotential cell lines, C2C12 and UAMS32, and in primary cultures of murine calvaria cells, as assessed by induction of alkaline phosphatase (AP) activity or osteocalcin. These effects were blocked by ICI 182,780 or flutamide, the BMP antagonist noggin, the Wnt antagonist Dkk1, the Src inhibitor PP1, the PI3K inhibitor wortmannin, and the JNK inhibitor SP600125. Estren also upregulated the expression of AP, osteocalcin, BMP-2 and Runx2, as assessed by real time PCR, in cultures of C2C12 cells and MC3T3-E1 pre-osteoblasts. Further, estren induced mineralization in MC3T3-E1 cells and the uncommitted mesenchymal progenitor cell line ST2. In addition, estren rapidly and transiently stimulated the phosphorylation of Smad1/5/8 in cultures of C2C12 and calvaria cells and this effect was blocked by ICI, flutamide, noggin, Dkk1, PD98059 (an inhibitor of MEK), wortmannin and SP600125; however, cycloheximide was ineffective. Moreover, estren upregulated the expression of Smad6, a Smad1/5/8-specific transcriptional target. Importantly, E_2, DHT or 19-nortestosterone, a potential androgenic metabolite of estren, at concentrations five orders of magnitude higher than estren did not exhibit these properties, perhaps because of counter-regulatory genotropic actions. Consistent with the abrogation of the effects of estren by Dkk1, estren stimulated Wnt/β-catenin-mediated transcription from a TCF-luciferase reporter in MC3T3-E1 cells. Finally, estren, but not E_2 or DHT, upregulated by at least 2-fold the expression of Wnt1, the Wnt receptor Frizzled 1 and the Wnt/β-catenin transcriptional target Axin2 in C2C12 cells. These results provide a mechanistic explanation for the bone anabolic effects of estren and suggest the existence of a large signalosome in which inputs from steroid receptors, BMPs, Wnt signaling and kinases converge. Activation of this signalosome is a property of ANGELS, but not of classical sex steroids or androgenic metabolites.

Runx2-independent Stimulation of Osteoblastogenesis and PPARγ-Mediated Inhibition of Adipogenesis by the Homeobox Gene Msx2. F. Ichida*[1], K. Hata*[1], F. Ikeda[1], T. Matsubara[1], K. Hisada*[1], H. Yatani*[1], A. Yamaguchi[2], R. Nishimura[1], T. Yoneda[1]. [1]Dept Biochem Osaka Univ Grad Sch Dent, Osaka, Japan, [2]Dept Pathol Tokyo Medic and Dent Univ Grad Sch, Tokyo, Japan.

Increased adipose tissue and decreased bone mass in bone marrow are associated with osteoporosis and aging. Given that adipocytes and osteoblasts share the common precursors of mesenchymal origin, either stimulation of osteoblastogenesis or inhibition of adipogenesis is critical to maintain bone volume. Msx2 is a homeobox gene which regulates development, morphogenesis and cell differentiation. Recent observations that mice deficient in Msx2 gene showed a defect in skull ossification and reduction in bone formation with decreased osteoblast number and apparently increased adipocytes suggest that Msx2 is a potential regulator of osteoblastogenesis and adipogenesis in bone development. To study this, we used the multipotent mesenchymal cell line C3H10T1/2 that is capable to differentiate into osteoblasts and adipocytes by the treatment with BMP2. BMP2 induced osteoblastogenesis by elevating ALP activity in C3H10T1/2 cells with an induction of Msx2 and Runx2 expression. Overexpression of Msx2 in C3H10T1/2 cells using an adenovirus system induced osteoblast differentiation. This effect of Msx2 was enhanced in the presence of BMP2. To understand the molecular basis of these findings, the interactions of Msx2 with Runx2 in osteoblast differentiation were examined. Msx2 had no effects on BMP2-induced Runx2 expression. BMP2 induced Msx2 expression in Runx2-deficient calvarial mesenchymal cells. Furthermore, Msx2 overexpression induced osteoblast differentiation in Runx2-deficient mesenchymal cells. A dominant-negative Runx2 did not affect the stimulatory effect of Msx2 on osteoblast differentiation. We subsequently investigated the role of Msx2 in adipogenesis with a special focus on the interactions with C/EBP and PPARγ, both of which are well-characterized regulators of adipogenesis. Adipocyte differentiation of C3H10T1/2 cells upon treatment with BMP2 was abolished by Msx2 introduction. Msx2 profoundly impaired the stimulatory effects of C/EBP α, β and γ on adipogenesis. In addition, Msx2 markedly suppressed PPARγ promoter activity and PPARγ expression that were up-regulated by C/EBP β and γ. Msx2 inhibited adipogenic action and transcription activity of PPARγ. In conclusion, our results show that Msx2 stimulates osteoblast differentiation without the interactions with Runx2 and inhibits adipocyte differentiation by inhibiting C/EBP α, β and γ and PPARγ. Thus, Msx2 might contribute to increase bone mass by directing mesenchymal stem cell differentiation to osteoblasts and preventing adipogenesis.

ß1ß2-Adrenergic Receptor KO Mice Have Decreased Total Body and Cortical Bone Mass Despite Increased Trabecular Number. D. D. Pierroz[1], P. Muzzin*[2], V. Glatt*[3], M. L. Bouxsein[3], R. Rizzoli[1], S. L. Ferrari[1]. [1]Div of Bone Diseases, University Hospital, Geneva, Switzerland, [2]Medical Biochemistry, University Medical Center, Geneva, Switzerland, [3]Orthopedic Biomechanics Laboratory, Harvard Med School, Boston, MA, USA.

Leptin is a central inhibitor of bone mass, whose negative effects on osteoblasts are reportedly mediated by the ß-adrenergic (adr) system, more specifically through the ß2-adr receptor. Accordingly, vertebral trabecular bone density, particularly trabecular number, is increased in leptin- and leptin receptor-deficient male mice (ob/ob and db/db, respectively) and in the dopamine ß-hydroxylase deficient mice. In contrast, the effect of leptin on cortical bone is controversial. To further elucidate the role of adr stimulation on trabecular (Tb) and cortical (Cort) bone compartments, we investigated bone mass (by pDXA) and microarchitecture (by µ-CT) in 8 and 20 wks old male mice null for ß1ß2-adr receptor (ß-AR KO) (n=4-7/group). Furthermore, we compared wild-type (WT) growing male mice treated for 8 weeks with a ß-adr agonist, isoproterenol (ISO, 10 mg/kg/d) or vehicle (VEH) (n=4-6/group).

In ß-AR KO mice, total body (TB) BMC was significantly decreased compared to WT mice at both 8 and 20wks (-18 to -28%), as were mid-femoral cross-sectional area (CSA) (-12 to -35%) and Cort thickness (Th) (-5 to -20%) (all P<0.0001 for ß-AR KO vs WT, by 2F-ANOVA). In marked contrast, vertebral Tb number (N) was higher (+9%, P=0.0004) and Tb spacing was consequently decreased (-10%, P=0.0001). Since Tb Th was decreased (-6 to -10%, P=0.0038) in ß-AR KO mice compared to WT, Tb bone density (BV/TV) was similar in both genotypes. ßAR-KO had increased percentage fat mass at 8 wks compared to WT (+18%, P=0.0326), with a persistent trend at 20 wks. In WT, ISO markedly decreased TB BMC gain (-33%, P<0.0001), as well as vertebral Tb BV/TV, Tb N, and Cort Th compared to VEH (-24 to -34%, p=0.031 to 0.0001). ISO significantly decreased the percentage fat mass (-77%, P=0.0067), lowered circulating leptin levels, and reduced seminal vesicles weight (-30%, P=0.0084), a marker of androgenic activity.

Altogether these data confirm that the adrenergic system is involved in the regulation of bone mass and architecture. Although activation of the leptin-adrenergic system consistently inhibits TbN, its effects on other Trab and Cort bone architectural parameters are more complex, as they involve alterations in fat mass and gonadal steroids that contribute to bone mass regulation. Hence, pharmacological modulation of the adrenergic system may not lead unequivocal and consistent effects on the various bone compartments.

β-Adrenergic Receptor KO Mice Have Increased Bone Mass and Strength But Are Not Protected from Ovariectomy-Induced Bone Loss. H. Dhillon*[1], V. Glatt*[1], S. L. Ferrari[2], M. L. Bouxsein[1]. [1]Beth Israel Deaconess Medical Center & Harvard Medical School, Boston, MA, USA, [2]Geneva University Hospital, Geneva, Switzerland.

Mice devoid of leptin (ob/ob) or the signaling form of its receptor (db/db) have markedly increased trabecular bone mass, despite reduced gonadal function (1). Recent evidence suggests that the inhibitory effects of leptin on bone may be mediated by the β-adrenergic system and that β-adrenergic antagonists inhibit bone loss after estrogen deficiency (2). Thus, we hypothesized absence of β-adrenergic signaling will lead to increased bone mass and strength, and will inhibit bone loss after ovariectomy (OVX). To test this, we evaluated mice that lack the three known β-adrenergic receptors (β-AR KO)(3) using in vivo bone densitometry, ex vivo microCT and femoral biomechanics. We studied 6- and 16-week old male β-AR KO and WT (n=7-9/gr), and female β-AR KO and WT mice 8 wks after OVX or sham-OVX (n=10-12/gr). Body weight and % fat were signficantly increased in β-AR KO, particularly at 16 wks. Leptin levels were 2-fold higher in β-AR KO than WT (7.63 ±; 0.94 vs 3.93 ±; 1.02 ng/ml). Total body bone mass was 14 to 22% higher (p<0.05) in β-AR KO than WT males. At 6 weeks male β-AR KO mice had 1.3 and 3.5-fold higher vertebral and distal femoral trabecular bone volume fraction (p<0.001 for both); these differences were less prominent at 16 wks. Mid-femoral cross-sectional area, bone area and cortical thickness were also significantly increased in 16 wk old β-AR KO, as was femoral failure load (+49%), stiffness (+28%) and energy to failure (+41%) (p<0.01 for all). OVX induced similar deficits in vertebral trabecular BV/TV in β-AR KO (-15.5%, p=0.11) and WT (-18.4%, p=0.05) compared to sham-OVX. Altogether these data support a role for β-AR signaling in the regulation of bone mass, but do not preclude direct positive effects of leptin on bone as well. Bone loss following estrogen-deficiency is not prevented by the absence of β-AR signaling. Additional studies are needed to delineate the relative roles of the different β-AR sub-types, as well as the independent contributions of increased fat mass and/or other hormonal and growth factor differences that may contribute to bone mass alterations in mice deficient in β-adrenergic signaling.

Pleiotropic Responses to Hypothalamic Neuropeptide Y1 Receptor Deletion are Associated with a High Bone Mass Phenotype. P. A. Baldock*[1], S. Allison*[1], A. Sainsbury*[2], D. Lin*[3], R. F. Enriquez*[1], M. During*[3], H. Herzog*[2], E. Gardiner[1]. [1]Bone and Mineral Program, Garvan Institute of Medical Research, Sydney, Australia, [2]Neurobiology Program, Garvan Institute of Medical Research, Sydney, Australia, [3]Department of Molecular Medicine & Pathology, University of Auckland, Auckland, New Zealand.

Recent studies have revealed pathways within the brain that regulate bone formation. Neuropeptide Y Y2 and leptin receptors of the hypothalamus are known to modulate such pathways. Y2 deletion results in few non-osteoblast effects, while loss of leptin signalling is associated with both metabolic and hormonal changes. Other Y receptors are expressed in the hypothalamus and interactions between these have produced unexpected results in bone. Gender specific changes in Y2Y4 delete mice have suggested pleiotropic effects on bone tissue as a result of central neural changes. This study investigated Y1 receptor deletion and its effects on bone homeostasis and interaction of Y1 deletion with Y2 and leptin. Germline and conditional hypothalamic Y1 delete mice were assessed for both cancellous and cortical phenotypes. Y1Y2 and Y1ob double mutant mice were assessed and Y1 delete mice following hyperleptinemia after weight gain induced by hypothalamic NPY over expression.

Y1 deletion resulted in a high bone mass phenotype in both germline (13.9% ± 1.9 vs 6.6 ± 1.4) and hypothalamic delete models (17.4% ± 3.0 vs 7.8 ± 0.4). Osteoblast function was increased with mineral apposition rate (MAR) elevated compared to wild type (1.9 um/d ± 0.2 vs 0.96 ± 0.03). Contrary to Y2 delete mice, osteoclast surface was also increased (16.3% ± 1.3 vs 8.0 ± 0.9) as was body weight (29.7g ± 1.0 vs 24.4 ± 0.8) due to greater fat mass. Again unlike Y2 delete mice, IGF-1 levels were reduced by around 50%. There was no effect on cortical bone size or length.

Y1Y2 double delete mice had increased bone volume (12.4% ± 0.9) but was not different to Y1 or Y2 (12.4% ± 1.7) alone, with no increase in osteoclast surface (7.0 % ± 0.7). There was no cortical phenotype and body weight was normal.

Y1ob mice had reduced bone volume (8.5% ± 1.3) compared to Y1, but not ob/ob (10.3% ± 1.0); this reduction was consistent with increased osteoclast surface. Hypothalamic over expression of NPY greatly increased leptin levels, and was associated with reduced bone in Y1 (10.0% ± 0.9 vs 6.6 ± 1.2), consistent with a reduced MAR (2.0 um/d ± 0.2 vs 1.1 ± 0.2).

Hypothalamic Y1 receptors are potent modulators of cancellous bone volume and bone cell function. As with ob/ob, Y1 receptor deletion results in pleiotropic effects with hormonal and metabolic effects in addition to osteoblastic and osteoclastic changes, in contrast to Y2 deletion.

The Age-Related Increase in Bone Area Assessed by QCT Is Site- but not Sex-Specific: Age, Gene/Environment Susceptibility-Reykjavik Study. G. Sigurdsson[1], T. Aspelund*[1], B. Jonsdottir*[1], A. Gudmundsson*[1], T. B. Harris*[2], V. Gudnason*[1], T. F. Lang[3]. [1]Icelandic Heart Association, Kopavogur, Iceland, [2]National Institute on Ageing, San Francisco, CA, USA, [3]University of California, San Francisco, CA, USA.

Quantitative computerized tomography (QCT) is a novel technology that allows estimation of the trabecular and cortical bone but there are few data on this measurement in populations. We compared cross-sectional QCT measures of bone size by age and gender in the axial skeleton (lumbar spine) and appendicular skeleton (hip and mid-femur) in the Age, Gene/Environment Susceptibility-Reykjavik Study (AGERS). In AGERS, an ongoing population-based study in Icelandic men and women 67 years and older, we measured the cross-sectional area of L_1 and L_2 (VCSA) and mid-vertebral integral bone mineral density (BMD) to derive a figure for vertebral compression strength (g^2/cm^4=BMD^2xVCSA). We also measured the min. cross-sectional area in femoral neck (MINCSAFN), max. area through the intertrochanteric plane (MAXCSATR), total, medullary and cortical cross-sectional areas through mid-femur. Study population consists of 638 men and 568 women, 67-93 years old, and excludes 1036 persons with evidence of fracture in L_1 or L_2 or on medication affecting bone. We used regression models to assess the effects of age and gender adjusting for current and measured height in mid-life for cohort effects in height.
Average VCSA (L_1 and L_2) increased by 5%/10 years of age in men (trend for age, $p<0.001$) and 4% in women ($p<0.001$), with no significant difference by gender. Vertebral integral BMD decreased significantly more in women than men, 12% vs. 6%/10 years ($p<0.01$ for gender). Vertebral compressive strength decreased by 26% in women compared to 11% in men/10 years ($p<0.01$ for gender). The MINCSAFN did not change significantly with age or gender, whereas the MAXCSATR increased by 2%/10 years of age in both sexes (trend for age, $p<0.01$). Mid-femoral cross-sectional area (MFCSA) increased by 1.8% in men and 1.4%/10 years of age in women ($p<0.01$). While gender differences in MFCSA were not significant, the medullary area in mid-femur increased by 15%/10 years of age in women compared with 3% in men ($p<0.01$ for gender). The cortical area in mid-femur decreased by 2.8%/10 years in women with no change in men. In the lumbar vertebrae, the decline in compressive strength with age is accompanied by greater decline in BMD than in bone size with differences greater in women than men. In mid-femur, the main age-related change was an increase in medullary area, greater in women than men. Our cross-sectional data indicate that bone size changes with age differ by anatomic site but the differences are not consistently significant by gender.

GGT (gamma-glutamyltranspeptidase) as a Pathogenic Factor of Bone Loss. K. Hiramatsu*[1], S. Tatsumi*[1], Y. Nimura*[2], H. Takasu[1], S. Niida[1], M. Ito[3], K. Ikeda[1]. [1]Department of Bone and Joint Disease, National Center for Geriatrics and Gerontology (NCGG), Obu, Japan, [2]Department of Surgery, Nagoya University Graduate School of Medicine, Nagoya, Japan, [3]Department of Radiology, Nagasaki University Hospital, Nagasaki, Japan.

We have recently identified GGT (gamma-glutamyltranspeptidase) as an osteoclastogenic factor, in Xenopus oocyte expression screening of cRNA derived from T lymphoma cells that cause osteolysis when injected into nude mice (J Biol Chem 2004). GGT is an ectoenzyme that catalyzes cleavage of glutathione (GSH) and transfer of gamma-glutamyl moiety to acceptors. GGT is most abundantly expessed in proximal renal tubules, while its serum activity is widely used as a biochemical marker of alcoholic liver disease. We have demonstrated that purified GGT from rat kidney as well as recombinant human GGT induces the formation of multinucleated functional osteoclasts in murine bone marrow cultures. Interestingly, GGT's enzymatic activity is not required for its osteoclastogenic function, raising the possibility that GGT has a cytokine mode of action. In order to examine if GGT induces osteoclastogenesis in vivo and stimulates bone resorption, we have generated transgenic mice that over-express GGT using Cre-loxP system. Crossing of floxed eGFP-GGT mice with CAG-Cre gave rise to CAG-GGT mice that produce GGT systemically. They show markedly elevated serum GGT activity and significant increases in serum calcium concentrations (10.1 mg/dl vs. 8.8 mg/dl in WT) with relative decrease in urinary calcium excretion. Micro CT scanning of tibia of CAG-GGT mice revealed decreased 3D BV/TV with increased trabecular separation. Bone histomorphometry showed increased osteoclast number with tendency of suppressed bone formation. Bone marrow macrophages from CAG-GGT mice, when stimulated with M-CSF and sRANKL, generated 2 times more osteoclasts, compared with WT-derived cultures, suggesting increased sensitivity of osteoclast precursors by GGT. Thus, GGT may play a pathogenic role in bone diseases due to accelerated osteoclastic activity, including osteoporosis, arthritis and bone metastasis.

Increased Adipogenesis in Bone Marrow Associated with Decreased BMD in Mice Deficient in Thyroid Hormone Receptors. J. M. Kindblom[1], E. Gevers*[2], S. Movérare*[1], M. K. Lindberg*[1], S. Göthe*[3], B. Vennström*[3], C. Ohlsson[1]. [1]Internal Medicine, Sahlgrenska Academy, Gothenburg, Sweden, [2]National Institute for Medical Research, Division of Molecular Endocrinology, London, United Kingdom, [3]Karolinska Institute, Dept of Cell and Molecular Biology, Stockholm, Sweden.

Mice deficient in thyroid hormone receptor α1 and β (TRα1-/-β-/-) have a severe skeletal phenotype with growth retardation, delayed maturation of long bones and decreased trabecular and total bone mineral density (BMD). The aim of the present study was to investigate the molecular mechanisms behind the skeletal phenotype in TRα1-/-β-/- mice. Global gene expression analysis was performed on total vertebrae from wild type (WT) and TRα1-/-β-/- mice using DNA microarray and the results were verified by real-time PCR. The mRNA levels of six genes (AdipoQ, Adipsin, fat-specific protein 27 (FSP 27), lipoprotein lipase (LPL), retinol-binding protein (RBP) and phosphoenolpyruvate carboxykinase (PEPCK)) expressed by mature adipocytes were increased in TRα1-/-β-/- compared with WT mice. In contrast, markers of early adipocyte differentiation were unchanged in TRα1-/-β-/- mice. Quantitative image analysis revealed an increased amount of fat (225% over WT) due to an increased number but unchanged size of adipocytes in the bone marrow of TRα1-/-β-/- mice. The total BMD was inversely correlated to the expression of genes expressed by mature adipocytes and to the number of adipocytes in the bone marrow. Interestingly, the mRNA levels of the key regulator of osteoclastogenesis, receptor activator of NF-κb ligand (RANKL), were dramatically decreased in TRα1-/-β-/- mice, which might at least partly explain the reduced bone turnover observed in hypothyroidism. In conclusion, TRα1-/-β-/- mice have decreased BMD associated with an increased number of mature adipocytes. One may speculate that disrupted thyroid hormone receptor signalling causes an imbalance in the osteoblast-adipocyte differentiation, leading to a reduced amount of trabecular bone and an increased amount of fat in the bone marrow of TRα1-/-β-/- mice.

The Effects of Differentially Modified Forms of Shh on Endochondral Bone Formation. K. I. Larsen[1], D. J. Robbins*[2], R. Serra[1]. [1]Cell Biology, University of Alabama at Birmingham, Birmingham, AL, USA, [2]Pharmacology and Toxicology, Dartmouth Medical School, Hanover, NH, USA.

During endochondral bone formation, chondrocyte proliferation and differentiation are tightly regulated to achieve proper bone size. The morphogen, Indian hedgehog (Ihh), is secreted from prehypertrophic chondrocytes as they commit to terminal differentiation, inhibiting hypertrophic differentiation in a Pthrp-dependent manner. Ihh binds its receptor, Patched (Ptc), on target cells resulting in increased Ptc expression, which can be used as a read-out for signaling activity. Sonic Hedgehog (Shh), another member of this morphogen family, is highly homologous to Ihh and has comparable activity in several biological assays. Shh was used as a functional substitute for Ihh in these studies. Shh and Ihh are uniquely lipid modified with cholesterol and palmitate, which increase hydrophobicity. We hypothesized that lipid modification of Ihh alters its ability to move through the cartilage matrix and/or affect signaling in target cells. The purpose of this study was to characterize activity in response to differentially modified forms of Shh in the mouse metatarsal organ culture system. Conditioned medium from 293 cells that had been transfected with different Shh constructs was collected and Shh quantified by ELISA and Western analysis. Biological activity of the Shh-conditioned medias was measured by alkaline phosphatase activity in limb micromass cultures. Metatarsal rudiments from E15.5 $Ptc^{(LacZ/+)}$ mice, which contain a targeted knock-in of the β-gal gene into the *Ptc* locus, were incubated with the different Shh-conditioned medias or recombinant Shh (rShh-N), which lacks all lipid modification. Metatarsals were stained with X-gal and Ptc expression was determined by light microscopy of whole mount and cryosectioned bones. Metatarsals incubated with media containing native lipid modified Shh potently increased Ptc expression in prehypertrophic chondrocytes and in the perichondrium only adjacent to the hypertrophic zone, the physiologic Ptc expression zone. Pre-incubation of media with 5E1 neutralizing antibody blocked this increase demonstrating specificity of the Shh signal. Media containing Shh with only the palmitate modification gave the same activation pattern but at much reduced potency suggesting the cholesterol is critical for potency. rShh-N and conditioned media containing Shh without any lipid modification induced Ptc expression in round proliferating chondrocytes and perichondrium along the entire length of the bone. We conclude that lipid modification of Shh alters its potency and range of signaling during endochondral bone formation.

Nkx3.2/Bapx1 Delays Chondrocyte Maturation by Repressing Runx2 Expression. S. Provot*[1], H. Kempf[2], L. C. Murtaugh*[2], U. Chung*[1], H. M. Kronenberg[1], A. B. Lassar*[2]. [1]Endocrine Unit, MGH - Harvard Medical School, Boston, MA, USA, [2]Bcmp, Harvard Medical School, Boston, MA, USA.

The proper formation and growth of limb bones requires tight control over the rate at which cartilage cells divide and mature. A feedback loop between Indian hedgehog (Ihh) and parathyroid hormone related protein (PTHrP) is essential to maintain a pool of dividing, immature chondrocytes at the epiphyses of growing long bones; in the absence of these signals, the proliferative cells are depleted by premature maturation. Conversely, the transcription factor Runx2 is required for chondrocyte maturation. Here we present evidence that the transcription factor Nkx3.2/Bapx1 acts as a key participant in the Ihh/PTHrP loop, at least partly by inhibiting *Runx2* expression, and therefore chondrocyte maturation. In chick and mouse, expression of *Nkx3.2/Bapx1* is restricted to the proliferative zone, and is down-regulated as maturation begins. Artificially preventing this down-regulation, by misexpression of chick *Nkx3.2* through retroviral infection of wing buds of 3.5 days chick embryos, inhibits maturation and traps the chondrocytes in an immature state. Nkx3.2 acts as a transcriptional repressor, and we show that its DNA binding activity as well as its repression activity is essential for its ability to inhibit maturation. Conversely, a "reverse function" mutant of Nkx3.2 that has been converted into a transcriptional activator hastens chondrocyte maturation. We also show that *Nkx3.2/Bapx1* appears to lie downstream of PTHrP, as its expression is lost in *PTHrP*$^{-/-}$ and *PTHrP-receptor*$^{-/-}$ mouse E18.5 growth plates, and is maintained by retroviral *PTHrP* misexpression in infected chick wings. Furthermore, we demonstrate that Nkx3.2 represses *Runx2* expression partially in infected chick embryos, and dramatically in cultures of chick somite explants, and that *Runx2* misexpression can rescue the Nkx3.2-induced delayed maturation, both *in vivo* and *in vitro*. Taken together, these results suggest that Nkx3.2 is a mediator of the effects of PTHrP signaling on chondrocytes, in which it acts to repress the expression of *Runx2*, normally required for the progression of chondrocyte maturation.

Nkx3.2 Repression of Runx2 Gene Activity Promotes Mesenchymal Chondrogenesis. C. J. Lengner, C. Lepper*, J. L. Stein*, A. J. van Wijnen, J. B. Lian, G. S. Stein. Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA.

The DNA-binding transcription factor Runx2 has been shown to be required for osteoblast maturation. We and others have recently shown Runx2 gene activity in pre-cartilaginous condensing mesenchyme in the developing embryo. Here we examine the regulation of Runx2 gene activity in mesenchymal progenitor cells by pro-chondrogenic signaling molecules and transcription factors as well as examine the role of the Runx2 protein during entry of a mesenchymal progenitor cell into the chondrocytic lineage. We identify the homeodomain protein Nkx3.2 as a potent repressor of the Runx2 P1 promoter. We show that Nkx3.2 binds to the Runx2 promoter in a sequence-specific manner at a consensus sequence approximately 100 bp upstream from the transcriptional initiation site and that this binding results in a 5-fold repression of promoter activity. In order to understand the biological significance of this repression, we utilize the C3H10T1/2 pluripotent mesenchymal progenitor cell line as a model system for mesenchymal chondrogenesis. We find that upon induction of the chondrogenic phenotype there is an activation of Nkx3.2 and a concomitant repression of Runx2 gene activity in accordance with our *in vitro* findings. By infecting C3H10T1/2 cells with a Runx2-expressing adenovirus prior to initiation of chondrogenic differentiation, we can by-pass the observed Runx2 repression and prevent the induction of the chondrocytic phenotype, as assessed by Sox9 and Collagen Type II gene expression. If, however, Runx2 is introduced into C3H10T1/2 cultures after the induction of chondrogenesis, there is no effect on the expression of chondrocyte phenotypic genes. Taken together our results demonstrate that Runx2 is a direct target of Nkx3.2-mediated transcriptional repression, and that repression of Runx2 in mesenchymal progenitor cells prior to chondrogenic differentiation is a prerequisite for the activation of chondrocyte phenotypic gene expression. These findings establish a novel role for Runx2 in mesenchymal progenitor cells and identify Runx2 as the first bona fide target of the pro-chondrogenic transcriptional repressor Nkx3.2.

Identification of the Tissue-specific Enhancer Element Responsible for Mouse Type X Collagen Gene Expression *In vivo*. Q. Zheng*[1], B. Keller*[1], G. Zhou[1], D. Napierala*[2], Y. Chen*[1], A. Parker*[3], B. Lee[2]. [1]Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA, [2]Howard Hughes Medical Institute, Houston, TX, USA, [3]Respiratory and Inflammation Research Area, Astrazeneca, Cheshire, United Kingdom.

Type X collagen (*Col10a1*) gene is specifically expressed in hypertrophic chondrocytes of the growth plate during endochondral ossification. Its deficiency in human causes Schmid metaphyseal chondrodysplasia (SMCD). Multiple regulatory elements within human, murine and chicken *Col10a1* promoter regions have been reported to direct type X collagen gene expression at different levels by in vitro transfection studies. Our previous studies showed that 4 kb *Col10a1* promoter containing Runx2 elements can specifically drive weak reporter gene (*LacZ*) expression in the lower hypertrophic zone of transgenic mice. However, cis elements directing its high level expression throughout the hypertrophic chondrocyte-specific expression *in vivo* have not yet been described. In this study, we report identification of the tissue-specific enhancer element responsible for high level mouse *Col10a1* expression by generating additional transgenic mouse lines harboring various *Col10a1* promoter and intronic fragments driving *LacZ* as reporter. An 8 kb *Col10a1* regulatory region encompassing the same 4 kb proximal promoter and second intron can direct reporter gene expression throughout the zone of hypertrophy, albeit at low level. In another transgenic mouse line containing a 10 kb regulatory element, high level tissue-specific expression throughout the hypertrophic zone was observed. These in vivo data suggest the presence of enhancer elements in both *Col10a1* distal promoter and second intron that cooperate with the Runx2 binding elements in the proximal promoter to specify its tissue-specific expression. *In silico* cross species analysis of *Col10a1* shows highly conserved elements within both the *Col10a1* distal promoter and second intron. These elements contain putative AP-1 (Activator protein-1) and Cdx (mouse homologue of Drosophila homeobox gene, caudal) binding sites respectively. We found that transgenic mice using the 6 kb and 4.6 kb *Col10a1* element could direct *LacZ* expression within the hypertrophic zone. This suggests that the conserved *Col10a1* distal promoter element (-4.6 to -3.9 kb) acts as a critical tissue-specific enhancer for *Col10a1* (reporter) expression *in vivo*. Further characterization of this cis element and the putative transcriptional factors that confer its tissue specificity in hypertrophic chondrocytes is essential for understanding the molecular mechanisms that specify endochondral ossification and the pathogenesis of the metaphyseal chondrodysplasias.

Dishevelled Is Required for Chondrocyte Proliferation and Differentiation. N. Zhong*, R. Gersch*, M. Hadjiargyrou. Biomedical Engineering, SUNY, Stony Brook, Stony Brook, NY, USA.

Wnt signaling is crucial for regulating cell proliferation and differentiation leading to the development of many organisms, including Hydra, D. melanogaster, C. elegans and mammals. Previously, we have reported on the activation of Wnt signaling during the early stages of mammalian bone regeneration. In this study, we focused on Dishevelled (Dvl), the first intracellular molecule that is activated following binding of Wnt proteins to its receptors, Frizzled and LRP5/6. Subsequently, Dvl induces the dissociation of the GSK3/Axin/β-catenin complex which normally leads to phosphorylation of β-catenin followed by its polyubiquitination and proteosomal degradation. In the absence of this inhibitory complex, dephosphorylated β-catenin enters the nucleus where it binds to members of the LEF/TCF family of transcription factors and alters the activity of Wnt target genes. As such, Dvl represents a pivotal molecule in the Wnt signaling pathway. Herein, we show that Dvl1, 2, and 3 were upregulated during the early phases of fracture repair, more specifically in proliferating chondrocytes and osteoblasts. Similarly, Dvl 2 and 3 were upregulated during differentiation of chondroblast RCJ3.1(C5) cells. To directly study the functional contribution of Dvl in RCJ differentiation, we utilized RNA interference (RNAi) to specifically target each of the Dvl members. Results indicate significant suppression (19-33%) of cell proliferation following separate transient transfection of Dvl1, 2 and 3 RNAi (as compared to empty vector control). Additionally, following a 4 day transient trasfection of Dvl1, 2, and 3 RNAi, we observe a dramatic suppression of chondrocyte differentiation (as determined by quantitative alcian blue staining), with a 21%, 67%, and 63%, respectively. Similarly, following a 6 day Dvl RNAi transfection, we found a similar trend in suppression of chondrocyte differentiation. Lastly, we find that in the presence of Dvl 1, 2, and 3 RNAi, the expression of both early (Sox9, COL2A1) and late (COL10) chondrogenic differentiation markers, were also significantly suppressed. Taken together, the data indicates the expression and functional significance of Dvl in chondrocytes. It is interesting to note that Dvl2 -/- mice have vertebral and rib malformations and that these skeletal defects were more pronounced in mice deficient for both Dvl1 and Dvl2. Morover, our data strongly suggests that all Dvl1, 2 and 3 function as key components of Wnt signaling. Since the biochemical mechanism by which Dvl regulates Wnt signaling is not fully understood, further work is required to identify which of the many Dvl interacting proteins are also required specifically for chondrocyte proliferation and differentiation.

The Novel Collagen Triple Helix Repeat Containing Gene (Cthrc1) Indicates a Role in Cartilage and Bone Formation via Regulation of Collagen Matrix Production. V. Lindner, P. Pyagay*, Q. Wang*, L. Liaw*. Center for Molecular Medicine, Maine Medical Center Research Insitute, Scarborough, ME, USA.

The purpose of the present study was to understand the function of the novel gene Cthrc1 using both in vitro and in vivo approaches.

Transgenic mice overexpressing Cthrc1 were generated and analyzed using established methods. Routine cell transfection procedures were used to establish CTHRC1 overexpressing and CTHRC1 depleted cell lines. CTHRC1 is a secreted 26.5kDa protein that is glycosylated and highly conserved from lower chordates to mammals. The sequence contains a short collagen domain which prompted the name 'collagen triple helix repeat containing 1'. Cthrc1 mRNA expression is regulated by TGF-ß family members.

During mouse development at 8.5dpc, strong expression of Cthrc1 is observed in the caudal notochord and anterior ventral neural tube and prominent expression is seen at 9.5dpc in the somites and branchial arches. At later stages CTHRC1 was abundant in the developing heart, proliferating chondrocytes and in the surrounding periosteum. Expression of CTHRC1 protein was examined by immunohistochemistry and Western blotting with an antibody raised against recombinant CTHRC1. Expression of CTHRC1 was prominent in the adventitial matrix of injured but not normal blood vessels, distal tubules of the kidney, in the basal layer of the epidermis, airway epithelium, the chorioid plexus and Purkinje cells of the cerebellum. Immunoreactive CTHRC1 was abundant in the bone matrix of growing and adult bones and it was expressed by osteocytes and osteoblasts. In growing bones, CTHRC1 was expressed by chondrocytes of the resting and proliferating zone of

the growth plate but CTHRC1 immunoreactivity was absent from the hypertrophic cartilage. No CTHRC1 expression was seen in the cartilage of adult bones but expression persisted in the perichondrium and periosteum. Overexpression of Cthrc1 in transgenic mice caused severe skeletal abnormalities with disorganized mesenchymal condensations and markedly reduced cartilage proteoglycan as well as brittle bones and skull ossification defects with reduced amounts of bone matrix. The affected tissues revealed reduced levels of mature collagen type 1 while corresponding mRNA levels were markedly increased. Overexpression of Cthrc1 in vivo and in vitro was associated with decreased levels of the procollagen C-proteinase BMP-1. These data indicate that CTHRC1 may inhibit processing of procollagen by reducing BMP-1 expression levels.

Physiological Role and Expression of Fgf-23 *in vivo*. D. Sitara[1], R. G. Erben[2], C. Carr*[3], H. Jüppner[4], B. Lanske[1]. [1]Oral and Developmental Biology, The Forsyth Institute and Harvard School of Dental Medicine, Boston, MA, USA, [2]Institute of Physiology, Physiological Chemistry and Animal Nutrition, Ludwig - Maximilians University, Munich, Germany, [3]Oral and Developmental Biology, The Forsyth Institute, Boston, MA, USA, [4]Endocrine Unit, Massachussetts General Hospital and Harvard School of Medicine, Boston, MA, USA.

FGF-23 has recently been recognized as the circulating phosphaturic factor associated with renal phosphate wasting. To study the expression of Fgf-23 *in vivo* and to determine its physiological role, we generated an animal model in which the entire coding region of mouse *Fgf-23* was replaced with *lacZ.* Heterozygous Fgf-23-ablated mice (Fgf-23$^{+/-}$) appeared to be normal and were fertile. *LacZ* staining of Fgf-23$^{+/-}$ animals showed expression in liver, heart, and somites as early as E11.5 suggesting a specific role during embryonic development. Homozygous Fgf-23-ablated mice (Fgf-23$^{-/-}$) were born according to Mendelian frequency and were macroscopically indistinguishable from their normal littermates at birth. Starting at 10 days postnatally, however, we observed remarkable growth retardation in Fgf-23$^{-/-}$ mice. Body weight and size were significantly reduced when compared to wild-type (WT) littermates (10 days: 6.1 ± 0.4 vs. 6.6 ± 0.5 g, 24 days: 6.2 ± 0.5 vs. 11.3 ± 0.9 g, 40 days: 7.1 ± 0.5 vs. 16.7 ± 1.2 g). The life span of Fgf-23$^{-/-}$ mice was markedly shortened with the longest survival of 9 weeks. Compared to WT mice, homozygous mutant animals exhibited significantly increased serum phosphate concentrations (16.3 ± 0.3 vs. 9.6 ± 0.5 mg/dl). Preliminary data furthermore suggest that serum PTH levels of Fgf-23$^{-/-}$ mice were indistinguishable from those of WT litter mattes at 3 weeks of age, but significantly decreased at 6 weeks of age. Full body skeleton staining using Alizarin Red S showed diminished mineralization in most bones, but more than normal mineralization in other parts of the skeleton. Bone mineral density as measured by pQCT and Piximus was reduced in extremities of Fgf-23$^{-/-}$ mice. Histological examination of bones from Fgf-23$^{-/-}$ revealed severe osteoidosis in the axial and appendicular skeleton, gross deformities and woven bone formation especially in ribs and vertebrae,and disorganized growth plates with reduction in hypertrophic chondrocytes, abnormal formation of secondary ossification center, and hypermineralisation of the primary spongiosa. Taken together, our data suggest that FGF-23 has a role beyond its involvement in the regulation of phosphate homeostasis.

A Pro253Arg Mutation in Mouse FGFR2 Causes Craniosynostosis. L. Yin*[1], J. Wang*[1], X. Du*[1], L. Zhao*[1], N. Su*[1], L. Chen[1], C. Li*[2], C. Deng*[2]. [1]Daping Hospital, Chongqing, China, [2]NIH, Bethesda, MD, USA.

Apert syndrome (AS) is one of the most severe craniosynostosis and is characterized by premature fusion of coronal sutures, craniofacial anomalies, and syndactyly of the digits. Nearly all known cases of AS are caused by mutations of either Ser252Trp or Pro253Arg in fibroblast growth factor receptor 2 (FGFR2). Using knock-in strategy, recently we generated a mouse model which mimic human AS that caused by a Pro253Arg mutation in FGFR2. We showed here the mutant mice exhibit premature fusion of coronal sutures, brachycephaly and smaller body size but no syndactyly of the digits. Some of the mutant mice exhibit distorted skulls with proptosis too. The ossification of calvaria is accelerated in mutant embryo and accompanied by decreased, rather than increased, bone formation. Examination of the coronal sutures of postnatal mutant mice revealed premature fusion. The osteoblast proliferation is slightly decreased but the osteoblast differentiation is not obviously altered in the mutant coronal suture. We did not find premature fusion of the cranial base, but the mutant synchondroses had slightly shorter columns of proliferating chondrocytes. The abnormalities of mutant skull appear before the premature fusion of coronal suture. Thus, the retarded growth of cranial base may also play an important role in the early pathogenesis of skull deformation of AS, while the role of premature fusion of coronal suture is more important in later development stage.

Circulating Osteogenic Cells in Heterotopic Bone Formation. R. J. Pignolo[1], P. C. Billings*[2], R. K. Suda*[1], E. M. Shore[2], F. S. Kaplan[2]. [1]Department of Medicine, University of Pennsylvania, Philadelphia, PA, USA, [2]Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, USA.

Cells with osteogenic potential, including mesenchymal precursors, can be found in a variety of tissues. Recently, osteogenic precursor cells have been identified in the circulation as a population of mononuclear blood-derived adherent cells (BdACs) that can produce bone in vivo. To test the hypothesis that BdACs are more abundant in patients who are predisposed to heterotopic bone formation, we used peripheral blood samples from patients with fibrodysplasia ossificans progressiva (FOP) and from unaffected individuals to determine relative circulating levels of these osteogenic precursor cells. BdACs were isolated from 22 subjects in a blinded fashion, 11 who were later identified as unaffected individuals and 11 individuals with FOP. The presence of BdACs was analyzed by direct visualization using light microscopy 72 hours after introduction of cells into culture. FOP patients with recent exacerbations (episodes of heterotopic ossification) had significantly higher numbers of BdACs compared to patients with stable disease or unaffected individuals. Using immunofluorescence, we characterized BdACs as a type I collagen+/CD34+ subpopulation that may be related to circulating fibrocytes, initially described in the context of wound repair, but subsequently found to participate in granuloma formation and various fibrosing disorders. We further demonstrated by assays of in vitro mineralization and in vivo bone formation that fibroblast-like BdACs from patients with FOP are osteogenic. These cells differ most notably from those derived from unaffected individuals by their ability to form polyclonal cultures with bone-forming capacity. The possibility that circulating fibroblast-like cells with osteogenic potential can seed sites of inflammation and tissue injury with resultant ectopic bone formation has tremendous clinical implications. The greater abundance and osteogenic potential of FOP BdACs may portend a possible pathophysiologic role for these cells as osteoprogenitor cells and, to our knowledge, would represent the first example of their involvement in heterotopic ossification.

Evidence that Osteoblast Lineage Cells are Present in the Peripheral Circulation and Increase Markedly During the Pubertal Growth Spurt. G. Z. Eghbali-Fatourechi, J. Lamsam*, D. Fraser*, B. L. Riggs, S. Khosla. Mayo Clinic, Rochester, MN, USA.

That osteoclast lineage cells circulate is well accepted. Using assays requiring adherence to plastic, rare concentrations [<1 in 10^8 mononuclear cells (MNC)] of osteoblast (OB) lineage cells have been detected in peripheral blood in humans, but larger numbers comparable to those reported for osteoclasts and correlations of these cells with bone turnover markers have not been reported. Since circulating OB lineage cells may lack the capacity to adhere to plastic (or to other matrices), we used flow cytometry with an anti-osteocalcin (OCN) antibody (Ab) to search for OB lineage cells and identified cells in the circulation of adult humans that express OCN (~1% of MNC). These cells have low forward/side-scatter, consistent with a small, mononuclear phenotype, and the majority do not express the myeloid/stromal marker, CD34. Under appropriate culture conditions [expansion of cell numbers in stem cell medium for 3 weeks (including isolation and re-addition of non-adherent cells with media changes) followed by OB differentiation medium for 3 weeks], sorted OCN+ form mineralized nodules in vitro. Moreover, as shown in panel A, when compared to adult male subjects (n = 11, mean age 38.7 yrs), the percentage of these OCN+ cells is markedly increased in the circulation of adolescent boys going through the pubertal growth spurt (n = 11, mean age 14.5 yrs), who also have increased bone formation indices [serum OCN (mean ± SE), 145 ± 17 vs 25 ± 1 ng/mL and bone alkaline phosphatase (BAP), 148 ± 19 vs 29 ± 2 U/L in the boys vs men, P < 0.001 for both). Panel B shows the flow cytometry profile of these cells in the circulation of an adolescent boy (OCN Ab and isotype control). Finally, we also found that in the two merged groups, the percent OCN+ cells correlated directly with serum OCN (R = 0.72) and BAP (R = 0.77, P < 0.001 for both).

We conclude that OB lineage cells circulate in significant numbers. Because they correlate directly with bone formation markers and are markedly increased during the pubertal growth spurt, they may represent a heretofore unrecognized circulatory component to the process of bone formation. Further, these methods potentially provide a powerful new tool for studying OB differentiation without bone or bone marrow sampling and for investigating the pathophysiology of osteoporosis and other metabolic bone diseases.

Crohn's Disease in Childhood Is Associated with Decreased Trabecular Density, Cortical Dimensions and Muscle Mass. M. B. Leonard, R. M. Herskovitz*, K. M. Howard, R. N. Baldassano*, J. M. Burnham, B. S. Zemel. Pediatrics, The Children's Hospital of Philadelphia, Philadelphia, PA, USA.

Pediatric Crohn's disease (CD) is associated with decreased bone mass and increased risk of fracture; however, the effects of CD on muscle mass, trabecular density and cortical geometry have not been well-characterized. The objective of this longitudinal study was to identify bone deficits at the time of CD diagnosis, and to evaluate changes in bone measures over the subsequent 12 months.

Peripheral quantitative computed tomography (Stratec XCT 2000) measurements of the tibia were obtained in 68 incident CD subjects (36M/32F) and 159 healthy controls (73M/86F), ages 5 to 18 yr. To date, 31 CD subjects have completed the 12 month visit. Trabecular volumetric BMD (vBMD) was measured at the 3% distal site; cortical vBMD, cross-sectional area (CSA), and stress-strain index (SSI, density-weighted section modulus) at the 38% site; and muscle CSA at the 66% site.

Height and BMI were converted to age and gender specific Z-scores using national reference data. Multivariable linear regression models were developed to evaluate pQCT results in the baseline CD subjects, compared with controls. In order to examine changes over the 12 months, bone and muscle measures were expressed as gender-specific Z-scores derived from linear regression models in the controls.

At diagnosis, CD was associated with decreased height and BMI Z-score (both $p< 0.001$). Trabecular vBMD was significantly decreased ($p< 0.001$), adjusted for age, gender and race. Cortical vBMD did not differ between CD and controls. CD was associated with significant deficits in cortical CSA ($p < 0.001$), SSI ($p < 0.05$), and muscle CSA ($p < 0.001$), adjusted for gender, race and tibia length. When the models for bone outcomes were adjusted for muscle CSA, the deficits in cortical CSA and SSI were no longer statistically significant, and the deficits in trabecular vBMD were attenuated.

Baseline and 12 month Z-scores are summarized below for the CD subjects completing the 12 month visit. Z-scores for trabecular vBMD and muscle CSA Z-scores increased significantly; however, cortical CSA and SSI Z-scores decreased further.

This is the first prospective, longitudinal study using pQCT to evaluate bone health in a chronic childhood disease, demonstrating significant deficits in trabecular density, cortical geometry and muscle.

Gender-Specific Z-Scores (Mean ± SD) at Baseline and 12 Months in CD

VARIABLE	Baseline	12 Month	p
Height-Z	-0.42 ± 0.90	-0.34 ± 0.87	NS
BMI-Z	-0.81 ± 0.92	-0.35 ± 0.74	< 0.0001
Trabecular vBMD-Z*	-1.51 ± 1.51	-1.1 ± 1.32	< 0.01
Cortical CSA-Z**	-0.41 ± 1.23	-0.65 ± 1.11	0.05
Cortical SSI-Z**	-0.20 ± 1.00	-0.50 ± 0.88	< 0.001
Muscle CSA-Z**	- 0.75 ± 1.11	-0.41 ± 0.92	< 0.01

* Adjusted for age. ** Adjusted for tibia length.

Bone Defects in NSE/hIL-6 Mice Overexpressing IL-6 Reminiscent of the Human Systemic Juvenile Idiopathic Arthritis. F. De Benedetti*[1], A. Funari*[2], S. Berni*[3], P. Ballanti*[3], C. Di Giacinto*[2], R. Paro*[2], E. Spica*[2], N. Rucci[2], A. Teti[2]. [1]Ospedale Bambino Gesù, Rome, Italy, [2]University of L'Aquila, L'Aquila, Italy, [3]University La Sapienza, Rome, Italy.

Stunted growth is a complication of childhood diseases characterized by chronic inflammation or infections. Systemic juvenile idiopathic arthritis (s-JIA) is an inflammatory disease characterized by prominent IL-6 production and elevated IL-6/sIL-6R complexes. We have generated the NSE/hIL-6 transgenic mice, over-expressing IL-6 under the control of the rat neurospecific enolase (NSE) promoter, and observed a bone phenotype reminiscent of the human s-JIA syndrome. NSE/hIL-6 mice expressed high circulating levels of IL-6 since birth and showed a marked decrease in growth rate leading to adult mice 50-70% the size of wild-type littermates. The growth defect was completely abolished by neutralization of IL-6. X-ray analysis showed significant reduced length of tibia and femurs, which persisted throughout life. Conventional histomorphometry of tibias showed decreased bone trabecular volume and number in the secondary spongiosa of the proximal and distal chondro-osseous junctions to the diaphysis in 5- to 20-d old mice, fully rescued in adult mice. Histochemical analysis revealed increased osteoclast and decreased osteoblast numbers and surfaces. Remarkable reduced cortical thickness characterized juvenile mice, with rescue in adult animals at the proximal and, to a lesser extend, distal ends of the diaphysal collar, but not in the mid-diaphysis. Dynamic measurements by calcein/alizarin red labelling showed no endosteal and 50% reduced periosteal apposition in the NSE/hIL-mice compared to controls. Consistently, increased osteoclast numbers and bone resorption was observed in the endosteal surface of the transgenic mice suggesting that endosteal erosion and reduced periosteal deposition contributed to cortical thinness. Clear-cut reduction of growth plate thickness was consistent with reduction of secondary spongiosa. In young mice, secondary ossification centers were delayed at both epiphyses, as they appeared less extended, showed less hyperthrophic chondrocytes, blood vessels, osteoclast and osteoblast precursors, and were not mineralised as indicated by negative von Kossa staining. NSE/hIL-6 mice showed normal serum growth hormone and low IGF-I, the latter due to marked decreased levels of IGFBP-3 and subsequent increased IGF-I clearance. In conclusion, NSE/hIL-6 mice mimic the systemic juvenile idiopathic arthritis, represent a faithful animal model of the growth impairment associated with chronic inflammatory diseases, and emphasize a role for IL-6 and/or for IGF-I catabolism in stunted skeletal growth.

Regulation of Runx2 Action during Osteoblast Development by a Novel Runx2-interacting Protein. G. Zhou[1], P. Hermann*[2], E. Munivez*[2], R. Morello*[1], Y. Chen*[2], Q. Zheng*[1], B. Lee[2]. [1]Dept. of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA, [2]Dept. of Molecular and Human Genetics/Howard Hughes Medical Institute, Baylor College of Medicine, Houston, TX, USA.

RUNX2 is one of three vertebrate members of the runt family of transcription factors which have in common an 128 amino acid motif that mediates both DNA binding and protein-protein interaction. Runx2 null mice have complete absence of osteoblast and bone but an intact cartilagenous skeleton and loss of function mutations of RUNX2 result in the human skeletal disorder-cleidocranial dysplasia (CCD). While Runx2 is essential for osteobalst differentiation and chondrocyte maturation, additional factors are likely required to regulate the differentiation program. To identify potential RUNX2-interacting proteins, we screened a human osteosarcoma cDNA library using a yeast two-hybrid approach with RUNX2 as bait and isolated a 500-bp partial cDNA which was termed RIP(Runx2-interacting protein). Multiple human tissue Northern blot analysis and in situ hybridization on mouse E15.5 embryos revealed ubiquitous expression including osteoblasts. RIP encodes a 297 amino acid polypeptide with no homology to known proteins in the database. Sequence analysis revealed a multidomain structure characterized by several protein-protein interaction domains and a nuclear localization signal. The physical interaction between RIP and RUNX2 was confirmed by GST pulldown experiment. In transient transfection RIP down-regulated the transactivation by RUNX2 in a dose-dependent manner in 10T1/2 cells and it also decreased the activity of an osteoblast-specific reporter in ROS17/2 cells by 50%. Furthermore immunofluorescent staining showed that RIP mainly localized in the nucleus. Both human and mouse RIP gene is encoded by 11 exons dispersed over 40kb of genomic DNA. FISH and radiation hybrid mapping studies showed that RIP localizes to chromosome 8q22 syntenic with a hypothesized second CCD-like locus. Interestingly RIP expression is upregulated in CCD-like patient cells with 8q22 rearrangements, supporting its function as a repressor of RUNX2. We would predict that upregulation of a putative repressor of Runx2 would cause loss of Runx2 transactivation and hence a CCD-like phenotype in vivo. To elucidate the potential effect of RIP on skeletogenesis, we are studying its action by generation RIP null mice and transgenic mice overexpressing RIP in osteoblasts.

The High-Mobility-Group Transcription Factor Sox8 Regulates Osteoblast Differentiation in a Runx2-Dependent Manner. T. Schinke[1], K. Schmidt*[2], M. Haberland*[1], M. Priemel[1], A. F. Schilling[1], C. Mueldner*[1], J. M. Rueger*[1], E. Sock*[2], M. Wegner*[2], M. Amling[1]. [1]Trauma Surgery, Hamburg University, Hamburg, Germany, [2]Institute of Biochemistry, Friedrich-Alexander University Erlangen-Nuernberg, Erlangen, Germany.

Bone remodeling is an important physiologic process that is required to maintain a constant bone mass from the end of puberty until gonadal failure. This is achieved through a well-balanced activity of bone-resorbing osteoclasts and bone-forming osteoblasts that needs to be tightly regulated. In this study we have identified the high-mobility-group transcription factor Sox8 as a physiologic regulator of osteoblastic bone formation. Sox8-deficient mice show normal bone development, but display an osteopenic phenotype at the age of six months. This phenotype is caused by an impaired osteoblast differentiation, since the numbers of functional osteoblasts are largely reduced in Sox8-deficient mice compared to wildtype littermates (5.63 + 2.51 vs. 17.86 + 2.25 osteoblasts per bone perimeter, n=6, $p<0.005$). Surprisingly, primary osteoblasts derived from these mice show an accelerated mineralization ex vivo as well as a premature expression of Runx2, a key transcription factor involved in the regulation of bone formation. Taken together, these results suggested that Sox8 is a negative regulator of osteoblast differentiation acting in a Runx2-dependent manner. To confirm this hypothesis we have generated transgenic mice expressing Sox8 under the control of an osteoblast-specific Col1a1 promoter fragment. These Col1a1-Sox8-trangenic mice have a severely impaired bone formation and display a phenotype that is reminiscent of cleidocranial dysplasia. Accordingly, we observed a marked reduction of Runx2 expression in Col1a1-Sox8-trangenic mice compared to wildtype littermates, thereby suggesting an involvement of Sox8 in the regulation of Runx2 expression. This hypothesis is consistent with the finding that functional Sox8 binding sites overlap with the autoregulatory Runx2 binding sites in the promoter region of the Runx2 gene. Taken together, these data demonstrate that Sox8 is a physiologic regulator of postnatal bone formation, whose coordinated expression is critical for osteoblast differentiation.

Msx2 Regulates Mesenchymal Cell Fate & Body Composition Via Paracrine Wnt-Dkk Signaling. S. Cheng, J. Shao*, N. Charlton-Kachigian*, A. Loewy*, D. A. Towler. Div. of Bone and Mineral Diseases, Dept. of Med, Washington University School of Medicine, St. Louis, MO, USA.

Msx2 promotes osteogenic differentiation of mesenchymal and vascular progenitors while suppressing adipogenic potential. Along with cell autonomous actions, conditioned medium (CM) from Msx2-transduced cells controls cell fate; Msx2 CM enhances alkaline phosphatase (ALP) activity of C3H10T1/2 cells by 50%, but inhibits adipogenesis by > 90%. Since Wnts exert similar activities, we studied effects of Msx2 on Wnt and Dkk signaling. Msx2-transduced 10T1/2 cells and myofibroblasts express significantly elevated Wnt1, Wnt3a, Wnt5a, and Wnt5b levels. In contrast, Dkk expression is decreased to <24% of control (Dkk1 in myofibroblasts, Dkk2 in 10T1/2 cells). Msx2 transduced cells exhibit

enhanced nuclear accumulation of beta-catenin, consistent with enhanced canonical Wnt signaling. Moroever, Msx2 CM stimulates canonical Wnt-regulated LEF-TCF transcription activity. Importantly, 1 µg/ml recombinant Dkk1 suppresses Msx2-dependent ALP induction; in addition, Dkk1 partially reverses Msx2 suppression of adipogenesis (by Oil Red O staining). To confirm these results, we generated CMV-Msx2 transgenic mice. Msx2 is significantly over-expressed in aorta, bone marrow cells, and osteoblasts isolated from transgenic mice (2.9, 1.6, and 2.6 fold, respectively) as compared to wild type littermates (WT). Wnt3a levels in aorta and osteoblasts are increased in Msx2 transgenics (2.7 and 3.8 fold), with a concomitant decrease in Dkk1 in aorta and Dkk2 in osteoblasts (27% and 64% of WT). Mineralization of cultured osteoblasts derived from these transgenic mice is enhanced as compared to cultures derived from non-transgenic WT littermates. DXA was used to assess body composition. The BMD of Msx2 transgenic mice is significantly higher than WT littermates after 4 and 8 weeks of a high fat diet challenge (2.7% and 3.5% increase), and persisted out to 16 weeks of dietary challenge. By contrast, total body fat is significantly decreased in Msx2 transgenic mice as compared to WT, and serum leptin levels are concomitantly lower (452.1+/- 174.4 vs. 1773.1+/- 383.6 pg/ml). Thus, Msx2 regulates mesenchymal cell fate and body composition in part via paracrine Wnt-Dkk signals.

DeltaFosB Interacts with a Novel Zinc-finger Containing Protein (MC-33) which Downregulates Expression of Runx2 and Alkaline Phosphatase. M. Wu, F. Morvan, J. Zhang*, L. Neff*, W. Philbrick*, W. C. Horne, R. Baron. Cell Biology, Yale University, New Haven, CT, USA.

We have previously demonstrated that overexpression of ΔFosB in transgenic mice resulted in a severe and progressive, but reversible osteosclerotic phenotype that led to increased bone volume. *Ex vivo* and *in vitro* studies demonstrated that increased levels of Δ2ΔFosB, an N-terminally truncated isoform, mimicked most of the effects of ΔFosB, i.e. increased expression of osteoblast markers (collagen type 1, osteocalcin, osteopontin, and Runx2) as well as an increased rate and amount of bone nodule formation. This effect was shown to be cell autonomous to the osteoblast lineage. In an effort to identify the mechanism by which ΔFosB and Δ2ΔFosB regulate bone formation and osteoblast differentiation, we performed a yeast two-hybrid screen to identify Δ2ΔFosB binding partners. In addition to interacting with Runx2, we identified a novel clone (MC-33) as a Δ2ΔFosB binding partner. The 3.9 kb open reading frame of the full-length cDNA of MC-33 encodes a protein of approximately 180 kDa with multiple zinc fingers that localizes to the nucleus in transiently transfected cells. Northern blotting demonstrates that MC-33 is mostly expressed in brain, heart, lung, and skeletal muscle, but is also expressed at lower levels in spleen, kidney and liver as well as bone and fat. Primary osteoblasts cultured from calvarial preparations exhibit high levels of MC-33 expression. In-situ hybridization studies demonstrate that during bone development, MC-33 mRNA is expressed in mesenchymal condensations as early as embryonic day 12. Expression is maintained at high levels through embryonic day 18 and birth, with expression in the preosteoblastic layers and in the growth plate. *In vitro*, MC-33 mRNA is downregulated by stimulation with BMP-2 and adipogenic agents (indomethacin, hydrocortisone and IBMX). Further, transient transfection of MC-33 into C3H10T1/2 and MC3T3-E1 cells results in suppression of the Δ2ΔFosB-induced increase in Runx2 expression. Finally, MC-33 decreases alkaline phosphatase activity in transiently transfected primary osteoblasts. We propose that MC-33 modulates the control of osteoblast differentiation and that overexpressed Δ2ΔFosB binds MC-33, thereby disturbing the balance of transcriptional regulators.

Identification and Functional Characterization of a Novel Osteoclast-Derived Osteoblastic Factor (ODOF). T. Phan*, R. Han*, T. Davey*, V. Smuts*, M. H. Zheng, J. Xu*. Orthopaedic Surgery, The University of Western Australia, Nedlands WA, Australia.

Intercellular communication between osteoblasts and osteoclasts is the quintessential mechanism in bone remodelling. Here we report the identification and functional characterization of an Osteoclast-Derived Osteoblastic Factor (ODOF), which is expressed by osteoclasts, binds specifically to osteoblasts and elevates cytosolic calcium ($[Ca^{2+}]_i$) resulting in the proliferation of osteoblastic cells. The ODOF gene was identified in $RAW_{264.7}$ cell-derived osteoclasts utilising a PCR-selected subtractive hybridisation screening process. Further investigations using reverse transcriptase PCR, revealed that ODOF mRNA was up-regulated during RANKL-induced osteoclastogenesis but was not expressed in osteoblasts or osteoblast-like cells. Recombinant His-tagged ODOF was subsequently produced and labelled with ^{125}I to ascertain its binding profile. The protein exhibits highly specific binding to primary calvarial osteoblasts with a binding affinity of 1.7±0.4nM and $2.7x10^4$±306 receptors per cell but not with osteoclasts and their precursor cells. Functional studies demonstrated that ODOF stimulates an increase in the growth and proliferation of osteoblastic cells. In contrast, the protein did not promote osteoclastogenesis, osteoclast survival or bone resorption. Mechanistic analysis revealed that ODOF, alone, elevates intracellular $[Ca^{2+}]_i$ through the PLC-IP3 induced depletion of calcium stores. Moreover, western blot analysis reveals that ODOF induces the activation of the PI3K-Akt and ERK pathways in osteoblasts. Taken together, our results provide evidence for a novel cross-talk mechanism between the osteoclast and osteoblast and indicate that osteoclasts play a role in regulating osteoblastic growth and proliferation.

Dlx3 Is a Transcriptional Regulator of Osteoblast Differentiation and Increases Expression and Promoter Activity of Runx2. M. O. Hassan*[1], A. Javed[1], M. I. Morasso*[2], J. Karlin*[1], M. Montecino*[3], A. J. van Wijnen[1], G. S. Stein[1], J. L. Stein*[1], J. B. Lian[1]. [1]Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA, [2]Developmental Skin Biology Unit, NIAMS, National Institutes of Health, Bethesda, MD, USA, [3]Departmento de Biologia Molecular, Universidad de Concepcion, Concepcion, Chile.

In response to the osteogenic BMP2 signal, multiple homeodomain HD) proteins are induced by BMP2 within 1-4 hrs and exhibit distinct temporal expression profiles during osteoblast differentiation. Among these are Msx and Dlx family members. While null mouse phenotypes indicate Msx2 and Dlx5 HD proteins support their roles in skeletal development, ablation of the closely related Dlx3 gene results in early embryonic lethality. Here we examined the role of Dlx3 in bone formation. In the mouse embryo, Dlx3 is expressed in periosteum and osteoblasts associated with sites of new bone formation. Dlx3 overexpression in osteoprogenitor cells promotes a 3-6 fold induction of bone markers, while RNAi knock-down of Dlx3 delays upregulation of these which include BSP, collagen I, osteopontin and osteocalcin (OC) during MC3T3 cell maturation. We characterized regulation of the bone specific OC gene by Dlx3 in relation to Dlx5 which is also reported to stimulate osteoblast differentiation and to the repressor HD protein Msx2. Interaction of these proteins with the OC gene during primary rat osteoblast differentiation was examined using chromatin immunoprecipitation assays. Two molecular switches in the association of HD proteins with the OC gene promoter were observed. In proliferating osteoblasts, the transcriptionally repressed OC gene is occupied by Msx2 at the homeodomain regulatory element; while Dlx3, Dlx5 and Runx2 are recruited post-proliferatively when transcription is initiated. A second switch occurs at the mineralization stage when Dlx5 occupancy increases and Dlx3 interaction declines. We also show that Dlx3 protein-DNA interactions stimulate Runx2 and OC promoter activity, while Dlx3 and Runx2 form a co-regulatory complex and this protein-protein interaction reduces OC transcription. Thus, our findings provide direct cellular and molecular evidence that Dlx3 contributes to regulating osteoprogenitor cell differentiation and supports both positive and negative regulation of gene transcription. Further our results show that distinct homeodomain proteins sequentially associate with promoter regulatory elements during progression of differentiation. We propose that multiple HD proteins in osteoblasts constitute a regulatory network which mediates development of the bone phenotype.

Resistive Vibration Exercise Prevents Bone Loss During 8 Weeks of Strict Bed Rest in Healthy Male Subjects: Results from the Berlin BedRest (BBR) Study. J. Rittweger*[1], D. Felsenberg[2]. [1]Institute for Biophysical and Clinical Research into Human Movement, Manchester Metropolitan University, Alsager, United Kingdom, [2]Center for Muscle and Bone Research, Charite - University Medicine Berlin, Campus Benjamin Franklin, Berlin, Germany.

Introduction: Muscle atrophy and bone loss pose problems in clinical immobilisation, but also during space flight. No effective countermeasure is available. For space flight, this restricts the possibility to perform long term missions. Bed rest studies are recognized as ground based models for microgravity. We hypothesized that vibration exercise (VbX), combined with progressive resistive training is an effective countermeasure to prevent bone loss from the lower body half during prolonged bed rest.

Method: 20 young healthy males were reqruited and randomly assigned to either the control group (Ctrl) or to the exercise group (Vbx). All subjects completed 8 weeks of strict bed (BR) rest under video surveillance. Bone mineral content (BMC) and muscle cross sectional area (mCSA) were measured by quantitative computed tomography in the calf and the forearm, and leg muscle volume by MRI. Jumping height and power were assessed along with peak isometric torque in knee extension and foot dorsiflexion and plantarflexion before and after BR. Exercise was performed in supine position in 4 bouts of 1 minute twice per day on 6 days/week. Vibration frequency was 19-23 Hz, and peak forces during squat exercise were around 2000 N.

Results: Since the last 4 subjects will be re-ambulated on 16/05/2004, this abstract is based on 16/20 subjects only. An interim analysis, however, shows that the final results will be very similar to these.

Percent Changes in the Left Calf; mean (SD); Different from Ctrl: * = p<0.05, *** = p<0.001

	Ctrl	VbX
Calf mCSA	-16.5 % (3.9 %)	-8.6 % (3.9 %) ***
BMC Tibia Epiphysis	- 4.0 % (1.7 %)	-0.5 % (0.9 %) ***
BMC Tibia Metaphysis	-1.2 % (1.0 %)	-0.2 % (.7 %) *
BMC Tibia Diaphysis	-1.3 % (0.4 %)	-0.4 % (0.5 %) *

Significant group differences were found in all BMC and mCSA variables, with the VbX group having smaller changes than the Ctrl group. Bone loss from the tibia was non-significant in the VbX group. Results in the right limbs were equivalent to those obtained in the left limbs. Immediately after reambulation, jumping height had decreased by 31.4% (SD 19.8%) in the Ctrl and by 13.1 % (SD 4.2%) in the VbX group (p<0.01), and peak power declined by 26.2 % (SD 11.6 %) in the Ctrl and by 10.5 % (SD 6.4 %) in the VbX group (p<0.01).

Conclusion: Resistive vibration exercise, as applied here, appears to completely prevent bone loss from the tibia during prolonged bed rest. It is thus the first effective countermeasure found.

Rest-Inserted Loading, When Supplemented with IGF-1, Enhances Bone Formation and Bone mass in the Aged Skeleton. S. Srinivasan, K. A. King*, N. A. Rabaia*, M. Sheafor*, S. Warner, T. S. Gross. Orthopaedics and Sports Medicine, University of Washington, Seattle, WA, USA.

Previously, we reported that inserting rest (10-s unloaded intervals) between low-magnitude load cycles was perceived by bone cells and tissues as a potently osteogenic regimen. More recently, we observed that aging substantially blunted the osteogenic response to rest-inserted loading, primarily via deficits in mineral apposition by osteoblastic cells. We proposed that explicitly countering this deficit via systemic IGF-1 administration (given the role of IGF-1 in modulating osteoblast function), might provide a means to enhance and sustain bone formation in the aged skeleton. Here, we tested this proposal by subjecting aged female C57BL/6 mice (23 Mo) to long-term rest-inserted loading protocols, with and without IGF-1 supplements. Animals (n = 12) were subject to 50 c/d of rest-inserted loading, 3 d/wk for 9-wk. Within this cohort, one group received rhIGF-1 on loading days (2 mg/Kg, n = 7). Adaptive responses were assayed via dynamic histomorphometry and microCT imaging. By 3-wk, the tissue responses in intact contralateral tibia of mice receiving IGF-1 were no different from that in animals that did not receive IGF-1. Rest-inserted loading alone significantly ($p < 0.05$) enhanced mineralizing surface (MS, 35% compared to control) but did not significantly elevate either mineral apposition (MAR) nor bone formation rates (BFR). In contrast, rest-inserted loading, when supplemented with IGF-1, significantly enhanced MS (70%), MAR (45%) and BFR (150%) compared to controls and MAR (45%) and BFR (70%) compared to animals receiving rest-inserted loading alone. As well, similar response trends were observed at 9-wk. Finally, over the longer-term, rest-inserted loading, when supplemented with IGF-1, significantly enhanced cortical bone volume in aged mice (by 6%, $p = 0.03$). As such, while rest-inserted loading initiated bone cell activity in aged animals (increased MS), it was not sufficient to sustain activity over the short (21-d) or longer-terms (63-d). In contrast, low-dose IGF-1, when utilized as a supplement with rest-inserted loading, augmented bone mass in senescent animals, via enhanced and sustained mineral apposition by osteoblastic cells. Given these promising observations, mechanisms via which rest-inserted loading and IGF-1 interact in the aged skeleton are being explored. More broadly, our observations serve as a model for how select pharmacological agents in concert with potent mechanical stimuli such as rest-inserted loading might provide a means to counteract mechanotransduction deficits precipitated by aging.

A School Curriculum Based Exercise Program Increase Bone Mineral Accrual in Boys and Girls During Early Adolescence - Three Years data from the POP-study (Pediatric Osteoporosis Prevention Study) - a Prospective Controlled Intervention Study in 223 Children. C. Linden*, P. Gardsell*, O. Johnell, K. Obrant, M. Karlsson. Department of Orthopaedics, Malmö University Hospital, Malmö, Sweden.

The longest reported prospective controlled intervention study with exercise in growing children which evaluate the accrual of bone mineral density (BMD) span 20 months. The purpose of this study was to evaluate the effect of an exercise intervention program within the school curriculum during the first school years, to catch also children not specifically interested in exercise, and to present the so far longest controlled follow-up data of exercise during growth. A population based cohort including 76 healthy Caucasian boys (aged 7.8 ± 0.6 at baseline) and 48 girls (aged 7.6 ± 0.6) in the only school in the Bunkeflo society outside Malmo, Sweden, were included in a school curriculum with 40 minutes physical activity every school day. Ninety nine healthy age and gender matched children (55 boys and 44 girls) in three nearby schools, subjected to the general Swedish curriculum of physical activity (60-90 min/w), served as controls. Bone mineral density (BMD; g/cm2) were measured with dual X-ray absorbtiometry (DXA) at total body (TB), lumbar spine (LS), femoral neck (FN) and leg before initiation of the intervention and after 3 years. Data is presented as mean ± SD. There were no differences in height, weight, total lean body mass, total fat content or BMD at baseline when comparing the groups. In boys, the annual gain in BMD in the LS was greater in the intervention group in comparison with the controls during the 3 year follow-up, 0.028 ± 0.011 vs. 0.023 ± 0.009, $p<0.05$. In girls, a similar effect was seen at most sites; TB 0.031 ± 0.012 vs. 0.024 ± 0.009, LS 0.038 ± 0.023 vs. 0.023 ± 0.012, FN 0.051 ± 0.031 vs. 0.036 ± 0.027 and leg 0.059 ± 0.018 vs. 0.049 ± 0.015, all $p < 0.05$ respectively. The discrepancies remained after adjusting for differences in baseline age, weight gain and pubertal development during the study. A school based exercise program within the general curriculum during the first three school years seems to increase the accrual of BMD. This is the first published intervention study that is population based and include the intervention within the school curriculum. Furthermore, it is so far the only intervention study that exceeds 20 months. This is extremely important as it is only when we can show that exercise increase the accrual of BMD during several years, that we can draw conclusions that exercise may increase peak bone mass. Based on the data in this study it seems that increased time spent in physical education classes may increase peak bone mass and subsequently can be used as a prevention strategy for osteoporosis.

Sciatic Denervation Increases Load-induced Cortical New Bone Formation Independently of the Sympathetic Nervous System. C. C. Chenu, R. L. De Souza*, A. A. Pitsillides, L. E. Lanyon, T. M. Skerry. Veterinary Basic Sciences, Royal Veterinary College, London, United Kingdom.

Recent studies have shown evidence for neural regulation of bone remodelling involving the sympathetic nervous system (SNS). While the SNS mediates disuse bone loss, the contribution of innervation to bone's adaptative response to its strain environment is unclear. We therefore examined the effect of sciatic denervation, which induces limb immobilisation and decreased nerve fibers density in the tibiae, on cortical bone formation in response to loading and whether the SNS is directly involved in such load-induced responses. In a first experiment, 40 female C57Bl/J6 mice, aged 10 weeks, were divided randomly into 4 groups. Two groups were submitted to surgical sciatic neurectomy (N) with and without loading, while two groups were sham-operated with and without loading. The loaded regimen used was non-invasive axial loading of the tibiae that induced 2000 µstrain on the lateral midshaft cortex. Tibiae were cyclically loaded, 3 days after surgery, at a frequency of 1 Hz, for a period of 7min, 3days/week for 2 weeks, and received calcein on the third and last days of loading. The mice were killed 18 days after surgery. Tibiae were processed for histomorphometry, and transverse confocal images from 3 diaphyseal sites were analysed. N alone induced a decrease in both periosteal and endocortical bone formation in the tibial midshaft. Both sham and N groups had increased cortical bone formation after loading, but periosteal and endosteal bone formations at the midshaft were significantly higher (+183% and +203% respectively) in the N group compared to sham. To determine the effect of loading on long-term established bone loss, another 2 groups of mice (sham-operated and N) were loaded 100 days after surgery. Similarly, N mice showed significantly increased endosteal (+137%) and periosteal (+120%) new bone formation compared to the sham-loaded group. To establish the contribution made by the SNS to those responses, another 40 female C57Bl/J6 mice, aged 10 weeks were treated daily for 3 weeks either with vehicle (C) or with guanethidine sulphate (GS) (40mg/kg/day) which chemically inactivates the SNS. Half of the C and GS groups were loaded *in vivo*, 2 weeks after the start of injections. GS alone did not affect cortical new bone formation; C and GS-treated mice had similarly increased periosteal and endosteal new bone formation in response to mechanical loading. Our data indicate that sciatic neurectomy enhances loading-related new bone formation in the tibia in the absence of loading function, and that such response cannot be attributed to SNS blockade. This suggests that the SNS does not mediate the load-induced new cortical bone formation.

Site-Specific Osteopenia and Decreased Mechanoreactivity in Lrp5-Mutant Mice. K. Sawakami*[1], A. G. Robling[1], N. D. Pitner*[1], S. J. Warden[1], J. Li[1], M. Ai*[2], M. L. Warman[2], C. H. Turner[1]. [1]Indiana University School of Medicine, Indianapolis, IN, USA, [2]Case Western Reserve University, Cleveland, OH, USA.

LRP5 has an important role in bone mass regulation. Loss-of-function mutations in LRP5 cause osteoporosis pseudoglioma syndrome (OPPG), an autosomal recessive disorder associated with low bone mass and increased bone fragility in humans. We have found that Lrp5-mutant mice (Lrp5-/-) exhibit site-specific osteopenia, especially in mechanically relevant sites, which suggests that LRP5 regulation of bone mass might involve mechanotransduction pathways. We hypothesize that the loss-of-function mutation in LRP5 decreases responsiveness to mechanical loading. We compared Lrp5-/- mice to wild-type controls (+/+) to investigate the impact of Lrp5 on site-specific bone mass regulation and trabecular bone microarchitecture. Further, we investigated the role of Lrp5 in mechanoreactivity by subjecting Lrp5-/- and +/+ mice to *in vivo* ulnar loading. Longitudinal *in vivo* pDXA scans of the whole body from Lrp5-/- mice showed significantly less BMD from 4-week-old compared to age-matched +/+ mice ($p<0.05$). Peak BMD in the femur and, spine from Lrp5-/- mice was ~22% lower than +/+ mice, whereas BMD in the skull, a non-loaded site, was only 15% lower in Lrp5-/- mice. Detailed analysis of the trabecular bone microarchitecture of the distal femur using micro-CT revealed significantly lower BV/TV (75.1%), Tb.N (47.0%), Tb.Th (20.0%), and connectivity (82.9%) in Lrp5-/- vs. +/+, whereas the spine revealed a milder disparity in BV/TV (43.1%), Tb.N (32.6%), Tb.Th (6.8%), and connectivity (40.1%). The right ulnae of 16-week-old mice of both genotypes were loaded at three different magnitudes, 2 Hz, 60 cycles/day for 3 consecutive days. The bone formation response was measured using histomorphometry, and the relative bone formation rate (rBFR/BS) was calculated. Lrp5-/- mice were significantly less responsive to mechanical loading than +/+ mice (Figure). Lrp5-/- mice required much more mechanical strain to initiate bone formation and, once initiated, the rBFR/BS per strain unit was much smaller indicating lower mechanoreactivity. We conclude that loss-of-function mutation in Lrp5 decreases the osteogenic response following mechanical loading. The mechanism by which Lrp5 participates in skeletal mechanoreactivity remains to be elucidated.

Skeletal Imaging of [^{18}F]Fluoride Ion with PET Reveals Damage- and Time-Dependent Responses to Fatigue Loading in Rats. B. A. Uthgenannt*, J. R. Rutlin*, J. S. Lewis*, M. J. Welch*, M. J. Silva. Orthopaedic Surgery, Washington University, St. Louis, MO, USA.

Fatigue damage of bone plays a critical role in stress fractures and may contribute to age-related skeletal fragility. Yet little is known about the *in vivo* bone response to fatigue damage. Our aims were to develop a model with controlled levels of bone fatigue damage, and to evaluate the *in vivo* response to a range of damage levels. Right forelimbs of anesthetized rats (4-5 mo) were fatigue loaded in axial compression (2 Hz, constant peak force); left (control) forelimbs were not loaded. During fatigue-to-fracture tests (n = 22), fracture consistently occurred after peak displacement increased 2 mm from its initial value. Subsequently, we performed sub-fracture fatigue loading to displacement increases of 0.6, 0.9, 1.3 or 1.7 mm. After loading, time-zero properties of ulnae were assessed by μCT and three-point bending. Bone damage increased with increasing fatigue displacement. No cracks were seen at the 0.6 mm displacement level, while increased cracking occurred at 0.9 to 1.7 mm ($p < 0.01$; Table). Accordingly, mechanical properties of the ulna were unchanged at 0.6 mm and decreased progressively at higher displacements ($p < 0.05$; Table). The *in vivo* damage response was assessed by quantifying uptake of a bone-binding isotope ([^{18}F]fluoride ion) using positron emission tomography (PET) 2, 4, 7, 9, 11, 14, 18, 24 and 30 days after loading. [^{18}F]fluoride uptake increased with damage level, with no change in the 0.6 mm displacement group and increases from 0.9 to 1.7 mm ($p < 0.05$; Figure). Uptake increased by day 2 and returned to normal by day 24. In conclusion: 1) we developed a model that allows modulation of the level of structural bone damage; 2) non-invasive *in vivo* monitoring using [^{18}F]fluoride PET reveals a damage-dependent response that peaks 4-11 days after loading, indicating the time of peak bone turnover. We hypothesize that the displacement-dependent increases in uptake reflect periosteal bone formation in proportion to the level of acute damage.

Displacement	0.6 mm	0.9 mm	1.3 mm	1.7 mm
Crack length per bone area (mm^{-1}) (n = 5)	0.0± 0.0	1.31± 1.53	3.09± 0.88	4.40± 0.87
Ultimate Force (Loaded/Control) (n = 7)	0.95± 0.08	0.82± 0.25	0.55± 0.11	0.39± 0.19

Sex-Hormone Status Is Related to Rate of Expansion of Proximal Femur Diameter in Women. S. Kaptoge[1], N. Dalzell*[1], K. Khaw*[1], T. Beck[2], N. Loveridge[1], M. Dowsett*[3], J. Reeve[1]. [1]Public Health and Medicine, U Cambridge, Cambridge, United Kingdom, [2]Radiology, JHU, Baltimore, MD, USA, [3]Biochemistry, U London, London, United Kingdom.

The femur gains structural rigidity as its subperiosteal diameter (PD) increases. Conversely cortical instability, measured as critical buckling stress, increases if the lateral cortex is located further away (d-lat) from the centre of gravity of the cross-section. The extent to which sex-hormone status determines the rates of increase in PD and d-lat is unknown. We studied the effect of sex-hormone status adjusting for key biochemical analytes, on the growth of proximal femur PD and d-lat in a random sample of 161 women aged 67-79 (mean 72y) at recruitment into the longitudinal EPIC-Norfolk study. Up to 4 hip DXA scans were performed within 8-years of follow up: 2 scans (n=152, 3.0y); 3 scans (n=134, 5.6y) and 4 scans (n=41, 7.5y). Hip structural analysis (HSA) software was used to measure PD and d-lat from the DXA scans on three narrow regions; narrow neck (NN), intertrochanter (IT) and shaft (S). The biochemical analytes measured in serum at baseline were: sex hormone binding globulin (SHBG, median=58nmol/l), estradiol (E2, median=22pmol/l), PTH, creatinine, albumin, calcium, phosphate, potassium, sodium, iron, 25(oh)vitD, 1,25(oh)vitD, Glu and Gla osteocalcin. A standard physical activity and lifestyle questionnaire was administered at baseline. A linear mixed model with random intercept and random slope for age was used to model longitudinal rates of change and associations with predictor variables. Continuous interactions with age at measurement were tested to determine if any of the predictors significantly modified the effect of aging. Aging was associated with increasing PD and d-lat and their rates of increase significantly differed ($P<0.0001$) by region: PD (NN=0.021cm/y, IT=0.014cm/y, S=0.005cm/y; all $P<0.006$); d-lat (NN=0.010cm/y, IT=0.011cm/y, S=0.002cm/y; all $P<0.027$). Baseline SHBG significantly modified the effect of aging on both PD and d-lat ($P<0.003$), with higher values being associated with faster rates of increase. Baseline SHBG values 2SD above the mean increased rates of change with age by 0.007cm/y for PD and 0.004cm/y for d-lat in all 3 regions. E2 had no significant additional effect. Higher baseline creatinine was independently associated with subsequent faster increase in d-lat with aging ($P=0.004$).

These results show large effects of SHBG on the regulation of proximal femur strength via subperiosteal expansion. Unless this is explained through an undescribed effect of SHBG acting through the SHBG receptor, it is likely that SHBG increases proximal femur expansion through reducing the bioavailability of E2.

Volumetric Bone Mineral Density and Bone Size among Older Men in Relation to Endogenous Estradiol and Testosterone Levels. L. M. Marshall[1], L. C. Lambert[1], T. F. Lang[2], E. S. Orwoll[1]. [1]Oregon Health & Science University, Portland, OR, USA, [2]University of California, San Francisco, San Francisco, CA, USA.

Effects of androgens and estrogens on skeletal material and geometric properties among older men have yet to be clarified. We studied the associations femoral neck (FN) and lumbar spine volumetric bone mineral density (vBMD) and cross-sectional area (CSA) with bioavailable fractions of testosterone and estradiol among 1,256 US men ages ≥65 years sampled from the Osteoporotic Fractures in Men (MrOS) Study. Estradiol, testosterone, SHBG and albumin concentrations were measured with sensitive assays in serum stored from a fasting blood draw at baseline. Bioavalable fractions of testosterone (BioT) and estradiol (BioE) (nM/l) were derived from mass action equations. The skeletal measures were obtained from quantitative computed tomography scans of the FN and of the L1 vertebral body exclusive of the spinous and transverse processes. FN measures were: total and trabecular vBMD (g/cm^3) and CSA (cm^2). L1 vertebral body measures were: trabecular vBMD (g/cm^3) and CSA (cm^2). The relations of vBMD and CSA at each anatomic site with BioT and BioE were estimated with generalized linear models. Each model included terms for BioE, BioT, age, race, study site, height, lean body mass and fat mass. Total and trabecular vBMD in the FN and L1 vertebra were positively associated with BioE, but were unrelated to BioT (Table). In both the FN and L1 vertebra, CSA was inversely related to BioE. BioT was positively associated with FN CSA, but was unrelated to L1 vertebral body CSA. Notably, associations that were statistically significant explained a very small portion of variance in the skeletal measures (partial $r^2 \leq 0.012$). In summary, this cross-sectional study among older men demonstrated that BioE was consistently associated with skeletal measures in the FN and lumbar spine, but BioT was not. Specifically, BioE was strongly associated with the measures of trabecular vBMD, suggesting inhibition of trabecular bone loss. Possibly divergent effects of BioE and BioT on CSA were observed, especially in the FN. These effects, although small, are consistent with the hypothesis that BioT promotes, but BioE inhibits, periosteal apposition. The clinical importance of these small but statistically significant associations warrants further study with longitudinal data.

Table. Relation of femoral neck and lumbar spine vBMD and CSA with sex steroid hormones.

	Bioavailable Estradiol (nM/l)			Bioavailable Testosterone (nM/l)		
	β	p-value	partial r^2*	β	p-value	partial r^2*
vBMD (g/cm^3)						
FN Total	0.21	0.05	0.003	0.0001	0.91	0.00
FN Trabecular	0.22	0.01	0.006	-0.0002	0.76	0.00
L1 Trabecular	0.28	<0.0001	0.012	0.0001	0.96	0.00
CSA (cm^2)						
Femoral Neck	-5.04	0.08	0.002	0.04	0.03	0.003
L1 Vertebra	-6.62	0.05	0.002	0.02	0.26	0.001

* partial r^2 indicates the proportion of variance in the dependent variable explained by the sex hormone variable independent of other factors. Abbreviations: vBMD=volumetric BMD, CSA=cross-sectional area, FN=femoral neck, β=regression coefficient.

Relationship of Bone Density, Geometry and Strength Indices to Patterns of Fragility Fractures in the Peripheral Skeleton. B. L. Riggs[1], L. J. Melton[2], E. J. Atkinson*[3], A. L. Oberg*[3], M. L. Bouxsein[4], S. Khosla[1]. [1]Endocrinology, Mayo Clinic, Rochester, MN, USA, [2]Clinical Epidemiology, Mayo Clinic, Rochester, MN, USA, [3]Biostatistics, Mayo Clinic, Rochester, MN, USA, [4]Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center, Boston, MA, USA.

Although the relationship of decreases in volumetric bone mineral density (vBMD) to risk of fragility fractures (fx) is well established for the spine and hip, there is limited information about the distal radius (DR) and distal tibia (DT), the two common sites of fragility fx in the peripheral skeleton. We assessed vBMD (g/cm^3), geometry and indices of bone strength using peripheral quantitative computed tomography (Densiscan, Scanco, Inc.) at the sites of these fractures in age-stratified, population samples. The table gives mean±SEM for 75 young (20 - 40 yrs) females (YF), 75 young males (YM), 141 elderly (≥65 yrs) females (EF), and 121 elderly males (EM). MOI (cm^3) reflects the distribution of bone relative to a central axis whereas ΣEA (N) and ΣEI (N x cm) estimate the resistance of bone to compressive and bending forces, respectively, and incorporate both material and geometric properties. In this population, we previously found that the incidences of DR and DT fx were 10- to 20-fold higher in F than M, and, although estimated trauma was similar, that DR fx were 2- to 3-fold higher than DT fx.

Variable	Total vBMD	MOI	ΣEA	ΣEI
DR YF	0.58±.08	1.3±0.3	3.3±0.5	9.7±2.2
DR EF	0.47±.10	1.5±0.5	2.8±0.6	8.8±2.4
DR YM	0.64±.08	2.7±0.8	5.2±0.7	20.8±4.9
DR EM	0.52±.10	3.4±1.3	4.7±0.9	21.3±6.4
DT YF	0.53±.07	8.4±1.8	8.3±1.1	56.4±11.4
DT EF	0.43±.08	9.5±3.0	7.0±1.4	48.8±13.3
DT YM	0.58±.06	15.0±3.8	12.1±1.6	104.7±22.5
DT EM	0.50±.08	16.3±5.0	10.6±1.7	95.2±22.2

For M vs F, vBMD for DR or DT was only ~10% higher. However, except for ΣEI at DT, the indices of bone strength (MOI, ΣEA and ΣEI) were much higher (51% to 114%) in M vs F and were even higher (125% to 646%) for the DT vs DR scanning sites. Most of these indices declined by only 9% to 15% with aging. By ANOVA, all sex differences (except for DR at EI) and scanning site differences (except for ΣEI at DT) were significant (P<0.001). Conclusions: 1) Superior geometric properties achieved in pubertal growth, rather than large differences in vBMD, may explain why late in life that males have a lower incidence of fx at DT and DR than females and why fx at DT are less frequent than at DR; and 2) Biomechanical indices of bone strength, which now can be calculated from QCT scans, will play an increasingly important role in assessing fx risk in the future.

Postmenopausal Hormone Therapy and Body Composition --- Results from the Women's Health Initiative E + P Trial. Z. Chen[1], T. Bassford*[1], S. B. Green*[2], M. Leboff[3], K. L. Margolis*[4], A. LaCroix[5], R. D. Jackson[6], J. Cauley[7], M. L. Stefanick*[8]. [1]University of Arizona, Tucson, AZ, USA, [2]Arizona Cancer Center, Tucson, AZ, USA, [3]Brigham and Women's Hospital, Boston, MA, USA, [4]Hennepin County Medical Center, Minneapolis, MN, USA, [5]Fred Hutchinson Cancer Research Center, Seattle, WA, USA, [6]The Ohio State University, Columbus, OH, USA, [7]University of Pittsburgh, Pittsburgh, PA, USA, [8]Stanford School of Medicine, Stanford, CA, USA.

The primary objective of this study is to test the hypothesis that treatment with estrogen plus progestin (E+P) alters body composition among postmenopausal women from the randomized, controlled clinical trial of E +P in the Women's Health Initiative (WHI). Only women with body composition measurements at baseline and year three were included in the analysis. Among them, 437 were women in the treatment group and 398 were in the placebo group. Body composition was assessed by dual-energy x-ray absorptiometry. The mean age at baseline was 62.9 and 63.4 years for the treatment and placebo group respectively. On average, women in this study were 13.8 years past menopause and approximately 82% of them were from a non-Hispanic white ethnic background. There was no difference in baseline measurements for the treatment and placebo groups respectively: 74 kg vs. 75 kg in body weight, 37.9 kg vs. 38.5 kg in total body lean mass, 32.7 kg vs. 33.0 kg in total body fat mass, 1.266 to 1.295 in trunk to leg fat mass ratio, 53.2% vs. 53.4% in percent lean mass, and 44% vs. 43.8% in percent fat mass.

Absolute Changes between Year Three and Baseline

Body Composition	E +P (N = 437)	Placebo (N = 398)	Difference	95% CI		p value
				Lower	Upper	
Weight (kg)	0.59	0.10	0.49	-0.48	1.46	0.320
BMI (kg/m^2)	0.43	0.14	0.29	-0.02	0.60	0.070
Lean Mass (g)	-39	-438	399	158	640	0.001

* Trunk to Leg Fat Mass Ratio

In comparison to women on placebo, women in the treatment group had significantly less loss in lean tissue mass (p = 0.001) and a small but significant change in the distribution of body fat as indicated by the reduced trunk to leg fat mass ratio (p = 0.003). Previous results from this WHI E+P trial indicate that E+P treatment significantly prevents fractures. It is possible that the reduced loss of lean tissue mass by E+P treatment contributed to the lower fracture risk through maintaining bone mass and balance.

In conclusion, E+P treatment has significant positive effects on body composition by reducing both lean tissue mass loss and truck to leg fat mass ratio. Whether the reduced fracture risk by E+P is partially mediated through the effect of E+P on body soft tissue composition remains to be determined.

Labyrinthectomy Decreases Bone Mineral Density in the Femoral Metaphysis in Rats. R. Levasseur[1], O. Etard*[2], J. P. Sabatier*[3], J. Corvisier*[2], C. Potrel-Burgot*[4], A. Réber*[5], P. Denise*[2]. [1]Rheumatology CHU, Caen, France, [2]Physiologie, Faculté de Médecine, Caen, France, [3]Nuclear Medicine CHU, Caen, France, [4]Cetor, Faculté de Médecine, Caen, France, [5]UFR Sciences, Rouen, France.

Recently, it has been shown that sympathetic nervous system regulates bone remodeling (Takeda et al. Cell 111:305, 2002. Levasseur et al. Joint Bone Spine 70:515, 2003). As it is well known that vestibular system influences the sympathetic system (Yates et al. Brain Res Rev 17:51, 1992) it might also affect bone remodeling. To answer this question, we started an experiment on 14 pigmented male adult rats (DA/HAN). Seven of them were bilaterally labyrinthectomized, the seven others were sham-operated. Bone mineral density (BMD, g/cm²) was measured by dual energy X-rays absortiometry (Hologic QDR 4500A) before and 30 days after vestibular lesions, in the distal femoral metaphysis (DFM), the femoral cortical diaphysis (CD), the lumbar spine (SP) and the whole body (WB). Body weight (BW, g), lean mass (LM, g) and fat mass (FM, g) were also measured in each rat. Comparatively to sham-operated rats, labyrinthectomized animals showed a significantly reduced BMD in distal femoral metaphysis (P=0.007) : the changes in BMD between day 0 (D0) and day 30 (D30) were +3% for controls and -13.9% for labyrinthectomized rats. BMD gain in femoral CD was also significantly decreased in labyrinthectomized rats compared to sham operated (+10.4 vs + 16.5, P=0.015). No significant difference between the 2 groups was observed in the whole body or in the lumbar spine BMD (P=0.12 an P=0.06, respectively). The body weight, the lean mass and the fat mass of control and bilaterally labyrinthectomized rats were not different at D0 nor at D30 (P=0.39, P=0.20, P=0.89, respectively). The major finding of the present study is that bilateral labyrinthectomy in rats decreases bone mineral density of the distal femoral metaphysis but not of the spine or of the whole body. These results suggest that the peripheral vestibular apparatus is a modulator of bone mass and more specifically in weight bearing bone. This bone loss is not due to reduced motor behavior since the evolution of lean mass is the same between the 2 groups during the experiment and it has been also recently demonstrated that the tonic muscular activity is not decreased after vestibular lesions (Kasri M et al, Exp Neurol. 185:143, 2004). We suggest that the vestibular system is involved in the control of bone remodeling via the sympathetic system and that the vestibular system could be implicated in the osteoporosis observed during space flight.

A Cellular Mechanism for Dietary Protein-induced Increases in Calcium Absorption. S. Busque*[1], J. Kerstetter[1], J. Geibel*[2], K. Insogna[2]. [1]School of Allied Health, U of CT, Storrs, CT, USA, [2]Yale University, New Haven, CT, USA.

Several studies indicate that increasing the level of dietary protein increases the efficiency of intestinal calcium (Ca) absorption. The basis for this is unclear but modulation of the calcium sensing receptor (CaSR) by amino acids in the stomach could potentially enhance gastric acid secretion, improving ionization and bioavailability of dietary Ca. When over-expressed in kidney cells, the CaSR is allosterically activated by amino acids at sub-stimulatory concentrations of extracellular Ca. It has recently been shown that Ca stimulates acid production in gastric parietal cells. To determine if the endogenously expressed parietal cell CaSR is also influenced by amino acids, we examined the effect of L-phenylalanine (phe) on luminal pH in isolated rat stomachs. Rats were fasted for 24h prior to experimentation to reduce basal acid secretion, anesthetized, and a total gastrectomy was performed. One cc of non-buffered isotonic saline was infused, and the stomach incubated for 60 min at 37ºC in oxygenated Ringers, pH 7.4. In 9 stomachs incubated in buffer alone, mean luminal pH was 4.07±0.37, and in 9 separate preparations in buffer plus 50 mM L-phe, the mean pH was significantly lower, 2.69±0.22 (p=0.003). In contrast, 50 mM D-phe had no effect on gastric pH. To monitor intracellular pH or calcium, individual rat gastric glands were hand-dissected and loaded with the pH sensitive dye BCECF or Fluo-3 respectively. Proton extrusion by parietal cells was monitored by measuring the recovery of cytosolic pH as an index of H,K-ATPase activity, following intracellular acidification with 20mM NH_4Cl and subsequent perfusion with a Na free buffer containing 2 mM Ca or 2 mM Ca plus 30 mM L-phe. The rate of cellular pH recovery, measured as the rise in cytosolic pH over time, was significantly more rapid in cells exposed to amino acids (0.08±0.03 pH units/min) than buffer alone (0.04±0.01; p<0.0001). The effect of amino acids was lost when the Ca concentration in the buffer was lowered to 0.5 mM. In contrast, blocking the H2 receptor with cimetidine did not attenuate the recovery of cytosolic pH (0.07±0.01). Furthermore, cytosolic calcium increased by 16% (p<0.0001) over baseline upon perfusion with amino acids. We conclude that L-phe directly stimulates parietal cell acid secretion by increasing H,K-ATPase activity in the absence of neuronal/hormonal stimulation. The sterio-specificity, dependence on extracellular calcium, and induced rise in cytosolic Ca are consistent with the conclusion that L-phe is an allosteric activator of the CaSR. These data identify a cellular mechanism by which dietary protein enhances Ca absorption via activation of the CaSR on parietal cells.

Gs-alpha Expression Is Biallelic in Normal and Fibrous Dysplastic Bone. M. Riminucci[1], N. Cherman*[2], K. Holmbeck*[2], S. Michienzi*[3], L. Travaglini*[3], P. Bianco[4], P. Gehron Robey[2]. [1]Experimental Medicine, University of L'Aquila, L'Aquila, Italy, [2]NIDCR, NIH, DHHS, Bethesda, MD, USA, [3]Parco Scientifico Roma San Raffaele, Rome, Italy, [4]Experimental Medicine and Pathology, University La Sapienza, Rome, Italy.

Activating mutations of the Gs-alpha gene (GNAS) cause a wide range of pathological phenotypes (McCune-Albright Syndrome (MAS), isolated fibrous dysplasia (FD) and endocrine lesions, Mazabraud's syndrome) each of which is characterized by a remarkable heterogeneity of clinical expression. Although the postzygotic nature of the mutation provides an immediate explanation for the clinical variability of Gs-alpha related diseases, the contribution of epigenetic mechanisms, such as imprinting, can not be excluded. Clinical evidence, in fact, suggests that Gs-alpha has a predominant maternal expression in some tissues such as pituitary and thyroid (although different studies have failed to show promoter methylation) and recently it has been shown that imprinting of Gs-alpha is lost during neoplastic growth of pituitary cells in some somatotroph adenomas.

FD is a skeletal disease that reflects the impact of activating Gs-alpha mutations in bone marrow stromal cells. Skeletal involvement in FD patients ranges from localized, clinically silent lesions to a diffuse severely crippling disorder. In this study, we asked whether Gs-alpha is imprinted in bone marrow stromal cells, and if imprinting affects the expression of the mutated allele in FD lesions. To address this issue, we took advantage of the polymorphism (ACT/ATT) within exon 5 of GNAS, which allows recognition of the allelic origin of the Gs-alpha transcript in heterozygous patients. FD patients (N=16) were analyzed by PCR amplification of the relevant gDNA fragment, followed by digestion with the restriction enzyme, FokI (which recognizes the ACT allele), and DNA sequencing. Gs-alpha mRNA was analyzed in stromal cells isolated from 3 informative (polymorphic) patients. Clonal populations of normal and mutant cells were grown in order to separately analyze the imprinting status of Gs-alpha in cells with the normal and disease genotype. Using FokI digestion followed by subcloning and DNA sequencing, we demonstrated that Gs-alpha mRNA is biallelic in all the samples analyzed, with no difference between normal and mutant cells. Our work shows for the first time the lack of imprinting of Gs-alpha in the stromal component of the bone microenvironment, which gives rise to bone, and excludes any major role for Gs-alpha imprinting in the clinical expression of FD.

PTH (1-34) Accelerates Osteoblast Differentiation via a PLC-Independent PKC Pathway. D. Yang, J. Guo, F. R. Bringhurst. Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

PTH regulates osteoblastic function by activating PTH/PTHrP receptors (PTH1Rs), which trigger several signaling pathways in parallel. In addition to adenylyl cyclase (AC)/PKA, PTH1Rs activate PKCs via both PLC-dependent and PLC-independent mechanisms. To probe the biological function of the PLC-independent PTH1R PKC pathway in osteoblasts, we employed mutant PTH peptide analogs that can selectively activate only subsets of these various signaling pathways .

An osteoblastic cell line ("wt9') stably expressing PTH1Rs (80,000-100,000 sites/cell) was generated by stable transfection of PTH1R cDNA into F1-14 PTH1R-null clonal osteoblasts. To control the pattern of PTH1R signaling, two PTH(1-34) analogs were employed: [G1,R19]hPTH(1-28) ("GR1-28"), which cannot activate PLC and also lacks the 29-34 domain of hPTH(1-34) required for PLC-independent PKC activation and [G1,R19]hPTH (1-34) ("GR1-34"), which lacks only PLC signaling but retains PLC-independent PKC activity. Both analogs stimulated cAMP accumulation comparably to hPTH(1-34) at a high concentration (100 nM) but neither GR1-28 nor GR1-34 could activate PLC, even at a concentration of 1000 nM (at which PTH(1-34) induced a 4-fold stimulation).

We observed that several PKC isoforms -beta I, gamma, delta, epsilon and zeta - were expressed by wt9 cells, of which PKC-delta and PKC-epsilon were phosphorylated within minutes in response to PTH(1-34). Isoform-specific western blots and pulldown kinase assays showed that both PTH(1-34) and GR1-34, but not GR1-28 , could increase the phosphorylation and activation of PKC-delta, suggesting that these were mediated by a PLC-independent receptor signaling event .

To investigate PTH1R signals involved in regulating osteoblast differentiation, PTH peptides (100 nM) were applied to wt9 cells every 48 hours. On day 16, von Kossa stain and calcium mass measurements showed that PTH(1-34) and GR1-34, but not GR1-28, could increase both the formation of calcified nodules and the total amount of calcium deposited in the cell cultures.

We conclude that PTH1R activation of AC (as by GR1-28) is not sufficient to phosphorylate and activate PKC-delta or to increase differentiation by intermittent peptide administration in osteoblasts. The ability of GR1-34 to mimic these actions of PTH(1-34) points to a key role for AC- and PLC-independent PTH1R signaling, possibly involving activation of PKC-delta, in control of osteoblast differentiation.

Measles Virus Nucleocapsid Protein (MVNP) Increases p62 and IKK-gamma Expression to Enhance TNF-α-induced Osteoclast (OCL) Differentiation and Activation in Paget's disease. M. Ito[1], N. Kurihara[1], S. V. Reddy[1], G. D. Roodman[2]. [1]Medicine-Hematology/Oncology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Medicine-Hematology/Oncology, University of Pittsburgh and Dept. of Veterans Affairs Medical Center, Pittsburgh, PA, USA.

Osteoclasts (OCL) from Paget's patients (PD) are abnormal and contain MVNP transcripts. Furthermore, human OCL precursors transfected with MVNP demonstrate many features of pagetic OCL. We previously reported that OCL precursors from patients with Paget's disease are hyperresponsive to RANKL and 1,25-$(OH)_2D_3$ and that expression of MVNP in normal OCL precursors increases their responsivity to RANKL and 1,25-$(OH)_2D_3$. We recently found that OCL precursors from PD were also hyper-responsive to TNF-α. Since TNF-α does not induce RANKL, we determined if MVNP could also increase TNF- responsivity of OCL precursors. To test this hypothesis, NIH3T3 cells were used as surrogate for OCL precursors and transfected with MVNP or empty vector (EV). Western blot analysis showed that TNF-α treatment of empty vector (EV)-transfected NIH3T3 cells increased the expression of IKK-γ approximately 40% compared to media alone. Treatment of MVNP-transfected NIH3T3 cells with TNF-α increased both p62 and RIP expression levels approximately 50% but increased IKK-γ 5-fold compared to results with EV-transfected cells. IKK-γ is an important regulatory of NFκB signaling induced by TNF and is absolutely required for IKK activation by TNF. Consistent with these results in NIH3T3 cells, MVNP-transfected normal human CFU-GM showed increased responsivity to TNF-α and increased expression of p62 and IKK-γ approximately 2 fold. We then determined if these effects resulted in enhanced NF-κB signaling. We observed a 1.4-fold increase in basal NF-κB reporter gene activity in MVNP-transfected NIH3T3 cells compared to EV-transfected cells and this was increased 2.1- to 2.6-fold when MVNP-transfected cells were treated with TNF-α. Since TNF-α also stimulates the MAPK signaling pathway via TRAF2 to activate OCL, we then determined if TNF-α increased MAPK signaling in MVNP-transfected NIH3T3 cells, by Western blot analysis of phospho-MAPK (p42/44). TNF-α increased the phosphorylation of MAPK in MVNP-transfected NIH3T3 cells by 50% compared with EV-transfected cells within 15 minutes after addition of TNF-α. These results demonstrate that MVNP increases TNF-α induced OCL differentiation and activation by increasing NFκB signaling through increased expression of p62, and IKK-γ and increased MAPK signaling. These results suggest that MVNP's effects on TNF-a signaling may contribute to the increased OCL formation in PD.

A Mutation in FGF-23 Gene Enhances the Processing of FGF-23 Protein and Causes Tumoral Calcinosis. K. Araya*[1], S. Fukumoto[2], R. Backenroth*[3], Y. Takeuchi[2], K. Nakayama[2], N. Ito*[2], Y. Yamazaki*[4], T. Yamashita[4], J. Silver[3], T. Igarashi*[1], T. Fujita*[2]. [1]Department of Pediatrics, University of Tokyo Hospital, Tokyo, Japan, [2]Division of Nephrology & Endocrinology, Department of Medicine, University of Tokyo Hospital, Tokyo, Japan, [3]Minerva Center for Calcium and Bone Metabolism, Nephrology and Hypertension Services, Hebrew University Hadassah Medical Center, Jerusalem, Israel, [4]Pharmaceutical Research Laboratories, KIRIN Brewery, Takasaki, Japan.

Tumoral calcinosis is a disease characterized by high serum phosphate and 1,25-dihydroxyvitamin D (1,25D), and ectopic calcification. These clinical features are mirror images of several hypophosphatemic rickets/osteomalacia including autosomal dominant hypophosphatemic rickets/osteomalacia and tumor-induced osteomalacia. Recently, FGF-23 was shown to play important roles in the development of these hypophosphatemic diseases. It was also shown that full-length FGF-23 is processed between Arg^{179} and Ser^{180} and this processing abolishes its effect to cause hypophosphatemia. Two kinds of assay for FGF-23 have been developed. A full-length assay detects only biologically active full-length FGF-23 and a C-terminal assay measures both full-length and processed C-terminal fragment of FGF-23. We have examined the involvement of FGF-23 in tumoral calcinosis. A twenty-eight year old patient of consanguineous parents had had subcutaneous lumps. He presented with intermittent claudication and a plain film of his legs showed an angiogram-like picture. Laboratory tests showed hyperphosphatemia of 5-10 mg/dl (normal 3 - 5), hypophosphaturia with TRP of 96-100% (80 - 90) and high serum1,25D levels of 89 pg/ml (15-55). Serum calcium, alkaline phosphatase, pH and creatinine were all normal. Two brothers had a similar syndrome and he was diagnosed as having tumoral calcinosis. Serum level of FGF-23 was low normal (11.0 pg/ml: normal 10 - 50) by full-length assay, but extremely high (5874 RU/ml: < 150) by C-terminal assay. Direct sequencing of FGF-23 gene revealed a homozygous S129F mutation. Immunoprecipication followed by Western blotting detected both full-length and processed N- and C-terminal fragments of FGF-23 when wild-type FGF-23 was expressed in vitro. However, only the C-terminal fragment but not full-length and N-terminal fragment of FGF-23 was detected when this mutant FGF-23 was expressed. These results suggest that this mutation in FGF-23 gene enhances the processing of FGF-23 protein. The biochemical features of this patient are similar to those with FGF-23 knockout mice suggesting that activity of full length FGF-23 is essential for normal phosphate and vitamin D metabolism in man.

Direct Binding of MEPE by PHEX via the ASARM-motif Is Confirmed by Surface Plasmon Resonance: Implications for Impairment of Mineralization in X-linked Rickets. P. S. N. Rowe[1], I. R. Garrett[2], P. M. Schwarz*[1], D. L. Carnes[1], E. M. Lafer*[1], G. R. Mundy[3], G. E. Gutierrez[2]. [1]Periodontics, University of Texas HSC, San Antonio, TX, USA, [2]Osteoscreen, San Antonio, TX, USA, [3]Cell & Struc, UTHSCSA, San Antonio, TX, USA.

Impaired mineralization is a key feature of X-linked rickets (HYP) but the mechanisms responsible remain unclear. MEPE and proteases are elevated and PHEX is defective. PHEX prevents proteolysis of MEPE and potentially the release of a protease-resistant MEPE-ASARM-peptide (mineralization inhibitor). We hypothesize that binding of MEPE by PHEX regulates mineralization and in HYP, mutated-PHEX increases ASARM-peptide release, thereby impairing mineralization. To test this, we examined 1. whether PHEX binds specifically to MEPE; 2. whether the binding involves the ASARM-motif; and 3. whether ASARM-peptide affects mineralization *in-vivo.*

ASARM-peptide and etidronate mediated mineralization-inhibition *in-vivo* and *in-vitro* were determined by quenched calcein-fluorescence in hind limbs and calvariae in mice and by histological Sanderson stain. Protein interactions between MEPE and soluble PHEX (secPHEX) were measured using Surface-Plasmon-Resonance (SPR) and SPR experiments were performed on a Biacore 3000 high performance system. Briefly, secPHEX, MEPE and control protein (IgG) were immobilized on a Biacore CM5 sensor-chip. Pure secPHEX was then injected at different concentrations and interactions with immobilized proteins measured. To determine MEPE sequences interacting with secPHEX the inhibitory effects of MEPE-ASARM-peptides (phosphorylated and nonphosphorylated), control peptides and MEPE-RGD-peptides on secPHEX binding to chip-immobilized MEPE were measured.

Subcutaneous administration of ASARM-peptide resulted in marked quenching of fluorescence in calvariae and hind-limbs relative to vehicle controls indicating impaired mineralization. Similar results were obtained with etidronate. Sanderson-stained calvariae also indicated a marked increase in unmineralized osteoid with ASARM-peptide and etidronate groups. A specific, dose-dependent and Zn-dependent protein-interaction between secPHEX and immobilized-MEPE occurs (EC_{50} of 553 nM). The MEPE PO4-ASARM-peptide inhibited the PHEX-MEPE interaction (K_{Dapp} = 15 uM and $B_{max/inhib}$ = 68%). In contrast, control and MEPE-RGD-peptides had no effect.

We conclude that the ASARM-peptide impairs mineralization *in vivo*, and that PHEX and MEPE binding involves the carboxy-terminal MEPE-ASARM-motif. The binding of MEPE and ASARM-peptide by PHEX and the finding that this peptide inhibits mineralization in-vivo, may explain why loss of functional PHEX results in defective mineralization in HYP.

Genetic Dissection of Phosphate- and Vitamin D-Mediated Regulation of Circulating Fgf23 Concentrations. X. Yu*[1], Y. Sabbagh[2], S. I. Davis*[1], M. B. Demay[2], K. E. White[1]. [1]Department of Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

The mechanisms that control serum phosphate are complex and our current models are incomplete. Fibroblast growth factor-23 (FGF23) is a phosphaturic factor that plays critical roles in phosphate and vitamin D metabolism. Previous studies demonstrated that serum Fgf23 increases in mice after treatment with 1,25-dihydroxy vitamin D, however potential concomitant changes in serum phosphate may contribute to this change in circulating Fgf23. The goal of the present studies was to examine the mechanisms that direct the vitamin D-phosphate-FGF23 homeostatic axis. To test the regulation of Fgf23, wild type (WT) mice were fed either standard (0.67% phosphorus) or low-phosphate (0.02%) diets, followed by determinations of serum phosphate, and intact Fgf23, measured by ELISA. WT mice on standard diet had a mean serum phosphate of 9.5±0.5 mg/dl and an Fgf23 concentration of 99±18 pg/ml, whereas mice on the low-phosphate diet had a serum phosphate of 3.0±0.3 mg/dl (P<0.01), and a markedly suppressed Fgf23 value of 11±5.0 pg/ml (P<0.01). We then examined vitamin D receptor knockout (VDR-/-) mice, a model for Hereditary Vitamin D Resistant Rickets, characterized by resistance to 1,25-dihydroxy vitamin D, hypocalcemia, hypophosphatemia, and hyperparathyroidism. After 35 days on standard diet, WT and VDR+/- mice had comparable Fgf23 values of 57±19 and 76±21, respectively, whereas Fgf23 was undetectable in VDR-/- mice. Following one year on standard diet, WT mice had an Fgf23 of 173±34 pg/ml and levels in VDR-/- mice remained low at 8.5±8.9 pg/ml (P<0.02). To determine the relative contributions of hypophosphatemia and 1,25-dihydroxy vitamin D resistance to the suppression of Fgf23 in the VDR -/- mice, Fgf23 levels were measured in VDR-/- mice placed on a diet that normalizes serum calcium and phosphorus levels (1.25% phosphorus, 2% calcium and 20% lactose). This supplemented diet increased the Fgf23 levels of the control VDR+/- mice to 465±264pg/ml, and increased the Fgf23 levels of VDR-/- mice to 484±182 pg/ml (P<0.9 vs VDR+/-). In summary, serum Fgf23 is suppressed in diet-induced hypophosphatemia, as well as in hypophosphatemia associated with hyperparathyroidism secondary to VDR ablation. Normalization of serum phosphate by diet in VDR-/- mice increases serum Fgf23. Thus, our results demonstrate that Fgf23 is suppressed during hypophosphatemia, protecting against renal phosphate loss. Finally, the regulation of serum Fgf23 levels by phosphate is independent of the genomic effects of vitamin D.

Calcium Receptor Haploinsufficiency Increases Mammary PTHrP Secretion, Reduces Mammary Calcium Transport and Accelerates Bone Loss During Lactation. J. VanHouten[1], L. Ardeshirpour*[1], E. Brown[2], M. Pollak[2], J. Wysolmerski[1]. [1]Yale Medical School, New Haven, CT, USA, [2]Brigham and Women's Hospital, Boston, MA, USA.

Calcium-sensing receptor (CaR) expression is dramatically induced on mammary epithelial cells (MECs) at the start of lactation and extracellular calcium inhibits PTHrP production and stimulates transepithelial calcium transport by lactating MECs. In order to determine if these effects were mediated by the CaR, we studied the effects of CaR haploinsufficiency on PTHrP secretion and milk calcium content in lactating heterozygous CaR-null ($CaR^{+/-}$) mice.

$CaR^{+/-}$ mice lactated without difficulty and their mammary glands displayed normal histology and expression of milk protein genes. The growth curves of pups suckling $CaR^{+/-}$ mothers were indistinguishable from those suckling WT mothers suggesting that overall milk production was normal. As measured by real-time RT-PCR, CaR mRNA levels were reduced by 50% in the mammary glands of lactating $CaR^{+/-}$ mice as compared to WT littermates. This led to a doubling of PTHrP mRNA levels in the $CaR^{+/-}$ glands. PTHrP secretion was also elevated; the PTHrP concentration in milk from CaR $^{+/-}$ mice was 41.7±8.0 nM as compared to 20.5±4.3 nM in milk from WT mice. In contrast, milk calcium content was decreased in $CaR^{+/-}$ mice by 25%. Finally, $CaR^{+/-}$ mice lost more bone during lactation than control mice. At the onset of lactation spine, femur and total body bone mineral density (BMD) were similar in $CaR^{+/-}$ mice and controls. Both types of mice lost significant bone by day 12 of lactation. However, by this point BMD at all three sites was statistically lower in $CaR^{+/-}$ mice as compared to controls, suggesting higher rates of bone loss in these mice.

In summary, haploinsufficiency for the CaR results in a reduction of CaR mRNA expression within the lactating mammary gland. This is associated with an increase in PTHrP gene expression and protein secretion by MECs. CaR deficiency also leads to a reduction in milk calcium content and accelerated bone loss during lactation. These data provide genetic evidence that the mammary gland becomes a calcium-sensing organ during lactation and that CaR signaling regulates PTHrP production and transepithelial calcium transport by MECs. In response to a perceived calcium deficiency, the lactating mammary glands of $CaR^{+/-}$ mice reduce the transport of calcium into milk and produce more PTHrP. The accelerated loss of bone by the $CaR^{+/-}$ mice suggests that some of this excess PTHrP circulates and acts to mobilize more calcium from the skeleton. Expression of the CaR thus allows the lactating mammary gland to act as an "accessory parathyroid" and integrate systemic calcium and bone metabolism with milk production.

Modulation of Bone Remodeling by Osteoprotegerin in Mice Expressing a Constitutively Active PTH/PTHrP Receptor. R. Chiusaroli[1], M. C. Knight*[1], P. Kostenuik[2], E. Schipani[1]. [1]Medicine, MGH-Harvard Medical School, Boston, MA, USA, [2]Metabolic Disorders Research, Amgen Inc., Thousand Oaks, CA, USA.

A transgenic mouse model (CL2) in which a constitutively active PTH/PTHrP receptor (PPR) was expressed in cells of the osteoblast lineage has been recently reported. The Cl2 phenotype is characterized by exuberant increase in both bone formation and resorption, with the net result of increased trabecular bone and cortical porosity. To study whether bone resorption is a prerequisite for PPR-induced bone formation, we injected adult CL2 mutant mice and wild-type (wt) control littermates with recombinant human osteoprotegerin (OPG-Fc) for 10 days. Treatment of both wt and CL2 mice with OPG-Fc resulted in the significant reduction in osteoclast numbers. In situ hybridization also revealed significant reductions in TRAP and MMP9 mRNA with OPG-Fc treatment. These changes were also associated with suppression of osteoblastic markers such as osteocalcin, osteopontin and collagen type I mRNAs in both Cl2 and wt mice treated with cOPG. Histomorphometric analysis revealed significant reductions in osteoblast number and activity in the trabecular bone of both wt and CL2 animals treated with OPG-Fc. Despite the impairment of bone formation, trabecular bone volume was not reduced in mice treated with OPG-Fc in comparison to vehicle-treated mice. The suppression of bone formation was likely to be an indirect coupling response to the profound suppression of bone resorption upon OPG-Fc administration. In order to further study the role of bone resorption in mediating the PPR receptor-dependent increase of bone formation, and to rescue the cortical porosity of the CL2 mice, we cross-bred CL2 mice with transgenic mice overexpressing soluble OPG under the control of the ApoE promoter (ApoE-OPG). ApoE-OPG mice displayed significant suppression of osteoclast and osteoblast activity, along with the previously described osteopetrotic phenotype. Interestingly, however, the OPG transgene expressed in a CL2 background decreased osteoclast number without significantly affecting osteoblast number and activity. The net result of these actions was a further increase in trabecular bone volume and a rescue of the cortical bone porosity. Taken together, our findings suggest: 1) basal and PPR-stimulated bone formation are, at least in part, dependent on bone resorption; 2) OPG-dependent inhibition of bone resorption rescues the increased cortical porosity observed upon activation of PPR.

Sustained, but not Transient, Elevation of PTH Reduces SOST Gene Expression: Evidence That Osteocytes Participate in the Increase in Osteoblast Number that Occurs in Hyperparathyroidism. T. Bellido, A. A. Ali, L. I. Plotkin, Q. Fu, I. Gubrij, X. Liu*, R. A. Wynne*, C. A. O'Brien, S. C. Manolagas, R. L. Jilka. Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Sclerostin, a product of the SOST gene, is produced mainly by osteocytes and it antagonizes the pro-differentiating actions of BMPs on osteoblasts. Genetic evidence in mice and humans indicates that sclerostin negatively regulates bone formation, suggesting that osteocytes can influence bone homeostasis by changes in SOST expression. PTH exerts potent effects on osteoblast number and bone formation. Because SOST is a Runx2-dependent gene, and PTH downregulates Runx2 levels via proteasomal degradation, we have examined here whether administration of PTH to mice alters SOST expression. We found that SOST expression in tibia, as measured by quantitative real-time PCR, was not affected at 1, 2, 4 or 16 hours following a single injection of 100 ng/g of PTH(1-84) to adult female Swiss Webster mice; or after 4 daily injections when osteoblast number had increased 3-fold. Therefore changes in SOST expression appear not to contribute to the anabolic effect of intermittent PTH. In contrast, continuous elevation of PTH(1-84) by infusion with an osmotic pump, which raised circulating PTH(1-84) levels from a basal level of 15 pg/ml to 500 pg/ml, decreased SOST expression in tibia and vertebrae to less than 20% of that in control mice, beginning as early as 18 h. After 96 h when osteoblast number had increased by 2-fold, SOST expression remained at 20% of basal values. Consistent with a direct effect of the hormone on SOST expression, addition of 50 nM PTH to osteoblastic OB-6, or osteocytic MLO-Y4 cells, reduced SOST expression by 50% within 3h, and to undetectable levels after 24 h. Because of the high level of SOST expression in osteocytes compared to osteoblasts, and the fact that osteocytes are the most abundant cell type in bone, the reduction in SOST expression caused by continuous PTH most likely reflects a direct effect of the hormone on osteocytes. We propose that the increase in osteoblast number that occurs as part of the increased remodeling caused by continuous elevation of PTH is due to down-regulation of sclerostin secretion by osteocytes, thereby permitting increased BMP action and increased osteoblast differentiation. Moreover, our findings reinforce the notion that intermittent and continuous PTH administration increase osteoblast number via distinct mechanisms: attenuation of apoptosis in the former and increased differentiation in the latter.

SOST Is a Target Gene For PTH Action During Bone Formation. H. Keller, H. Jeker*, A. Studer*, J. Wirsching*, M. Kneissel. Bone Metabolism, Novartis Institutes for BioMedical Research, Basel, Switzerland.

Intermittent application of parathyroid hormone (PTH) is a well established pharmacological principle to stimulate bone formation in animals and humans. However, the mechanisms responsible for the bone anabolic effects of PTH are still poorly understood. Recently, sclerostin (SOST), which is structurally most closely related to the DAN/cerberus family of BMP antagonists, was identified as a potent osteocyte expressed negative regulator of bone formation in vitro, in vivo and in patients with the bone overgrowth disorders Sclerosteosis and Van Buchem disease. Therefore, we have analyzed SOST expression during PTH-induced bone formation in a classical model of local bone formation. 8-month-old OF/IC female mice (n=7/group) were injected twice daily with 100 nM hPTH(1-34) or vehicle onto the calvaria for 5 days and were then sacrificed or left untreated for a week to allow for the full bone formation response. Bone formation was assessed by fluorochrome label based histomorphometry and gene expression was measured by real-time quantitative PCR at day 5 and day 12. As expected, PTH stimulated bone formation: bone formation rates were increased 2-fold at the 1st and 6-fold at the 2nd measurement time point. SOST expression was significantly reduced in calvaria of PTH-treated animals compared to controls at day 5 four hours after the last PTH administration, whereas expression of the house keeping gene GAPDH was unchanged. In addition, osteocalcin was also weakly reduced at day 5, but clearly increased at day 12 in PTH-treated animals. SOST expression was not significantly different in treated and control mice at day 12 seven days after cessation of PTH treatment, as well as GAPDH. Next, we analyzed the effect of PTH on SOST expression in calvaria organ cultures of newborn mice. 100 nM PTH(1-34) suppressed SOST expression within 6 hours by about 95%. A similar time-course and efficacy was observed in cell culture using an osteoblastic cell line with robust endogenous SOST expression. An IC_{50} of about 5 nM was determined by a dose-response curve. The effect of PTH was specific as 100 nM bovine PTH(7-34) was inactive. PTH inhibited SOST expression also in the presence of the protein synthesis inhibitor cycloheximide indicating a direct regulation of the SOST expression by PTH. Finally, PTH did not influence SOST mRNA stability in the presence of actinomycin D suggesting a regulation of SOST transcription by PTH. In summary, we have shown that PTH directly inhibits SOST expression in vivo and in vitro suggesting that SOST reduction may play an important role in PTH-induced bone formation.

Growth without Growth Hormone Receptor: Estradiol Is a Major Growth-Hormone Independent Regulator of Hepatic Insulin-like Growth Factor-I Synthesis. K. Venken*[1], S. Boonen[1], J. Kopchick*[2], K. Coschigano*[2], S. Movérare*[3], R. Bouillon[1], C. Ohlsson[3], D. Vanderschueren[1]. [1]K.U. Leuven, Leuven, Belgium, [2]Ohio University, Athens, OH, USA, [3]Gothenburg University, Gothenburg, Sweden.

Growth hormone (GH) stimulates postnatal growth. Its action is mediated by GH-induced hepatic and local insulin-like growth factor-I (IGF-I) synthesis. Estrogens are also essential for pubertal growth and bone mineral accrual. These effects may reflect estrogen-induced GH secretion, providing a GH-dependent mechanism for the effects of estrogens on skeletal growth. It is presently unclear to what extent estrogens may be able to regulate pubertal growth and bone mineral acquisition independently of GH and its receptor. To this end, we examined the effects of estradiol (E_2) replacement (0.03 µg/day via subcutaneous silastic implants) in orchidectomized (orch) male mice with a disrupted GHR (GHRKO) and corresponding WT mice during late puberty (6-10 weeks). Results are expressed as % gain or loss compared to orch. E_2 stimulated growth of the appendicular skeleton as it significantly enhanced femur length (+ 9%), induced thickening of the growth plate (+ 16%) and fully rescued the longitudinal growth rate (+ 182%) to WT levels in orch GHRKO mice, while no changes were observed in WT. Growth of the axial skeleton, as assessed by crown-rump length, was accelerated by E_2 in both GHRKO and WT (+ 7% and + 8% respectively). E_2 also stimulated radial bone growth as reflected by a significant increase in cortical thickness (+ 27%) and periosteal perimeter (+ 11%) in orch GHRKO mice. In addition, the periosteal bone formation rate, which was severely impaired in GHRKO compared to WT (- 76%), was fully rescued to control WT levels, associated by an increase in osteoblast number (+ 127%) at the femoral periosteal site. Measurement of IGF-I mRNA levels in GHRKO mice revealed a pronounced E_2-induced increase in IGF-I synthesis in the liver from 1.4% to 53% of control WT levels, while IGF-I expression in bone was unaffected. This E_2-induced upregulation of hepatic IGF-I mRNA levels resulted in a 10-fold increase in serum IGF-I, which, in turn, correlated strongly with the rate of periosteal bone formation ($r = 0.86$, $P = 0.01$). Our data provide the first evidence for stimulation of skeletal growth through upregulation of hepatic IGF-I by a hormone other than GH and support the concept that E_2 rescues pubertal skeletal growth during GH resistance through a novel mechanism of GH-independent stimulation of IGF-I synthesis in the liver. Estrogen or estrogen-like compounds (e.g., SERMs) merit investigation as potential IGF-I secretagogues to restore serum IGF-I levels in disease-related or age-dependent GH/IGF-I deficient or resistant conditions.

Liver-Derived Insulin-Like Growth Factor I Is Permissive for Ovariectomy-Induced Bone Loss. N. Andersson[1], M. K. Lindberg[1], S. Movérare[1], J. Svensson*[1], T. Chavoshi*[2], K. Venken[3], D. Vanderschueren[3], H. Carlsten*[2], C. Ohlsson[1]. [1]Center for Bone Research at the Sahlgrenska Academy, Department of Internal Medicine, Göteborg University, Göteborg, Sweden, [2]Department of Rheumatology and Inflammation Research, Göteborg University, Göteborg, Sweden, [3]Laboratory for Experimental Medicine and Endocrinology, Katholieke Universiteit Leuven, Leuven, Belgium.

Estrogen deficiency as a result of ovariectomy (ovx) results in a pronounced trabecular bone loss. Insulin-like growth factor I (IGF-I) is involved in the regulation of bone metabolism and a major part of serum IGF-I is derived from the liver.

The aim of the present study was to investigate the role of liver-derived IGF-I for ovx-induced bone loss. Three-month-old mice with Cre-loxP induced liver specific IGF-I inactivation (LI-IGF-$I^{-/-}$) and wild type mice (WT) were either ovx or sham operated. As expected, five weeks after ovx, there was a pronounced reduction in trabecular bone mineral density (BMD) in WT mice as measured using pQCT (-52%, $p<0.001$). The decreased trabecular BMD was caused both by a reduced number (-45%, $p<0.01$) and thickness (-13%, $p<0.01$) of trabeculae compared with sham operated mice as measured using µCT. The trabecular bone mass in sham operated LI-IGF-$I^{-/-}$ mice was similar to that seen in sham operated WT mice. Interestingly, the trabecular bone parameters were not affected by ovx in LI-IGF-$I^{-/-}$ mice.

Recent studies indicate that skeletal homeostasis is influenced by several components of the immune system. Therefore, we measured the number of T cells in bone marrow of the femur using flow cytometric analysis. Ovx increased the number of T cells in the bone marrow of the femur in WT (193% over sham, $p<0.001$) but not in LI-IGF-$I^{-/-}$ mice. Interleukin 7 (IL-7) has been reported to stimulate the formation and function of osteoclasts by inducing the expression of receptor activator of NF-κB ligand (RANKL) on T-cells. The expression of IL-7 was increased by ovx in WT (26% over sham, $p<0.05$) but not in LI-IGF-$I^{-/-}$ mice as studied by real time PCR analysis. Similarly, ovx of WT mice resulted in an increase in the RANKL/ osteoprotegerin ratio (52% over sham, $p<0.05$), while this ratio was unaffected by ovx in LI-IGF-$I^{-/-}$ mice. In conclusion, liver-derived IGF-I is permissive both for ovx-induced trabecular bone loss and for the associated increase in number of T-cells in bone marrow. Our mechanistic studies indicate that the permissive effect of liver-derived IGF-I for ovx-induced trabecular bone loss involves modulation of the expression of IL-7 and a subsequent modulation of RANKL on T-cells in the bone marrow.

Raloxifene In Combination with Teriparatide Reduces Teriparatide-Induced Stimulation of Bone Resorption but not Formation in Postmenopausal Women With Osteoporosis. C. Deal[1], M. Omizo*[2], E. N. Schwartz*[3], E. F. Eriksen[4], P. Cantor*[4], J. Wang*[4], E. V. Glass*[4], S. L. Myers*[4], J. H. Krege*[4]. [1]Cleveland Clinic Foundation, Cleveland, OH, USA, [2]Oregon Osteoporosis Center, Portland, OR, USA, [3]Foundation for Osteoporosis Research and Education, Oakland, CA, USA, [4]Eli Lilly & Co, Indianapolis, IN, USA.

Teriparatide (rDNA) injection [rhPTH(1-34)] increases bone turnover, stimulates new bone formation, and reduces fracture risk in postmenopausal women with osteoporosis. To assess the effects of combination teriparatide and raloxifene therapy in postmenopausal women with osteoporosis, we conducted a 6-month randomized, double-blind trial comparing combination teriparatide plus raloxifene (n=69) versus teriparatide plus placebo (n=68). Women were osteoporosis treatment naïve and received calcium and vitamin D. Fasting serum N-terminal propeptide of type 1 collagen (PINP) and C-terminal telopeptide of type I collagen (CTX) were monitored at baseline, and after 1, 3 and 6 months treatment. Bone mineral density was measured by DXA at baseline and 6 months.

TABLE: Results are mean +/- SE of percent change from baseline to endpoint.

	TPTD + placebo	TPTD + RLX	P-value*
Formation (PINP)	167±30†	148±31†	0.66
Resorption (serum CTX)	96±15†	44±15‡	0.01
DXA Lumbar Spine BMD	5.19±0.67†	6.19±0.65†	0.28
DXA Femoral Neck BMD	1.03±0.67	2.23±0.64†	0.19
DXA Total Hip BMD	0.68±0.59	2.31±0.56†	0.04

*P-value for between group comparisons, † P<0.001, ‡ P=0.005 for within group change from baseline. Results are ITT by last observation analysis.

Baseline demographics were similar between groups. Bone formation (PINP) increased similarly in both groups. However, the increase in bone resorption (CTX) was significantly reduced (-52%, P=.01) in the combination group. In the teriparatide-alone group, lumbar spine BMD increased significantly from baseline. In the combination group, lumbar spine, femoral neck, and total hip BMD increased significantly from baseline, and the increase in total hip BMD was significantly greater than in the teriparatide alone group. In the teriparatide-alone group, mean serum calcium levels increased from baseline to endpoint (0.30±0.06 mg/dl, P<.001) and mean serum phosphate was unchanged. In the combination group, mean serum calcium was unchanged, and mean serum phosphate decreased (-0.20±0.06 mg/dl, P<.001) from baseline to endpoint. Serum calcium (P<.001) and phosphate (P<.004) changes from baseline to endpoint were significantly different between the teriparatide-alone and combination groups. Therapy in both groups was well tolerated.

Compared to teriparatide alone, raloxifene plus teriparatide increased bone formation to a similar degree. However, compared to teriparatide alone, combination therapy induced a lesser increase in bone resorption and significantly increased total hip BMD.

Fracture Risk Reduction During Treatment with Teriparatide Is Independent of Pretreatment Bone Turnover. P. D. Delmas[1], A. A. Licata*[2], G. G. Crans*[3], P. Chen*[3], D. A. Misurski*[3], R. B. Wagman[3], B. H. Mitlak[3]. [1]INSERM Research Unit 403, Claude Bernard University of Lyon, Lyon, France, [2]Department of Endocrinology, Diabetes, and Metabolism, The Cleveland Clinic, Cleveland Clinic Foundation, Cleveland, OH, USA, [3]Lilly Research Laboratories, Indianapolis, IN, USA.

In the Fracture Prevention Trial, postmenopausal women with osteoporosis randomized to teriparatide 20 mcg/day or 40 mcg/day for a median of 19 months had a reduced risk of fracture compared to women on placebo (Neer, 2001). However, the relationship between baseline bone turnover and anti-fracture efficacy remains unclear. To assess this relationship, data from women enrolled in the Fracture Prevention Trial were examined using logistic regression analysis. A subset of 520 women had biochemical markers of bone turnover (serum bone-specific alkaline phosphatase [BSAP], serum carboxy-terminal extension peptide of procollagen type 1 [PICP], urinary N-terminal telopeptide [NTX], and urinary free deoxypyridinoline [DPD]) measured at baseline. A partially overlapping subset of 771 women also had serum amino-terminal extension peptide of procollagen type 1 [PINP] evaluated at baseline. A total of 45 osteoporotic fractures (vertebral and non-vertebral) occurred in the four-marker subset and 74 occurred in the partially overlapping PINP subset. The relationship between bone markers and fracture risk was modeled as a function of therapy (placebo or pooled teriparatide), baseline bone marker covariate, and therapy-by-baseline bone marker covariate interaction. Higher bone turnover was associated with increased fracture risk. For each bone marker, the main effect of therapy was statistically significant ($p < 0.05$); however, therapy-by-baseline bone marker covariate interaction was not significant, suggesting that the ability of teriparatide to reduce fracture risk is independent of baseline bone turnover. The effects of pretreatment biochemical marker concentrations are shown below. Women with the highest pretreatment bone turnover had the greatest risk of fracture. The anti-fracture efficacy of teriparatide was similar regardless of baseline bone turnover.

Table. Effect of different pretreatment biochemical marker concentrations on the estimated relative risk of new osteoporotic fracture in women receiving teriparatide therapy compared to women in placebo group.

Percentile	BSAP RR (95% CI)	PICP RR (95% CI)	PINP RR (95% CI)	NTX RR (95% CI)	DPD RR (95% CI)
25th	0.41 (0.11-0.71)	0.40 (0.15-0.65)	0.31 (0.15 - 0.47)	0.38 (0.13 – 0.63)	0.41 (0.13- 0.70)

Daily Nasal Spray of hPTH(1-34) for 3 Months Increases Bone Mass in Osteoporotic Subjects. T. Matsumoto[1], M. Shiraki[2], T. Nakamura[3], H. Hagino[4], H. Iinuma*[5]. [1]University of Tokushima, Tokushima, Japan, [2]Research Institute and Practice for Involutional Diseases, Nagano, Japan, [3]University of Occupational and Environmental Health, Fukuoka, Japan, [4]Tottori University, Tottori, Japan, [5]The Cardiovascular Institute, Tokyo, Japan.

Intermittent administration of PTH has been shown to develop strong anabolic effects on bone. However, invasiveness of currently available formulas given by daily subcutaneous (sc) injections has been a considerable disadvantage for patient acceptance. We, therefore, have developed a nasal spray formula of hPTH(1-34), and found that similar peak serum hPTH(1-34) concentrations to those obtained after sc injections of 20 µg hPTH(1-34) can be achieved by nasal spray of 1000 µg hPTH(1-34). Furthermore, hPTH(1-34) was absorbed from nasal mucosa much more quickly than by sc injections. In order to determine clinical efficacy as well as safety and tolerability of nasal hPTH(1-34) spray, a randomized, open-labeled clinical trial was conducted in subjects with osteoporosis.

Ninety-two osteoporotic subjects 52 to 84 years of age (mean age, 66.6 years) were enrolled in this study. The subjects were randomly assigned to receive either 250 µg (PTH250, n=31), 500 µg (PTH500, n=30), or 1000 µg (PTH1000, n=31) of daily nasal hPTH(1-34) spray for 3 months. All the participants received daily supplements of 300 mg Ca and 200 IU vitamin D_3.

Daily nasal hPTH(1-34) spray for 3 months increased lumbar bone mineral density (L-BMD) in a dose-dependent manner, and PTH250, PTH500 and PTH1000 groups showed 0.1 (p=0.817), 0.7 (p=0.165), and 2.4% (p=0.012) increase in L-BMD from the baseline, respectively. Among bone formation markers, serum PINP and osteocalcin increased in a dose-dependent manner at 3 months, and were significantly increased from the baseline in PTH1000 group by 16.7 and 20.6%, respectively. Interestingly, urinary CTX and NTX did not increase but were suppressed in PTH500 and PTH1000 groups after 3 months. At the baseline, 0.5, 1, 2, and 3 months, serum Ca was monitored before and 3 hours after nasal hPTH(1-34) spray. Two subjects in PTH250 group, and 5 in PTH1000 group developed hypercalcemia over 10.4 mg/dL but less than 11 mg/dL 3 hours after nasal hPTH(1-34) spray. None of the subjects developed hypercalcemia before nasal spray. There were no significant treatment differences in the number of subjects with at least one adverse event.

These results demonstrate that nasal hPTH(1-34) spray is safe, well-tolerated, and is associated with an early increase in L-BMD. Based upon the pharmacokinetics of nasal hPTH(1-34) spray with quick absorption and short half-life, the present results warrant further studies to examine its long-term efficacy on bone mass and fractures.

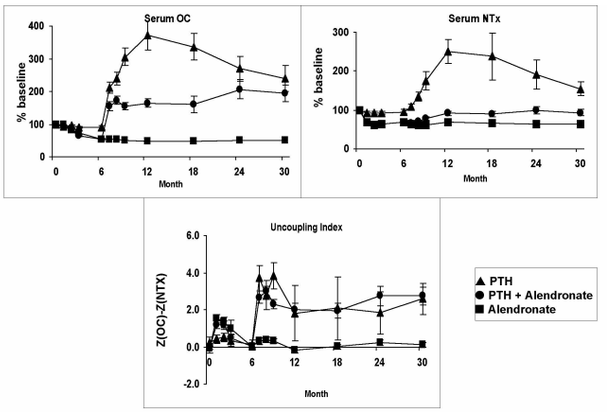
Effects of PTH, Alendronate, or Both on Bone Turnover in Osteoporotic Men. B. Z. Leder, J. J. Wyland*, R. M. Neer, A. Hayes*, J. Hunzelman*, K. Gibson*, J. S. Finkelstein. Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA.

We recently reported that alendronate (AL) impairs the ability of PTH to increase spine and femoral neck BMD, but not total body BMD, in men. Here we report the effects of AL, PTH, or the combination (A+P) on bone turnover in the same population. 83 men age 46-85 with lumbar spine or femoral neck T-scores < -2 were randomized to receive AL 10 mg daily, hPTH-(1-34) 40 mcg sc daily, or both. AL was given for 30 months whereas PTH was begun at month 6. Serum osteocalcin (OC) and N-telopeptide (NTX) were measured at months 0, 1, 2, 3, 6, 7, 8, 9, 12, 18, 24, and 30 and between-group differences in the area under the curve (AUC) between month 6 and 30 were compared by ANOVA. To assess changes in the balance of bone formation and resorption, we also compared changes in an Uncoupling Index (UI) defined by the equation: Z-score OC - Z-score NTX. Only subjects who completed the study are included in this analysis (AL n=26, A+P n=20, PTH n=17). Changes in OC, NTX, and UI (+ SE) are shown below.



Differences were found for all between-group comparisons in OC and NTX (P<0.001). In the PTH group, markers peaked at month 12 (6 months after initiation of therapy) and then gradually fell during the remaining 18 months of treatment. Both NTX and OC decreased in the A+P group during the first 6 months of AL therapy. The addition of PTH at month 6, however, restored NTX to its pre-treatment level and increased OC to double its pre-treatment level. In contrast to the PTH alone group, markers in the A+P group continued to increase from month 12 through 30. UI increased significantly and similarly in the PTH and A+P groups. This increase was greatest 1-3 months after initiation of PTH. Changes in OC were associated with changes in NTX in all groups (PTH group: R=0.78, P<0.001; A+P group: R=0.86, P<0.001: AL group: R=0.42, P=0.03).

In conclusion, pre-treatment with AL diminished the ability of PTH to stimulate bone formation and resorption in men, eliminated the up-and-down pattern of stimulation, but did not alter the relationship between formation and resorption as assessed by UI. Individual changes in bone formation and resorption were strongly linked in both PTH-treated groups. The BMD effects of the sustained increase in bone turnover in the combination group may be best assessed in studies of even longer duration.

Normal Bone Histomorphometry and 3D Microarchitecture After 10 Years Alendronate Treatment of Postmenopausal Women. R. Recker[1], K. Ensrud[2], S. Diem*[2], E. Cheng*[2], S. Bare*[1], P. Masarachia[3], P. Roschger*[4], P. Fratzl*[5], K. Klaushofer*[4], A. Lombardi[6], D. Kimmel[3]. [1]Creighton University, Omaha, NE, USA, [2]University of Minnesota, Minneapolis, MN, USA, [3]Merck Research Laboratories, West Point, PA, USA, [4]Ludwig Boltzmann Institute of Osteology, Vienna, Austria, [5]Max Planck Institute of Colloids and Interfaces, Potsdam, Germany, [6]Merck Research Laboratories, Rahway, NJ, USA.

FLEX (FIT Long-term EXtension) was a 5-year randomized, placebo (PBO)-controlled trial, designed to assess the efficacy and safety of long-term treatment with alendronate (ALN). 1099 postmenopausal women who had received 3-6 years treatment with ALN (5 mg/d during the first two years and 10 mg/d thereafter) in the Fracture Intervention Trial (FIT), were randomized to placebo (ALN/PBO) (N=437), ALN* 5 mg/d (N=329) or 10 mg/d (ALN/ALN) (N=333). Transilial bone biopsies were obtained following dual fluorochrome labeling from 31 women. Trabecular bone turnover, quantity, microarchitecture and mineralization were assessed. Twenty-nine specimens were suitable for quantitative back-scatter electron microscopy (qBEI; MCC and CAW), eighteen for histomorphometry (2D) and fourteen for micro-computed tomography (3D). Since there were no differences between the 5mg/d and 10mg/d ALN groups, the two groups were pooled. Results are shown in the table.

Abbrv	Mean (S.D.)	ALN/PBO (N=14)	ALN/ALN (N=15)
MCC	Mean Calcium Concentration (%)	22.1 (0.58)	22.4 (0.54)
CAW	Calcium Width	3.57 (0.38)	3.48 (0.45)
	2D Endpoints	**(N=9)**	**(N=9)**
BV/TV	Bone Volume (%)	18.3 (5.2)	19.5 (6.2)
OV/BV	Osteoid Volume (%)	1.1 (0.4)	0.9 (0.7)
Tb.N	Trabecular Number (#/mm)	1.3 (0.2)	1.3 (0.2)
Tb.Th	Trabecular Thickness (µm)	142 (27)	148 (35)
OS/BS	Osteoid Surface (%)	11.6 (4.7)	9.9 (6.3)
O.Th	Osteoid Thickness (µm)	4.8 (0.4)	5.1 (0.7)
MAR	Mineral Apposition Rate (µm/d)	0.6 (0.1)	0.5 (0.1)
MS/BS	Mineralizing Surface (%)	3.0 (3.4)	1.4 (1.6)
	3D Endpoints	**(N=6)**	**(N=8)**
BVF	Bone Volume Fraction (%)	16.5 (4.9)	16.6 (6.0)
BSD	Bone Surface Density mm^2/mm^3)	1.0 (0.4)	1.2 (0.5)
Tb.N	Trabecular Number (#/mm)	1.3 (0.2)	1.4 (0.3)
Tb.Th	Trabecular Thickness (µm)	130 (20)	121 (26)

In this study, all patients were initially treated with ALN for ~5 years, followed by an additional five years of PBO or ALN. All patients in both ALN/PBO and ALN/ALN groups displayed double fluorochrome label in trabecular bone. The cortical and trabecular bone tissue of both groups appeared normal, lacking qualitative abnormalities such as woven bone, osteitis fibrosa, defective mineralization, and non-lamellar bone. There were no differences between the groups for any quantitative endpoint (p=NS). These data, from a limited sampling, suggest that iliac trabecular bone tissue remains normal following use of ALN 5 or 10 mg/d for 5-10 years.

A 5 Year Randomized Trial of the Long-term Efficacy and Safety of Alendronate: The FIT Long-term EXtension (FLEX). D. Black[1], A. Schwartz[1], K. Ensrud[2], A. Rybak-Feiglin*[3], J. Gupta*[3], A. Lombardi[3], R. Wallace*[4], S. Levis[5], S. Quandt[6], S. Satterfield*[7], J. Cauley[8], S. Cummings[9]. [1]U CA, SF, CA, USA, [2]U MN, Minn, MN, USA, [3]Merck & Co., Rahway, NJ, USA, [4]U IA, Iowa City, IA, USA, [5]U Miami, Miami, FL, USA, [6]Wake Forest U, Winston-Salem, NC, USA, [7]U TN, Memphis, TN, USA, [8]U Pitt, Pitt, PA, USA, [9]CA Pac. Med. Ctr., SF, CA, USA.

Alendronate (ALN) has been shown to increase BMD and reduce fracture risk in trials up to 5 years but optimal longer term use remains an important clinical question. FLEX was a 5-year randomized, placebo-controlled trial to test the hypothesis that in women previously on ALN for 3-6 years, continued ALN would preserve or increase total hip BMD vs placebo (PBO). BMD at other sites and bone turnover were secondary endpoints; fractures were exploratory.

Women on ALN in the Fracture Intervention Trial (FIT) with T-scores > -3.5 were eligible. 1099 participants with a mean of 5 (range 3-6) years previous ALN (5 mg/d in yrs 1-2 & 10 mg/d thereafter) in FIT were randomized to 5 years of PBO (n=437) or ALN 5 mg/d (n=329) or 10 mg/d (n=333).

The mean age at FLEX baseline was 73 yrs; mean total hip BMD T-score was -1.77. As shown below, women switched to PBO had significant loss of hip BMD (p<0.001) and significant increases in bone turnover (p<0.001) relative to FLEX baseline. In contrast, spine and total body BMD were preserved in the PBO group.

Mean % Changes in BMD and Markers Among Women with 3-6 Years Prior ALN

Endpoint	PBO	ALN+	Difference (95% CI)
Total hip BMD	-3.4**	-1.0**	2.4% (1.8, 2.9)^
Femoral neck BMD	-1.5**	0.5	1.9% (1.2, 2.7)^
Lumbar spine BMD	1.5**	5.3**	3.8% (3.0, 4.4)^
Total body BMD	-0.3	1.0**	1.3% (0.7, 1.9)^
Urinary NTx	33.7**	1.2	-32% (-44, -21)^
Serum BSAP	27.7**	4.9**	-23% (-28, -17)^

**p<0.001 vs. BL; ^p<0.001 between groups; + =pooled doses of ALN

Compared to FIT baseline, women treated with ALN up to 11 years increased their spine BMD by 14.8%, total hip BMD by 2.4%, and total body by 3.6%. Women treated with PBO in the last 5 of 11 years had respective changes (vs. FIT baseline) of 11.0% (p<0.001 vs. continuous ALN), -0.2% (p<0.001), and 2.5% (p=0.005). During the 5 years of FLEX, clinical spine fracture risk was reduced in ALN vs PBO (RR=0.45, 95% CI (0.23,0.84)) but risks were similar for non-spine fractures (RR=1.0, 95% CI (0.76,1.32)) and morphometric spine fractures (0.87, 95% CI (0.61,1.25)). Adverse experiences were similar in both treatment groups.

We conclude that 4-6 years of ALN followed by continued treatment with ALN for up to 5 additional years increases spine BMD, maintains other BMD measures and preserves decreases in bone markers. Decreases in hip BMD and increases in bone turnover markers occurred among those who stopped ALN during FLEX; nevertheless, BMD levels were similar or higher and marker levels remained slightly lower than at FIT baseline 11 years earlier.

Convergence of BMP2/TGFβ, MAPK and Runx2 Signaling in Subnuclear Foci During Osteogenic Lineage Induction. A. Javed, F. Afzal*, J. Pratap, A. J. van Wijnen, J. L. Stein*, J. B. Lian, G. S. Stein. Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA.

The Runx2/Cbfa1 transcription factor is a scaffold protein that interacts with mediators of signal transduction pathways critical for bone formation. We have previously shown that a knock-in mutation in the mouse that ablates the Runx2 C-terminus results in absence of a mineralized skeleton (Choi et al, PNAS, 2001). The C-terminus contains a Runx family unique nuclear matrix targeting signal (NMTS) and a SMAD interacting domain. Although the coordinated activity of Runx2 and BMP/TGFβ-activated Smads are necessary for bone formation, the precise structural basis for the Runx2/Smad interaction and its requirement for osteoblast differentiation has not been resolved. Using a series of mutations, we have defined a sequence in Runx2 required for physical and functional interaction with Smads. Smad responsive transcriptional activity was retained upon deletion of the C-terminus to amino acid 432, but lost with deletion to amino acid 391. Deletion to 391 also abolished the in situ association of Runx2 and Smad at subnuclear sites. Thus the domain of Runx (391-432) required for Smad binding and function overlaps the well-defined nuclear matrix targeting signal (NMTS). We further established using heterologous Gal4 fusion proteins that the NMTS is necessary and sufficient for interaction with either BMP or TGFβ responsive SMADs. Moreover, formation of Runx2 and Smad complexes are dependent on Runx2 phosphorylation through the MAPK signaling pathway. Finally we demonstrate that the 391-432 Runx2- SMAD domain is essential for BMP2 mediated induction of C2C12 cells into the osteogenic lineage. Our findings demonstrate that the Runx-Smad interaction (i) is dependent on MAPK phosphorylation of Runx2, (ii) is required for osteogenic induction by TGFβ/BMP2, and (iii) supports Runx2 gene transcription in subnuclear domains. We propose the genetic requirement for the Runx2 C-terminus in bone formation in vivo is causally related to the integration of these three signaling pathways to promote osteogenic differentiation.

The Zinc Finger Transcription Factor Gli2 Enhances BMP-2 Gene Transcription, Osteoblast Differentiation and Bone Formation. M. Zhao[1], M. Qiao*[1], J. A. Sterling[1], D. Chen[1], B. O. Oyajobi[1], I. R. Garrett[2], G. Gutierrez[2], G. Rossini*[2], G. R. Mundy[1]. [1]Cellular and Structural Biology, UTHSCSA, San Antonio, TX, USA, [2]Osteoscreen, San Antonio, TX, USA.

BMP-2 is an important skeletal growth factor, but regulation of its transcription in osteoblasts is not well understood. Expression of BMP family members is mediated by hedgehog signaling, but the mechanism is unknown. The Gli family of zinc finger transcriptional factors mediate hedgehog signaling in other organ systems. Thus, we reasoned that the Gli family may directly regulate BMP-2 gene transcription and thereby subsequent skeletal development. We examined specifically Gli2 since Gli2 has been shown to be the major mediator of hedgehog signaling in other cells. Gli2 null mutant mice ($Gli2^{-/-}$) are embryonic lethal with severe skeletal abnormalities. Recently, we found the one third of two-month old $Gli2^{-/+}$ nulls were smaller and had profound osteopenia associated with impaired bone formation as shown by decreased bone mineral density, trabecular bone volume and cortical bone thickness. A similar osteopenic phenotype occurs in transgenic mice unresponsive to BMP-2 because of a dominant negative BMP type IB receptor targeted to osteoblasts. Culture of Gli2-deficient calvarial cells from $Gli2^{-/-}$ mice showed significant inhibition of BMP-2 gene expression, alkaline phosphatase (ALP) activity and mineralized bone nodule formation. Gli2 siRNA, which inhibited Gli2 expression by 90% in osteoblast precursor C2C12 and 2T3 cells, markedly decreased osteoblast differentiation and also decreased basal BMP2 promoter activity. In contrast, overexpression of Gli2 in these cells caused increases in BMP2 mRNA expression, ALP activity and mineralized nodule formation. Gli2-enhanced ALP activity was blocked by noggin. These results indicate that Gli2 stimulates osteoblast differentiation at least partially through up-regulation of BMP2 expression. Promoter studies showed that transfection of Gli2 in C2C12 cells increased BMP2 promoter activity by 10-fold and that two Gli2-responsive regions lie between -202/-312 and -1997/-2712. Three putative Gli response elements in these areas bound Gli2 protein as demonstrated by gel shift and supershift in EMSA. Co-transfection showed a synergistic effect of Gli2 with Smad1 on BMP-2 transcription, suggesting that Gli2 may directly interact with Smad1 and co-activate target genes. We have previously reported that truncated Gli3 is a repressor of BMP-2 gene and taken together with this new data, we propose that the Gli family of zinc finger proteins control BMP2 transcription in osteoblasts and subsequent osteoblast differentiation, in which Gli2 serves as a powerful stimulant for BMP-2 gene expression.

Ectopic Bone Formation in Tooth Pulp, Absence of Cementum, Hyperplastic Periodontal Ligament and Reduced or no Dentin in Mice Lacking Bone Morphogenetic Protein Receptor Type 1A (BMPR1A). l. ye[1], Y. Mishina*[2], J. Zhang*[3], S. Zhang*[1], Y. Xie*[1], N. Kamiya*[2], V. Dusevich*[1], L. Li*[3], D. Eick*[1], L. Bonewald[1], J. Q. Feng[1]. [1]Oral Biology, University of Missouri-kansas city, School of Dentistry, Kansas City, MO, USA, [2]NIEHS/NIH, Research Triangle Park, NC, USA, [3]Stowers Institute, Kansas City, MO, USA.

Three type 1 receptors, BMPR1A, BMPR1B, and ActRI, are responsible for signaling of the Bone Morphogenetic proteins. It is known that recombinant BMP-2 or -4 can induce both *de novo* dentin and bone formation at the same induction site. It is unclear which receptors determine the fate of precursors for bone or dentin *in vivo*. Whereas, the *Bmpr1b* null mouse is viable and has a mild skeletal phenotype, the *Bmpr1a* null is lethal. To examine the function of BMP1A in mineralized tissue, a tissue specific null mouse was generated using the loxP/Cre approach. To delete the *Bmpr1a* gene specifically in osteoblasts, periodontal ligament (PDL) cells, cementoblasts and odontoblasts, *Col 1a1*-cre mice were crossed to floxed *Bmpr1a* mice. Histological analyses revealed a striking phenotype in the tooth as well as in bone. A dramatic reduction of alveolar and calvarial bone is observed in *Bmpr1a* null mice which maintains a woven bone character compared to compact bone in normal mice. A more dramatic phenotype was observed in the teeth as both the acellular and cellular layers of cementum are absent and the PDL is hyperplastic and replaced by loosely disorganized fibers. Dentin is extremely thin (one eighth of normal to missing) with few odontoblasts. The tooth pulp is replaced by poorly mineralized bone-like osteoid, and the remaining pulp cells appear degenerated. The dentin peritubules, equivalent to lacunae in bone, are ~1/2 normal size, Instead of forming secondary dentin in the normal response to the dentin fractures, a bone canus is formed. Immunohistochemistry of the ectopic bone in the tooth pulp shows higher expression of periostin and decorin compared to normal bone. This dental phenotype is similar to “shell teeth”, a genetic disease in humans. Based on these observations, we propose that BMPR1A is an essential signaling molecule in determining the cell fate of cementoblasts, odontoblasts, and PDL cells from mesenchymal precursors. In the absence of this receptor, the mesenchymal precursor cells by default differentiate into bone cells however, the bone fails to mature, but maintains the characteristics of immature woven bone, therefore BMPR1A is also critical for bone maturation.

Twisted Gastrulation Is a Bone Morphogenetic Protein Agonist in Cartilage but not in Bone. E. Gazzerro[1], V. Deregowski[1], L. Stadmeyer*[1], A. N. Economides[2], E. Canalis[1]. [1]Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA, [2]Functional Genomics, Regeneron Pharmaceuticals, Inc., Tarrytown, NY, USA.

Twisted gastrulation (Tsg) is a secreted glycoprotein that binds bone morphogenetic proteins (BMP) -2 and -4, and it is unique since it can display both BMP agonist and antagonist functions. Tsg can form a ternary complex with BMP and its antagonist chordin, enhancing chordin actions, or it can induce the cleavage of chordin by the metalloprotease BMP-1/tolloid, releasing BMP into the extracellular matrix. Tsg dual activities depend on the developmental stage, and on relative concentrations of BMP, chordin and BMP-1/tolloid in the target tissues. Tsg is expressed in chondrocytes and osteoblasts, and it acts as a BMP agonist in cells of the chondrocytic lineage. However, its actions in adult skeletal tissue *in vivo* are not known. A targeted deletion of the Tsg gene was created by replacing the first two Tsg coding exons with a LacZ cassette in frame with the first codon on a BAC clone containing Tsg genomic sequences. The LacZ reporter gene, with an associated neomycin selectable marker, were introduced by homologous recombination into the BAC clone. The deletion of the Tsg gene was confirmed by RT-PCR from calvarial mRNA. Tsg null mice were mostly viable, exhibited kinking of the tails, a 20% decrease of femoral length and a 40% decrease in body size when compared to age-sex matched wild type controls of equal genetic background. Dynamic histomorphometric analysis revealed no evidence of impaired BMP activity that would suggest an agonist role of Tsg since trabecular bone volume, mineral apposition rate, mineralizing surface and bone formation rate were not decreased in Tsg null mice compared to wild type controls. An increase in the percentage of osteoblast surface/bone surface was noted in Tsg null mice, and this is in accordance with the known effect of BMP on osteoblast cell differentiation. In an attempt to confirm a function of Tsg in bone, primary marrow stromal cells from Tsg null mice and wild type controls were cultured in osteoblastic differentiating conditions in the presence or absence of BMP-2. Cells from Tsg null mice were more susceptible to BMP-2 effects, forming mineralized nodules earlier than wild type controls, indicating an antagonist, and not an agonist role of Tsg. In conclusion, Tsg deletion in adult skeletal tissue reveals a modest BMP antagonist effect in bone, which is in contrast with the agonist effect of Tsg in cartilage.

Antagonism between BMP and FGF Signaling Pathways in the Growth Plate Revealed by Analysis of BMPRIA and BMPRIB Mutant Mice. B. S. Yoon*[1], Y. Mishina*[2], I. Yoshii*[1], R. R. Behringer*[2], K. M. Lyons[1]. [1]Molecular, Cell, Developmental Biology, UCLA, Los Angeles, CA, USA, [2]Department of Molecular Genetics, M. D. Anderson Cancer Center, Houston, TX, USA.

During endochondral ossification, chondrocytes form a cartilaginous template for bone formation, known as the growth plate. Growth plate chondrocytes undergo a highly organized differentiation program. Cells at the ends of skeletal elements form the resting zone. Cells exiting the resting zone form the proliferative compartment. These cells eventually exit the cell cycle and differentiate into prehypertrophic chondrocytes, which terminally differentiate to form the hypertrophic zone.

Bone Morphogenetic Proteins (BMPs) are members of the Transforming Growth Factorβ (TGFβ) superfamily, and signal through receptor complexes that subsequently activate intracellular smad proteins. Although it is known BMPs are required for chondrogenesis, little is known about their roles in specific regions of the growth plate. In order to examine these roles, we generated mice null for BMPR1B (*Bmpr1b*$^{-/-}$) and conditionally null (CKO) for BMPR1A in cartilage (*Bmpr1a*^{CKO}). *Bmpr1a*^{CKO} mice die postnatally due to general chondrodysplasia with mild growth plate defects. This phenotype is exacerbated by the loss of one allele of *Bmpr1b*. *Bmpr1a*^{CKO} ;*Bmpr1b*$^{+/-}$mice have hypocellular proliferative zones and an abrupt transition to expanded hypertrophic zones. We demonstrate that the defects in proliferative zones are caused by increased apoptosis and severe defects in proliferation, as evidenced by decreased PCNA levels and increased production of cyclin inhibitors. Furthermore, *Bmpr1b*$^{+/-}$*; Bmpr1a*^{CKO} mice exhibit increased STAT and Erk1/2 MAPK signaling, both components of the Fibroblast Growth Factor (FGF) signaling pathway. Although the ability of FGFs to antagonize BMPs signals in the growth plate is established, our results provide *in vivo* evidence for this inhibition, and demonstrate that reciprocal inhibition of FGF pathways by BMPs is required for proliferation and differentiation of chondrocytes. Using the rat chondrosarcoma (RCS) cell line, we also show that smad-mediated BMP signaling is inhibited by FGFs, and demonstrate a direct mechanism for the antagonistic relationship. In summary, our results show that BMP signaling is required in the growth plate *in vivo*, in part to antagonize FGF signaling.

Smad3 Deficient Chondrocytes Have Accelerated Differentiation and Enhanced BMP Signaling. T. Li*, M. J. Zuscik, D. Chen, E. M. Schwarz, R. N. Rosier, H. Drissi, R. J. O'Keefe. Orthopaedics, University of Rochester, Rochester, NY, USA.

Although TGF-β inhibits terminal differentiation of chondrocytes, the relative importance of various downstream signals as mediators of this effect remains unclear. Mice lacking Smad3 expression have accelerated chondrocyte maturation that results in post-natal dwarfism and premature osteoarthritis. We examined the rate of differentiation, responsiveness to TGF-β and BMP signaling, and expression of various signaling molecules in chondrocytes isolated from the sterna of neonatal wild type (Smad3$^{+/+}$) and knock out (Smad3$^{-/-}$) mice. In culture, wild type (wt) chondrocytes had abundant expression of *col2*, but had minimal spontaneous expression of *colX* over 8-days. *Col2* expression was even greater in knock out (ko) cells, and high levels of *colX* expression occurred in these cultures by 2-days and remained elevated for 8 days. Other markers of maturation, including *alkaline phosphatase*, *osteocalcin*, and *VEGF* were also elevated in ko cells. Experiments were performed to assess the responsiveness of the chondrocytes to TGF-β and BMP signaling. As anticipated, TGF-β failed to induce the Smad3 specific reporter, SBE-Luc in ko cells, and had reduced activation of P3TP-Luc, which is activated by TGF-β through Smad3 and other signals. In contrast, the BMP responsive reporter 9X GCG-Luc was more highly activated by BMP-2 in ko cells, suggesting an up-regulation of BMP responsiveness in cells lacking Smad3. Real time RT-PCR and Western blot was used to examine Smad expression. Similar levels of Smad2 and Smad4 were found in wt and ko chondrocytes, demonstrating the absence of a compensatory up-regulation of these factors. Furthermore, ko cells had reduced TGF-β1 and the type I TGF-β receptor expression (approximately 50% each), suggesting down-regulation of TGF-β signaling in chondrocytes lacking Smad 3. In contrast, components of the BMP signaling pathway were up-regulated in ko cells, including Smad1 (70%), Smad5 (80%), BMP-2 (2-fold), and BMP-6 (2.2-fold). BMP-2 markedly enhanced chondrocyte differentiation in both wt and ko cells, but the effect was much greater in ko cells**.** The maximal effect was 50-fold in ko cells and 5-fold in wt cells at 8-days. TGF-β continued to suppress maturation in ko cells (50%) suggesting that remaining components of the signaling pathway are functional. However, while TGF-β markedly suppressed alkaline phosphatase activity in wt cells (> 90%), the effect was much less in ko cells (50-75%). Thus, absence of Smad3 results in enhanced BMP signaling and responsiveness and is not associated with a compensatory increase in TGF-β signaling molecules. These changes account for the enhanced maturation observed in Smad3$^{-/-}$ chondrocytes.

Transgenic Overexpression of IGFBP-5 in Mice Leads to Unexpected Decrease in Peak BMD in a Gender Specific Manner: Evidence for IGF-independent Mechanism of Action. D. A. Salih*[1], Y. Kasukawa[2], G. Tripathi*[1], F. A. Lovett*[1], N. F. Anderson*[1], E. J. Carter*[1], J. E. Wergedal[2], D. J. Baylink[2], J. M. Pell*[1], S. Mohan[2]. [1]The Babraham Inst, Cambridge, United Kingdom, [2]JLP VAMC / LLU, Loma Linda, CA, USA.

Past studies have shown that IGFBP-5 (BP-5) stimulates bone formation (BF) parameters *in vitro* and *in vivo* by mechanisms involving stimulation of IGF actions and IGF-independent action. To test the hypothesis that BP-5 overexpression promotes acquisition of peak BMD, we generated transgenic (Tg) mice overexpressing BP-5 using the CMV, a regulatory element shown to drive expression in chondrocytes, osteoblasts, lining cells and cells within the marrow. In Tg mice, BP-5 concentrations were increased by 8.8 fold (P<0.001) at 3 wks. We found two unexpected findings in BP-5 Tg mice. First, BP-5 Tg mice were 35% smaller compared to wild type (WT) mice at 8 wks. Second, BMD as measured in femora and tibiae at 3, 5 and 8 wks by DEXA was decreased and showed a gender specific effect. BMD in Tg females was reduced by 19% compared to WT siblings (P<0.001) at 8 wks. The BMD reduction in Tg males (31%) was significantly greater than that of females (P<0.001) at 8 wks. Femoral BMD was reduced by 17% in males from a second Tg line overexpressing BP-5 at an intermediate level. Total vBMD measured by pQCT at the mid diaphysis was significantly less in Tg males compared to females (76±1 vs 91±4% of WT, P<0.01). Serum osteocalcin levels were reduced (P<0.01) by 25-40% in BP-5 Tg mice compared to WT mice. Histomorphometric studies revealed that while BF rate and mineraling surface at the periosteum was significantly decreased (P<0.01) in the BP-5 Tg mice, they were increased (P<0.01) at the endosteum, suggesting opposite effects of BP-5 overexpression on periosteal and endosteal osteoblasts. If the observed inhibitory effects of BP-5 on the skeletal phenotype upon continuous exposure to high levels of BP-5 from early development are only due to sequestration of IGFs, then we would anticipate the skeletal phenotype of BP-5 transgenic mice to be similar to that of IGF-I/-II null mice. However, our findings in BP-5 Tg mice on the gender specific effects and the differential effects at the periosteum vs endosteum are different from what we observed for the skeletal phenotypes of IGF-I/-II null mice and support a model involving IGF-independent effects of BP-5. Conclusions: 1) BP-5 overexpression decreases peak BMD, periosteal BF and serum osteocalcin levels in mice; 2) BP-5 overexpression increases endosteal BF; 3) BP-5 effects in Tg mice are gender specific; and 4) The observed phenotype in BP-5 Tg mice cannot be explained solely on the basis of IGF sequestering effects of BP-5 and provide the first *in vivo* evidence for IGF-independent effects of BP-5 in bone.

Functional Analysis of a 395-kilobase Region Surrounding the Mouse Bmp2 Gene: In Vivo BAC Transgenes and Comparative Analysis. R. L. Chandler*, K. J. McDermott*, D. P. Mortlock*. Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN, USA.

The Bmp2 gene is implicated as a key regulator of bone and articular cartilage maintenance and as a genetic risk factor for osteoporosis. However, little is known about the regulatory mechanisms that control Bmp2 transcription in vivo. To identify potentially distant cis-regulatory DNA elements that regulate Bmp2 transcription, we have performed in vivo functional analysis of a 395-kilobase genomic region flanking the mouse Bmp2 gene. Since other BMP family member genes are known to require distant cis-regulatory elements, we engineered Bmp2 bacterial artificial chromosomes (BAC) into reporter transgenes. Two overlapping BAC clones that extend far 5' and 3' to the Bmp2 promoter region were engineered to contain a LacZ reporter cassette inserted into the Bmp2 transcription unit using homologous recombination in bacteria. Modified BAC clones were injected into fertilized mouse eggs, and transgenic embryos were analyzed for LacZ expression at midgestation stages. The robust patterns of LacZ expression detected in our transgenic BAC embryos recapitulate many sites of endogenous Bmp2 expression in the developing skeleton. These included hypertrophic chondrocytes of the developing long bones, ribs and vertebrae, bone collar flanking ossifying regions, intervertebral joints, and incisor buds. Transgene expression was also detected in bone ossification centers, suggesting differentiating osteocytes. However, each BAC clone directed a different subset of normal Bmp2 expression patterns. Thus, a modular arrangement of distant 5' and 3' regulatory elements exist around the Bmp2 gene. Specifically, our data suggest that cis-regulatory sequences directing Bmp2 expression in hypertrophic chondrocytes are separate from those that control expression in the bone collar, intervertebral discs, and teeth, with the latter regulatory elements most likely located greater than 50 kilobases from the Bmp2 promoter. Although the Bmp2 gene resides in a large genomic region devoid of other genes, significant 'islands' of conserved sequence exist across this region. This is consistent with the presence of numerous Bmp2 cis-regulatory sequences in distant flanking regions. Our findings demonstrate that distant, complex regulatory elements direct Bmp2 expression in different locations within the developing skeletal system.

Genetic and Environmental Contributions to Hip Strength: In Female Twins Aged 18 and Over. L. M. Paton*[1], T. J. Beck[2], L. Semanick*[3], S. Kantor*[1], R. Teh*[1], C. Nowson*[4], J. D. Wark[1]. [1]Department of Medicine, University of Melbourne, Parkville, Australia, [2]School of Radiology, Johns Hopkins University School of Medicine, Baltimore, MD, USA, [3]Department of Radiology, Johns Hopkins University School of Medicine, Baltimore, MD, USA, [4]School of Health Sciences, Deakin University, Burwood, Australia.

The technique of hip structural analysis (HSA) allows the mechanical properties of bone to be estimated from densitometric scans of the proximal femur. We postulated that, like BMD, the variation in HSA-derived biomechanical parameters may have a significant genetic component which may help explain the familial aggregation of fractures.

Proximal femur scans from 508 female twin pairs (238 monozygotic, 270 dizygotic) with a mean (SD) age of 42.2 (14.7), range 18 - 89 years, were analyzed. HSA provided measures of BMD (g/cm2), cross-sectional area (CSA, cm2), cross-sectional moment of inertia (CSMI, cm4), subperiosteal width (cm), section modulus (cm3), average cortical thickness (cm) and buckling ratio (BR) at the narrowest region of the femoral neck (NN), intertrochanteric (IT), and femoral shaft (FS) regions. [Mechanosensitivity index (MI) was calculated for the NN [((section modulus/moment arm of the NN)/lean body mass)), where the moment arm is the NN length*sin(180-neck shaft angle)]]. The intraclass correlations for rMZ and rDZ twin pairs were used to estimate the proportion of variance due to genetic (G = 2*(rMZ - rDZ), common environment (C = rMZ - G) and unique environmental effects (E = total variance - rMZ).

There was a moderate to strong genetic influence on almost all HSA-derived parameters which persisted after height and height-weight adjustment. Particularly at the NN, the strength of the genetic influence appeared to be less in the 45+ age group(section modulus G = 0.27) compared with 18 -45 years (section modulus G = 0.91) while the environmental component of variation appeared to be greater in the older group.

The finding suggest that environmental exposure may be more important than genes in determining hip fracture risk.

Table. The range in genetic variance for HSA parameters for the NN, IT and SF regions.

	Age		Age-height-weight	
	18 - 45 years	45+ years	18-45 years	45+ years
Section modulus	0.75 - 0.94	0.22 - 0.58	0.52 - 0.91	0.27 - 0.71
Cross-sectional area	0.79 - 0.90	0.48 - 0.73	0.72 - 0.88	0.45 - 0.74
Subperiosteal width	0.48 - 0.77	0.28 - 0.76	0.27 - 0.74	0.35 - 0.81
Endocortical diameter	0.33 - 0.63	0.22 - 0.90	0.30 - 0.60	0.37 - 0.84
Average cortical thickness	0.57 - 0.70	0.28 - 0.55	0.51 - 0.61	0.16 - 0.77

Prediction of Hip Fracture in the Elderly by Fall-related Factors. N. D. Nguyen, C. Pongchaiyakul, J. R. Center, J. A. Eisman, T. V. Nguyen. Bone and Mineral Program, Garvan Institute of Medical Research, Sydney, Australia.

Although bone mineral density (BMD) is a primary determinant of hip fracture risk, it cannot reliably discriminate individuals with fracture from those without. The aim of this study was to examine the contribution of fall-related factors to the prediction of hip fracture in the elderly.

The study included 960 female and 689 male participants in the Dubbo Osteoporosis Epidemiology Study (DOES), from whom measurements of femoral neck BMD, postural stability, and quadriceps strength were obtained at baseline in 1989 and every subsequent 2 years. Incidence of hip fractures was ascertained during the study period of 1989 and 2003. Apart from traditional proportional hazards analysis, postural instability, quadriceps weakness, fall history, fracture history and age were dichotomized in two categories: risk presence (1) and risk absence (0) that was based on the significant relative risks adjusted for FNBMD and gender. The sum of these risk factors was then derived for each individual and was termed "risk score" with range being 0 to 5. Incidence of hip fracture was analyzed according to the risk score.

During the 14-year follow-up period, 115 (86 women and 29 men) have sustained a hip fracture. Each standard deviation (0.12 g/cm^2) reduction in FNBMD was associated with a 3.8-fold (95% CI: 3.5 to 4.7) increased risk of hip fracture in women and a 3.3-fold (95% CI: 2.5 to 4.1) in men. Each 5-year increase in age was associated with a 1.6-fold (95% CI: 1.4 to 1.8) increased risk of hip fracture after adjusting for FNBMD and sex. Individuals with the highest tertile of postural sway (>16.2cm^2 for women and >14.5cm^2 for men) and lowest tertile of quadriceps strength (≤15kg for women and ≤28kg for men) had a relative risk of hip fracture of 2.7 (95% CI: 1.6 to 4.5) and 3.0 (95% CI: 1.3 to 6.8), respectively, after adjustment for FNBMD. In addition, a fall during the preceding 12 months and a prior low trauma fracture were independent predictors of hip fracture. For each level of BMD, the risk of hip fracture increased exponentially with the number of these risk factors. Individuals with risk score ≥ 3 had the highest risk of hip fracture (RR= 4.0, 95% CI: 2.5 to 6.0) compared to < 3 risk scores independent of BMD.These results suggest that postural instability, quadriceps weakness and a prior fall and a prior fracture are BMD-independent predictors of hip fracture in both men and women. These risk factors could be incorporated into an assessment model for prediction of hip fracture in the elderly population. The prevention of hip fracture should move beyond the "paradigm" of bone alone to include aspects of falls risk.

Secondary Causes of Osteoporosis in Older Men and Women. H. A. Fink[1], B. C. Taylor*[2], E. S. Orwoll[3], E. Barrett-Connor[4], J. M. Zmuda[5], D. C. Bauer[6], C. B. Lewis[7], D. Sellmeyer*[6], K. E. Ensrud[1]. [1]for the MrOS and SOF Research Groups, VAMC, Mpls, MN, USA, [2]U of MN, Mpls, MN, USA, [3]OHSU, Portland, OR, USA, [4]UC, SD, CA, USA, [5]U of Pitt, Pittsburgh, PA, USA, [6]UC, SF, CA, USA, [7]UA, Birmingham, AL, USA.

Secondary osteoporosis (OP) involves underlying risk factors (RF) other than aging or menopause. The relative importance of secondary RF for OP between men and women has not been directly studied.

We examined the cross-sectional association between putative, self-reported secondary RF and OP in community-dwelling men (MrOS, n=5994) and women (SOF, n=7959) aged ≥65y. RF were considered if comparably defined in MrOS and SOF and included self-reported medical conditions, current medications, current smoking and increased alcohol use (defined as >2 drinks/day). OP was defined as femoral neck BMD T-score <-2.5 (Hologic 4500 DXA) using sex-specific reference values (male cut-point 0.59 g/cm^2; female cut-point 0.57 g/cm^2). Prevalence of each individual RF and of ≥1 RF among subjects with OP (%), and age-adjusted odds of OP associated with each RF and with ≥1 RF (OR, 95% CI) were determined for each sex using logistic regression. Subjects were then pooled, and sex and an interaction term (sex*RF) added to each RF model to evaluate whether the strength of the association between RF and OP differed significantly by sex (p<0.10 for interaction term).

	Men		Women	
Risk factor (RF)	**OP men (n=290) with RF (%)**	**Age-adj OR of OP in men with RF (95%CI)**	**OP women (n=1993) with RF (%)**	**Age-adj OR of OP in women with RF (95%CI)**
Hyperthyroidism	2.4	1.4 (0.6-3.1)	10.8	1.1 (0.9-1.3)
Gastrectomy	11.7	1.5 (1.0-2.2)*	2.6	2.7 (1.8-4.0)
COPD	15.9	1.6 (1.1-2.2)	12.0	1.5 (1.3-1.8)
Parkinsonism	1.0	1.0 (0.3-3.3)	1.0	2.2 (1.2-4.0)
Stroke	8.3	1.2 (0.8-1.9)	3.0	1.0 (0.7-1.3)
Oral corticosteroid	5.3	2.0 (1.1-3.8)	3.6	2.1 (1.5-3.0)
Nonbenzodiazepine anticonvulsant	3.1	1.0 (0.5-2.3)	1.2	1.3 (0.8-2.1)
Current smoking	5.5	2.5 (1.5-4.4)	11.1	1.6 (1.4-1.9)
Increased alcohol use	2.8	0.6 (0.3-1.2)	0.8	0.8 (0.4-1.4)
≥1 RF	44.3	1.5 (1.1-1.9)	34.2	1.4 (1.3-1.6)

*p<0.10 for interaction term

There appeared to be no significant difference in overall prevalence of self-reported secondary RF in men and women with OP (44% vs. 34%). For most individual self-reported RF we found relationships with OP to be similar in men and women, though gastrectomy appears to be a stronger RF in women.

Hypovitaminosis D in a Sunny Country and its Relation to Musculoskeletal Health in the Elderly. A. Arabi[1], R. Baddoura[2], H. Awada*[2], M. Salamoun*[1], G. El-hajj Fuleihan[1]. [1]Internal Medicine, American University of Beirut, Beirut, Lebanon, [2]Rheumatology, Saint Joseph University, Beirut, Lebanon.

Osteoporosis is proposed as the long term latency disease for hypovitaminosis D. We have demonstrated a high prevalence of vitamin D deficiency among school children and young adults in Lebanon (1,2), but the prevalence of hypovitaminosis D in the elderly population is not clear. This is particularly important in view of the effect of vitamin D on muscle strength, fall risk, BMD, and therefore on fracture risk.

The aims of this study are to determine the prevalence of hypovitaminosis D and its effect on the musculoskeletal health in elderly subjects from a sunny country.

460 ambulatory, home-dwelling elderly subjects, aged 65-85 years, were randomly recruited from the Greater Beirut area, based on geographical maps. BMD and body composition were measured using Hologic QDR 4500A and Hologic QDR 4500W device in two centers. A cross-calibration formula was derived by having 30 subjects simultaneously measured BMD on both devices. Serum 25 hydroxy-vitamin D (25OHD) levels were measured between December and March.

The clinical characteristics of the study population are shown in the Table.

Variable	Females N=301	Males N=159	p-value[b]
Age (years)	73.4±5.2	74.1±5.2	NS
BMI (kg/m^2)	30.6 ± 6.5	27.3 ± 4	NS
25 (OH) vit D <10 ng/ml	56%	37%	<0.001
25 (OH) vit D 10-20 ng/ml	39%	57%	< 0.001
25 (OH) vit D >20 ng/ml	5%	5%	<0.001
Lumbar Spine Z-score	0.004±1.3	-0.6±1.4[a]	<0.001
Total hip Z-score	-0.1±1.0[a]	-0.5±1.0[a]	<0.001
1/3Radius Z-score	-0.5±1.3[a]	-1.2±1.6[a]	<0.001

a p< 0.05 compared with western databases
b p-value (t-test or chi-square)for difference between genders

In both genders, only 5% of the study participants had 25OHD levels >20 ng/ml. In both genders 25OHD levels correlated with BMD. In males, correlation coefficients were as follows: spine (r=0.21, p=0.01), total hip (r=0.25, p=0.001), femoral neck (r=0.21, p=0.008), trochanter (r=0.29, p=0.001) and forearm (r=0.20, p=0.01). In females, the coefficients were (r=0.17, p=0.002) at the total hip, (r=0.19, p=0.001) at the femoral neck, (r=0.18, p=0.002) at the trochanter and (r=0.12, p=0.03) at the forearm. There was no significant correlation between 25OHD and lean or fat mass. In a linear regression model, 25OHD was a significant independent predictor of BMD at multiple skeletal sites, after adjustment for age and BMI, in both genders.
This study refutes the erroneous assumption that hypovitaminosis D is non-existent in sunny Mediterranean countries. It documents a deleterious impact of vitamin D insufficiency on bone health in the elderly, and provides evidence for the institution of cheap and efficacious preventive health strategies to fight its latent manifestation, namely osteoporosis.

Increased Mortality Following Acute Hip Fracture: Secular Trends in California 1990-2001. S. L. Silverman[1], D. Zingmond*[2]. [1]Cedars-Sinai, Los Angeles, CA, USA, [2]UCLA, Los Angeles, CA, USA.

Purpose: The care of acute hip fracture has changed dramatically of the past two decades - lengths of stay have shortened, while patient illness has increased. Improvements in patient management may not translate into better patient outcomes. We studied in-hospital, 30-day, 60-day, 180-day and 365-day mortality, and length of stay following hip fracture.
Methods: Using inpatient discharge abstracts from the California Office of Statewide Health Planning and Development (OSHPD)'s inpatient discharge database (PDD), all patients hospitalized in California with acute hip fracture and repair were identified between 1990 and 2001. Out-of-hospital death was ascertained by linkage to the state death registry through 2001. Independent impact of temporal trends were estimated using multivariate logistic and Cox regressions controlling for patient characteristics.
Results: Between 1990 and 2001, 268,611 individuals were discharged from California hospitals with acute hip fracture repairs. Overall, 73% were female; 86% were White, 2.7% were Black, 6.5% Latino, and 3.4% Asian. During the period, the percent of Latinos admitted doubled. Medicare paid for 80% of hospitalizations. Ten percent of patients were admitted from nursing homes. Comorbidity, measured by Charlson Index, steadily increased from 0.8 to 1.3 over the decade. Mean hospital length of stay decreased from 9.2 to 5.8 days by 1997, but increased to 6.3 days by 2001. Similarly, in-hospital death decreased from 3.0 to 2.1% by 1997 and increased to 2.4% by 2001. Total mortality increased over the period: 30-day - 6.6 to 7.4%; 60-day - 9.0 to 11.0%; 180-day - 14 to 18%; and 365-day - 19 to 23%. In multivariate analyses, temporal trends regarding in-hospital and total mortality and length of stay were significant and were consistent with unadjusted analyses.
Conclusions: Improvements in the care of patients with hip fracture have not been consistent or maintained. Decreasing early mortality and hospital length of stay in the early 1990's were not been matched by decreases in intermediate mortality for these patients. Increasing in-hospital mortality and length of stay since 1997 implies that inpatient care is worsening or that improvements in patient care are insufficient for increasingly old and frail elderly. Future research should focus on identifying the cause of worsening outcomes and whether these outcomes are generalizable to other regions.

Prevalence of Low Bone Mass in Women - Secular Trends Over 30 Years. H. G. Ahlborg[1], O. Johnell[1], T. L. N. Järvinen[2], M. K. Karlsson[1]. [1]Department of Orthopaedics, Malmö University Hospital, Malmö, Sweden, [2]Department of Orthopaedics and Traumatology, Tampere University Hospital, Tampere, Finland.

The burden of hip fractures has during the last decades dramatically increased worldwide. In Malmö, Sweden, the incidence of hip fractures has increased by 100% in women aged 50 and above, and by 30% in women aged 80 and above between 1970 and 2001. However, whether also the prevalence of osteoporosis within this population has increased during the same period is unclear. This study was therefore designed to characterize the secular trends in bone mineral density (BMD) in women during the last three decades.
Between 1971 and 2001, normative bone densitometry data of the female population aged 40 and above was collected in Malmö, Sweden. BMD (mg/cm^2) in the distal forearm was measured both at a site 1 cm and 6 cm proximal to the styloid process of the ulna by single-photon absorptiometry. The same densitometer was used throughout the study, and no long-term drift, determined by measurements of a standardized phantom every other week, was observed during the study period. Altogether, the study population consisted of 1591 women; 516 were measured between 1971 and 1978 (cohort A), 625 between 1988 and 1993 (cohort B), and 450 between 1998 and 2001 (cohort C). We present data for the women divided into two age groups, 40 to 64 years (cohort A n=452; cohort B n=350; cohort C n=115) and 65 years and above (A n=64; B n=275; C n=335). A linear regression model with adjustment for age was used to compare BMD between the three cohorts.
In women aged 40 to 64, there was no difference in mean (±SD) age-adjusted BMD between the three cohorts, either at the 1 cm [A 308(70); B 303(69); C 308(69)] or the 6 cm [A 532(67); B 539(65); C 530(66)] measurement site. In women aged 65 and above, cohort C [250(68)] had a higher age-adjusted BMD compared to both cohort A [228(68), p<0.05] and cohort B [238(68), p<0.05] at the 1 cm measurement site. However, at the 6 cm site, cohort C [391(74)] had a lower age-adjusted BMD compared to cohort B [421(74), p<0.001] but not significant different compared to cohort A [398(73)]. Furthermore, there was no significant difference in the proportion of women with osteoporosis (i.e. lower than -2.5 SD of young women) between the three cohorts in either age group or measurement site. In women aged 65 and above, the proportion of women with osteoporosis at the 1 cm measurement site was 17% in cohort A, 17% in cohort B, and 16% in cohort C; and 25%, 22% and 28% in cohort A,B, and C respectively at the 6 cm measurement site.
These data suggests that within a population with increased incidence of hip fracture during the last three decades, the proportion of women with low BMD has not increased during the same period.

Volumetric and Areal Bone Mineral Density Measures Are Associated with Cardiovascular Disease in Older Men and Women: The Health Aging and Body Composition Study (Health ABC). G. N. Farhat*[1], E. S. Strotmeyer[1], A. B. Newman*[1], K. Sutton-Tyrrell*[1], D. C. Bauer[2], T. Harris*[3], K. C. Johnson*[4], D. Taaffe[5], J. A. Cauley[1]. [1]U of Pittsburgh, Pittsburgh, PA, USA, [2]UCSF, San Francisco, CA, USA, [3]NIA, Bethesda, MD, USA, [4]U of Tenn., Memphis, TN, USA, [5]UQ, Queensland, Australia.

Low bone mass has been related to increased cardiovascular mortality, morbidity, and subclinical measures of cardiovascular disease (CVD). Studies that investigated these associations have focused mostly on white women; none have employed volumetric measures of bone mineral density (BMD). In this cross-sectional analysis, we tested the hypothesis that volumetric (vBMD) and areal (aBMD) BMD measures are inversely associated with clinical CVD and subclinical peripheral arterial disease (PAD) in men and women.
Data are from the baseline assessment of Health ABC which included 3075 well-functioning white and black men and women (42% Black; 51% women) between the ages of 70-79 years. Existing clinical CVD was defined as diagnosis of coronary heart disease, PAD, congestive heart failure, or cerebrovascular disease. Subclinical PAD was defined as a low ankle-arm index (≤0.9) in the absence of clinical CVD. Total hip aBMD was measured using DXA (Hologic 4500A). Trabecular and integral vBMD of the spine were measured using QCT (GE 9800 Advantage) in a subset (n=1489). Multiple logistic regression was used to assess the contribution of BMD measures (per SD) to clinical CVD and subclinical PAD after adjusting for age, race, gender, anthropometric measures, blood pressure, lipids, hypertension, diabetes, physical performance scores, and other important covariates. Models in women were additionally adjusted for time since menopause and hormone use.
The prevalence of clinical CVD in this population was 25%. Among participants without clinical CVD, 11% had subclinical PAD. Integral vBMD was inversely associated with clinical CVD in the whole group (OR=0.80, 95%CI 0.69-0.93), in men (OR=0.75, 95%CI 0.61-0.90), and in women (OR=0.72, 95%CI 0.56-0.94). Similar results were found for trabecular vBMD (OR for all participants= 0.85, 95% CI 0.73-0.99). aBMD was associated with subclinical PAD among all participants (OR=0.69, 95%CI 0.56-0.84) and in each gender separately. However, it was significantly correlated with clinical CVD only in women (OR=0.80, 95%CI 0.67-0.96).
In conclusion, both vBMD and aBMD measures were inversely related to clinical CVD and subclinical PAD in a biracial cohort of older men and women independent of shared risk factors between osteoporosis and CVD. These associations maybe mediated, in part, by endogenous sex hormones or cytokines, which are implicated in both atherogenesis and bone remodeling.

Vascular Pressure in the Lower Limbs and Bone Mineral Density. K. J. McLeod, R. Spathis*. Bioengineering, Binghamton University, Binghamton, NY, USA.

Interstitial fluid flow is essential for the maintenance of bone mass. Interstitial flow refers to the extravasated fluid and nutrients which leave the vascular supply and are subsequently collected by the lymphatic system and returned to the circulatory system. This flow is dependent both on vascular pressure and the microfiltration coefficient of the capillaries. Correspondingly, vascular pressure is dependent on the blood pressure due to heart contraction and on the hydrostatic pressure column of blood above the site of interest. In the lower limbs of the body, the hydrostatic pressure component serves to significantly increase total vascular pressure. Here, we determined the association between vascular pressure in the lower limbs and bone mineral density of the femoral neck, using a dataset containing 31,000 subjects.

Data on age (range 20-90 years), sex, ethnicity, height, weight, systolic pressure, and femoral neck BMD were obtained from the Third National Health and Nutrition Examination Survey, 1988-1994. Subjects being treated for hypertension were excluded. BMI was calculated from height and weight data, and total vascular pressure in the lower limbs was calculated from systolic pressure, body height and blood density. Stepwise regression was performed on the BMD data using age, BMI, and total vascular pressure as independent variables, with all interaction terms included (SPlus 6.0). Significance was established at the p=0.01 level.

Stepwise regression modeling of the white women in this population (N=3240), showed that neither BMI nor age were significant predictors of femoral neck BMD, but total vascular pressure was a highly significant correlate (p=0.006). For black women (N=2120), age (p=0.001), BMI (p=0.009), and total vascular pressure (p=0.002) were all found to be significant predictors of femoral neck BMD. For Hispanic women (N=1805), only BMI (p=0.0001) and total vascular pressure (p=0.0002) were significant predictors of neck BMD. For males, age was a significant predictor for all three ethnic groups, and total vascular pressure was significant for the white male population (p=0.001).

These results lend support to the concept that adequate interstitial flow across bone tissue is essential to the maintenance or enhancement of bone tissue. While upright posture has long been known to be important in the prevention of bone loss, this observation is commonly interpreted as indicating that mechanical loading of the skeleton is responsible for bone tissue integrity. Instead, we suggest that upright stance plays an important role through its dramatic effect on vascular pressure in the lower limbs, thereby significantly enhancing interstitial fluid flow.

Silencing of TGFbeta Signaling in T Cells Stimulates T Cell Production of Osteoclastogenic Cytokines and Abolishes the Bone Sparing Effect of Estrogen. Y. Gao[1], W. Qian*[1], K. Dark*[1], A. S. P. Lin*[2], R. E. Guldberg[2], R. A. Flavell[3], M. N. Weitzmann[1], R. Pacifici[1]. [1]Division of Endocrinology, Metabolism and Lipids, Emory University School of Medicine, Atlanta, GA, USA, [2]Woodruff School of Mechanical Engineering, Georgia Institute of Technology, Atlanta, GA, USA, [3]Section of Immunobiology, Yale University School of Medicine, New Haven, CT, USA.

A key mechanism by which ovariectomy (ovx) leads to bone loss is through an expansion of TNF producing T cells that results in TNF potentiation of RANKL induced osteoclastogenesis. Ovx increases T cell number by promoting T cell activation, but the responsible mechanism is poorly understood. One of the involved factors is TGFbeta, a cytokine stimulated by estrogen (E) and repressed by ovx. Overexpression of TGFbeta1 in vivo prevents ovx induced bone loss. Furthermore, transplantation of T cells insensitive to TGFbeta signaling into E replete T cell deficient nude mice is followed by significant bone loss, despite the presence of E. These data suggest that TGFbeta signaling in T cells is required for E to prevent bone loss. We have now examined transgenic mice containing T cells rendered insensitive to TGFbeta by the T cell specific overexpression of a dominant negative TGFbeta type II receptor (dnTGFbIIR). We found that dnTGFbIIR mice displayed significantly lower bone density than wild type (WT) littermates starting from the age of 8 weeks. After surgery, all groups of dnTGFbIIR mice (intact, sham operated, ovx and E treated ovx) lost as much bone as ovx WT mice. The finding that E replete dnTGFbIIR mice lost as much bone as ovx WT mice demonstrates that silencing of TGFβ signaling in T cells abolishes the bone sparing effect of E. T cells from both E replete and ovx dnTGFbIIR mice secreted ~3 fold higher levels of TNF and RANKL than T cells from E replete WT mice, thus demonstrating that T cells insensitive to TGFbeta produce maximal amounts of osteoclastogenic cytokines in spite of the presence of E. Ovx increases T cell activation through enhancement of macrophage antigen presenting cell (APC) activity and expression of the APC regulating gene CIITA. We found that T cells from all groups of dnTGFbIIR mice also produced high levels of IFNgamma, a cytokine which upregulates APC activity through CIITA. Macrophages from both E replete and ovx dnTGFbIIR mice expressed high levels of CIITA mRNA and exhibited increased APC activity. In contrast, only macrophages from ovx WT mice exhibited increased CIITA levels and APC activity. In summary, the data confirm that T cells play an essential role in ovx induced bone loss and suggest that TGFβ mediates the repressive effect of E on T cell activation thus preventing T cell production of bone wasting cytokines.

Osteoprotegerin Tightly Regulates the Shedding of RANKL by Osteoblasts and Activated T Cells. Y. Nakamichi[1], N. Udagawa[2], M. Nakamura[2], Y. Kobayashi[1], M. Mogi*[3], N. Takahashi[1]. [1]Institute for Oral Science, Matsumoto Dental Univ., Shiojiri, Japan, [2]Biochemistry, Matsumoto Dental Univ., Shiojiri, Japan, [3]Pharmacology, Aichi Gakuin Univ., School of Dentistry, Nagoya, Japan.

OPG is a decoy receptor for RANKL. OPG-deficient ($OPG^{-/-}$) mice exhibit aberrant bone metabolism characterized by accelerated bone resorption and formation. Recent studies have shown that serum levels of RANKL are markedly elevated in patients with OPG-deficient juvenile Paget's disease and in $OPG^{-/-}$ mice. Using $OPG^{-/-}$ mice, we investigated (i) which organ is responsible for the elevated serum levels of RANKL; (ii) whether serum RANKL levels reflect the state of bone resorption; (iii) whether OPG and OPG-related proteins inhibit the shedding of RANKL; and (iv) which proteases are involved in the shedding of RANKL. When $1,25(OH)_2D_3$ was daily administered into $OPG^{-/-}$ mice for 4 days, serum levels of RANKL as well as calcium were increased. RANKL mRNA expression was increased in bone but not in thymus or spleen in the $1,25(OH)_2D_3$-treated mice. Treatment with $1,25(OH)_2D_3$ increased RANKL mRNA expression and the release of RANKL in cultures of calvarial cells and bone marrow-derived stromal cells but not T cells prepared from $OPG^{-/-}$ mice. In addition, serum RANKL levels in $OPG^{-/-}$ mice decreased in an age-dependent manner when the assay was performed at 1-18 weeks of age. The release of RANKL in cultures of $OPG^{-/-}$ osteoblasts as well as RANKL-induced osteoclast formation was dose-dependently inhibited by adding OPG and a soluble form of RANK but not other OPG-related proteins such as DR6 (death receptor 6) and DcR3 (decoy receptor 3). Normal $CD4^+$ T-cells activated with anti-mouse CD3 antibody produced a large amount of soluble RANKL but not OPG. Treatment of activated T cells with OPG or soluble RANK inhibited the release of soluble RANKL. OPG and T cell-double deficient mice produced by crossbreeding $OPG^{-/-}$ mice with athymic nude mice showed serum RANKL levels equivalent to those of $OPG^{-/-}$ mice. Among several protease inhibitors examined, inhibitors of membrane-type matrix metalloproteases (MT-MMPs) efficiently blocked the shedding of RANKL from $OPG^{-/-}$ osteoblasts in culture. These results suggest (i) that soluble RANKL in $OPG^{-/-}$ mice is derived from osteoblasts; (ii) that serum RANKL levels sharply reflect the bone resorption state; (iii) that OPG and soluble RANK inhibits the RANKL shedding, with a dosage similarity to their inhibitory action on osteoclastogenesis; and (iv) that MT-MMPs are involved in the shedding of RANKL in osteoblasts. Altogether these findings establish a key role for OPG in maintaining locally expressed RANKL which is essential for normal bone development and function.

Dominant Negative N-cadherin Inhibits Osteoclast Differentiation by Suppressing RANKL Expression through Wnt Pathway. C. S. Shin[1], S. J. Her*[1], J. A. Kim*[1], D. H. Kim*[1], S. W. Kim*[1], S. Y. Kim*[1], J. G. Kim[2], H. S. Kim*[1], R. Kitazawa*[3], S. Cheng[4], R. Civitelli[4]. [1]Department of Internal Medicine, Seoul National University College of Medicine, Seoul, Republic of Korea, [2]Department of Obstetrics and Gynecology, Seoul National University College of Medicine, Seoul, Republic of Korea, [3]Division of Molecular Pathology, Kobe University Graduate School of Medicine, Kobe, Japan, [4]Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA.

Cadherin is a calcium dependent cell adhesion molecule, which plays major role during embryonic development. Classic cadherins interacts with β-catenin, which is also involved in the wnt signaling pathway. We have previously demonstrated that cadherin-mediated cell-cell adhesion is involved in maturation and function of osteoblasts both in vitro and in vivo. We tested whether disruption of N-cadherin function in stromal cells by dominant negative cadherin affects the ability to support osteoclastogenesis by altering heterotypic interaction with osteoclast precursors. Immunoblotting analysis showed that primary bone marrow stromal cells, and two stromal cell line, ST2 and MC3T3-G2/PA6, expressed N-cadherin. The expression of N-cadherin was also identified in bone marrow macrophages(BMM) and RAW 264.7 cell line by RT-PCR analysis. Retroviral expression of extracellular domain- truncated, dominant negative cadherin (NcadΔC) in ST2 cells resulted in slightly decreased cell-to cell adhesion but markedly impaired the formation of TRAP-positive osteoclasts (>40%) when cocultured with BMMs. However, the inhibition of osteoclatogenesis was not reproduced by neutralizing antibody against N-cadherin and addition of Ncad-Fc, a soluble cadherin, did not recover the decreased formation of osteoclasts by NcadΔC expression, suggesting that decreased cellular adhesion has only partly contributed to the decreased formation of osteoclasts by NcadΔC. Expression of NcadΔC, however, strongly suppressed β-catenin/Tcf transcriptional activity in ST2 cells, which was rescued by stably-active β-catenin adenovirus (Ad ΔN46 β-catenin). As a potential downstream target of wnt signaling, we have found that the expression of RANKL was decreased in ST2 cells expressing NcadΔC. Expression of OPG was not different. Moreover, Wnt-3A conditioned medium, Ad ΔN46 β-catenin, and lithium chloride increased the expression of RANKL and enhanced the transcriptional activity of mouse RANKL promoter in ST2 cells. In conclusion, these results suggest that expression of dominant negative cadherin in ST2 cells suppressed osteoclastogenesis by suppressing RANKL expression, which seems to be regulated by wnt signaling pathway.

Akt1/Akt2 and mTOR/Bim Play Critical Roles in Osteoclast Differentiation and cEll Survival, Respectively, while Akt Is Dispensable for Cell Survival in Isolated Osteoclast Precursors. T. Sugatani, K. A. HrUSKA. Pediatrics, Washington University, St.louis, MO, USA.

Akt, also known as protein kinase B, is a serine/threonine protein kinase with antiapoptotic activities. Akt is also a downstream target of phosphatidylinositol-3-kinase (PI3K), and recently, Akt has been implicated in cell differentiation. Here we show that Akt1/Akt2 play a critical role in osteoclast differentiation but not cell survival, while the mammalian target of rapamycin (mTOR) and Bim, a member of the BH3-only subfamily of cell death activators, are required for cell survival in isolated osteoclast precursors. To investigate the function of Akt1, Akt2, mTOR and Bim in osteoclast precursors, we employed a retroviral system for delivery of small interfering RNA (siRNA) into cells. Akt1 and/or Akt2 siRNA-induced post-transcriptional gene silencing abolished phosphorylation of IKK α/β and IκB-α during treatment of murine osteoclast precursors with RANKL, and loss of Akt1 and/or Akt2 protein suppressed nuclear translocation of NFκB p50. Moreover, depletion of Akt1 and/or Akt2 protein inhibited NFκB p50 DNA-binding activity. Consistent with these data, Akt1 and/or Akt2 siRNA gene silencing reduced TRAP-positive multinucleated osteoclast formation number. One possible explaination of the data is that TRAP-positive multinucleated osteoclast formation number was reduced by Akt1 and/or Akt2 siRNA-induced apoptosis. Therefore, we investigated whether Akt1 and/or Akt2 siRNA gene silencing promoted apoptosis in isolated osteoclast precursors. Surprisingly, loss of Akt1 and/or Akt2 protein did not stimulate cleaved caspase-3 activity and failed to induce apoptosis in the apoptosis detection in situ marker assay. Moreover, in a cell viability assay, there was no difference between control and infected cells after M-CSF withdrawal, strongly suggesting that Akt1/Akt2 are dispensable for cell survival in isolated osteoclast precursors. Conversely, mTOR siRNA gene silencing markedly stimulated cleaved caspase-3 activity and quickly induced apoptosis after M-CSF withdrawal in the cell viability assay. In contrast, Bim siRNA gene silencing did not stimulate cleaved caspase-3 activity, but induced precursors resistant to M-CSF withdrawal-induced apoptosis. In addition, we found that mTOR is downstream of PI3K but not Akt, and M-CSF down-regulates Bim expression through mTOR activation for cell survival in osteoclast precursors. Thus, we provide the first evidence that Akt1/Akt2 are among the key elements of osteoclast differentiation but not survival, and that the M-CSF-mediated mTOR/Bim axis is essential for cell survival in isolated osteoclast precursors.

TREM2, a DAP12-Associated Receptor, Functions During *In Vitro* Osteoclast Differentiation, Migration, and Resorption. M. B. Humphrey, E. C. Niemi*, M. C. Nakamura, M. R. Daws*. Medicine, VA Medical Center and University of California, San Francisco, CA, USA.

TREM2 (Triggering Receptor Expressed in Myeloid cells-2) associates with the signaling adapter DAP12 in myeloid lineage cells including osteoclasts. TREM2 mutations and deletions are associated with the human bone and brain disorder, Nasu-Hakola. We and others recently demonstrated the critical requirement for ITAM signals through DAP12 and/or the FcRγ chain during osteoclast development. In earlier studies we demonstrated that direct stimulation of TREM2 transfected into RAW264.7 enhanced *in vitro* osteoclastogenesis. To further define the role of TREM2, we generated anti-TREM2 antibodies, analyzed preosteoclasts and mature osteoclasts for TREM2 surface expression and determined the effect of antibody ligation on *in vitro* osteoclast differentiation, migration, and resorptive function. In addition, we utilized TREM2 RNAi introduced by lentivirus to disrupt expression of TREM2 in osteoclast precursors. Our studies reveal that by flow cytometry TREM2 is weakly expressed (4-5%) on C57BL/6 non-adherent bone marrow macrophages (BMM) maintained in MCSF and is upregulated during culture with RANKL (18% at 72 hours). Anti-TREM2 antibody treatment in addition to RANKL and MCSF enhances the formation of multinuclear, TRACP+ C57BL/6 osteoclasts compared to control antibody treatment, while antibody treatment of RAW264.7 treated with RANKL/TGFβ increases the formation of multinuclear, TRACP+ osteoclasts 3-fold. Anti-TREM2 antibody treatment inhibited migration of C57BL/6 BMM and RAW246.7 preosteoclasts (treated 3 days with RANKL/MCSF) in response to 100ng/ml MCSF ($p<0.05$). RAW264.7 osteoclasts (Day 4 RANKL/TGFβ) treated with anti-TREM2 antibody exhibit decreased resorption on artificial calcium-phosphate substrate, while isotype control antibody had no effect.

Following prolonged *in vitro* culture, we noted that RAW264.7 cells often lose capacity to form multinuclear, TRACP+ osteoclast-like cells in response to RANKL/TGFβ. Examination of these cells compared to highly osteoclastogenic RAW264.7 cells reveals that the level of expression of TREM2 correlates with osteoclastogenic capacity. Additionally, we designed aTREM2 RNAi that effectively decreases TREM2 surface expression in RAW264.7 cells and inhibits the formation of osteoclast-like cells with RANKL/TGFβ. TREM2 RNAi that did not reduce TREM2 expression had no effect on osteoclastogenesis. These data support a role for TREM2 in formation of multinucleated osteoclasts and also osteoclast migration and resorptive functions. The role for TREM2 may be of particular importance during *in vitro* osteoclastogenesis, particularly in RAW264.7 cells.

Mmp9 Plays a Critical Role in Bone Remodeling in the Absence of Cathepsin K. C. Li*[1], B. Gelb*[2], K. J. Jepsen[1], D. M. Laudier*[1], G. Bouyer*[1], R. Ni*[2], J. Zhang*[2], G. Opdenakker*[3], M. B. Schaffler[1]. [1]Orthopaedics, Mount Sinai School of Medicine, New York, NY, USA, [2]Human Genetics, Mount Sinai School of Medicine, New York, NY, USA, [3]Rega Institure, University of Leuven, Leuven, Belgium.

Cathepsin K (Ctsk) is a lysosomal cysteine protease expressed in osteoclasts and plays the major role in degradation of organic matrix during bone resorption. However, recent studies also show that bone resorption is still possible in the absence of Ctsk, suggesting that other enzymes play an essential role driving bone matrix solubilization. In the present study we examined whether Mmp9 plays a critical role in osteoclast-mediated bone remodeling when Ctsk is absent. Ctsk knockout mice (Ctsk-/-) and mice lacking both Ctsk and Mmp9 (Ctsk-/-/Mmp9-/-) were generated. Bone phenotypes were examined histomorphometrically in metaphyseal cancellous bone and diaphyses from 10-week-old mice. Ctsk-/-: Compared to wild type mice, Ctsk-/- mice showed normal femur length, mild osteopetrosis in metaphyses (Tb.Ar/T.Ar +85%), accumulation of calcified cartilage near the growth plate and evidence of increased osteoclastogenesis (osteoclast number and surface). Small regions of demineralized bone matrix within Howship's lacunae were occasionally noted, suggesting a qualitative change in osteoclast function. Long bone cortices were thicker (+42%), marrow cavities smaller (-28%) and intracortical porosity was increased. Ctsk-/-/Mmp9-/-: Combined Ctsk-/-/Mmp9-/- mice were profoundly affected, with shorter femurs, severe osteopetrosis (Tb.Ar/T.Ar +40% compared to Ctsk-/- alone) and large accumulations of calcified cartilage near the growth plate. Osteoclastogenesis was dramatically increased. The majority of Howship's lacunae contained areas of unresorbed demineralized matrix, overlaid by flattened, bone lining-type cells. Long bones had thicker cortices, marked reduction of marrow space (-53%) with extensive presence of unresorbed trabecular bone in the marrow cavity of the mid-diaphysis, and increased intracortical porosity (~3 fold) when compared to Ctsk-/-. Together, these data indicate that Mmp9 plays a critical role in the coupling of bone resorption and formation, allowing the required bone remodeling for the longitudinal and transversal growth of long bone in the absence of CatK.

TIEG Expression Is a Key Factor in Osteoclast Differentiation and Osteoblast Support of Osteoclast Differentiation. G. A. Gorny*[1], M. Subramaniam[1], T. C. Spelsberg[1], M. J. Oursler[2]. [1]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA, [2]Endocrine Research Unit, Mayo Clinic, Rochester, MN, USA.

During pathological bone loss there are increased osteoclast (OC) numbers. Given the limited effective therapies for this bone loss, it is vital to investigate means of targeting OC differentiation. We have shown that TGF-β Inducible Early Gene 1 (TIEG) plays an important role in osteoblast (OB) differentiation and TIEG overexpression in human OBs mimics TGF-β effects on these cells. In order to study the effects of TIEG expression on OC differentiation, marrow- and spleen-derived OC precursors and calvarial OBs were harvested from $TIEG^{+/+}$ and $TIEG^{-/-}$ mice and their ability to function during OC differentiation *in vitro* was examined.

$TIEG^{-/-}$ OC precursors co-cultured with ST2 stromal support cells or $TIEG^{+/+}$ calvarial OBs exhibited less OC differentiation when compared to $TIEG^{+/+}$ OC precursors. There were significantly fewer multinucleated OCs when either $TIEG^{+/+}$ or $TIEG^{-/-}$ precursors were co-cultured with the $TIEG^{-/-}$ OBs compared to $TIEG^{+/+}$ OBs.

The RANKL/OPG expression ratio was lower in $TIEG^{-/-}$ OBs compared to $TIEG^{+/+}$ OBs. RANKL addition to $TIEG^{-/-}$ calvarial OBs co-cultured with $TIEG^{+/+}$ OC precursors resulted in partial restoration of differentiation, whereas M-CSF addition alone or in combination with RANKL had no impact of differentiation. There was no difference in RANK or c-fms receptor expression levels comparing $TIEG^{+/+}$ to $TIEG^{-/-}$ spleen cells. Flow cytometry detected no difference in $CD11b^+$ and/or $RANK^+$ and/or $c\text{-}fms^+$ OC precursors in either marrow or spleen. When equal numbers of $CD11b^+$ OC precursors were cultured with RANKL and M-CSF, differentiation was observed in the $TIEG^{+/+}$ cultures. Interestingly, less differentiation occurred in the $TIEG^{-/-}$ $CD11b^+$ cultures.

There was a dose dependent increase in OC differentiation of $TIEG^{+/+}$ cells when treated with TGF-β . In contrast, there was no TGF-β impact on $TIEG^{-/-}$ precursor differentiation. When spleen cells cultured with RANKL and M-CSF were treated with TGF-β , there was a significant increase in RANK and c-fms expression in $TIEG^{+/+}$ cells, but not in $TIEG^{-/-}$.

In summary, TIEG expression in OC precursors and OBs is important in OC differentiation. The RANKL/OPG ratio is one component of OB support of differentiation, but other factors must also contribute. The defect in OC precursors is not at the level of either precursor number or expression of RANK or c-fms. Moreover, TIEG-mediated increases in RANK and c-fms expression may be the mechanism by which TGF-β stimulates OC differentiation. We conclude from these data that TIEG expression in both OC precursors and OB support cells is important in normal OC differentiation.

Cbl-b Deletion Increases RANK Expression, Cell-autonomous Increase in Bone Resorption and Osteopenia in Vivo. A. Sanjay, R. Chiusaroli, A. Nakajima, W. C. Horne, R. Baron. Orthopedics, Yale University school of Medicine, New Haven, CT, USA.

Cbl proteins (Cbl and Cbl-b) are both expressed in cells of hematopoietic origin including osteoclasts. Although Cbl is a critical substrate of Src in osteoclasts, deletion of cbl gene in mice leads only to a subtle bone phenotype with delay in osteoclast migration both in vivo and in vitro suggesting compensation by the other family member. To better understand the role of these two family members in bone resorption, we have compared the phenotypes of Cbl and Cbl-b knock out mice. In contrast to the mild phenotype of the Cbl-deficient mice, Cbl-b-deficient mice have a 30% decrease in trabecular bone volume in both vertebrae and long bones. Although no changes were detected in osteoblast or osteoclast surface or numbers, there was a significant increase in serum C-terminal collagen telopeptide (82 ng/ ml Cbl-b-/- vs. 51 ng/ml WT, $p<0.05$). In vitro, the pit formation capacity of the Cbl-b deficient osteoclasts was enhanced 2 to 2.5-folds as compared to the wild type counterparts, further substantiating the in vivo findings. Bone marrow cells derived from Cbl-b-deficient mice differentiated more rapidly, with 2-fold more mature osteoclasts present on days 4 and 6 than with WT precursors. Similarly the mRNA levels of c-Fos, one of the osteoclast differentiation marker, was upregulated during the differentiation of the Cbl-b deficient bone marrow cells. Given the role of Cbl proteins in the regulation of receptor degradation, we next looked at the surface expression of c-Fms and RANK, two proteins that are critical for osteoclast differentiation and function. The surface expression of c-Fms was not changed in the absence of Cbl-b. In contrast, the surface expression RANK and effectors of RANK signaling, (e.g. Jun kinase and Erk kinase) were enhanced in the Cbl-b deficient osteoclasts suggesting that RANK-mediated signaling maybe enhanced in the absence of Cbl-b. These results suggest that in spite of similarity in structural organization and function, some unique aspects of Cbl-b not being compensated by Cbl. One such unique function appears to involve the down-regulation of RANK and signaling.

Cinacalcet HCl Is an Effective Therapy for the Hypercalcemia of Primary Hyperparathyroidism across a Broad Range of Patients. M. Peacock[1], J. P. Bilezikian[2], S. Scumpia*[3], M. A. Bolognese*[4], M. A. Borofsky*[5], S. A. Turner*[6], M. D. Guo*[6], L. C. McCary*[6], D. M. Shoback[7]. [1]Indiana Univ Sch Med, Indianapolis, IN, USA, [2]Columbia Univ Med Ctr, New York, NY, USA, [3]Ctr for Clin Research, Austin, TX, USA, [4]Bethesda Health Research, Bethesda, MD, USA, [5]Clin Research Ctr of Reading, LLP, West Reading, PA, USA, [6]Amgen Inc., Thousand Oaks, CA, USA, [7]Dept of Veterans Affairs Med Ctr, Univ of California, San Francisco, San Francisco, CA, USA.

The calcimimetic, cinacalcet, is a potential therapy for primary hyperparathyroidism (PHPT) because it reduces parathyroid hormone and serum calcium by increasing the sensitivity of the calcium-sensing receptor to extracellular calcium. Although parathyroidectomy (PTX) can be curative, there are patients for whom a specific pharmacologic approach is needed. These patients include the following: those with recurrent PHPT after unsuccessful PTX, patients for whom PTX is contraindicated or who refuse PTX; and others who do not meet current guidelines for surgery but in whom reduction of the serum calcium is desired. For these patients, an unmet medical need exists.

For this analysis, 122 patients with PHPT who participated in clinical trials with cinacalcet were divided into 3 groups: 1) patients with recurrent PHPT post-PTX (n = 30); 2) patients who met ≥ 1 criteria for PTX, but had not had surgery (n = 66); and 3) other PHPT patients (n = 26). Three double-blind, placebo-controlled and two open-label, single arm studies were included in this analysis. The dose range of cinacalcet used was 30 mg twice daily to 90 mg four times daily for from 2 weeks to 3 years of therapy. A positive response to cinacalcet was defined as a decrease in serum calcium to ≤ 10.3 mg/dL. In all 3 groups, cinacalcet normalized serum calcium in more patients than placebo (Table). Reductions in serum calcium were sustained in the 18 patients who were treated for 3 years. Cinacalcet was generally well-tolerated in each group.

	Group 1		Group 2		Group 3	
	Cinacalcet n = 20	Placebo n =10	Cinacalcet n = 37	Placebo n = 29	Cinacalcet n = 18	Placebo n = 8
Mean (SE) Baseline Calcium (mg / dL)	11.2 (0.2)	10.6 (0.2)	11.1 (0.1)	10.6 (0.1)	11.0 (0.1)	10.7 (0.1)
Mean (SE) Baseline iPTH (pg / mL)	123 (23)	121 (14)	136 (12)	120 (11)	114 (12)	87 (8)
% Patients with Calcium ≤ 10.3 mg / dL after Rx	80%[a]	33%	81%[a]	24%	83%	38%
Mean (SE) % Change in Calcium	-13.0 (2.3)[b]	-0.8 (1.1)	-13.5 (1.0)[b]	-0.2 (1.0)	-12.6 (1.9)[b]	-0.7 (2.2)

[a]$P < 0.05$ using Fisher's exact test to compare between treatment groups.

[b]$P < 0.05$ using two sample t-test to compare between treatment groups.

This analysis of several clinical trials indicates that cinacalcet effectively normalized the serum calcium across a broad range of patients with PHPT, including those for whom PTX is not a treatment option. Cinacalcet has the potential to be an effective alternative to PTX in some patients with PHPT.

Lysyl Oxidase Is a Downstream Target Gene for PDGF-A Signaling in a Rat Model for Parathyroid Bone Disease. S. Lotinun[1], M. Zhang*[1], A. A. Leontovich*[2], R. T. Turner[1]. [1]Department of Orthopedics, Mayo Clinic, Rochester, MN, USA, [2]Department of Experimental Pathology, Mayo Clinic, Rochester, MN, USA.

Parathyroid hormone (PTH)-induced osteitis fibrosa is common in patients with renal osteodystrophy. The peritrabecular fibrosis in these patients contributes to the deterioration of bone quality and commensurate increase in fracture risk. The migration of fibroblasts to bone surfaces requires tissue remodeling to allow cellular infiltration. Targeting pathological tissue remodeling is a potential treatment for fibrosis. Histological changes identical to osteitis fibrosa can be induced in rats by continuous administration of PTH. Microarray analysis was used to identify candidate genes by comparing the skeletal response to intermittent (bone anabolic) and continuous (catabolic and fibrotic) PTH treatment. Continuous but not intermittent PTH upregulated mRNA levels for several genes associated with tissue remodeling (e.g., platelet-derived growth factor A, PDGF-A; secreted frizzled-related protein 4, Sfrp 4; matrix metalloproteinase 14, Mmp 14; decorin, Dcn; and lysyl oxidase, LOX). We investigated the hypothesis that these candidate genes are involved in the initiation of PTH-induced peritrabecular fibrosis. PTH (40 mg/kg/d) was continuously infused into 6-month-old female Sprague-Dawley rats for 1, 3, 5, 7, 14 and 28 d. Additionally, after 7 d PTH was withdrawn for 7 and 21 d. Total RNA from distal femur metaphysis was isolated and mRNA levels for PDGF-A, Sfrp 4, Mmp 14, Dcn and LOX were measured by RT-PCR. These analyses confirmed the upregulation of mRNA levels for Sfrp 4 within 3 d and PDGF-A, Mmp 14, Dcn and LOX within 5 d of initiation of PTH infusion, consistent with the appearance of peritrabecular fibroblasts on d 5. One week following termination of PTH, the mRNA levels were decreased to the control level and the peritrabecular fibroblasts disappeared. These data suggest a direct relationship between genes regulating tissue remodeling and peritrabecular fibrosis. Using cDNA microarray analysis we compared rats treated with continuous PTH to rats treated with PTH and trapidil. Trapidil, a PDGF-A signaling antagonist, antagonizes PTH-induced fibrosis. RT-PCR confirmed that trapidil prevented the increase in LOX mRNA level induced by PTH. In contrast, trapidil had no effect on Sfrp 4, Mmp 14 and Dcn. LOX which catalyzes the final step of collagen and elastin cross-linking required for the biosynthesis of mature functional extracellular matrices and is known to play an important role in tissue remodeling associated with cancer metastasis. These findings suggest that LOX is a downstream target gene of PDGF-A signaling induced peritrabecular fibrosis.

Generation and Therapeutic Potential of ABX10241, a Fully Human Neutralizing Monoclonal Antibody (mAb) to Human Parathyroid Hormone (huPTH). L. Roskos*[1], I. Foltz*[2], Q. Zhou*[1], R. H. Arends*[1], C. King*[2], M. Liang*[1], N. Raie*[1], S. Klakamp*[1], H. Lu*[1], G. M. Bell[1]. [1]Abgenix, Inc., Fremont, CA, USA, [2]Abgenix BioPharma, Inc., Burnaby, BC, Canada.

Current therapies often inadequately control primary and secondary hyperparathyroidism (HPT) and consequent bone disease. A fully human mAb to PTH has the potential to tightly regulate PTH levels while offering high specificity and a prolonged duration of action. To realize this potential, a neutralizing mAb (ABX10241) with very high affinity to huPTH was generated from transgenic IgG2κ XenoMouse® animals and was characterized in preclinical models.

Mice were immunized with huPTH(1-34) and B cells were analyzed with XenoMax™ technology. B cell cultures containing huPTH-specific antibodies were identified by ELISA and a mAb with the desired affinity was found. ABX10241 has picomolar affinity for huPTH(1-84), (1-34), (7-84), and cynomolgus (cyno) monkey PTH(1-84); nanomolar affinity for rat PTH(1-84); and no crossreactivity with PTHrp. ABX10241 neutralized huPTH(1-34) in a concentration-dependent manner, as measured by blockade of huPTH(1-34)-induced mobilization of intracellular calcium in UMR-106 cells.

Due to the low affinity of ABX10241 for rodent PTH (precluding the study of many HPT models), HPT was modeled in vivo by infusing huPTH into Sprague-Dawley rats or cyno PTH into cyno monkeys. Serum total (tCa) and ionized (iCa) calcium were monitored in rats (N=6/group) infused with subcutaneous huPTH(1-34) at 14.4 μg/day for 6 days and in cyno monkeys (N=4/group) infused with intravenous (iv) cyno PTH(1-84) at 24 μg/day for 17 days; animals received a single iv bolus of ABX10241 or an isotype control mAb on Day 3 of PTH infusion.

Control rats infused with huPTH(1-34) had a ≥ 20% elevation of iCa for 6 days; ABX10241 as a single 3 or 10 mg/kg iv bolus reversed iCa to the normal range for the 4 remaining days of the study. Control monkeys infused with cyno PTH(1-84) experienced stable hypercalcemia (iCa ≥ 20% over baseline) for 17 days; ABX10241 (single 1 or 4 mg/kg iv bolus) caused reversal of hypercalcemia lasting ≥ 4 days in the 1 mg/kg group and ≥ 12 days in the 4 mg/kg group (see figure).

ABX10241 exhibited potent, prolonged suppression of PTH-induced hypercalcemia in preclinical models after a single dose, suggesting that ABX10241 may have therapeutic value in the treatment of HPT.

Methylation of ABC Transporter Genes in Parathyroid Adenomas Affect Sestamibi Imaging. N. C. Greep, D. S. B. Hoon*, A. E. Giuliano*, N. M. Hansen*, H. Wang*, F. R. Singer. John Wayne Cancer Institute, Santa Monica, CA, USA.

Parathyroid ^{99m}Tc-sestamibi scans (^{99}MIBI) facilitate the surgical management of parathyroid adenomas (Ad) but are negative in about 20% of cases. To understand why some scans are negative, we studied adenoma size and the activity of two ATP-binding cassette (ABC) membrane transporter genes [Multiple Drug Resistance (MDR1) and MDR-associated Protein (MRP)] whose products (P-gp and MRP, respectively) are thought to extrude ^{99}MIBI from normal parathyroid glands (Nl). Paraffin-embedded tissue were obtained from 27 Ad (13 ^{99}MIBI + and 14 ^{99}MIBI- cases) and 16 normal (^{99}MIBI-) parathyroid glands. Polyclonal goat anti-human MDR1 and MRP antibodies were used to detect P-gp and MRP by immunohistochemistry (IHC), and Quantitative Real Time reverse transcriptase polymerase chain reaction (qPCR) was used to quantify transporter specific mRNA [with glyceraldehyde-3-phosphate dehydrogenase (GAPDH) as an internal reference for RNA integrity]. Hypermethylation (HM) of CpG islands in the promoter region of MDR1 and MRP was assessed with quantitative methylated PCR. Both P-gp and MRP proteins were present in 100% of Nl but in only 30% of Ad. Referenced to GAPDH, the mean±SE mRNA for each gene was higher in IHC+ compared to IHC- glands (P-gp 88±15 vs. 33±9, p=0.003; MRP 937±141 vs. 299±45, p<0.001). In Ad, HM of the ABC gene was more common for MDR1 than for MRP (70% vs. 30%), but in 11 Nl, none was hypermethylated in the MDR1 gene and only 1 in the MRP gene. Methylation status of the MDR1 (p<0.001) but not the MRP (p=ns) gene was associated with reduced presence, detected by IHC, of its transporter. HM of the MDR1 (100% vs. 43%) but not the MRP (15% vs. 14%) gene was greater in ^{99}MIBI+ than in ^{99}MIBI- Ad. Presence of P-gp and MRP by IHC were both lower in ^{99}MIBI+ than in ^{99}MIBI- Ad (P-gp 0% vs. 57%; MRP 8% vs. 50%). We compared the weight of 120 ^{99}MIBI+ and 33 ^{99}MIBI - adenomas from all cases operated on at our hospital over the past 2 years. ^{99}MIBI+ Ad were ~ 2X heavier than ^{99}MIBI- Ad (888 vs. 450 mg, p=0.009) and the smallest Ad which could be detected 80% of the time was 250 mg. Among all Ad, 13 of 13 ^{99}MIBI+ scans were accounted for by the absence of both P-gp and MRP (12) or absence of P-gp alone (1). Twelve of 14 ^{99}MIBI- scans were accounted for by either small size (2) or the presence of P-gp and/or MRP (10), leaving only 2 large Ad (>1000mg) whose failure to image with ^{99}MIBI was not explained by small size or presence of an ABC transporter. In conclusion, down regulation of the MDR gene by HM and the MRP gene by some other mechanism occurs in Ad and accounts for most ^{99}MIBI+ scans, whereas persistence of P-gp and/or MRP and small size accounts for most ^{99}MIBI- adenomas.

A Novel Deletion Upstream of GNAS Causes a Form of Autosomal Dominant Pseudohypoparathyroidism Ib and Delineates a Region Crucial for Maintaining Exon A/B Methylation. A. Linglart*, H. Jüppner, M. Bastepe. Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

Autosomal dominant pseudohypoparathyroidism Ib (AD-PHP-Ib) (OMIM#603233) is an imprinted disease characterized by isolated renal resistance to parathyroid hormone, which was mapped to a region centromeric of *GNAS*. This complex imprinted locus gives rise to transcripts that are paternally (antisense, XLαs, A/B), maternally (NESP55, Gsα in proximal renal tubules) or biallelically expressed (Gsα in most other tissues).

Recently, we identified in 16 different families with autosomal dominant PHP-Ib (AD-PHP-Ib) an identical 3-kb deletion, removing exons 4-6 of *Syntaxin16* (*STX-16*), a non-differentially methylated gene located about 280kb upstream of *GNAS*. In another large AD-PHP-Ib kindred (lod score at *D20S171* = 2.7, θ=0), we now identified an overlapping novel microdeletion. Southern blot analysis using three different restriction endonucleases and a probe telomeric of *GNAS*, revealed an approximately 4.3-kb deletion. This deletion was found in all affected individuals and obligate carriers, but was not found in the unaffected individuals by multiplex PCR using primers across both predicted breakpoints. Besides indistinguishable clinical findings, affected individuals in this latter family showed epigenetic abnormalities identical to those previously observed in kindreds with the 3-kb deletion, i.e. loss of exon A/B methylation, but no additional changes at other differentially methylated regions (DMRs) of *GNAS*. The novel deletion overlaps with the previously described 3-kb deletion by 899 nucleotides and, like the latter, it disrupts the *STX-16* gene. Using total RNA from a patient-derived lymphoblastoid cell line, the deleted and normal *STX-16* products were amplified by RT-PCR and sequenced directly. These studies revealed that nucleotides derived from *STX-16* exons 2, 3 and 4 were missing in the product derived from the mutant allele. Our results show that AD-PHP-Ib when associated with methylation abnormalities restricted to the exon A/B DMR is caused by a deletion in *STX-16* region. Since we found *STX-16* to be biallelically expressed, it appears likely that an as-of-yet undefined regulatory element within this 899-bp region, rather than haploinsufficiency of *STX-16*, is involved in the maintenance and/or establishment of downstream imprinting at exon A/B.

The P392L Mutation in the Sequestasome-1 Gene (p62) that Is Linked to Paget's Disease (PD) Is not Sufficient to Induce a Pagetic Phenotype in Osteoclast (OCL) Precursors. N. Kurihara[1], S. Reddy[1], J. Windle*[2], F. Singer[3], D. Roodman[4], M. Subler*[2]. [1]Univ of Pittsburgh, Pittsburgh, PA, USA, [2]Virginia Commonwealth Univ, Richmond, VA, USA, [3]John Wayne Cancer Ctr, Santa Monica, CA, USA, [4]Univ of Pittsburgh & VA Med Ctr, Pittsburgh, PA, USA.

Pagetic OCL precursors are hyper-responsive to 1,25-$(OH)_2D_3$, RANKL, and TNF-α, and express high levels of TAF_{II}-17. However, the basis for these abnormalities is unclear. Both viral and genetic factors have been implicated in PD. OCL from PD patients express measles virus nucleocapsid (MVNP) transcripts, and up to 40% of patients have an affected 1st degree relative. In addition, there are families with PD with an autosomal dominant mode of inheritance. Recently, mutations in the p62 gene ($p62_{MUT}$) have been linked to 30% of patients with familial PD and 12% of sporadic PD. The p392L mutation is the most frequent mutation reported. However, the role of $p62_{MUT}$ in PD is unclear. Some patients with $p62_{MUT}$ do not have PD. p62 is involved in NF-κB activation. It is our hypothesis that $p62_{MUT}$ increases RANKL and TNF-α induced OCL formation but not 1,25-$(OH)_2D_3$ responsivity or TAF_{II}-17 expression, since RANKL and TNF-α signal via NF-κB. To test this hypothesis, we used OCL precursors from PD patients carrying the $p62_{MUT}$. Peripheral blood monocytes from PD patients formed OCL at much lower concentrations of RANKL, TNF-α, and 1,25-$(OH)_2D_3$ than normals, and had increased TAF_{II}-17 expression. However, $p62_{MUT}$ patient OCL precursors contained both MVNP and $p62_{MUT}$. To further dissect the role of $p62_{MUT}$ in PD we transfected normal OCL precursors with the $p62_{MUT}$ gene or empty vector (EV). $p62_{MUT}$ transfected OCL precursors had increased TNF-α and RANKL sensitivity, but had no increased 1,25-$(OH)_2D_3$ responsivity or increased expression of TAF_{II}-17. In addition, nuclear number per OCL was not increased in $p62_{MUT}$ cells. To confirm the effects of $p62_{MUT}$ in vivo, we targeted $p62_{MUT}$ to the OCL lineage in transgenic mice using the TRAP promoter. At four mths of age, the $p62_{MUT}$ mice had osteopenia. $p62_{MUT}$ and wild type mice marrow cells were cultured with 1,25-$(OH)_2D_3$, RANKL or TNF-α to induce OCL formation. OCL precursors from $p62_{MUT}$ mice were hyper-responsive to RANKL and TNF-α and formed increased numbers of OCL, but were not hyper-responsive to 1,25-$(OH)_2D_3$ nor expressed high levels of TAF_{II}-17. Furthermore, $p62_{MUT}$ marrow cultures did not form OCL with increased nuclei per OCL. These results show that the $p62_{MUT}$: a) increased NF-κB signaling and OCL formation in response to RANKL, TNF-α; b) does not increase 1,25-$(OH)_2D_3$ responsivity nor induce TAF_{II}-17. These data suggest that $p62_{MUT}$ increases basal OCL formation in PD patients but is not sufficient to induce the complete PD phenotype in OCL precursors.

Homozygosity for a Dominant Mutation in col1a1 Restores Pup Survival, Bone Mechanics and Histology and Collagen Fibril Diameter to Near-wt Values, in Comparison to the Moderately Severe Bone Disease (Type IV OI) Present in Heterozygous Brtl Mice. K. M. Kozloff*[1], C. Bergwitz*[2], T. E. Uveges*[2], T. Chen*[3], M. D. Morris*[3], G. Gronowicz*[4], F. Ledgard*[4], S. A. Goldstein[1], J. C. Marini[2]. [1]Ortho Res Labs, U Mich, Ann Arbor, MI, USA, [2]Bemb, NICHD/NIH, Bethesda, MD, USA, [3]Dept Chem, U Mich, Ann Arbor, MI, USA, [4]U Conn Heath Ctr, Farmington, CT, USA.

The Brtl mouse is a dominant-negative model for type IV osteogenesis imperfecta (OI). Brtl is heterozygous for a glycine substitution (G349C) in one col1a1 allele. Brtl pups have 30% perinatal lethality; surviving Brtl mice have reduced BFR and MAR and smaller, weaker, and more brittle bones than WT. Unexpectedly, mice homozygous for the G349C mutation are not lethal but have viability and size indistinguishable from WT. Only mutant α1(I) mRNA is detected and virtually all α1(I) chains form homodimers. This study characterizes the 1st mouse in which homozygosity for a dominant mutation (Brtl/Brtl) attenuates the phenotype of the heterozygous mouse. Femurs from 2 month Brtl, Brtl/Brtl, and WT mice were assessed for areal BMD by PIXImus, geometry and vBMD by μCT, load to failure in 4-pt bending, and histomorphometry. Tibial sections were imaged by Raman spectroscopy to measure collagen cross linking. Areal and vBMD are normal in the Brtl/Brtl. Femoral cross sectional area is intermediate between Brtl and WT. While Brtl femurs fail earlier in bending than WT, Brtl/Brtl femurs appear normal. Furthermore, Brtl/Brtl femurs do not demonstrate the reduced post-yield displacement characteristic of the Brtl mouse. Ultrastructural parameters suggest Brtl/Brtl appears to rescue hypermineralization and abnormal collagen cross linking in the Brtl matrix. On static histomorphometry, Brtl/Brtl TbN is equal to WT, and significantly higher than in Brtl. TbTh of Brtl/Brtl is intermediate between Brtl and WT, as is BV/TV. Percent ObS and OcS, MAR and BFR/BS were the same in all genotypes. Dermal fibril diameter was significantly larger in Brtl/Brtl than Brtl or WT. In Brtl, approximately 25% of α1(I) chains are linked as a homodimer by S-S bonds between mutant Cys 349 residues. The homodimers form efficiently in collagen heterotrimers and are well-secreted from the cells. Collagen triple helices containing a single mutant chain comprise 50% of the intracellular collagen of Brtl; these helices are not well secreted (30-50%) from cells but do occur in media and matrix. The moderately severe bone phenotype in Brtl may result from a combination of collagen matrix insufficiency and the dominant negative effect of the reactive cysteine moiety. Surprisingly, bone composed entirely of type I collagen containing an S-S dimer appears to be sufficient for supporting normal functional requirements.

Three Closely Mapped Genetic Loci in Chromosome 1 Acting via Different Mechanisms Contribute To BMD Phenotype. B. Edderkaoui[1], D. J. Baylink[1], J. Wergedal[1], N. Dunn*[1], K. Shultz*[2], W. G. Beamer[2], L. R. Donahue[2], S. Mohan[1]. [1]JLP VAMC / Loma Linda Univ, Loma Linda, CA, USA, [2]Jackson Laboratory, Bar Harbor, ME, USA.

In previous studies, using an F2 population from the intercross CASTt/EiJ (CAST) and C57BL/6J (B6) mouse strains, 4 quantitative trait loci (QTL) that contribute to bone mineral density (BMD), were identified (Beamer, et al 99). Our subsequent studies have focused on Chromosome 1 (Chr 1) QTL since it is the major QTL contributing to approximately 30% of the femur BMD variation between CAST and B6 strains. In order to fine map the location of the BMD QTL, we performed additional genotyping for 565 F2 mice using 29 markers mapped within the 30 cM QTL region. Linkage analysis using MAPQTL and MapMaker revealed evidence for the presence of 3 significant BMD QTL in this region.Three markers (D1mit453, D1mit354 and D1mit359) showed significant association with total vBMD with LOD scores of 12, 12.9 and 11 respectively using MAPQTL. In order to confirm and narrow the location of BMD QTL genes, we developed subcongenic lines that contain different regions of the 30 cM Chr 1 QTL region from CAST strain placed in a B6 background. Phenotypic analyses of the sub-congenic line 1.3 (Cong1.3) which carries markers at D1Mit354 and D1Mit359 but not D1Mit 453 from CAST revealed a 9.9% increase ($P<0.01$) in total vBMD in congenic mice compared to control B6 mice at 16 weeks of age. Cong 1.3 showed significant 4% increase in periosteal circumference but not endosteal circumference compared to control mice, and as a result both bone area (9%) and cortical thickness (9%) were significantly higher in Cong 1.3 compared to control mice. Histomorphometeric studies revealed 37% higher ($P<0.01$) periosteal bone formation rate in the Cong 1.3 mice compared to control mice. Sub-congenic line 1.6 (Cong 1.6) which carries marker at D1Mit 453 but not D1Mit354 or D1Mit359 exhibits 10.6% higher total vBMD. In contrast to Cong 1.3, Cong 1.6 did not show an increase in periosteal circumference but did show a 7% decrease in endosteal circumference. These data demonstrate that increased bone accretion at the periosteum (Cong 1.3) and endosteum (Cong 1.6) contributes to BMD change. This result suggests different mechanisms for BMD change in these two subcongenic lines. Conclusions: 1) The major BMD QTL in Chr 1 contains 3 genetic loci that show significant association with total vBMD; 2) Our data using congenic mice together with phenotypic analyses are consistent with the idea that genetic loci within chromosome 1 act via different mechanisms to regulate BMD.

P2X7 Nucleotide Receptors Induce Membrane Blebbing in Osteoblasts through a Pathway Involving Lysophosphatidic Acid. N. Panupinthu*[1], F. Possmayer*[2], S. M. Sims*[1], S. J. Dixon[1]. [1]CIHR Group in Skeletal Development and Remodeling, Department of Physiology & Pharmacology, The University of Western Ontario, London, ON, Canada, [2]Department of Biochemistry, The University of Western Ontario, London, ON, Canada.

Extracellular nucleotides, released in response to mechanical and inflammatory stimuli, signal through P2 nucleotide receptors in many cell types including osteoblasts. P2X7 receptors are ATP-gated ion channels that can induce formation of large membrane pores. We have shown previously that a subpopulation of osteoblasts expresses functional P2X7 receptors. Deletion of the gene encoding this receptor leads to decreased periosteal bone formation. Our purpose was to investigate the signaling pathways coupled to P2X7 receptor activation in osteoblasts. Cells were isolated from calvariae of newborn mice by sequential collagenase digestion. Live cell imaging techniques were used to monitor responses of osteoblasts to nucleotides. Within 4-6 min, benzoylbenzoyl-ATP (BzATP, a relatively potent P2X7 receptor agonist) induced dynamic membrane blebbing in 45 ± 3% of cells, an effect that was reversible upon removal of BzATP. Since BzATP activates a number of P2 receptors in addition to P2X7, we tested responses of osteoblasts from P2X7 receptor knockout (KO) mice. BzATP did not induce blebbing in osteoblasts from KO mice, consistent with involvement of P2X7 receptors. Treatment with phospholipase D (PLD) inhibitor 1-butanol, but not its inactive analog 3-butanol, suppressed BzATP-induced blebbing. Inhibition of phospholipase A_2 (PLA_2) by arachidonyltrifluoromethyl ketone or bromoenol lactone also suppressed BzATP-induced blebbing. Activation of PLD and PLA_2 leads to production of lysophosphatidic acid (LPA), which signals through G protein-coupled receptors of the endothelial differentiation gene (Edg) family. We found that LPA itself caused dynamic membrane blebbing similar to that induced by BzATP, but with faster onset (2-3 min). LPA-induced blebbing was not affected by inhibition of PLD or PLA_2, suggesting that these phospholipases function upstream of LPA. Interestingly, desensitization of LPA responses by prolonged incubation with LPA suppressed blebbing induced by both LPA and BzATP. Moreover, inhibition of Rho-kinase using Y27632 abolished blebbing induced by both ligands. Taken together, these findings indicate that activation of P2X7 receptors leads to synthesis of LPA, which in turn signals through Rho-kinase to induce membrane blebbing. Thus, we have identified a role for LPA in mediating downstream effects of P2X7 receptor activation on osteoblasts. This pathway may contribute to the stimulatory effect of P2X7 receptors on bone formation *in vivo*.

Increased Bone Formation in Mice Lacking Apolipoprotein E. A. F. Schilling[1], T. Schinke[1], C. Münch*[1], M. Gebauer*[1], A. Niemeier*[2], M. Priemel[1], T. Streichert*[3], J. M. Ruegerr*[1], M. Amling[1]. [1]Trauma Surgery, Hamburg University, Hamburg, Germany, [2]Orthopaedic Surgery, Hamburg University, Hamburg, Germany, [3]Clinical Chemistry, Hamburg University, Hamburg, Germany.

Apolipoprotein E (ApoE) is a major protein component of very low-density lipoproteins and chylomicron remnants and facilitates their clearance from the circulation. This is confirmed by the phenoytpe of ApoE-deficient mice that have high plasma cholesterol levels and spontaneously develop atherosclerotic lesions. The bone phenotype of these mice has not been analyzed to date, although an association between certain ApoE alleles and bone density has been reported. Using a genome-wide expression analysis during the course of osteoblast differentiation we found that ApoE gene expression is strongly induced upon mineralization of the cultures. Since we did not observe expression of other apolipoprotein genes, we hypothesized that ApoE may have a specific function in bone remodeling. This was confirmed by the histomorphometric analysis of ApoE-deficient mice that display a high bone mass phenotype at the age of 3 and 8 months. This phenotype is caused by an increased bone formation rate (BFR(μm3/μm2/y): wt 85.08±12.98 vs ApoE-/- 131.91±30.15, n=6), whereas bone resorption is not affected. Since vitamin K, a cofactor required for γ-carboxylation of osteocalcin, is transported by ApoE-containing triglyceride-rich lipoproteins (TRL), we speculated that ApoE expression in differentiated osteoblasts could be required for the maximal uptake of vitamin K. Using primary osteoblasts from wildtype and ApoE-deficient mice we were able to demonstrate that TRL-uptake is indeed diminished in the absence of endogenous ApoE production. Furthermore, after separation on a hydroxyapatite column, we found that the amount of undercarboxylated osteocalcin is strongly elevated in the serum of ApoE-deficient mice, whereas carboxylated osteocalcin is barely detectable. Thus, the high bone mass phenotype observed in the ApoE-deficient mice is possibly due to a reduction of functional osteocalcin, since the targeted deletion of osteocalcin in mice leads to a similar phenotype. Taken together, these data provide the first evidence for a physiologic role of ApoE in the regulation of bone formation.

A Structure Function Analysis of the Twist Box Reveals an Additional Function for Twist-1 During Skeletogenesis. P. E. Bialek*, M. Sage*, M. Justice*, G. Karsenty. Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA.

Runx2 is both necessary and sufficient for osteoblast differentiation. Recently we showed using genetic and molecular means that the Twist proteins, acting via the Twist box, delay osteoblast differentiation by transiently inhibiting Runx2 function. In this work, we used as a tool, a hypomorphic allele of Twist-1, called Charlie Chaplin (CC) that harbors a Ser192Pro mutation in the Twist box. Through our continued analysis of CC/CC mice, we uncovered a novel function of Twist-1 during bone development. Indeed, CC/CC mice exhibit multiple skeletal patterning defects including radial and tibial aplasia as well as missing clavicles and cranial bones. A developmental study showed that the defects can be ascribed to a failure to form mesenchymal condensations. That Twist-2 null embryos do not have any skeletal patterning abnormalities raised the questions as to whether this is a specific function of Twist-1. To address this question, we generated CC/+; Twist-2+/- double heterozygotes. CC/+; Twist-2+/- mice do not show any patterning defects but do exhibit advanced osteoblast differentiation in both ribs and limbs. This indicates that while both Twist-1 and -2 are involved in controlling the onset of osteoblast differentiation during endochondral ossification, only Twist-1 is involved in skeletal patterning. That this function was uncovered in CC/CC embryos, indicate that it is also mediated by the Twist Box. This led us to pursue our analysis of the Twist box through biochemical and evolutionary means. While Ser192Pro, the CC mutation, binds the Runt domain poorly, Ser192Ala binds as strongly as wild type suggesting that the Ser192 does not play a critical role and that the phenotype of CC was secondary to a change in the Twist-1 tertiary structure caused by the introduction of a proline residue in the Twist box. This is important since Drosophila Twist, which can also inhibit Runx2 activity, does not have a serine at this location. Further deletion analysis identified residues187-200, a region highly conserved between Drosophila and mouse Twist-1, as the core of the Twist box. In summary, our analyses demonstrate that Twist-1 regulates skeletal patterning in addition to osteoblast differentiation through the Twist box and identifies a core sequence within the Twist box. Further in vivo analysis will determine the range of functions of the Twist box.

Transgenic Modification of MAP Kinase Signaling in Osteoblasts Leads to Altered Bone Formation and Osteoblast Activity. C. Ge*, G. Xiao, D. Jiang*, R. T. Franceschi. Periodontics, Prevention, Geriatrics, University of Michigan School of Dentistry, Ann Arbor, MI, USA.

The Erk branch of the mitogen-activated protein kinase (MAPK) pathway plays an important role in osteoblast growth and differentiation. Short-term inhibition of MAPK activity in cell culture using either specific inhibitors or dominant negative MEK (MEK-DN) inhibited osteoblast specific gene expression and responsiveness to BMPs (Xiao et al, 2002 JBMR 17:101, 2002). Furthermore, activation of the MAPK pathway with constitutively active MEK (MEK-SP) stimulated phosphorylation and activation of Runx2 (Xiao et al, JBC 275:4453, 2000). Recently, RSK2, a kinase downstream of Erk, was also shown to stimulate osteoblast activity by activating ATF4 (Yang et al., Cell 117:387,2004). To elucidate the function of the MAPK pathway in osteoblasts in vivo, transgenic mice were developed in which the murine 0.6 kb mOG2 promotor was used to drive MEK-DN or MEK-SP synthesis. Bone-specific expression of both transgenes was confirmed by RT-PCR. Transgenic hemizygotes were viable and showed no gross abnormalities at birth except that the body weight of MEK-DN mice was slightly less than wildtype littermates. Analysis of embryos revealed no clear differences before E14.5. Beginning at E15.5, MEK-DN embryos were smaller while MEK-SP embryos were larger than non-transgenic littermates ($p<0.01$). Differences were also apparent when bone size and onset of mineralization were measured. Femurs and clavicles were longer in MEK-SP embryos and shorter with the MEK-DN transgene ($p<0.01$). Alcian blue and alizarin red staining revealed an overall delay in mineralization with MEK-DN and an acceleration with MEK-SP at multiple sites including the skull, vertebrae and long bones. In addition, initial vascular invasion and formation of ossification centers in long bones was delayed at E14.5 in MEK-DN and stimulated in MEK-SP embryos. Consistent with these results, calvarial osteoblasts isolated from 5 week old MEK-DN animals exhibited a clear differentiation defect as measured by reduced alkaline phosphatase activity, mineral formation and expression of osteoblast marker mRNAs (osteocalcin and BSP) although they proliferated at the same rate as cells from non-transgenic littermates. The differentiation defect was most obvious during the first 10 d of culture, suggesting an overall delay in cell maturation. These studies support our hypothesis that the Erk MAPK pathway plays a major role in the regulation of osteoblast differentiation and bone formation.

Heparanase Regulates Osteoblast Function and Bone Mass. V. Kram*[1], E. Zcharia*[2], O. Yacoby-Zeevi*[3], Y. Gabet[1], R. Müller[4], I. Vlodavsky*[2], I. Bab[1]. [1]Bone Laboratory, Hebrew University of Jerusalem, Jerusalem, Israel, [2]Oncology, Hadassah-Hebrew University Medical Center, Jerusalem, Israel, [3]Insight Biopharmaceuticals, Rehovot, Israel, [4]Institute for Biomedical Engineering, ETH and University Zürich, Zürich, Switzerland.

Heparan sulfate proteoglycans (HSPGs) are ubiquitous macromolecules associated with bone cell surfaces and extracellular matrix. Furthermore, heparan sulfate (HS) chains bind a multitude of bioactive molecules thereby controling diverse normal and pathological processes. The mammalian gene encoding HS-degrading endoglycosidase, heparanase (Hpa), has been cloned and implicated in important biological processes such as inflammation, vascularization and cancer metastasis. The present study aimed at assessing Hpa regulation of bone cell activity and bone mass. RT-PCR analysis in murine bone marrow derived stromal cells undergoing osteoblastic differentiation showed progressive expression of the *hpa* gene. Immunohistochemistry using anti-Hpa antibodies identified a particular distribution of Hpa which was spread throughout the bone marrow with increasing concentration in osteoblasts and preosteoblasts. Hpa was also found in occasional osteocytes but not in growth plate chondrocytes. A similar distribution of Hpa positive cells was also found in the metaphyseal compartment of *hpa*-transgenic (*hpa*-tg) mice, but here hypertrophic chondrocytes were also positive. Micro-computed tomographic analysis in male and female *hpa*-tg mice showed approximately 2-fold increase in trabecular bone volume and connectivity densities secondary to increases in trabecular number and thickness. The cortical thickness of the *hpa*-tg mice was increased and the diameter of the medullary cavity decreased. Dynamic histomorphometry revealed a vast increase in bone formation rate. The osteoclast number was unchanged. In line with these findings, recombinant mammalian heparanase stimulated bone cell proliferation, alkaline phosphatase activity and matrix mineralization in primary bone marrow-derived stromal cell and MC3T3 E1 osteoblast cultures. Collectively these data demonstrate a highly potent anabolic activity of Hpa in bone via the stimulation of bone marrow derived osteoblastic cells.

Transgenic Overexpression of WIF-1, a Secreted Wnt Antagonist Expressed in Bone, Causes Decreased Bone Mineral Density and Increased Susceptibility to Bone Fracture in Mice: A Role for WIF-1 in Bone Biology. J. Cao*, S. Morony, K. Warmington*, J. Pretorius*, K. McDorman*, C. Paszty. Metabolic Disorders, Amgen Inc, Thousand Oaks, CA, USA.

Genes that might play a role in adult bone biology were identified by computer-based gene expression pattern mining of an expressed sequence tag (EST) database. One such gene, Wnt-inhibitory Factor-1 (WIF-1), encodes a secreted protein with Wnt antagonistic activity. Previous studies have established a role for Wnts in skeletal development, and recent work has shown the importance of the Wnt pathway (LRP5) in postnatal bone formation.

In situ hybridization of WIF-1 revealed strong expression in murine embryonic skeletal tissues, specifically cartilage primordium and zones of hypertrophy. In adult mice, there is strong expression in osteoblasts, endosteal lining cells, articular chondrocytes, as well as in a number of other tissues. *In situ* analysis of knee samples from older humans (normal, arthritic, and osteoporotic; ages 48-78) shows consistent, low level expression of WIF-1 in osteoblasts and endosteal lining cells.

To explore the impact of WIF-1 on bone biology in an *in vivo* setting, transgenic mice were made using a rat a1(I) collagen promoter transgene for overexpressing mouse WIF-1 in cells of the osteoblast lineage. Peripheral quantitative computed tomography (pQCT) analysis of tibia harvested from female transgenics revealed that the lowest bone mineral density (BMD) was present in the mouse with the highest WIF-1 transgene expression levels. Histopathology showed chondrodysplasia and decreased endochondral ossification in long bones. Male transgenic founders were mated with wild-type females to establish individual lines of WIF-1 transgenic mice. On the following day, one male was observed to be dragging its hind legs. Radiography showed that both tibias were broken, suggesting that overexpression of WIF-1 can increase susceptibility to bone fracture. Subsequent analysis of adult male mice from a stable breeding line of WIF-1 transgenics included the collection of lumbar vertebrae and tibiae for pQCT measurement of BMD. Total, trabecular and cortical BMD in vertebrae and tibiae were decreased in transgenics as compared to non-transgenic littermates. Significant decreases in cortical BMD of the lumbar vertebrae and tibial diaphysis (3.5% and 10% respectively vs. control) were noted, as well as decreases in the total tibial metaphysis BMD (7% vs. control).

The gene expression data for WIF-1 in mice and humans, together with the low BMD phenotype of WIF-1 transgenics, suggests that WIF-1 plays a role in bone biology as a negative regulator of bone mass. As such, antagonism of WIF-1 may have therapeutic potential in the treatment of osteoporosis.

Wnt Signaling Regulates Runx2 Expression In Vivo and Activates the Bone-Related Runx2 P1 Promoter. T. Gaur*[1], A. Javed[1], A. J. van Wijnen[1], J. L. Stein*[1], P. V. N. Bodine[2], B. S. Komm[2], G. S. Stein[1], J. B. Lian[1]. [1]Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA, [2]Women's Health Research Institute, Wyeth Research, Collegeville, PA, USA.

Wnt signaling plays a vital role in a variety of biological processes, including skeletal development and related diseases. Increased Wnt signaling either by gain-of-function mutation in the Wnt co-receptor LRP5 or by null mutation of sFRP1, a Wnt antagonist has resulted in increased trabecular bone formation. Here we characterized the mechanism linking Wnt signaling to increased bone formation. We examined bone phenotypic genes in the sFRP1 null mouse and find elevated levels of Runx2, an indispensable transcription factor for skeletogenesis and osteoblastic differentiation. We further show that the bone promoting function of Wnt is attributable to transcriptional control of the Runx2 gene. A Wnt responsive element in the bone related P1 promoter which corresponds to a binding site for LEF/TCF proteins was delineated. Transient transfection studies in the osteoblast progenitor cell line, MC3T3-E1, reveal that activation of the Runx2 promoter by TCF1 requires co-expression with canonical Wnt proteins (Wnt1, Wnt3, Wnt3a and Wnt6). The combination of TCF1 with any of these Wnts could provide 2-3 fold induction of Runx2 promoter activity. However, this response was not observed in cells representing the mature osteoblast phenotype, such as ROS 17/2.8 cells which expression high levels of Runx2. We also find that sFRP proteins inhibit the activation caused by Wnt1 and TCF1, consistent with their antagonistic function of Wnt signaling. Additionally, in the combined presence of Wnt1 and TCF1, a significant induction (~7-fold) of endogenous Runx2 mRNA levels in MC3T3-E1 cells was observed. Our findings provide critical evidence for the concept that Wnt signaling activates the Runx2 gene which is an early regulator of commitment to the osteoblast lineage. Thus, we have uncovered a potential regulatory relay that may function during development to mediate bone cell specification.

Decreased Bone Density and Limb Deformities in Mice Carrying Mutations in Both Lrp5 and Lrp6. S. L. Holmen*[1], T. A. Giambernardi*[1], C. R. Zylstra*[1], B. D. Buckner-Berguis*[1], J. H. Resau*[1], J. F. Hess*[2], M. Ai*[3], M. A. Bouxsein[4], M. L. Warman[3], B. O. Williams[1]. [1]Van Andel Research Institute, Grand Rapids, MI, USA, [2]Department of Human Genetics, Merck Research Laboratories, West Point, PA, USA, [3]Department of Genetics and Center for Human Genetics, Case Western Reserve University, Cleveland, OH, USA, [4]Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center, Boston, MA, USA.

The low-density lipoprotein receptor-related proteins 5 and 6 (LRP5 and LRP6) are co-receptors for Wnt ligands. Loss-of-function mutations in *LRP5* cause osteoporosis pseudoglioma syndrome(OPPG), an autosomal recessive disorder characterized by low bone mass and ocular pathology. *Lrp6*-deficient mice display phenotypes similar to, but not as severe as, those seen in several Wnt gene knockouts, and they die between e14.5 and birth (Pinson *et al*. 2000 *Nature* 407, 535-8). *Lrp5* is highly expressed in mouse embryos and may partially compensate for *Lrp6* loss. To better understand the role of Lrp5 and Lrp6 during development, mice deficient for *Lrp5* were generated and crossed to *Lrp6*-heterozygous mice. By DEXA and microCT, we demonstrate that loss of *Lrp5* and *6* affects normal limb development and bone mass accrual, in a dosage dependent manner. Mutant calvarial osteoblasts isolated from these mice and differentiated *in vitro* grew at a faster rate and had increased expression of an early differentiation marker compared to the normal cells. These results suggest that both Lrp5 and Lrp6 play roles in osteoblast proliferation and differentiation. From these data we conclude that *Lrp5* and *Lrp6* encode proteins with partially overlapping functions.

Increases in Bone Mineral Density Are Maintained after 7 Years of Raloxifene Therapy: Results from the Continuing Outcomes Relevant to Evista (CORE) Study. S. T. Harris[1], E. S. Siris[2], J. L. Stock[3], P. M. Kulkarni*[3], Y. Qu*[3], S. R. Siddhanti*[3], B. D. Mitchell*[3], S. R. Cummings[1]. [1]University of California San Francisco, San Francisco, CA, USA, [2]Columbia University, New York, NY, USA, [3]Lilly Research Laboratories, Indianapolis, IN, USA.

Postmenopausal women (N=4011) from the 4-year Multiple Outcomes of Raloxifene Evaluation (MORE) osteoporosis treatment trial were observed for an additional 4 years in the multicenter, double-blind, placebo (PL)-controlled CORE study to investigate the effects of raloxifene 60 mg/d on the incidence of invasive breast cancer. An addendum studied the effects of raloxifene treatment, at 7 years after randomization in MORE, on lumbar spine (LS) and femoral neck (FN) bone mineral density (BMD) in women enrolled at U.S. sites of CORE. All women received elemental calcium (500 mg/d) and vitamin D (400-600 IU/d). Women randomized to PL in MORE continued receiving PL in CORE, while those randomized to either raloxifene dose (60 or 120 mg/d) in MORE received raloxifene 60 mg/d (RLX) in CORE. BMD was measured by DXA at Years 1 and 3 in CORE. The primary analysis was based upon 386 women who did not take other bone-active agents from the fourth year of MORE through Year 3 of CORE, who were at least 80% compliant with study medication in CORE, and who had a BMD measurement at Year 3 of CORE. Baseline characteristics at enrollment in MORE were not different between women in the PL (n=127) and RLX (n=259) groups. At Year 3 of CORE, the difference in mean BMD was 1.7% at the LS (P=0.30) and 2.4% at the FN (P=0.045), in the RLX group compared with the PL group. A pre-specified time-trend analysis showed a 4.3% increase from baseline in LS BMD after 7 years of RLX, which was 2.2% greater than the change in PL, and a 1.9% increase from baseline in FN BMD, which was 3.0% greater than the change in PL (both P<0.01). For the RLX group, the LS and FN BMD measurements were significantly increased from the baseline of MORE at all time points (P<0.01). The percent change in LS BMD from baseline in the RLX group was significantly greater, compared with that in the PL group, at Years 1 to 4 in MORE and Year 7 (Year 3 of CORE), while for FN BMD, this comparison was significantly greater at all time points. In conclusion, increases in BMD are maintained after 7 years of therapy with raloxifene.

A Novel, Nonsteroidal Selective Androgen Receptor Modulator (SARM) Increases Periosteal Bone Formation and Inhibits Trabecular Bone Turnover in Aged Intact and Orchidectomized Male Rats. H. Z. Ke, D. T. Crawford*, H. Qi, H. A. Simmons, M. Li, T. A. Brown, E. D. Salter*, J. P. O'Malley*, C. T. Salatto*, B. A. Lefker*, T. G. Gant*, R. J. Hill*, X. N. Wang*, D. D. Thompson*. Pfizer Global Research and Development, Groton, CT, USA.

SARMs have been investigated as a new approach for the treatment of osteoporosis. SARMs are hypothesized to have beneficial effects on bone without causing prostate hypertrophy in men or virilization in women. CMP1 is a newly identified nonsteroidal compound that selectively binds to androgen receptor (AR) with an IC50 of 5.7 nM, and acts as a receptor agonist with an EC50 of 0.012 nM in AR-transfected C2C12 cells. In animal study, male SD rats at 11 months of age were sham-operated or orchidectomized (ORX), and treated with CMP1 at an average daily dose of 3 or 10 mg/kg by s.c. injection for 8 weeks. ORX for 8 weeks induced significant decreases in weights of prostate and levator ani and trabecular and cortical bone mineral content. CMP1 significantly increased levator ani weight with minimal effects on prostate weight in both sham and ORX rats compared with their controls. Further, CMP1 at 10 mg/kg significantly decreased body weight by reducing fat body mass in both sham and ORX rats. In sham rats, CMP1 increased distal femoral metaphyseal (DFM) trabecular density by 11% and 10% at 3 and 10 mg/kg, respectively, compared with sham controls. Bone histomorphometric analysis showed that CMP1 in sham-operated rats at 10 mg/kg increased significantly mineral apposition rate (MAR), mineralizing surface (MS/BS) and bone formation rate (BFR/BS) on the periosteal surface of tibial shaft, while it significantly decreased these parameters on the endocortical surface of the tibial shaft and significantly decreased MS/BS, BFR/BS and osteoclast surface on trabecular bone of the proximal tibial metaphysis (PTM) compared with sham controls. In ORX rats, CMP1 at both doses completely prevented ORX-induced decreases in DFM trabecular density and trabecular bone volume. Trabecular MS/BS, BFR/BS and osteoclast surface of PTM decreased significantly in CMP1-treated ORX rats compared with ORX controls, indicating that CMP1 preserves trabecular bone mass by decreasing bone turnover. Histomorphometry of TS showed that CMP1 increased periosteal MS/BS and BFR/BS and decreased endocortical eroded surface, MS/BS and BFR/BS resulted in decreasing marrow cavity area and increasing cortical bone area in ORX rats as compared with ORX controls. These results indicate that this SARM stimulates bone formation on the periosteal surface and decreases bone turnover on endocortical and trabecular surfaces in intact and ORX aged male rats. Thus, SARMs have potentials for prevention and treatment of osteoporosis.

Sclerostin Antagonism in Adult Rodents, via Monoclonal Antibody Mediated Blockade, Increases Bone Mineral Density and Implicates Sclerostin as a Key Regulator of Bone Mass During Adulthood. K. Warmington*[1], S. Morony[1], I. Sarosi*[1], J. Gong*[1], P. Stephens*[2], D. G Winkler[2], M. K. Sutherland[2], J. A. Latham[2], H. Kirby*[2], A. Moore*[2], M. Robinson*[2], P. J. Kostenuik[1], S. Simonet[1], D. L. Lacey[1], C. Paszty[1]. [1]Metabolic Disorders, Amgen Inc, Thousand Oaks, CA, USA, [2]Celltech Group plc, Slough, United Kingdom.

In humans, complete lack of the protein sclerostin due to homozygosity for null mutations in the SOST gene is responsible for causing sclerosteosis, a rare genetic disease characterized by an early onset (mid-childhood) increase in bone mineral density (BMD) throughout the skeleton. Similar to humans with sclerosteosis, knock-out mice homozygous for a deletion of the SOST gene have increased BMD throughout their skeleton, but are otherwise essentially normal. *In situ* analysis of bone harvested from older rats and humans (55-78 years old) reveals robust expression of sclerostin in osteocytes, suggesting a role for sclerostin in regulating bone mass throughout life.

To further explore the biology of sclerostin and its therapeutic potential as a target in the treatment of osteoporosis, sclerostin neutralizing monoclonal antibodies were tested in mice and rats. Statistically significant increases in BMD, as determined *in vivo* by Dual Energy X-ray Absorptiometry (DEXA), were found in tibial metaphysis (26-38% increase versus vehicle) and lumbar vertebrae (35-40% increase) in young mice (4-wk old BDF1 strain males; 3-wk study). Serum osteocalcin, a marker of bone anabolic activity, was also increased by 35%. In studies using skeletally mature mice (4 month old males and females, various strains) similar increases in BMD were found. *Ex vivo* analysis of the tibial metaphysis by peripheral quantitative computed tomography (pQCT) showed statistically significant increases in total BMD (18-42%), trabecular BMD (30-64%) and cortical BMD (7-14%).

In a postmenopausal osteoporosis disease model study, treatment of aged ovarectomied (OVX) rats (9 months old, 3 months post OVX) for 6 weeks caused statistically significant increases in BMD in lumbar vertebrae (18% increase versus vehicle), femoral metaphysis

(17% increase) and femoral diaphysis (9% increase). The bone had normal lamellar structure as assessed by polarization microscopy. Gross observation, serum clinical chemistry and hematological panel analysis indicated no systemic abnormalities associated with pharmacological inhibition of sclerostin.
The genetic, phenotypic and expression data, coupled with the above *in vivo* data, point towards sclerostin being a key regulator of bone mass throughout life, and furthermore, suggests that inhibition of sclerostin may have therapeutic potential for the anabolic treatment of osteoporosis.

An Orally Bioavailable GSK3 α/β Dual Inhibitor Increases Markers of Cellular Differentiation *In Vitro* and Bone Mass *In Vivo*. N. H. Kulkarni*[1], M. Liu*[1], D. L. Halladay*[1], C. A. Frolik[1], T. A. Engler*[2], L. M. Helvering*[1], T. Wei*[3], A. Kriauciunas*[3], T. J. Martin[4], M. Sato[1], H. U. Bryant[1], J. E. Onyia[3], Y. L. Ma[1]. [1]Bone and Inflammation, Eli Lilly and Company, Indianapolis, IN, USA, [2]Discovery Chemistry, Eli Lilly and Company, Indianapolis, IN, USA, [3]Integrative Biology, Eli Lilly and Company, Indianapolis, IN, USA, [4]St. Vincent's Institute for Medical Research, Fitzroy, Victoria, Australia.

Glycogen synthase kinase 3 (GSK3) is a serine/threonine kinase that regulates β-catenin, a key component of the canonical Wnt signaling pathway which regulates bone mass in humans and rodents. Inactivation of GSK3 leads to the accumulation of cytosolic β-catenin which then enters the nucleus to activate Wnt target genes. To examine whether GSK3 directly regulates bone formation, we evaluated the effect of a small molecule GSK3 α/β dual inhibitor, 603281-31-8 in pre-osteoblasts *in vitro* and in osteopenic ovariectomized (Ovx) rats. C3H10T1/2 cells, were treated with 1 μM 603281-31-8 at different time points. β-Catenin stabilization (western blot), translocation (immunoflourescence), activation of canonical Wnt reporter gene and markers of bone formation (Northern/Real-Time PCR) were measured as indicated. In C3H10T1/2 cells, inactivation of GSK3 resulted in stabilization of β-catenin and activation of Wnt reporter gene. This was associated with ~2-fold increases in the expression of mRNA for collagen 1 and bone sialoprotein, markers of the osteoblast phenotype and bone formation activity. Furthermore, treatment with 603281-31-8 increased alkaline phosphatase activity by 2-fold in C3H10T1/2 cells. For *in vivo* studies, 6month old rats were Ovx, and permitted to lose bone for one month, followed by treatment with 603281-31-8 at 3mg/kg/d po for 60 days. The expression levels of bone formation genes were analyzed in the rat femur by Real-Time PCR. Gene expression analysis showed increases in the mRNA levels of collagen 1, collagen 5, alkaline phosphatase, biglycan, bone sialoprotein and osteonectin upon treatment with 603281-31-8 relative to ovariectomy controls in rat femur. DXA analysis of whole femora, midshaft and distal femora showed significant increases in BMD and BMC after 60 days treatment relative to Ovx, concordant with the increases in the gene expression levels of bone formation genes. These data showed that an orally active, small molecular weight, GSK3 α/β dual inhibitor increased bone mass in ovariectomized rats, induced osteoblast differentiation *in vitro* and increased markers of bone formation both *in vitro* and *in vivo*. These observations are consistent with the pronounced role played by the canonical Wnt pathway in osteogenesis.

First Demonstration of the Efficacy of an Anti-Osteoporotic Treatment in Very Elderly Osteoporotic Women. E. Seeman[1], B. Vellas*[2], C. Roux[3], S. Adami[4], J. Aquino*[5], J. Semler*[6], J. Graham*[7], O. Sorensen[8], J. Padrino*[9], R. Rizzoli[10], T. Spector[11], J. Kaufman[12], S. Boonen[13], J. Reginster[14]. Z. Gent Department of Internal Medicine, Gent, Belgium, [13]Center for Metabolic Bone Diseases, Leuven University, Leuven, Belgium, [14]University of Liège, Liège, Belgium.

The number and burden of fractures is increasing as age advances in relation with increased longevity. This is particularly the case in over eighty year-olds, a group at highest absolute risk for fracture and thus for whom the number needed to treat to prevent one event is the lowest. About 25 percent of all fragility fractures, and 50% of hip fractures, occur in this high risk group so prevention of fractures is likely to confer the highest benefit at a community level. Moreover, the burden of fractures will still increase as life-expectancy is increasing. Few, if any, drugs have proven anti-fracture efficacy in this high risk group**.** Strontium ranelate, a drug that allows continued production of bone while decreasing resorption at the cellular level, has been reported to reduce the risk of vertebral fracture by 41% (p<0.001) and hip fracture by 36% (p=0.046) over 3 years in the SOTI and TROPOS studies.
A pre-planned analysis was performed on the pooled data from these two phase III trials to evaluate the efficacy of strontium ranelate in patients aged 80 years and over (n=1488). Yearly spinal X- rays were performed in 895 patients, and assessed by grading (Genant method). Only documented non-vertebral fractures were considered. There was no difference between groups for baseline characteristics of age 83.5± 3.0 years; lumbar BMD T-score -2.7± 1.7; femoral neck BMD T-score -3.3± 0.7; 49% of the patients had at least one prevalent vertebral fracture and 36% had at least one prevalent osteoporosis-related non vertebral fracture. In the ITT population, strontium ranelate reduced the risk of vertebral fracture by 32% (p = 0.013) and of non vertebral fracture by 31% (p = 0.011) over 3 years compared to placebo. The drug had an excellent safety profile. To the best of our knowledge, this is the first experimental evidence of significant reduction of both vertebral and non-vertebral fractures of an anti-osteoporotic agent in osteoporotic women aged 80 years and over.

Effect of Annual Intramuscular Vitamin D_3 Supplementation on Fracture Risk in 9440 Community-Living Older People: The Wessex Fracture Prevention Trial. F. H. Anderson[1], H. E. Smith*[2], H. M. Raphael*[2], S. R. Crozier*[3], C. Cooper[3]. [1]Geriatric Medicine Group, University of Southampton, Southampton, United Kingdom, [2]Primary Medical Care, University of Southampton, Southampton, United Kingdom, [3]MRC Environmental Epidemiology Unit, University of Southampton, Southampton, United Kingdom.

Vitamin D supplementation may reduce fracture risk in older people, although results from previous trials are not entirely consistent. Giving vitamin D as a single annual injection before the onset of each winter is operationally feasible if linked to an existing programme of influenza immunisation and might be economically viable as a public health measure in the low-risk elderly population. We set out to test the hypothesis that an annual intramuscular vitamin D_3 injection would reduce fracture rate among men and women aged >75 years who were living in the community - i.e. not in institutional care.
The study, which was approved by the Southampton & South West Hampshire Research Ethics Committee, was a randomised, double-blind placebo-controlled trial of 300,000 IU intramuscular vitamin D_3 (Cholecalciferol) injection or matching placebo administered every autumn (fall) over three years.
9,440 community-dwelling older people (4,354 men and 5,086 women) aged 75 to 100 years were recruited from primary care registers throughout Wessex, England. After three years of follow up, 609 subjects had incident fractures (hip 110, wrist 107, ankle 24). Hazard ratios in the vitamin D group compared with the placebo group were 1.10 (95% CI 0.94-1.29 p= 0.23) for any first fracture and 1.48 (95% CI 1.01-2.17, p=0.04) for first hip fracture; and 1.17 (95% CI 0.80-1.71, p=0.43) for first wrist fracture, controlling for age and sex. Although the findings were similar among men and women, the difference between treatment groups for hip fracture appeared more pronounced among those aged 80 years and over than among those without previous fractures. No apparent protective effect was observed when the cohort was stratified by age, previous fracture, or level of mobility. Analysis of serum PTH and 25-hydroxyvitamin D concentrations in a subset of subjects suggested that the intervention achieved a 20% suppression in peak winter PTH levels.
We conclude that an annual intramuscular injection of 300,000 IU vitamin D is not effective in preventing hip and other non-spine fractures among elderly men and women resident in the general population.

Effect of Vitamin D_3 Plus Calcium on Fall Risk in Older Men and Women: a 3-year Randomized Controlled Trial. H. A. Bischoff-Ferrari[1], J. E. Orav*[2], B. Dawson-Hughes[3]. [1]Div. of Aging and Rheumatology, Brigham and Women's Hospital, Boston, MA, USA, [2]Div. of Biostatistics, Brigham and Women's Hospital, Brigham and Women's Hospital, MA, USA, [3]Jean Meyer USDA Human Nutrition Research Center on Aging, Tufts University, Boston, MA, USA.

Background: A recent meta-analysis suggested that vitamin D in any form should lower the risk of falling in older persons by more than 20%. However, there was limited evidence for vitamin D3 (cholecalciferol) and men. Furthermore, little is known about whether supplemental vitamin D3 plus calcium will lower risk of falling over the long term.
Aim: To assess the long-term effect of vitamin D3 plus calcium on the risk of falling in ambulatory older men and women, and active and inactive individuals.
Methods: This is a 3-year double-blind randomized controlled trial. We studied 176 men and 213 women living at home of age 65 or older. Individuals received either 700 IU of vitamin D3 plus 500 mg of calcium or placebo. The outcome of interest was the risk falling at least once during the 3-year follow-up. Falls were ascertained by postcards and by follow-up visits every 6 months. All analyses controlled for age, body mass index, calcium intake, baseline 25-hydroxyvitamin D, physical activity, smoking, alcohol intake and length of follow-up. Subjects were classified as less physically active if they were below the median of average physical activity measured across time.
Results: In 3 years 94 of 176 men (53%) and 125 of 213 women (59%) reported at least one fall. 53% of all first falls occurred in the first year, 27% in the second year and 21% in the third year. Mean baseline 25-hydroxyvitamin D levels were 33.1 ng/ml (SD±14.1) in men and 27.0 ng/ml in women (SD±12.9). Vitamin D3 plus calcium significantly reduced the odds of falling in women (OR = 0.55, 95% CI [0.30 , 0.996]), but not in men (OR = 0.92, 95% CI [0.50 , 1.72]). Independent of gender, vitamin D3 plus calcium significantly reduced the odds of falling in less active persons (OR = 0.54, 95% CI [0.29 , 0.993]). This effect was primarily found in less active women (OR = 0.34, 95% CI [0.14 , 0.79]) rather than in less active men (OR = 0.89, 95% CI [0.32 , 2.48]).
Conclusion: Within 3 years**,** dietary vitamin D3 plus calcium supplementation reduces the odds of falling in ambulatory older women by 45% and in less active subjects by 46%. Thus dietary vitamin D3 and calcium supplementation may be warranted in the long-term prevention of falls in ambulatory older persons, particularly in women and those who are less physically active.

Effects of Vitamin D and Calcium Supplementation on Falls and Parameters of Muscle Function - A Prospective, Randomized, Double-blind, Multi-center Study. M. Pfeifer[1], H. Dobnig*[2], B. Begerow*[1], K. Suppan*[2]. [1]Institute of Clinical Osteology, Bad Pyrmont, Germany, [2]Department of Endocrinology, Graz, Austria.

The effects of calcium and vitamin D supplements on falls, falls-related fractures and functional measures are well-known (Pfeifer et al. 2000, Bischoff et al. 2003, Dukas et al. 2004, Larsen et al. 2004). This prospective study was undertaken to test the influence of latitude, seasonal variations, possible threshold effects and duration of vitamin D efficacy after cessation of therapy. 242 healthy male and female subjects over 70 years of age and a 25-OH-D3 serum level below 78 nmol/l were recruited in Bad Pyrmont (52°N) and Graz (48°N) and were randomly assigned to two treatment groups: one receiving 1000 mg Calcium/day (Ca) and the other 1000 mg Calcium and 800 I.U. Vitamin D (Ca+D) over 12 months. This double blind intervention phase was followed by a treatment free observation phase over another 8 months. Falls as the primary efficacy parameter were recorded by diaries and phone calls every two months. Parameters of muscle function such as quadriceps strength, body sway and "timed up and go test" were measured every four months. Statistical evaluation was carried out using the statistics software of IDV, Gauting (Test + Estimation, Version 5.2, "CRO" Dr. Heinz, Vienna, Austria). Baseline parameters did not differ between groups.

TABLE 1 shows intention-to-treat analysis after 12 months of treatment and 8 months of follow-up:

Table 1

Parameter	Calcium mono	Calcium plus Vitamin D	P-Value
Mean number of falls per group	0.69	0.45	p<0.01
Number of falls per subject	1.61	0.95	p<0.01
Body sway frontal (mm)	12.9 +/- 9.1	9.2 +/- 7.9	p<0.01
Quadriceps strength left leg (Newton)	175 +/- 65	210 +/- 63	p<0.01
"Timed up and go"-test (seconds)	8.1 +/- 3.4	7.3 +/- 3.8	p<0.01
25-OH-Vit.D after follow-up (nmol/l)	38 +/- 13	48 +/- 16	p<0.01

Despite a relatively high inclusion criterion for vitamin D (78 nmol/l) and independent of latitude, we observed a significant reduction of falls and parameters of muscle function after supplementation with vitamin D and calcium (MaxiKalzD3). So far, we did not find any evidence for a threshold phenomenon or an effect of latitude.

Disclosures: ***M. Pfeifer****, None.*

Is Peak Bone Mass Attained In Early Adulthood? A. D. G. Baxter-Jones*, R. L. Mirwald*, R. A. Faulkner, D. A. Bailey. College of Kinesiology, University of Saskatchewan, Saskatoon, SK, Canada.

Peak bone mass is defined as the highest bone mineral content during adulthood. However, the age of attainment of peak bone mass is still debatable. The purpose of this study was to determine if peak bone mass had been obtained by early adulthood in a longitudinal study of individuals followed from childhood through to early adulthood. Subjects were from the Saskatchewan Pediatric Bone Mineral Accrual Study (PBMAS), a mixed longitudinal study which ran from 1991 through to 1997. Subjects were aged between 8 and 14 years at study entry and were subsequently measured annually for 6 consecutive years. Between 2002 and 2004, 49 males and 59 females were reassessed on a further two occasions. During follow-up the age range of the subjects was 17 to 27 years. Total body bone mineral content (TBBMC) was assessed annually by dual energy X-ray absorptiometry (DXA) (Hologic 2000). The precision of the DXA in vivo, expressed as the coefficient of variation, was 0.6 %. A change of ± 1.7% (2.8 times the instrument precision) was deemed a biologically significant difference. Although, the average lines of TBBMC with age appears to plateau at 20 years of age (see figure), individual analysis suggests otherwise. In 64% and 56% of males and females respectively, the difference between the two adult measures was within the error of the measurement (± 1.7%). In 16% of the males and 22% of the females, TBBMC increased by more than 1.7% (range 1.8 to 4.9%). In 20% of the males and 22% of the females it decreased by more than -1.7% (range -1.9 to -4.9%). These results suggest that age of attainment of peak bone mass cannot yet been defined. A plateau in TBBMC has not been detected in 36% of males and 44% of females. In fact, TBBMC is fluctuating outside the error of measurement, in a number of individuals. For consistency in change to be confirmed, individuals must be reassessed on at least one more occasion.

The Kinase Inhibitory Protein, p27, Is a Likely Mediator of the Vascular Protective Effects of Parathyroid Hormone-related Protein Following Arterial Angioplasty. N. M. Fiaschi-Taesch, K. K. Takane*, I. Cozar-Castellano*, A. F. Stewart. U Pittsburgh, Pittsburgh, PA, USA.

PTHrP contains a nuclear localization signal (NLS). Arterial expression of PTHrP is markedly induced by angioplasty in rodents and humans. In vivo, adenoviral overexpression of PTHrP worsens the neointimal response to angioplasty. In contrast, PTHrP mutants in which the NLS has been removed (ΔNLS-PTHrP) are potent inhibitors of vascular smooth muscle cell (VSMC) proliferation, blocking the phosphorylation of the retinoblastoma protein (pRb), and arresting VSMC in G_1/G_0. This is of clinical relevance, for adenoviral delivery of ΔNLS-PTHrP at angioplasty completely inhibits arterial re-stenosis in rats. In this study, we explored the mechanisms through which ΔNLS-PTHrP arrests the cell cycle, using A-10 VSMC stably overexpressing ΔNLS-PTHrP, and untransfected A-10 cells as controls.

By immunoblot, p107and p130, the two "pocket protein family" homologues of pRb, were not affected by ΔNLS-PTHrP overexpression. Similarly, protein levels of all members of the cyclin D family and cdk-4 were unchanged by ΔNLS-PTHrP, as was cdk-2. There was a marginal decrease in cyclin E and cdk-4 kinase activity. In contrast to the minimal or absent changes in these cell cycle regulators, cdk-2 kinase activity was specifically and dramatically (70%) downregulated by ΔNLS-PTHrP. This suggests that the cdk-2/cyclin E-complex is a likely site of regulation of pRb phosphorylation by ΔNLS-PTHrP.

To examine the upstream regulators of cdk-2/cyclin E activity, VSMC INK/KIP family members were investigated. By immunoblotting, p16 and p21 were unchanged in ΔNLS-PTHrP-expressing cells. In contrast, p27, a potent cdk-2/cyclin E kinase inhibitor, was dramatically (~5-fold) increased in ΔNLS-PTHrP-A-10 cells. Unlike p27 protein, p27 mRNA levels were identical in control and ΔNLS-PTHrP A-10 cells, suggesting that p27 is upregulated by ΔNLS-PTHrP at the translational or posttranslational level. To determine whether p27 upregulation is the central regulator of ΔNLS-PTHrP inhibitory actions on VSMC, we prepared siRNA oligonucleotides and can reduce p27 protein levels to baseline in ΔNLS-PTHrP A-10 cells. Flow cytometry studies are in progress. To explore whether the reduction in p27 was a specific effect of ΔNLS-PTHrP, p27 was examined in VSM cells overexpressing wild-type PTHrP, in which pRb phosphorylation and in S and G2/M cell cycle phases are increased. p27 was dramatically decreased in these wild-type PTHrP A-10 cells. These studies suggest that p27 is a critical downstream regulator of both ΔNLS-PTHrP and wild-type PTHrP effects on VSMC proliferation. Whether this is a common pathway in other PTHrP target cells requires further study.

Maturity- and Sex-related Changes in Tibial Bone Geometry, Strength and Muscle-bone Indices during Growth: A 20-month pQCT Study. H. M. Macdonald*[1], S. A. Kontulainen[2], K. J. MacKelvie-O'Brien[3], K. M. Khan*[4], H. A. McKay[5]. [1]Human Kinetics, University of British Columbia, Vancouver, BC, Canada, [2]Orthopaedic Engineering Research, University of British Columbia, Vancouver, BC, Canada, [3]Endocrinology and Diabetes Unit, British Columbia's Children's Hospital, Vancouver, BC, Canada, [4]Orthopaedics/Family Practice, University of British Columbia, Vancouver, BC, Canada, [5]School of Human Kinetics/Orthopaedics/Family Practice, University of British Columbia, Vancouver, BC, Canada.

Structural changes in bone and muscle across stages of maturity have not been well characterized. Our aim was to describe sex and maturity differences for 20-month changes in bone geometry and strength and the muscle-bone relationship. We measured height and weight in 128 children (69 girls, 11.9 ± 0.6 years at baseline). Girls were categorized as EARLY, PERI- or POST-pubertal based on menarcheal status and boys were similarly categorized based on Tanner pubic hair stage. We used peripheral quantitative computed tomography (pQCT) to measure 20-month change in total bone cross-sectional area (*ToA*, mm^2), cortical area (*CoA*, mm^2), section modulus (*Z*, mm^3) and muscle area (*MA*, mm^2) at the tibial shaft (50% site). We calculated two muscle-bone indices (*MBI*); *CoA/MA* and relative bone strength (*RBS*, [*Z*/(leg length/2)]/*MA*). Both EARLY boys and girls had smaller *ToA* and *CoA* at baseline than more mature, same-sex groups. There were no baseline sex differences in *ToA, CoA* (Fig) and *Z*; however, boys increased significantly more than girls in each maturity group. Baseline *MBI* did not differ between sexes in EARLY and PERI groups, whereas they were significantly greater for POST boys compared to POST girls ($p < 0.05$). Over 20-months, *MBI* decreased significantly among EARLY and PERI girls compared to EARLY and PERI boys ($p< 0.05$). However, due to greater gains in *MA* among POST boys (Fig), there was a trend towards decreased *MBI* compared to POST girls. The present study provides novel longitudinal descriptions of change in bone geometry and strength at the tibial shaft in three maturity categories of girls and boys using pQCT. Further, this study highlights how sex differences in bone structure and muscle strength influence the muscle-bone relationship. The sexual dimorphism in musculoskeletal development may influence how bone responds to mechanical loading during puberty.

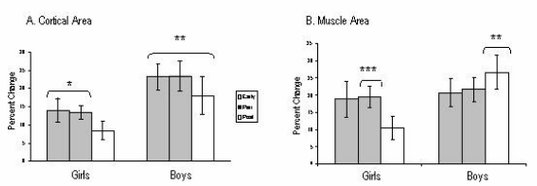

Figure. 20-month percent change in cortical area (A) and muscle area (B) for early, peri- and post-pubertal boys and girls. * EARLY & PERI > POST; ** Boys > Girls; *** PERI > POST. Bars indicate 95% confidence intervals. Noted differences significant at $p < 0.05$.

Bone Growth at the Distal Radius and Tibia Shaft in Pubertal Girls - A 2-year Longitudinal Study. Q. Wang*[1], M. Alén*[2], P. Nicholson*[1], A. Lyytikäinen[1], M. Suuriniemi[1], E. Helkala*[1], H. Suominen[1], S. Cheng[1]. [1]University of Jyväskylä, Jyväskylä, Finland, [2]PEURUNKA -Medical Rehabilitation Center, Jyväskylä, Finland.

We investigated growth trends in the distal radius and tibial shaft in 258 normal Finnish girls aged 10-13 years followed over two years in terms of geometric properties and bone density measured annually using peripheral quantitative computed tomography. Volumetric bone mineral density was assessed in the total bone (total vBMD) and, in the case of the tibia, also in the cortical compartment alone (cortical vBMD). A hierarchical linear statistical model with random effects was used to estimate polynomial functions representing the true longitudinal growth trends relative to menarche. The growth rates of distal radius cross-sectional area (CSA) and bone mineral content peaked at 16 and 9 months before menarche, respectively. This discrepancy between CSA and BMC trends was reflected in a decline in distal radius total vBMD up until 12 months before menarche. In contrast, in the tibial shaft both total and cortical vBMD increased steadily throughout puberty. Tibial cortical thickness increased linearly, and was accounted for mainly by bone formation at the periosteal surface before menarche, and at both the periosteal and endosteal surfaces after menarche. The ratio of cortical/total CSA increased, and the ratio of marrow/total CSA decreased, during puberty. Interestingly, for both radius and tibia, the growth rate in bone CSA peaked at the same time as the growth rate in body height (16-20 months before menarche), but the peak BMC growth rate occurred later, concurrent with the peak rate of increase in body weight (9-10 months before menarche). The results suggest that there is a transitional period of decreased distal radius total vBMD during puberty, and this may explain the increased forearm fracture incidence in puberty reported in previous epidemiological studies.

Gender-specific Differences in the Functional Muscle-bone Unit at Different Skeletal Sites in Children Assessed by DXA and pQCT. R. Ashby*[1], Z. Mughal*[2], J. Adams[1], K. Ward[1]. [1]Clinical Radiology, University of Manchester, Manchester, United Kingdom, [2]Central Manchester and Manchester Children's Hospitals NHS Trust, Manchester, United Kingdom.

The functional muscle-bone unit may be important for the evaluation of musculoskeletal development and health in children. The relationship between muscle and bone may be expressed as a ratio, where bone mineral content (BMC)(g) or area (BA)(cm2) is divided by lean mass (LM) (g). The aim of this study was to determine whether there are gender differences in BMC:LM and BA:LM of the whole body (WB) and regional body segments of growing children. As height is a major determinant of the muscle-bone unit, gender differences at different skeletal sites may be more apparent when the muscle bone unit is interpreted according to height.

250 healthy children (114 male [M], 136 female [F]; age 10.6±3.4, range 5-18 years; height 141.1±17.3, range 110.1-179.9cm) were studied. BMC, BA and LM values for the WB and regional body segments (trunk, arms and legs) were determined from WB DXA scans (Hologic QDR-4500A). The XCT-2000 pQCT scanner (Stratec) was used to measure cortical BMC (CC) (mg/mm), cortical BA (CA) (mm2) and cross-sectional muscle area (CSMA) (mm2) of the non-dominant midshaft radius. Bone:muscle ratios (BMC:LM, BA:LM, CC:CSMA and CA:CSMA) were determined for each subject. Data were split into 10cm height group increments. The differences in each height group between and within genders were then analysed.

Arm, leg and WB BMC:LM ratios increased with successive height groups in both males and females. Females had significantly higher arm BMC:LM at 130-169cm ($p<0.001$-0.007), trunk BMC:LM at 130-139 and 150-159cm ($p<0.001$-0.020) and WB BMC:LM at 150-169cm ($p=0.011$ & $p=0.048$) compared to males. There was a trend for greater CC:CSMA ratios in females vs males.

Arm BA:LM ratios reached peak values at 150-159cm in females; these ratios were greater in females between 120-179cm ($p<0.001$-0.036). Leg BA:LM ratios reached maximum values in both genders between 130-139cm, then declined with sequential height; females being higher than males ($p=0.004$-0.039). WB BA:LM ratios were greatest at 120-120cm in males and 130-139cm in females, then decreased in both genders. At the radius, CA:CSMA ratios increased with height and were greater in females, but this did not reach significance.

These data show females have greater BMC and BA relative to muscle mass compared to males of comparative heights, and supports the work of Schiessl (1998). Increased bone deposition in females may be due to oestrogen lowering the mechanostat remodelling threshold. This may be an adaptive mechanism whereby extra bone is stored as a reservoir for the potential demands of pregnancy and lactation.

Is Mechanical Homeostasis Faulty in Elderly Women Who Suffer Osteoporotic Fractures? M. M. Daphtary*[1], C. B. Ruff[2], K. L. Stone[3], S. R. Cummings[3], T. J. Beck[1]. [1]Radiology, Johns Hopkins University, Baltimore, MD, USA, [2]Cell Biology and Anatomy, Johns Hopkins University, Baltimore, MD, USA, [3]Department of Medicine, University of California San Francisco, San Francisco, CA, USA.

It is known that bones adapt strength to changing loading conditions, but does net bone loss in aging bones mean that homeostatic adaptation is less effective in those who fracture? To examine this question we evaluated load stresses in the proximal femurs of elderly women participating in the Study of Osteoporotic Fractures over two time points averaging 3.5 years apart. Theoretically, homeostatic adaptation should continually adapt bone strength to changing skeletal loading demands so that stresses remain constant. If homeostasis is defective, bone loss should cause stresses to increase over time. We computed magnitudes and rates of change in medial and lateral stresses at the femoral neck using body weight as load in an analytical model of a fall on the greater trochanter. BMD, BMC and structural dimensions including bone cross-sectional area (CSA) and section modulus (Z) were derived from dual energy x-ray absorptiometry scans of the hip using Hip Structure Analysis (HSA). Results were compared between 1079 women who remained free of all fractures at last follow-up (Fx-Free) and 1703 women who suffered incident or prevalent hip, vertebrae, rib, forearm or other fragility fractures (Fx). Group differences were assessed by ANCOVA and differences between time points by paired t-tests. Compared to Fx-Free at each time point, Fx women had ~2% lower body weights, but bone CSA and Z adjusted for differences in age, weight and knee height were ~7-8% lower hence stresses were ~7% higher (all differences $p<0.05$). Between time points, Z and CSA declined 0.5-0.6%/y in Fx women and skeletal load (weight) declined 0.3%/y (all changes $p<0.05$); neither strength nor weight changed in Fx-Free. Consequently, stresses did not change significantly in either group ($p > 0.05$). Interestingly BMD declined 0.8% and 1.07%/y in Fx-Free and Fx, respectively ($p<0.05$). BMC did not change in Fx-Free; the decline in BMD was entirely due to 0.5%/y expansion of diameter ($p<0.05$). In Fx, BMC declined 0.2%/y and diameter expanded 0.6%/y ($p<0.05$). These results indicate that whether or not women suffer osteoporotic fractures, their bones maintain the ability to adapt to changing mechanical loads and this is not reflected in the change in BMD. However, those who do fracture have bones apparently adapted to higher stress levels, i.e., of lower strength. Our findings suggest that, even in those who suffer osteoporotic fractures, bone loss in elderly women is not indicative of a defect in mechanical homeostasis that prevents adaptation to current loading conditions.

Twisted Gastrulation Inhibits Bone Morphogenetic Protein Actions and Prevents Osteoblast Cell Differentiation. E. Gazzerro, V. Deregowski, S. Vaira*, E. Canalis. Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA.

Twisted gastrulation (Tsg), a secreted glycoprotein that binds bone morphogenetic protein (BMP)-2 and -4, can display both BMP agonist and antagonist functions. Tsg can complex with BMP and its antagonist chordin, enhancing chordin actions, or it can facilitate chordin cleavage by the metalloprotease BMP-1/tolloid, releasing active BMP. Consequently, Tsg dual activities depend on the relative concentrations of BMP, chordin and BMP-1 in target tissues. Tsg null mice have defective endochondral ossification, indicating an agonist effect in cartilage. But, the actions of Tsg in bone and cells of the osteoblastic lineage are not known. To investigate the role of Tsg in cells of the osteoblastic lineage, we examined its expression and activity in ST-2 stromal cells. Tsg and BMP-1, but not chordin, transcripts were detected under basal conditions. BMP-2 induced chordin, downregulated Tsg, and did not modify BMP-1 transcripts. To define the effects of Tsg on stromal cells, ST-2 cells were transduced with a retroviral vector where Tsg expression is under the control of the CMV promoter and compared them to cells transduced with parental vector. ST-2 cells were cultured in osteoblastic differentiating conditions with and without BMP-2. Tsg overexpression precluded the formation of mineralized nodules induced by BMP-2 in control cells, and delayed the expression of osteoblastic gene markers. BMP can signal by activating the Smad pathway or the mitogen activated protein (MAP) kinases, ERK, p38 and JNK. In ST-2 cells, BMP-2 induced Smad 1/5/8 phosphorylation and the transactivation of a transfected 12x-SBE-Oc-pGL3 construct containing 12 repeats of a Smad binding site directing luciferase expression. In accordance with the phenotypic changes, Tsg overexpression opposed BMP-2 effects on Smad 1/5/8 phosphorylation and on the transactivation of the 12x-SBE-Oc-pGL3 construct. BMP-2 had a modest effect on ERK and no effect on p38 or JNK phosphorylation. The effects of Tsg appeared to be selective to BMP-2/Smad signaling, since Tsg did not alter the activity of a transfected Wnt/ß-catenin responsive construct containing Tcf4/Lef1 recognition sequences upstream of the reporter luciferase. In conclusion, Tsg inhibits BMP signaling and actions, preventing its effects on the differentiation of stromal cells toward the osteoblastic pathway. These results contrast the Tsg agonist role in cartilage, and demonstrate an antagonist role in cells of the osteoblastic lineage.

The Anabolic Response to Bone Morphogenetic Protein-2 Is Impaired in Fibroblast Growth Factor-2 Null Mice. T. Naganawa[1], L. Xiao[1], J. D. Coffin[2], T. Doetschman*[3], M. M. Hurley[1]. [1]Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]The University of Montana, Missoula, MT, USA, [3]University of Cincinnati, Cincinnati, OH, USA.

Bone Morphogenic Protein-2 (BMP2) is a member of the transforming growth factor beta (TGFb) super-family that plays an important role in the commitment and differentiation of osteoprogenitors to active osteoblasts. We made the novel observation that BMP2 stimulates fibroblast growth factor-2 (Fgf2) mRNA in osteoblast/stromal cells (OBs). FGF2 is a potent stimulator of osteoblast precursor proliferation and is anabolic in experimental animals. In addition, disruption of the Fgf2 gene resulted in reduced bone mass and bone formation in mice. To characterize the role of FGF2 in the BMP2 responses, we examined bone formation in vivo in response to BMP2 in Fgf2+/+ and Fgf2-/- mice. Three-month-old Fgf2+/+ and Fgf2-/- male mice were weighed and injected s.c. once daily with vehicle or BMP2 (20µg/kg body wt) for 5 days. Mice were injected with calcein (0.6 mg/kg) on day 7 and day12 to assess new bone formation. There were no significant differences in body wt pre- and post-BMP2 in either genotype. Histomorphometry of the calvaria showed that BMP2 significantly increased calvarial width by 13% (186.1±6.3 vs. 164.1±4.0, $p<0.05$) in Fgf2+/+ but caused only a 5% increase (161.5±10.9 vs. 153.3±6.1) in Fgf2-/- mice that was not significant. Bone formation rate (BFR/BS) was increased by 57% (0.74±0.07 vs. 0.47±0.06, $p<0.05$) in Fgf2+/+ mice but the changes were smaller 15% (0.53±0.12 vs. 0.46± 0.18) and not significant in Fgf2-/- mice. To assess the mechanism of reduced bone formation, bone marrow stromal cells from 3-month-old Fgf2+/+ and Fgf2-/- mice were cultured in differentiation medium in the absence or presence of BMP2 (30 ng/ml) or FGF2 (1 nM) for 7-21 days. In vehicle treated Fgf2-/- cultures, there were fewer alkaline phosphatase positive, mineralized nodules compared with Fgf2+/+ cultures. Treatment with FGF2 but not BMP2 rescued bone nodule formation in Fgf2-/- cultures. Since BMP2 signals via activation of Smad and p38MAPK, we examined the integrity of these pathways in OBs. Fgf2+/+ and Fgf2-/-OBs were treated with vehicle or BMP2 (50 ng/ml) for 30 to 120 mins and cellular proteins were analyzed by Western blot. BMP2 caused a marked induction of phospho-Smad1/5/8 and phospho-p38 within 30 mins in Obs from both Fgf2+/+ and Fgf2-/- mice. We conclude that FGF2 is crucial in the anabolic effect of BMP2 and that this may be independent of activation of Smad and MAPK signaling pathways.

Expression of PHOSPHO1 during Embryonic Development: Implications for Skeletal Mineralization. A. J. Stewart*, S. J. Roberts*, C. Farquharson. Roslin Institute, Midlothian, United Kingdom.

Matrix mineralization is a biphasic process that occurs within terminally differentiating chondrocytes, osteoblasts and ondontoblasts and is the mechanism by which cartilage, bone and tooth formation occurs by each of these cell types, respectively. The initial phase concerns the formation of Ca^{2+} ions and inorganic phosphate (P_i) within matrix vesicles (MVs). Accumulation of Ca^{2+} is controlled by calcium-binding molecules such as annexin I and phosphatidylserine. The accumulation of P_i is less clear. It has long been speculated that the generation of P_i results from the action of phosphatases, the most abundant being tissue non-specific alkaline phosphatase (TNAP). During skeletal development, the generation of P_i for mineralization does not appear to be due to the activity of TNAP. In newborn TNAP knockout mice, bone development and mineralization essentially appear normal, despite the subsequent observation of hypomineralization and other abnormalities. PHOSPHO1 is a novel phosphatase upregulated in mineralizing cells, which exhibits high specific phosphohydrolase activity toward phosphoethanolamine and phosphocholine and is localized to mineralizing regions of developing bone and cartilage. However, it is unclear if PHOSPHO1 is present in MVs. In this study we have investigated PHOSPHO1 mRNA expression during embryonic development in the chick by whole-mount *in-situ* hybridization. *In-situ* hybridization was done using digoxigenin labeled RNA probes. Cryosectioning of the whole mounts indicated that chondrification of the long bones occurred from day5/6 and von Kossa-positive staining was observed in both the femur and tibia from day 7. Mineralization was initially restricted to the bone collar within the mid-shaft of the diaphysis. At day-12 mineralization was observed over the entire length of the diaphysis. The localization of PHOSPHO1 mRNA was found in all long bones studied (femur, tibia, ulna, radius, metatarsals and phalanges). No hybridization was observed in any other tissues. Microscopically, its localization mirrored that of the von Kossa staining and was observed only at the developing bone collar. To determine the presence of PHOSPHO1 we isolated MVs from growth plates of juvenile (3-week-old) chicks by ultracentrifugation. High TNAP activity verified the identity of the MV-containing fraction. Immunoblotting using a PHOSPHO1 specific antiserum confirmed the presence of high levels of the enzyme. These studies provide further evidence that PHOSPHO1 is involved in the generation of P_i for matrix mineralisation during embryonic skeletal development.

Hypomineralization of Tibia in Nucleoside Triphosphate Pyrophosphohydrolase (NPP1) Deficient Mice. H. Clarke Anderson[1], D. Harmey*[2], N. P. Camacho[3], R. Garimella[1], J. B. Sipe*[1], S. Tague*[1], R. Terkeltaub[4], J. L. Millan[2]. [1]Pathology, University of Kansas Medical Center, Kansas City, KS, USA, [2]The Burnham Institute, La Jolla, CA, USA, [3]Hospital for Special Surgery, New York, NY, USA, [4]VA/UCSD, San Diego, CA, USA.

A study was undertaken to characterize long bone mineralization in mice with a genetic deficiency of the enzyme nucleoside triphosphate pyrophosphohydrolase (NTPPase), also known as PC-1 or NPP1. NTPPase is present at sites of biomineralization, i.e., at the surfaces of growth plate chondrocytes, metaphyseal osteoblasts and matrix vesicles (MVs). NTPPase hydrolyzes ATP yielding pyrophosphate (PP_i). Depending on the local concentration, PP_i has dual functions: at concentrations above 2mM, PP_i inhibits bone mineralization, but when present at low (micromolar) concentrations in the extracellular fluid of cartilage and bone, PP_i can promote calcification. At skeletal mineralization sites, PP_i is hydrolyzed to orthophosphate (P_i) by tissue-nonspecific alkaline phosphatase (TNAP) thus increasing the local concentration of P_i for incorporation into nascent hydroxyapatite mineral. Previously, we found that double deletion of the NPP1 and TNAP genes lead to correction of soft tissue calcification in the vertebral apophyses of the double mutant mice. In this study, we aimed at evaluating the extent of the corrective changes by examining long bone mineralization in the NPP1 and NPP1/TNAP double mutant mice. We also performed a detailed immunohistochemical study of NPP1 expression. Single or double knockout 10 day-old mouse upper tibias were examined by non-decalcified histology, mineral estimation by Alizarin red, micro CT, Fourier-transform infrared spectroscopy (FTIRIS) and by transmission electron microscopy (TEM). Unexpectedly, we found that bone mineralization was slightly reduced in NPP-1 deficiency and moderately to severely deficient in TNAP/NPP-1 double knockout mouse tibias. Our data indicate that the hypermineralization state of NPP1-deficient mice and the degree of correction attained by simultaneously ablating the TNAP gene is restricted to certain sites, e.g. the vertebral apophysis, but was not seen in tibial growth plate or metaphysis. Our immunohistochemistry data reveal that the differential rescue with respect to bone sites correlates with the local expression pattern of the NPP-1 protein. We found that sites of mineralization correction (e.g. vertebrae) express high levels of NPP-1 while sites such as tibia have low to undetectable levels of NPP-1 expression.

A Mouse Model of Jansen Metaphyseal Chondrodysplasia (JMC): Introduction of the H223R Mutation into the Murine PTH/PTHrP Receptor gene results in Delayed Endochondral Bone Formation. L. F. Fröhlich, U. I. Chung, J. Guo, H. Jüppner. Endocrine Unit, Massachusetts General Hospital/ Harvard Medical School, Boston, MA, USA.

JMC is a very rare form of short-limbed dwarfism associated with abnormalities in endochondral bone formation and mineral ion homeostasis. Four different heterozygous gain-of-function point mutations in the membrane spanning domains of the PTH/PTHrP type 1 receptor have been identified thus far as the cause of this autosomal dominant genetic disorder. These mutations lead to constitutive ligand-independent cAMP accumulation when tested in vitro.

We used gene targeting to introduce the human H2232R mutation into the murine PTH/PTHrP receptor (Pthr1) gene and to thereby generate a mouse model of JMC for functional analysis of a constitutively active Pthr1 in vivo.

At E12.5, 15.5, 16.5 and 18.5 homozygous fetuses were identified, however, no homozygous live neonates were thus far found, indicating that the H223R may be postnatally lethal. Mice heterozygous for the mutant receptor are viable and fertile, and exhibited no obvious abnormalities. However, one mouse was distinguished by its small size and developmental delay, while a few other animals showed lethal kyphosis possibly indicating that differences in the genetic background may affect the phenotype.

Histological analysis of the skeleton of neonatal and 5 week old heterozygotes was performed. A severe delay in endochondral bone formation was observed in sternum, vertebral column, femur and tibia of newborn mice. The growth plates of all investigated bones showed an obvious accumulation of proliferative as well as of hypertrophic chondrocytes at chondro-osseous junctions associated with a disturbance of regular columnar structures and a delay in vascular invasion. This finding was particularly pronounced in parts of sternum and vertebral column where different sternebrae and vertebrae completely lacked primary ossification centers and were smaller compared to those of wild-type littermates. By 5 weeks of age, the long bones of the H223R mutant mice appeared to have essentially normal histology, with the exception of some thickening in the growth plates. In comparison to wild-type controls, blood serum ionized calcium levels of heterozygous H223R-Pthr1 mice were slightly elevated (1.28 ± 0.05 mmol/l wt; n=8 vs. 1.34 ± 0.02 mmol/l het; n=8) at the age of 1 month.

Our results indicate that a mouse model of JMC has been generated and confirm that the H223R-Pthr1 mutation delays chondrocyte differentiation and leads to mild hypercalcemia. These mice will now be used to further explore the molecular mechanisms leading to the changes in endochondral bone formation and mineral ion homeostasis that are typically observed in JMC.

PTH-rP Expression in Cartilage Cells Is Regulated by the Gli Family of Transcription Factors. J. A. Sterling, B. O. Oyajobi, M. Zhao, A. Gupta*, M. Banerjee*, G. R. Mundy. Cellular and Structural Biology, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA.

Parathyroid hormone-related peptide (PTH-rP) has an important physiological role in the growth plate, where it regulates chondrocyte proliferation. Its expression is controlled by Indian hedgehog (Ihh), and both Ihh and PTH-rP null mutant mice have severe and similar growth plate abnormalities, with premature differentiation and decreased proliferation of growth plate chondrocytes resulting in small stature. Although these data suggest that Ihh controls PTH-rP expression in cartilage cells, the mediators responsible are unknown. In drosophila, hedgehog signaling is mediated by the transcriptional regulator cubitus interruptus (Ci), which is the ortholog of the Gli family of transcriptional activators in vertebrate cells. Gli2 null mice exhibit increased hypertrophic chondrocytes and decreased PTH-rP expression (Miao et al., 2004), suggesting similarities to deletion of Ihh and PTH-rP. Since the Gli family has been shown to mediate Hh signaling in other vertebrate cells, we reasoned that this same family may mediate Ihh effects on PTH-rP expression in cartilage cells. To examine this, we performed transfections of the growth plate chondrocyte cell line TMC-23 with PTH-rP promoter luciferase and Gli expression constructs. We found that Gli2 up-regulated the activity of a 1.1kb PTH-rP promoter luciferase construct by approximately 3-fold. This effect appears specific to Gli2 as transfections with the other family members, Gli3 or Gli1, had no effect on basal PTH-rP promoter activity. We and others have demonstrated that Gli3 is proteasomally processed to a truncated repressor form, similar to its ortholog Ci in drosophila . In TMC-23 this truncated repressor form of Gli3 blocked Gli2 mediated PTH-rP promoter activity. Furthermore, an siRNA for Gli2 that specifically decreases Gli2 expression by >90% dramatically blocked the Gli2 mediated PTH-rP promoter activity, suggesting that Gli2 is a physiologic regulator of PTH-rP expression in cartilage cells. Since the Gli family appears to be an important regulator of PTH-rP promoter activity, we analyzed the PTH-rP promoters for consensus Gli binding sites. The site with the closest homology was a 6/9 match, which by EMSA did not bind Gli2, indicating that the effects of Gli2 on the PTH-rP promoter are likely indirect. Taking all of these data together, we conclude that the Gli family of transcription factors mediates the effects of hedgehog proteins on PTH-rP expression and subsequent endochondral bone formation in the cartilage cells of the growth plate.

Hypoxia Promotes Chondrocytic Differentiation *in vitro* and Cartilaginous Matrix Synthesis in Organ Culture via p38 Kinase Pathway. M. Hirao*, N. Tamai*, N. Tsumaki*, A. Myoui, H. Yoshikawa. Department of Orthopaedics, Osaka University Graduate School of Medicine, Suita, Japan.

Cartilage is an avascular tissue that functions at a lower oxygen tension than do most other tissues. On the other hand, ossification is always accompanied by vascularization, suggesting high oxygen requirement. Under the hypothesis that oxygen tension plays an important role in the commitment to chondrocyte of the cells in mesenchymal lineage, we investigated the role of oxygen tension on chondrocytic differentiation induced by recombinant human bone morphogenetic protein-2 (rhBMP-2) using pluripotent mesenchymal cell line C3H10T1/2. These cells were cultured in normoxia (O2 20%) and hypoxia (O2 5%) conditions in the presence of rhBMP-2 (500ng/ml). Alcian blue staining revealed more abundant glycosaminoglican (GAG) synthesis in the cells cultured in hypoxia than in normoxia. In parallel, type II collagen (*Col2a1*) gene expression by Northern blotting was elevated in hypoxic condition, while type X collagen (*Col10a1*) gene expression and alkaline phosphatase (ALP) staining were suppressed by hypoxia. Since p38 mitogen activated protein kinase (p38MAPK) has been suggested to regulate chondrocyte differentiation and to play a key role in hypoxia-induced signaling, we next examined the role of p38MAPK in hypoxia-induced chondrocytic differentiation. We found that hypoxia up-regulated phosphorylation of p38MAPK in C3H10T1/2 cell culture but down-regulated that of Smad 1/5/8. An inhibitor of p38MAPK, FR167653 partially suppressed hypoxia-induced GAG synthesis and *Col2a1* gene expression. Furthermore, dominant-negative MKK3 that specifically inhibits p38MAPK pathway abolished hypoxia-induced GAG synthesis. On the other hand, wild type Smad6 that down-regulates Smad signaling did not alter the hypoxia-induced GAG synthesis. To investigate the role of oxygen tension in cartilage tissue development we performed organ culture of neonatal mouse forearm and histologically evaluated. Although hypoxia did not alter the proportion of zonal structure of growth cartilage, the width of growth cartilage was increased by hypoxia both in the absence and in the presence of BMP-2, suggesting increased cartilaginous matrix production. Hypoxia-promoted widening of growth cartilage was clearly suppressed by FR167653. These findings suggest that hypoxia promote chondrocytic differentiation of the pluripotent mesenchymal cells as well as matrix production in cartilage tissue via p38 MAPK pathway.

BMP Signaling Regulates Chondrocyte Differentiation and Maturation at Multiple Steps. T. Kobayashi[1], K. M. Lyons[2], A. P. McMahon*[3], H. M. Kronenberg[1]. [1]Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA, [2]University of California, Los Angeles, Los Angeles, CA, USA, [3]Harvard University, Cambridge, MA, USA.

In order to investigate roles of BMP signaling in cartilage development, we overexpressed a constitutively active form of BMPR1A receptor (*caBmpr-1a*) in chondrocytes. First, *caBmpr-1a* was overexpressed directly by a rat collagen 2 promoter. Acute transgenic embryos (*Col2-caBmpr-1a*) were analyzed. Second, *caBmpr-1a* was overexpressed using the GAL4/UAS system to establish transgenic lines. GAL4 is misexpressed in chondrocytes using the same rat collagen 2 promoter in the driver mouse (*Col2-Gal4*). *Col2-Gal4* mice were crossed to mice carrying *caBmpr-1a* sequence downstream of GAL4 responsive UAS elements (*UAS-caBmpr-1a*). *Col2-Gal4:UAS-caBmpr-1a* embryos (bigenic mice) were analyzed. Lastly, BMPR1B (*Bmpr-1b*) null mice were crossed to bigenic mice to examine whether expression of *caBmpr-1a* in the chondrocytic lineage was able to rescue the phenotype. Acute overexpression of *caBmpr-1a* in the chondrocytic lineage caused enlargement of cartilage elements and a relative reduction in proliferating chondrocytes. Expression of *Sox9* and *Noggin*, of which expression is augmented during chondrocyte maturation, was upregulated in transgenic vertebral cartilage, suggesting acceleration of chondrocyte maturation. A reduction in proliferating chondrocytes was also observed in bigenic *caBmpr-1a* mice. However, unlike acute transgenic mice, bigenic mice showed no enlargement of the cartilage elements. This difference between the two phenotypes may result from subtle differences in timing of *Bmpr-1a* expression. Target gene expression in the bigenic system requires earlier GAL4 protein synthesis, which may delay expression *caBmpr*-1a compared with acute transgenic mice. This may have restricted the *caBmpr-1a* expression in chondrocytes to more advanced stages in bigenic mice. It is, therefore, possible that BMP signaling in immature cells of the chondrocytic lineage stimulates commitment to form chondrocytes, whereas BMP signaling in committed chondrocytes stimulates their maturation and terminal differentiation.

The first and second phalanges of *Bmpr-1b-/-* mice fail to form cartilage molds. Overexpression of *caBmpr-1a* in the cartilage of *Bmpr-1b-/-* mice rescued the defect in phalange development, demonstrating that the loss of BMP signaling in prospective phalangeal cells of the chondrocytic lineage is responsible for the digit defect of *Bmpr-1b-/-* mice. The rescue also suggests that BMPR-1A signaling can substitute for BMPR-1B signaling in this setting. These results suggest that BMP signaling regulates cartilage development at multiple steps.

Mitogen-activated Protein Kinases Mediate Parathyroid Hormone Regulation of Indian Hedgehog Transcript in Chondrocytes. L. P. Lai*, J. Mitchell. Pharmacology, University of Toronto, Toronto, ON, Canada.

Endochondral ossification is the process by which long bones develop and grow. It is regulated by multiple paracrine factors including parathyroid hormone-related peptide (PTHrP) and Indian Hedgehog (Ihh). Pre-hypertrophic chondrocytes secrete Ihh, which stimulates PTHrP secretion from the perichondrium, and indirectly regulates chondrocyte terminal differentiation. Previous studies have shown that PTHrP can in turn inhibit the Ihh mRNA level in pre-hypertrophic chondrocytes, providing a negative feedback mechanism. In this study, we have examined the role of mitogen-activated protein (MAP) kinases in mediating the PTH regulation of Ihh mRNA levels in a chondrocytic cell line, CFK-2. Ihh mRNA levels were decreased in cells treated with U0126, a specific MEK1/2 inhibitor, as well as SB203580, a specific p38 MAP kinase inhibitor. Cells transiently transfected with constitutively active MEK1 or MKK3 had increased Ihh mRNA levels, while dominant-negative forms of MEK1, p38α or p38β all diminished the level of Ihh mRNA, implicating both ERK1/2 and p38 MAP kinase pathways in the regulation of Ihh expression. Activation of the common receptor for PTH and PTHrP with 10^{-8}M PTH (1-34) decreased the Ihh mRNA levels. PTH also caused a transient dephosphorylation of p38 MAP kinase that was maximal after 25 minutes, as well as dephosphorylation of ERK1/2 that was evident within 15 minutes and sustained for at least one hour. The PTH inhibition of MAP kinases was mimicked by 500nM forskolin, and was accompanied by the stimulation of MKP-1 expression, a specific MAP kinase phosphatase, within 30 minutes. The PTH down-regulation of Ihh mRNA levels was blocked by transfecting the cells with the constitutively active MEK1 but not by the constitutively active MKK3. Our data demonstrate the central role of MAP kinases in the regulation of Ihh expression in chondrocytes. Stimulation of the PTH/PTHrP receptor results in a sustained inhibition of ERK1/2 activity and subsequent down-regulation of Ihh mRNA levels, which is at least partially mediated by MKP-1. This study also suggests that a negative feedback loop between PTHrP and Ihh may extend to inhibition of Ihh gene transcription or mRNA stability.

Primary Chondrocytes from c-Fos Overexpressing and Knockout Mice Exhibit Altered BMP-Induced Differentiation and Chondrocyte Gene Expression. I. Anagnostopoulos*, J. Kan*, A. E. Grigoriadis. Craniofacial Development, King's College London, London, United Kingdom.

The c-Fos proto-oncogene, a member of the AP-1 transcription factor family plays an important role in bone and cartilage differentiation, as demonstrated in gain- and loss-of-function studies. We have generated a regulatable c-Fos inducible system *in vitro* in ATDC5 chondrocytes (clone DT12.4) and have shown that exogenous c-Fos expression inhibits chondrocyte differentiation and nodule formation. However, the mechanisms underlying this effect remain unknown.

We have now investigated whether altered c-Fos levels in chondrocytes affects their responsiveness to BMPs. Treatment of DT12.4 cells with BMP-2 or -4 rescued the c-Fos block in differentiation, and stimulated cartilage nodule formation to a greater extent in c-Fos-overexpressing cells compared with non-transgenic cells. The enhanced BMP effect in the presence of c-Fos was confirmed by RT-PCR analysis for types II and X collagen expression. It is unlikely that the BMP effects were caused by altered proliferation since preliminary BrdU assays suggested that induction of c-Fos had no effect on BMP-induced DNA synthesis. Northern blot analysis showed that induction of c-Fos decreased endogenous BMP-4 levels in DT12.4 cells, whereas there were no differences in BMP receptor expression.

We next investigated the role of c-Fos in modulating BMP signalling in primary chondrocytes isolated from c-Fos transgenic or knockout mice, both of which have cartilage phenotypes. BMP-2 treatment of chondrocytes from c-Fos-transgenic mice resulted in enhanced differentiation and a higher number of cartilage nodules compared to non-transgenic chondrocytes. Types II and X collagen expression were also enhanced in BMP-2-treated transgenic chondrocytes compared to wild-type cells. In addition, chondrocytes overexpressing c-Fos exhibited reduced levels of endogenous BMP-4. Thus, primary chondrocytes from c-Fos transgenic mice showed a similar phenotype to c-Fos-overexpressing DT12.4 cells. In contrast, the effects of BMP-2 and -4 on cartilage differentiation were suppressed in primary chondrocytes from c-Fos knockout mice, and this was paralleled by a decrease in types II and X collagen expression. Finally, preliminary BrdU experiments suggested that chondrocyte proliferation following BMP-2 and -4 treatment was enhanced in c-Fos null cells compared with wild-type cells.Taken together, these findings suggest that overexpression of c-Fos in chondrocytes results in enhanced BMP signalling, whereas inactivation of c-Fos results in suppressed BMP signalling. This altered BMP responsiveness may mediate the effects of altered c-Fos expression in chondrocytes *in vivo*.

Preservation of Bone Mass after Ovariectomy in Caf1-Deficient Mice through Activation of BMP Signaling in vivo. K. Oikawa[1], T. Nakamura*[2], M. Usui[1], K. Tsuji[1], I. Ishikawa*[3], A. Nifuji[1], T. Noda*[4], T. Yamamoto*[2], M. Noda[1]. [1]Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]University of Tokyo, Tokyo, Japan, [3]Periodontology, Tokyo Medical and Dental University, Tokyo, Japan, [4]Cancer Institute, Tokyo, Japan.

Postmenopausal osteoporosis is caused by depletion of estrogen as well as low peak bone mass, though the molecular mechanisms involved in the osteopenia due to postmenopausal bone loss have not yet been fully understood. Recently, we reported that Tob is involved in the determination of bone mass after ovariectomy-induced bone loss (PNAS 2004). Tob associates with Caf1 (CCR4-associated factor 1), which is a component of CCR4-NOT complex, and is involved in gene transcription and mRNA modulation in yeast. Therefore, we examined whether Caf1 could be involved in the determination of bone mass after estrogen depletion. Caf1-deficient (CAFKO) mice were born normally. Ovariectomy reduced cancellous bone volume (BV/TV) in wild type (WT) mice. In contrast, even after ovariectomy, BV/TV levels in CAFKO mice were preserved and similar to those in sham-operated wild type. High bone mass trend was observed in CAFKO of both genders. 3D-microCT analyses revealed that basal BV/TV was more in CAFKO mice compared to wild type. Bone formation rate (BFR) and mineral apposition rate (MAR) were enhanced in CAFKO compared to WT while osteoclast number and surface were not altered in CAFKO bone, indicating that Caf1 specifically targets osteoblasts in vivo. As mineralized nodule formation in ex vivo bone marrow cultures was enhanced in CAFKO cells while osteoclast formation in vitro was similar between WT and CAFKO. Thus, CAFKO effect was cell autonomous. To address the mechanism of CAFKO enhancement of osteoblastic activity, bone marrow ablation was conducted. Bone formation on day 14 after ablation was observed in 3/4 CAFKO mice compared to 1/5 in WT or heterozygote mice. This was similar to the observation that BMP injection onto the calvariae of newborn CAFKO mice induced more new bone formation in vivo than WT and that BMP treatment induced higher alkaline phosphatase activity in CAFKO calvaria-derived cells cultured in vitro compared to WT. Finally, BMP treatment enhanced Caf1 gene expression in MC3T3E1 osteoblastic cell line suggesting that Caf1 is involved in a negative feed back signaling system in osteoblasts. This Caf1 gene activation is specific to BMP as TGF-beta did not alter Caf1 gene expression. These observations suggest that Caf1 deficiency preserved bone mass after ovariectomy via enhancement of osteoblastic bone formation through BMP actions in vivo.

Runx1/Cbfa2 Induces Early Stages of Chondrogenesis in Mouse Limb Bud Cells. R. M. Belflower*, Y. Wang*, Y. Dong, J. E. Puzas, E. M. Schwarz, R. J. O'Keefe, H. Drissi. Orthopeadics, University of Rochester, Rochester, NY, USA.

Work to date has focused primarily on Runx2/cbfa1 since bone formation is abrogated in Runx2 null mice, while all cartilaginous structures are fully formed. Since Runx proteins share several structural and function features, we investigated the implication of Runx1 in chondrogenesis. Our in situ hybridization data shows that *Runx1* and *Runx2* expression overlaps during early stages of embryonic development in the cartilage primordia of various skeletal elements. *Runx* transcripts being expressed in mesenchymal condensations with the potential to form cartilage, we assessed their expression and regulation during chondrogenesis using limb bud mesenchymal progenitors from E11.5 embryos. Our real time RT-PCR data shows that both isoforms of *Runx1* and *Runx2* are regulated in these cells. The MASXS isoform of both Runx factors is up-regulated throughout chondrocyte maturation, as evidenced by expression of cartilage phenotypic genes. In contrast, the MRIPV isoform of both genes is more abundant during early stages of chondrocyte differentiation, and subsequently down regulated. This differential expression of the *Runx* isoforms predicts a distinct and sustained role for these proteins in chondrogenesis. The overall expression of *Runx1* mRNA remains significantly higher than *Runx2* mRNA levels throughout mesenchymal cell differentiation. We then treated limb bud cells for 4, 8 and 14 days with BMP-2 and PTHrP, which are known to respectively induce and delay chondrogenesis. Our gene expression analysis shows that BMP-2 induced both isoforms of *Runx1* and *Runx2*. However, a more potent and earlier induction of the MASXS isoform is observed for both factors. Interestingly the up-regulation of *Runx2* by BMP-2 is stronger than *Runx1*. In contrast, PTHrP inhibited both factors, with the most potent effect being on the *Runx1* transcripts. Our results clearly establish a potential role for Runx1 in early chondrogenesis while Runx2 may mediate later stages of chondrocyte maturation. In order to determine the function of Runx1 during chondrogenesis, we over-expressed both Runx1 isoforms using retroviral vectors to infect mouse embryonic limb bud cells. Our data show that *Runx1* over-expression results in a significant induction of the early chondrocyte differentiation markers, *type II collagen* and *alkaline phosphatase*, but not the marker for chondrocyte hypertrophy, *collagen X*.

In summary, our results strongly support a role for Runx1 in mediating the onset of the early stages of chondrocyte differentiation from mesenchymal stem cells. Thus our findings show for the first time, that the hematopoiesis related factor Runx1 acts as a novel mediator of cartilage development.

Adipocyte-Directed Expression of GFP in Transgenic Mice. M. S. Kronenberg[1], X. Jiang*[1], H. Li*[1], I. Kalajzic*[1], L. C. Pan[2], D. W. Rowe[1]. [1]Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, USA, [2]Cardiovascular and Metabolic Diseases, Pfizer Global Research and Development, Groton, CT, USA.

Adipocytic and osteogenic cells are two of the primary lineages of the bone marrow stromal system and evidence suggests that they are both derived from a common multipotential mesenchymal progenitor. In order to investigate this interrelationship we used a 7.6 kb promoter fragment from the adipocyte specific marker gene adipocyte protein 2 (aP2/FABP4) to express the topaz variant of enhanced green fluorescent protein (aP2/Tpz). Initial validation of this construct was done by transiently transfecting the pluripotent C3H10T1/2 mesenchymal cell line and then encouraging adipocytic differentiation by treatment with insulin, 9-cis-retinoic acid and rosiglitazone. After 5 days of treatment, cells expressing aP2/Tpz exhibited a differentiated, adipocytic morphology characterized by an accumulation of refractile cytoplasmic vacuoles. Subsequent injection of the aP2/Tpz construct into fertilized C57BL/6 eggs yielded 4 transgenic lines of which 3 then transmitted the GFP reporter gene. In samples from freshly killed mice, cytoplasmic GFP protein expression was only seen in white adipose tissue (WAT) isolated from the abdomens of animals from 2 different lines. Cryosections of fixed WAT confirmed this observation and also showed the presence of GFP in brown adipose tissue and in a small subset of cells in the bone marrow. Marrow stromal cell (MSC) cultures were established from long bones of PCR positive F1 transgenic mice and treated after 8 days with either a vehicle control, an adipogenic cocktail consisting of isobutylmethylxanthine, hydrocortisone and indomethacin (MHI) or the peroxisome proliferator-activated receptor gamma agonist ciglitazone (CIG). Fluorescent cells were evident in cultures from the 2 WAT-positive lines after 48 hours in both the MHI and CIG treated groups and the number and intensity of GFP-expressing cells increased over a period of 6 days. Based on the number of fluorescent cells containing refractile droplets and the Oil Red O staining of similar appearing cells in fixed cultures, CIG appeared to be more effective in promoting adipocytic differentiation of cells derived from bone marrow of aP2/Tpz mice. These results indicate that we have produced a real-time reporter for cells of the adipocytic lineage that will enable us to track this branch of the MSC family in vitro and in vivo. In addition, crossing these lines with our osteoblastic GFP reporter mice should allow us to better dissect the interplay between bone and fat cells in the marrow as that microenvironment changes during development, aging and pharmacologic intervention.

Missouri Variant of Human Spondyloepimetaphyseal Dysplasia (SEMDMO) due to Matrix Metalloproteinase 13 (MMP13) Mutation in the Pro-domain Results in Altered Secretion and Intracellular Auto-activation of MMP13. M. Inada*[1], M. H. Byrne*[1], A. M. Kennedy*[2], P. T. Christie*[2], M. P. Whyte[3], R. V. Thakker[2], S. M. Krane[1]. [1]CIID, Medicine, Mass General Hospital, Charlestown, MA, USA, [2]Nuffield Department of Clinical Medicine, University of Oxford, Oxford, United Kingdom, [3]Metabolic Research Unit, Shriners Hospital for Children, St. Louis, MO, USA.

Autosomal dominant SEMDMO (Patel et al. Medicine 72:326, 1993) is caused by a missense mutation encoding Phenylalanine56Serine (F56S) in the pro-domain of MMP13 (Kennedy et al. J. Bone. Miner. Res. 17[Suppl 1]:S175, 2002). Here, we examine possible mechanisms by which the F56S mutation could alter MMP13 function. Transformed human chondrocytes or HEK293 cells were transfected with mutant or wild type (wt) MMP13 cDNA inserts (± C-terminal fusion tags) in pcDNA3.1. Levels of wt and F56S mutant mRNAs in transfected cells were similar. Medium and cell lysates were harvested after 48 h and analyzed by Western blotting with antibodies directed towards the fusion tags or multiple epitopes in the pro-, catalytic or hinge domains of MMP13. These antibodies are useful for detection of proteolytic products that are formed after activation of the inactive zymogen. Whereas after transfection with wt cDNA, abundant intact MMP13 (~ 55kDa) was present in conditioned medium (CM), only traces of intact MMP-13 were found in CM after transfection with F56S cDNA; several lower Mr degradation fragments of F56S, however, were found in CM. Intact as well as degradation fragments of F56S were found in cell lysates. Addition to cell cultures of monensin, 2 mM, eliminated wt intact and F56S fragments in CM; wt intact and F56S intact and fragments were, however, retained in cell lysates. We constructed the catalytically inactive E204A wt MMP13 in pcDNA3.1 and it was expressed and secreted. The catalytically inactive compound mutant E204A /F56S MMP13 in pcDNA3.1 rescued the abnormal functioning F56S mutation since only pro-MMP13 compound mutant was found in CM or cell lysates. An engineered C77S mutant was also auto-activated and degraded intracellularly. F56S MMP13 in stable expressing clones intracellularly degraded transfected wt MMP13. Our results are consistent with misfolding of F56S MMP13 in which the downstream cysteine (C77) fails to contact the catalytic Zn and thus F56S MMP13 is auto-activated and it auto-degrades to low Mr fragments that lack collagenolytic activity. Thus, loss of collagenase activity could, in part, account for the dominant SEMDMO phenotype, since Mmp13-null mice also have chondrodysplasia.

RANKL and VEGF Signals Mediate Cortical Bone Healing Derived from Structural Autografts: Effective Transfer to Processed Allografts via Immobilized rAAV. H. Ito[1], M. Koefoed*[2], J. J. Goater*[2], R. J. O'Keefe[2], E. M. Schwarz[2]. [1]Orthopaedic Surgery, Kyoto University Graduate School, Kyoto, Japan, [2]University of Rochester, Rochester, NY, USA.

To the end of generating a remodeling structural allograft we developed a murine femoral model, which utilizes live autografts and processed allografts. The aim of this study was to characterize the role of RANKL and VEGF in autograft healing and to evaluate the effects of introducing these signals onto the cortical surface of femoral allografts via immobilized recombinant adeno-associated virus (rAAV). A 4 mm mid-diaphyseal segment was removed from 8-week-old C57BL/6 mice, and a segmental bone graft was secured with a intramedullary pin. The segment of bone graft was obtained from the same femoral shaft of the animal (autograft) or from that of a different stain of mouse: ICR mouse (allograft). For gene expression analysis, total RNA was extracted from the healing grafts and analyzed by real time RT-PCR and Affymetrix microarrays. Histomorphometry was performed on OrangeG/aclian blue, X-gal and tartrate resistant acid phosphatase (TRAP) stained sections. For loss of function studies, anti-mouse VEGF goat antibody, RANK:Fc fusion protein, or goat IgG was administered via intraperitoneal injection. *Ex vivo* gene transfer of β-galactosidase (LacZ), osteoprotegerin (OPG) and/or the soluble VEGF receptor (sFlt1) to live autografts were performed by harvesting the specimens, incubating them in rAAV/PBS solution for 10 min, and rapidly placing it back in the original donor. *In vivo* gene transfer of LacZ, RANKL and VEGF to processed allografts were performed by pipetting 1% sorbitol-PBS solution containing rAAV onto the cortical surface of the grafts. The allografts were then frozen, lyophilized, and stored at -80 ºC until they were transplanted. Gene expression analyses revealed that there is a significant decrease in *RANKL* and *VEGF* during allograft healing. Systemic inhibition with RANK:Fc & anti-VEGF, and local inhibition with rAAV-OPG & rAAV-sFlt1, demonstrated that both RANKL & VEGF are required for autograft healing. Using allografts containing freeze-dried rAAV-RANKL and rAAV-VEGF we demonstrate that both signals are sufficient to significantly increase new bone formation around the cortical surface of the allograft. We also noted that these factors induce allograft remodeling and vascularization, which leads to a new bone collar that spans the entire graft. Addition of either signal alone failed to yield significant effects. In conclusion we find that RANKL and VEGF are necessary and sufficient for efficient autograft healing and can be transferred via rAAV to revitalize structural allografts.

Role of the Serotonin Transporter (5-HTT) in Bone Metabolism. R. A. Battaglino[1], M. Joe*[1], U. Späte*[1], A. Sharma*[1], D. Graves*[2], T. Kohler*[3], R. Muller*[3], P. Stashenko*[1]. [1]Cytokine Biology, Forsyth Institute, Boston, MA, USA, [2]Boston University School of Dental Medicine, Boston, MA, USA, [3]ETH, Zurich, Switzerland.

Mounting evidence exists for the operation of a functional serotonin (5-HT) system in osteoclasts and osteoblasts, that involves both receptor activation and 5-HT reuptake. In previous work we demonstrated that the serotonin transporter (5-HTT) is expressed in osteoclasts and that its inhibition reduces osteoclast differentation *in vitro*. The purpose of the current study was to determine the effect of serotonin uptake on bone metabolism *in vivo*. To that end, we conducted histomorphometric and micro-computed tomographic imaging (micro-CT) analysis in 5-HTT deficient mice and in wild type (wt) mice treated with fluoxetine, a 5-HTT blocker. Mice homozygous for a deletion of the *5-htt* gene exhibited increased whole body bone mineral density (BMD) compared to age matched wild type (WT) controls. Micro-CT analysis revealed an increase in BV/TV in tibial cortical bone. This effect was confirmed by systemic administration of fluoxetine to Swiss-Webster mice for six weeks, which resulted in increased trabecular BV/TV in femurs, as a result of an increase in trabecular number and connectivity beta, and decreased trabecular spacing. The effect of blocking the 5-HTT on bone loss following challenge was also investigated. Subcutaneous injections of LPS over the calvariae of Swiss-Webster mice for 5 days resulted in increased numbers of osteoclasts and net bone loss, whereas new bone formation and a net gain in bone mass was seen when LPS was given with fluoxetine. In contrast, neither 5-HTT deficient mice nor WT mice given fluoxetine were protected against bone loss after ovariectomy. We conclude that inhibition of the 5-HTT *in vivo* leads to increased bone mass under normal physiologic or inflammatory conditions, but does not modulate bone loss associated with estrogen deficiency. These findings support the hypothesis that the serotonin system plays a crucial role in bone formation and remodeling, via effects on both osteoclast and osteoblast development and activity.

Nell-1, a Downstream Target of Cbfa1, in Bone Formation. K. Ting[1], X. Zhang*[2], T. Truong*[1], Y. Miao*[1], R. Chiu*[2], C. Soo*[3]. [1]Orthodontics, UCLA , Los Angeles, CA, USA, [2]Dental and Craniofacial Research Institute, UCLA , Los Angeles, CA, USA, [3]Plastic Surgery, UCLA , Los Angeles, CA, USA.

Nell-1 overexpression is associated with craniosynostosis in both human patients and transgenic mice. Initial promoter analysis of the *Nell-1* gene suggest that Cbfa1 may regulate human *Nell-1* transcription. The objective of the study is to examine the transcriptional regulation of *Nell-1* by Cbfa1. If Nell-1 is a downstream effector/target of Cbfa1, then we would expect Nell-1 to functionally compensate for some aspects of *Cbfa1* deficiency. A 2.2kb and 325bp fragment of the human *Nell-1* promoter was cloned into the pGL3 Basic luciferase reporter plasmid and used in transient transfection assays with Cbfa1. EMSA, supershift, and mutagenesis studies were conducted. *Nell-1* overexpression mice (*Nell-1*^{overexp}) were mated with heterozygous *Cbfa1* deficient mice (*Cbfa1*$^{+/-}$). Skeletal staining was performed using Alcian blue and Alizarin red. Micro-CT scans were also used. For the promoter analysis, Cbfa1 overexpression increased luciferase activity 6 fold from the 2.2 kb promoter construct, but had no effect on the 325 bp promoter construct. In cotransfection assays with increasing amounts of Cbfa1 plasmid, the 2.2 kb promoter construct, but not the 325 bp construct, exhibited a positive dose response of luciferase activity. Cbfa1 binds specifically to three OSE2 sites and induces luciferase activity. The Nell-1^{overexp},Cbfa1$^{+/-}$ mice confirmed the presence of significantly reduced fontanelle size and suture width and increased clavicle size. In conclusion, Cbfa1 positively regulates the human Nell-1 promoter. Nell-1 may partially compensate for Cbfa1 insufficiency and lend further support to the hypothesis that Nell-1 may be a central downstream target of Cbfa1.

Lack of the Tumor Suppressor Gene Vhlh Increases Trabecular Bone and Expands the Osteoblast/Stromal Cell Population. R. Chiusaroli, M. C. Knight*, E. Schipani. Medicine, MGH-Harvard Medical School, Boston, MA, USA.

The transcription factor Hypoxia-Inducible-Factor 1alpha(HIF-1alpha) is essential for chondrocyte growth arrest and survival. HIF-1alpha also inhibits adipocyte cell differentiation in vitro. The von Hippel Lindau tumor suppressor protein (pVHL) is a component of a ubiquitin ligase promoting proteolysis of HIF-1α. Conditional inactivation of Vhlh in the cartilaginous elements using the Cre-loxP strategy has demonstrated its critical role in endochondral bone development, at least in part through stabilization of HIF-1α protein. As previously reported, mice lacking Vhlh in cartilage are dwarf, and Vhlh null growth plates display a dramatic decrease of chondrocyte proliferation rate with an increased accumulation of extracellular matrix. In postnatal life, the Vhlh mutant mice developed a unique bone phenotype, very likely because the Cre recombinase driven by the rat collagen type II promoter is expressed in cells of the osteoblast lineage, as indicated through the use of reporter mice. As shown by histology and in situ hybridization analysis, this bone phenotype was already evident at two weeks of age, and was characterized by increased trabecular bone with significant expansion of the osteoblast/stromal cell population. HIF-1α transcriptional activity augments the expression of enzymes of the glycolytic pathway such as phosphoglycerokinase-1 (PGK-1) and angiogenetic factors such as vascular endothelial growth factor (VEGF). In adult long bones isolated from Vhlh mutant mice expression of both PGK-1 and VEGF mRNAs was clearly upregulated in osteoblasts in comparison to control littermates, as shown by in situ hybridization analysis. Notably, VEGF is an important autocrine/paracrine factor for osteoblast differentiation. Our current working hypothesis is that increased HIF-1a stability in the Vhlh null bone leads to expansion of the osteoblast/stromal cell population through up regulation of metabolic pathways and VEGF expression. Our data support the model that the VHL/HIF system is an important modulator of mesenchymal cell differentiation.

Skeletal Overgrowth in Tight Skin (Tsk) Mice. T. Barisic*, S. H. Clark*. Deparment of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, USA.

The tight skin (Tsk) mutation is an autosomal dominant mutation located on mouse chromosome 2. Mutant mice (Tsk/+) display a tightness of skin interscapular region, lung emphysema, myocardial hypertrophy, skeletal overgrowth and kyphosis. The Tsk mutation has been identified as a tandem duplication of the mouse fibrillin 1 gene. Fibrillin is a large extracellular matrix glycoprotein and is an important component of microfibrils. Several reports have suggested a role of fibrillin in the modulation of TGF-beta action on the regulation of the metabolism of matrix producing cells, i.e. fibroblasts and osteoblasts. It is hypothesized in this report that in the Tsk mice the presence of mutant fibrillin molecules in the matrix produced by mutant bone cells alter bone cell metabolism. In the present study we analyzed the phenotype of 2-month-old Tsk/+ mice and found that body length of the Tsk/+ and longitudinal femur length were significantly longer in Tsk male mice compared with control male littermates. These changes in the skeleton of Tsk/+ mice indicate that fibrillin 1 gene may regulate skeletal development and differentiation. In order to examine collagen expression in osteoblasts of Tsk mice we utilized the pOBCol2.3GFP transgene that has been documented to be expressed in mature osteoblasts. The pOBCol2.3GFP transgene was introduced by mating producing Tsk/+ and +/+ littermates carrying this transgene. The decalcified femur sections showed increased numbers of GFP expressing cells in Tsk/+ mice compared with +/+ littermates. In an effort to examine the potential impact of the mutant fibrillin molecule of the osteoprogenitor lineage, marrow stromal cell cultures were initiated from bone marrow isolated for one-month-old Tsk/+ and +/+ sibs. We examined the expression of osteoblast the specific genes, Col1a1, BSP and OC in these marrow stromal cell cultures at various time points. In the Tsk/+ cultures the pattern of gene expression was normal, however, a difference in the tempo of differentiation was observed. Specifically, there was a slowing in maturation of the Tsk cells indicated by delay in the appearance of OC expression. In summary the enlarged skeleton observed in the Tsk mouse is associated with an elevated number of osteoblasts actively producing collagen as well as an alteration in the tempo of osteoblast maturation. These initial experiments suggested the role of fibrillin 1 gene as important regulator of bone formation.

Integrin Ligands Arranged in Nanopatterns Modulate Focal Adhesion Assembly and Signaling in Osteoblasts. E. A. Cavalcanti-Adam[1], M. Bezler*[1], P. Tomakidi*[2], J. P. Spatz*[1]. [1]Biophysical Chemistry, Heidelberg University, Heidelberg, Germany, [2]Orthodontics, Heidelberg University, Heidelberg, Germany.

Integrin lateral clustering is a key event for the formation of focal adhesions and for the control of cell shape and mobility. The size and distribution of integrin clusters modulate extracellular matrix composition and organization, as well as cell growth and differentiation. To study the geometrical limits for single integrins in the assembly of focal adhesions and their effect on osteoblast function, we created regular patterns of adhesive nanodots coated with integrin ligands, separated by nonadhesive regions.

Surfaces were decorated with gold nanoparticles arranged in hexagonal pattern by using block-copolymer nanolithography. With this technique, nanoparticles are deposited on surfaces at defined, but variable distances (28, 58, 73 or 85nm), according to the molecular characteristics of the copolymers. The diameter of each nanodot is less than 8nm, so only one integrin binds per dot. The space between the nanodots is then passivated against cell adhesion and protein deposition by polyethylene glycols, and the nanodots are functionalized with c(RGDfK)-thiols to promote integrin binding.

Focal adhesion molecules were evaluated in primary human osteoblasts and in MC3T3E1 osteoblast-like cells cultured on nanopatterned substrates for 0-24hr.

On 28 and 58 nm patterns, cells presented elongated integrin clusters, colocalization of vinculin and organized actin stress fibers. A separation of >58nm between the nanodots resulted in limited cell spreading, and dramatically reduced formation of focal adhesions . We attributed these cellular responses to restricted integrin clustering rather than insufficient number of ligands, since micro-nanopatterned patches, with minimal local ligand density but optimal interdot distance, still supported osteoblast adhesion. Moreover, osteoblasts adhering to the 73nm pattern, exhibited characteristics of migrating cells, rich in focal complexes at the peripheral extensions. Since the maturation of focal complexes into focal adhesions is influenced by intracellular contractility and extracellular tension transmitted to the ECM, we evaluated the organization of ECM proteins secreted by osteoblasts. On the 58nm pattern, cells produced a matrix rich in collagen type I and fibronectin, organized in a network supporting and surrounding cells, while on the 73nm, the fibers were rather disorganized and packed under cell contacts.

Knowledge of these geometrical limits for integrin clustering is essential to elucidate the physical and molecular mechanisms by which integrins mediate bidirectional signal transduction in osteoblasts.

Myeloma Cells Suppress Osteoblast Differentiation by Secreting a Soluble Wnt Inhibitor, sFRP-2. T. Oshima*, M. Abe, E. Sekimoto*, Y. Tanaka*, H. Shibata*, T. Hashimoto*, S. Ozaki*, S. Kido, D. Inoue, T. Matsumoto. Department of Medicine and Bioregulatory Sciences, University of Tokushima, Tokushima, Japan.

Multiple myeloma (MM), a malignancy of plasma cells, develops in the bone marrow, and generates devastating bone destruction. Along with enhanced bone resorption, clinical evidence has also suggested suppression of bone formation as a contributing factor to a bone loss in MM. Despite recent advances in our understanding of the mechanisms of osteolysis enhanced in MM, little is known about factors responsible for impaired bone formation. A canonical Wingless-type (Wnt) signaling pathway has recently been shown to play a critical role in osteoblast differentiation. Therefore, in the present study, we aimed to clarify mechanisms of suppression of osteoblast differentiation by MM cells with a particular focus on a canonical Wnt signaling pathway. Because several secreted Frizzled related protein (sFRP) and DKK family members are known as soluble Wnt antagonists, we first examined the expression of sFRP-1, 2 and 3 and DKK-1 in MM cell lines including U266, RPMI8226 and ARH77. RT-PCR analysis revealed that all cell lines expressed sFRP-2 and sFRP-3 mRNA. However, sFRP-1 was not at all expressed, and DKK-1 was expressed only in U266 cells. By Western blot analyses for these factors, we were able to detect only sFRP-2 protein in immunoprecipitants of conditioned media (CM) as well as cell lysates of all these cell lines. No other factors were found at the protein level. Importantly, sFRP-2 mRNA and protein expression was detected in most MM cells from patients with advanced or terminal stages of MM (3/4 and 8/10, respectively). In order to examine a biological role for sFRP-2, we added recombinant sFRP-2 to MC3T3-E1 cell culture together with BMP-2. Exogenous sFRP-2 partially suppressed alkaline phosphatase activity but almost completely blocked mineralized nodule formation enhanced by BMP-2. Furthermore, sFRP-2 immunodepletion significantly restored mineralized nodule formation in MC3T3-E1 cells suppressed by ARH77 CM. These results suggest that sFRP-2 alone is able to suppress osteoblast differentiation induced by BMP-2 and that MM cell-derived sFRP-2 is among predominant factors responsible for defective bone formation in MM. Because MM cell-derived factors such as DKK-1, IGF-BP4 and IL-3 other than sFRP-2 have been implicated as an inhibitor of osteoblast differentiation, sFRP-2 may also act in concert with such other factors to potently suppress bone formation in MM. Thus, MM cells may cause an imbalance of bone turnover by enhancing osteoclastic bone resorption and at the same time suppressing bone formation, which leads to devastating destruction and a rapid loss of bone.

Noggin Inhibition of BMP-2 Decreases the Formation of Osteoblastic Lesions in Prostate Cancer. B. T. Feeley*[1], S. C. Gamradt*[1], L. Krenek*[1], W. K. Hsu*[1], N. Liu*[1], P. Robbins*[2], J. Huard*[2], J. R. Lieberman*[1]. [1]Orthopaedic Surgery, University of California, Los Angeles, Los Angeles, CA, USA, [2]Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, USA.

Bone morphogenetic proteins (BMPs) are growth factors that have a vital role in the growth and development of the skeletal system, and have been shown to have altered expression in multiple types of cancer. We have previously demonstrated that osteoblastic lesions express multple BMPs including BMP-2, -4, and -7. We examined the role of BMP-2 in the formation of an osteoblastic lesion in a murine metastatic cancer model. RT-PCR and Western blot analysis demonstrated that the prostate cancer osteoblastic cell lines LAPC-4 and LAPC-9 expressed BMP receptor subtypes I, IIa, and IIb, suggesting these cells would be responsive to host bone expression of BMPs. To determine the effects of BMP-2 on these cells *in vitro*, we performed cellular migration and invasion assays. At BMP concentrations of 10 ng/ml, 100 ng/ml, and 500 ng/ml, LAPC-4 cells were stimulated to both migrate and invade through extracellular tumor matrix ($p<0.001$ vs NIH-3T3 control cells). In addition, the effects of BMP-2 were able to be inhibited by 10 ug/ml of its inhibitor, noggin in both the cellular migration and invasion assays ($p<0.001$ vs. BMP-2 alone). To determine the effects of BMP-2 expression *in vivo,* we performed tibial injections into SCID mice of either LAPC-9 cells alone or LAPC-9 cells infected with a retrovirus overexpressing noggin (RetroNog). Noggin expression was confirmed with Western blot and a BMP activity assay. All 9 mice treated with LAPC-9 alone had developed osteoblastic lesions at 8 weeks. In contrast, 8 of the 9 mice treated with LAPC-9+RetroNog showed only minimal new bone formation on radiographic examination. The area of bone present in the LAPC-9+RetroNog treatment group was significantly less compared to LAPC-9 alone in histomorphometric analysis ($p<0.01$). There was no difference in tumor size at 8 weeks between the groups. We concluded that BMPs have a vital role in the development of the osteoblastic prostate cancer lesion. BMPs stimulated cellular migration and invasion *in vitro*, and blockade of BMP activity with its inhibitor noggin was successfully able to block *in vitro* activity and *in vivo* bone formation. We believe that local blockade of BMP activity may allow for future therapeutic strategies in the treatment of osteoblastic prostate cancer lesions.

Noggin Mediated Inhibition of Bone Morphogenetic Protein-2 Inhibits the Formation of Osteolytic Prostate Cancer Metastases. B. T. Feeley*[1], L. Krenek*[1], W. K. Hsu*[1], N. Liu*[1], J. Huard*[2], J. R. Lieberman[1]. [1]Orthopaedic Surgery, University of California, Los Angeles, Los Angeles, CA, USA, [2]Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, USA.

The majority of prostate cancer metastaseis to bone are osteoblastic in nature, but some lesions are mixed or purely lytic. The cytokine profiles of these different lesions have been shown to differ considerably. Bone morphogenetic proteins (BMPs) have been shown to have altered expression in multiple cancer cell lines. The purpose of this study was to identify the role of BMPs in the formation of an osteolytic lesion in a murine metastatic prostate cancer model. BMP receptor types Ia, Ib, and II were demonstrated to be present on the osteolytic prostate cancer cell line PC-3 with RT-PCR and Western blot analysis. Expression of these receptors suggested that PC-3 cells would be responsive to host bone expression of BMPs. Cell migration and invasion assays were performed to determine the effects of recombinant (Rh) BMP-2 on the oncogenic properties of PC-3 cells. At concentrations of 100 ng/ml and 500 ng/ml, BMP-2 stimulated a significant increase in PC-3 cell migration and invasion compared to controls ($p<0.001$). Addition of a BMP inhibitor, noggin, (50 ug/ml) inhibited the effects of BMP-2 on migration and invasion compared to BMP-2 alone ($p<0.01$). Addition of Rh-BMP-2 to PC-3 cells in serum free media resulted in a significant increase in cell growth ($p<0.01$ vs. control). Again, noggin inhibited the effects of BMP-2 on cell growth ($p<0.001$ vs. BMP-2 alone). Noggin was not cytotoxic to the cells. To determine the effects of BMP-2 expression on PC-3 cells *in vivo*, PC-3 cells were infected with a retrovirus overexpressing noggin (RetroNog) and injected into the proximal tibia of SCID mice. Noggin expression was confirmed with Western blot and a BMP activity assay. At 2, 4, 6, and 8 weeks, tumor size was significantly smaller in the PC-3+RetroNog group (n=20) compared to control PC-3 animals (n=20). Radiographic score was significantly less at each time point as well. Histologic analysis demonstrated no difference in the number of osteoclasts present between groups, suggesting that noggin had no effect on osteoclast activity. BMP-2 appears to play a key role in the cell growth, cell migration, and cell invasion of osteolytic prostate cancer PC-3 cells *in vitro*. The *in vivo* overexpression of noggin slows the rate of growth of osteolytic prostate cancer tumors in a murine metastatic model. This data suggests that BMP is a critical factor in the osteotropism of prostate cancer cells, and that it regulates cell growth in osteolytic prostate cancer cell lines.

Cadherin-11-mediated Interactions between Metastatic Breast Cancer Cells and Bone Marrow Stromal/Osteoblastic Cells Enhance Bone Metastases. D. Tamura*[1], T. Hiraga[2], A. Myoui[1], H. Yoshikawa[1], T. Yoneda[2]. [1]Orthopaedics, Osaka Univ Grad Med, Suita, Japan, [2]Biochemistry, Osaka Univ Grad Dent, Suita, Japan.

Bone is one of the most preferential sites where breast cancer spreads. Although the precise molecular mechanism is yet to be elucidated, cell adhesion molecules have been proposed to contribute to bone-selective metastasis of breast cancer. Cadherin-11, which was originally isolated from MC3T3-E1 osteoblastic cells and is one of the classical type-2 cadherin family members, has been shown to be constitutively expressed in bone marrow stromal cells. Of note, cadherin-11 expression is also found in some human breast cancers and its expression level is correlated with their aggressiveness. These results led us to hypothesize that the homophilic interactions between breast cancer cells and bone marrow stromal/osteoblastic cells via cadherin-11 played a role in the development of bone metastases. To study this, we established MDA-MB-231 human breast cancer cells and 293T human embryonic kidney cells that were stably transfected with cadherin-11 cDNA (MDA/Cad11 and 293T/Cad11, respectively) and examined for the capacity of these cells to develop bone metastases following heart inoculation into female nude mice. Radiographic and histomorphometric examinations demonstrated that the number and size of osteolytic lesions and tumor burden in bone were markedly increased in both MDA/Cad11 and 293T/Cad11 with elevated numbers of osteoclasts compared with parental cells (MDA/pa and 293T/pa). Subsequently, we examined whether cadherin-11-overexpressing cells exhibit enhanced homing to bone. FACS analysis using fluorescent dye-labeled cancer cells showed that the number of cells arrested in bone marrow shortly after the heart inoculation was greater in 293T/Cad11 than 293/pa cells. Cell motility assay using Boyden chambers revealed that chemotactic migration of cadherin-11-overexpressing cancer cells was significantly increased when co-cultured with ST2 or MC3T3-E1 cells, both of which constitutively expressed cadherin-11. Moreover, the conditioned medium harvested from the co-cultures of 293T/cad-11 and MC3T3-E1 cells stimulated TRAP-positive osteoclast-like cell formation in mouse marrow cultures, whereas the conditioned medium of 293T/pa and MC3T3-E1 cell co-cultures had little effects. These data show that cadherin-11 expression in cancer cells enhances homing and osteoclastogenesis via homophilic interactions with bone marrow stromal/osteoblastic cells, thereby stimulates bone metastases. Our results suggest that cadherin-11 contributes to the preferential spread of breast cancer cells to bone and is a potential therapeutic target.

A Nonpeptide Integrin avb3 Antagonist Inhibits Bone Metastasis Formation. J. Guglielmi*[1], I. Pecheur*[1], P. Pujuguet*[2], D. Minet*[2], R. Baron[2], P. Clement-Lacroix[2], P. Clezardin[1]. [1]U.403, INSERM, Lyon, France, [2]Proskelia, Paris, France.

Tumor cells expressing integrin avb3 have a greater propensity to metastasize to bone and subsequently stimulate osteoclast activity, leading to increased bone destruction. We have investigated here the effect of avb3 antagonist HMR1404 on bone metastasis caused by avb3-expressing tumor cells.

Because osteoclasts express avb3, the antiresorptive potency of HMR1404 was first studied in oophorectomized (ORX) mice. A continuous treatment of ORX animals with HMR1404 (2 x 10 mg/kg/day for 28 days) completely prevented castration-induced bone loss. Nude mice inoculated with CHO cells expressing avb3 (CHO b3wt) were then treated with HMR1404 using this dosing schedule. HMR1404 inhibited osteolytic lesions caused by tumor cells, as judged by radiography (HMR1404: 0.7 ± 0.8 mm2 vs placebo: 6.4 ± 4.5 mm2) and histomorphometry using the bone volume (BV) to tissue volume (TV) ratio (HMR1404: 12 ± 3.4 % vs placebo: 1.6 ± 0.3 %). Skeletal tumor burden was also reduced (HMR1404: 1% vs placebo: 92.3 ± 17.2 %). Thus, a continuous treatment with HMR1404 probably reduces bone metastasis formation through inhibition of osteoclast-mediated bone resorption. However, HMR1404 also dose-dependently inhibited CHO b3wt cell invasion and adhesion to vitronectin in vitro, suggesting that it could also directly act on tumor cells in vivo. CHO b3wt-bearing animals were therefore treated with HMR1404 using a dosing schedule (2 x 10mg/kg/day for 3 days) that did not inhibit bone resorption in ORX mice. Despite this, HMR1404 reduced osteolytic lesions (1.3 ± 0.4 mm2 vs placebo: 8 ± 1.2 mm2), increased the BV/TV ratio (11.3 ± 1.8 % vs placebo: 2.9 ± 0.6%), and decreased skeletal tumor burden (4.4 ± 0.4 % vs placebo: 100%). Similarly, a 3-day HMR1404 treatment inhibited osteolytic lesions caused by avb3-expressing B02 breast cancer cells that are stably transfected to express GFP (B02/GFP) (3.5 ± 4.2 mm2 vs placebo: 10.8 ± 4.7 mm2). It also increased the BV/TV ratio (12.7 ± 4.1 % vs placebo: 6.3 ± 1.3 %), and decreased tumor burden (6.4 ± 1.1 % vs placebo: 63.5 ± 11 %). Overall, these results suggested that a 3-day HMR1404 treatment could interfer with tumor cell trafficking in bone. To further address this question, animals receiving a 3-day treatment were sacrificed earlier than usual (7 days after tumor cell inoculation instead of 30 days), and bone marrow cells were analyzed by flow cytometry to detect fluorescent GFP-expressing B02 cells. HMR1404 inhibited by 80% the number of B02/GFP cells present in the bone marrow. In conclusion, our results indicate that avb3 antagonists may represent a novel therapeutic strategy for the treatment of patients with bone metastases.

BMP Inhibits the Prostate Cancer Cell Growth by Inducing Smad1 Interaction with Androgen Receptor. T. Qiu*, X. Cao. Pathology, University of Alabama at Birmingham, Birminham, AL, USA.

Prostate cancer is the most commonly diagnosed malignancy in men and is often associated with bone metastases. Bone Morphorgenetic Proteins (BMPs), a subfamily of transforming growth factor-β, has been suggested playing roles in the prostate cancer proliferation, differentiation, and osteoblastic bone metastases.

Here we have examined the potential function of BMP in prostate cancer. We found that BMP regulates androgen receptor (AR) transcription activity through interaction between BMP specific signal transducer Smad1 and AR. Our experiments show that Smad1 endogenously co-immunoprecipitates with AR, and Smad1 suppresses 5α-dihydrotestosterone-induced AR transactivation in the LNCaP prostate cells. Constitutively active BMP type IB receptor induces the interaction between Smad1 and AR, but BMP-2 can not induce the interaction, suggesting BMP receptor deficiency present in LNCaP cells. Interestingly, Smad6 can reverse the suppression of Smad1 on AR transactivation since Smad6 inhibits BMP signaling by competitively binding to phosphorylated Smad1. These results suggest that phosphorylated Smad1 contributes to the Smad1-mediated suppression. Furthermore, Smad1 represses ligand-independent activation of AR by IL-6 and ligand-dependent activation by a transcription activator Tip60. In addition, Smad1 associates with the endogenous HDAC activity, suggesting the change of acetylation status of AR may contribute to the suppression. Gel-shift assay indicates that Smad1 and AR can form a complex on an androgen response DNA element. Chromatin immunoprecipitation analysis reveals recruitment of Smad1 to the endogenous PSA gene promoter in androgen-dependent manner. Thus, Smad1 functions as an AR corepressor.

We also analyzed the effects of BMP/smad1 on prostate cell growth. Overexpression of Smad1 down-regulates the expression of cyclin D1, and flow cytometric analysis reveals that LNCaP cell growth is arrested in G1 phase. Importantly, 5α-dihydrotestosterone enhanced the cell cycle arrest by Smad1, suggesting Smad1-induced cell growth inhibition via its interaction with AR. Smad1-induced growth inhibition was attenuated when endogenous AR expression was knocked down using AR siRNA. In addition, in AR negative prostate cancer PC3 cells, Smad1 does not inhibit cell growth and Smad1 retains the ability to inhibit cell growth in AR-stably expressed PC3-AR cells. Again, the interaction of Smad1 with AR is required in such growth inhibition. Our studies reveal a molecular mechanism of BMP/Smad1 in prostate cancer, which may enable development of a BMP/Smad1 based therapeutic strategy for the treatment of prostate cancer, and improve anti-androgen treatment for prostate patients.

Novel Bisphosphonate Conjugates Decrease Metastatic Bone Tumor Burden in the 4T1/luc Mouse Model of Breast Cancer. M. M. Reinholz*[1], G. Reinholz[1], L. Jonart*[1], T. Yoneda[2], T. Spelsberg[1], W. Lingle*[1], M. Karpeisky*[3]. [1]Mayo Clinic College of Medicine, Rochester, MN, USA, [2]University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [3]MBC Research Inc., Boulder, CO, USA; Engelhardt Institute of Molecular Biology, Russian Academy of Sciences, Moscow, Russian Federation.

Metastatic bone disease is one of the major causes of morbidity and mortality in breast cancer patients. Bisphosphonates are currently used as effective bone-specific palliative treatments to reduce tumor-induced skeletal complications. We developed novel proprietary nucleotide-bisphosphonate conjugates, which were designed to bind bone with subsequent release of both drugs. We recently reported that the novel bisphosphonate analog, the anhydride formed between arabinocytidine (Ara-C) 5'-phosphate and etidronate, MBC-11, was the most potent inhibitor of in vitro MDA-MB-231 cell proliferation compared to Ara-C, etidronate, pamidronate and zoledronate alone. In this pilot study, we examined the in vivo effects of four conjugates, including MBC-11, the anhydride formed between medronate and Ara-C 5'-phosphate (MBC-29), and the anhydrides formed between 5-fluorouridine (5FU) 5'-phosphate and etidronate and medronate (MBC-1 and MBC-9, respectively) as well as zoledronate on bone tumor burden in mice orthotopically inoculated with 4T1/luc mouse tumor cells. These mice develop primary breast tumors, visceral organ metastases, as well as spontaneous bone metastases by 21 days after cell inoculation. Death typically occurs by day 28. Forty-four percent (8/18) of the mice treated daily with 0.04 μg of the novel conjugates did not have detectable bone metastases as measured by luciferase content in the tibiae and femurs of mice sacrificed at day 21 or 22. No luciferase activity was observed in the bones from 67% of these animals treated with MBC-11 (4/6) and MBC-29 (2/3). The bone luciferase content in the remaining three animals was below the average luciferase content in animals treated with zoledronate (0.04 μg, n = 2) and PBS (n = 6). In addition,we used histomorphometry to determine the percent bone volume in the femurs from endstage animals. Bone volume was approximately two-fold higher ($p < 0.001$) in animals treated with the 5FU conjugates (n = 14) and two-three-fold higher ($p < 0.001$) in animals treated with Ara-C conjugates (n = 11) compared to the animals treated with PBS (n = 9). As a positive control, bone volume was significantly increased (approximately 4-fold) in animals treated with zoledronate (0.04 μg; n = 3). In summary, our data suggest that these novel nucleotide-bisphosphonate conjugates are effective at decreasing metastatic bone tumor burden in mice inoculated with mouse breast cancer cells.

Smad4 Induced Apoptosis in Estrogen Receptor α Positive Cells. Q. N. Li, L. Wu*, Y. Wu*, N. Wang*, X. Shi, H. Chen*, X. Cao. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

Estrogens regulate differentiation and maintenance of reproductive, skeletal and other tissues by activating their estrogen receptors (ER). Estrogens also act as mitogens to promote cell proliferation in both normal breast tissue and breast carcinomas. In contrast, TGFβ is an inhibitor of cell cycle progression in epithelial cells and antagonizes the effects of ERα mitogenic effect. We have identified that Smad4, a common TGFβ signal transducer, functions as an ER transcriptional corepressor. In this study we found that Smad4 induces apoptosis in ERα positive breast cancer cells, but not in ERα negative cells, suggesting an a potential function of the interaction between Smad4 and ERα. MCF-7 ERα positive and MDA-MB-231 ERα negative cells were infected with a retrovirus encoding Smad4. Hoechst 33342 staining and Flow Cytometry analysis showed that Smad4 induced significant apoptotic cells in MCF-7 , not in MDA-MB-231 cells, within 48h of infection. Furthermore, stable Smad4 expression induces proapoptosis marker protein expression including BIM and Bax in MCF-7, again not in MDA-MB-231 ERα negative cells. To confirm that ERa is required, we expressed ERα siRNA in MCF-7 cells, which significantly reduced Smad4-induced Bax expression, cytochrome-C release and apoptosis. For the same purpose, ERα was stably introduced in MDA-MB-231 cells with retrovirus, and Smad4 was able to induce apoptosis MDA-MB-231 cells with acquired ERα expression. These results indicate that ERα is required for Smad4-induced cell apoptosis.

We then examined whether Smad4 also induces apoptosis in ERα positive cells in nude mice. MCF-7 ERα positive and MDA-MB-231 ERα negative cells were stably transfected with Smad4 or Green Florence Protein (GFP), and were inoculated in nude mice. The tumor volumes were measured every two days. The tumor sizes of MCF-7 breast cancer cells stably transfected with Smad4 are only one tenth of those expressing GFP, and Tunnel assays showed apoptosis positive cells were significantly induced in Smad4 tumor xenograft compared with its GFP control. Whereas in MDA-MB-231, tumor sizes in Smad4 transfected cells are not significantly different from GFP transfected cells. These tumor xenografts were further analyzed Western blot and immunihistochemical stain for apoptotic biomarkers, which showed that MCF-7 with Smad4 expression induced proapoptosis protein expression including BIM and Bax, but induction of these proapoptotic markers was not observed in nude mice bearing MDA-MB-231 tumor xenografts. These results indicate that presence of ERα is required in Smad4 inducing apoptosis in breast cancer cells. Therefore, our findings may provide a potential therapeutic intervention for breast cancer.

Targeting Skeletal Metastases in Prostate Cancer with a Novel VEGF121 Fusion Toxin. A. T. Poblenz*, K. Mohamedali*, M. G. Rosenblum*, B. G Darnay*. Experimental Therapeutics, University of Texas M.D. Anderson Cancer Center, Houston, TX, USA.

Osteolysis that accompanies bone metastasis is a major cause of morbidity, often resulting in severe bone pain and susceptibility to fractures, and results in a significant decline in the quality of life of cancer patients with bone disease. Bone destruction is primarily mediated by osteoclastic bone resorption and cancer cells that have metastasized to bone stimulate the formation and activation of osteoclasts adjacent to metastatic foci. The progression of osteolytic metastases itself is a result of complex interaction between tumor cells, osteoclasts, osteoblasts, and the many factors in the bone microenvironment. There are numerous cytokines involved in tumor growth, neovascularization and bone resorption. Vascular endothelial growth factor-A (VEGF-A) and its cognate receptors Flt-1 and Flk-1/KDR have been identified as central mediators of tumor neovascularization. We previously developed a novel fusion construct designated VEGF121/rGel, composed of VEGF121 and the plant toxin gelonin, which targets the tumor neovasculature and exerts impressive cytotoxic effects by inhibiting cellular protein synthesis in target cells. We have previously shown that in vivo administration of this molecule inhibits tumor growth in melanoma, bladder, breast, and prostate tumor xenograft models. Treatment of mice (iv) bearing PC-3 intrafemoral tumor xenografts with VEGF121/rGel was shown to dramatically suppresses PC-3 skeletal metastases. All control mice were sacrificed by day 67. In contrast, 50% of the VEGF121/rGel-treated mice survived past day 140 without any sign of osteolysis. VEGF and its receptors participate in the complex process involved in tumor-directed bone resorption; however, their roles have not been identified. We have investigated the direct effect of VEGF121/rGel on differentiation of RAW cells and mouse bone marrow-derived monocytes (BMM). VEGF121/rGel was shown to inhibit RANKL-mediated osteoclastogenesis. The observed effect was not mediated by either VEGF121 or gelonin alone, but is a characteristic unique to the combined fusion protein. While immunofluorescence studies clearly show VEGF121/rGel penetration into RAW cells, the receptor responsible for mediating the cellular entry of VEGF121/rGel is unknown. Preliminary data indicate that VEGF121/rGel most likely inhibits the growth of mouse BMM through an unknown mechanism in vitro. These studies demonstrate the best combined therapy for prostate cancer metastases in which one agent provides both a multi-modal attack targeting the blood supply feeding the tumors and the osteoclast precursors which are instrumental in developing lytic bone lesions.

The Bone Mineral Density in Childhood Study (BMDCS): Substudy Comparing DXA and CT Vertebral Bone Measurements in Healthy Children and Adolescents. T. A. L. Wren[1], V. Gilsanz[1], P. Pitukcheewanont[1], X. Liu*[1], M. Horlick[2], J. M. Lappe[3], H. Kalkwarf[4], B. S. Zemel[5], S. Mahboubi[5], J. A. Shepherd[6], M. M. Frederick[7], K. Winer[8]. [1]Childrens Hosp Los Angeles, LA, CA, USA, [2]St. Luke's-Roosevelt Hosp, NY, NY, USA, [3]Creighton Univ, Omaha, NE, USA, [4]Childrens Hosp Med Ctr, Cincinnati, OH, USA, [5]Childrens Hosp of Philadelphia, Philadelphia, PA, USA, [6]University of Calif San Francisco, SF, CA, USA, [7]Clinical Trials & Surveys Corp, Baltimore, MD, USA, [8]NICHD, Rockville, MD, USA.

The BMDCS was designed to establish reference standards for bone mineral density (BMD) in healthy children in the U.S., and the purpose of this substudy was to optimize pediatric bone measurements using DXA. Comparisons were made between DXA and CT values for bone mineral content (BMC) and BMD in a subgroup of 64 boys and 60 girls, ages 6-17 yr, who participated in the BMDCS and had bone measurements using both techniques. Chronological age, height, weight, body mass index (BMI), skeletal age and Tanner stage of sexual development were recorded. DXA BMC (g) and areal aBMD (g/cm^2), CT volumetric vBMD (mg/cm^3), vertebral cross-sectional area, vertebral height and vertebral volume of the lumbar spine were obtained. CT-BMC was calculated by multiplying vertebral density and vertebral volume. Volumetric densities were estimated from DXA measurements using published correction factors [vBMD1=aBMD/sqrt(DXA-area); vBMD2=aBMD/bone height]. Linear regression was used to compare DXA-BMC vs. CT-BMC and CT-vBMD vs. DXA aBMD, vBMD1, and vBMD2. Multiple regression including the anthropometric measures was also performed. There was excellent agreement between DXA-BMC and CT-BMC (r^2=.94). There was only moderate agreement between DXA aBMD and CT vBMD (r^2=.39). Geometric corrections to calculate DXA volumetric densities resulted in only slight improvement in the correlations with CT density (r^2=.49 for vBMD1; r^2=.55 for vBMD2). Accounting for age, height, weight, BMI, Tanner stage, and skeletal age improved the agreement between DXA aBMD and CT vBMD to r^2=.91, lower than the agreement for BMC. In conclusion, measurements of DXA-BMC were very accurate when compared with CT-BMC. This suggests that inclusion of the posterior elements by DXA and the effects of soft tissue distribution were not significant for the healthy children in this study who were all in the 3rd to 97th percentiles for height, weight, and BMI. In children of more extreme body size, fat and soft tissue distribution may contribute to greater errors. Much greater variability occurred when BMDs were compared, even when corrections for the DXA beam direction were employed, suggesting that BMC may be a more accurate and reliable measure for assessing bone properties in pediatrics when using DXA.

Prediction of Non Vertebral Osteoporotic Fracture Risk by High Resolution Peripheral Quantitative Computerized Tomography (hrpQCT) of the Distal Radius or Tibia in a Sample of 953 Elderly Ambulatory Swiss Women. M. A. Dambacher[1], M. Neff[2], P. Pancaldi*[3], M. Krieg*[4], P. Burckhardt[4], J. Cornuz*[4], R. Kissling*[5]. [1]Rheumatology and Rehabilitation, University Clinic Balgrist, Zürich, Switzerland, [2]Center for Osteoporosis, Zürich, Switzerland, [3]Osteoporosis Center, Locarno, Switzerland, [4]CHUV Hospital Cantonal, Lausanne, Switzerland, [5]Dept. of Rheumatology and Rehabilitation, University Clinic Balgrist, Zürich, Switzerland.

As a part of the SEMOF (Swiss Evaluation of Methods of Osteoporotic Fracture Risk) study, 1'046 women aged 75.5 ± 3.2 years (mean ± SD) have been measured with the hrpQCT system (Densican 1000, Scanco Medical, Zürich, Switzerland).

From the 1'046 women included in the study, 953 women, have been prospectively followed by 6 monthly questionnaires during a mean follow-up of 2.9 years, which represents a global follow-up of 2'730 women-years.

The measurement site was the non dominant distal radius (n=942). The 2 centers of Zürich also measured the non dominant distal tibia (n=723). 3 regions of interest were considered: D50 (trabecular bone, central area), D100 (total area); D100-50 (cortical bone, peripheral area).

During the follow-up, non vertebral osteoporotic fractures were recorded. Were considered: low trauma hip fractures, and fractures of the forearm or of the humerus. Each reported fracture was confirmed by the family physician or the hospital in charge of the patient. During the whole follow-up, 44 low trauma non vertebral fractures were recorded. Statistical analysis were performed on Stata 7.0 software.

For the whole variables, the mean absolute values were significantly lower ($p<0.01$) in the group of women who reported an incident low trauma non vertebral fracture than in the group of women without any fracture.

All variables were predictive of low trauma non vertebral fracture risk

The prediction value was lower when measuring cortical site (D100-50) at the radius or at the tibia compared with the prediction value of D100 ($p<0.05$).

Mean baseline values. Comparison between non fractured and fractured women (Student's t-test).

	No incident fracture group		Incident fracture group	
	n	Mean ± SD	n	Mean ± SD
Radius				
D50 (g/cm^3)	898	195.3 ± 75.5	44	155.0 ± 63.3**
D100 (g/cm^3)	898	427.3 ± 98.0	44	378.2 ± 77.7**
D100-50 (g/cm^3)	898	659.2 ± 143.8	44	601.4 ± 114.0**
Tibia

Utility of Densitometric Vertebral Fracture Assessment in Men. N. Vallarta-Ast, D. Krueger, N. Binkley. University of Wisconsin, Madison, WI, USA.

Vertebral fracture assessment (VFA) using bone densitometers is an excellent means to detect unappreciated vertebral compression fracture in women. However, little evaluation of VFA utility in men has been performed. This study evaluated applicability of VFA in a population of men referred for clinically indicated bone mineral density (BMD) measurement at the Wm. S. Middleton VAMC. Additionally, we explored potential VFA indications in men and, in those with no known prior low-trauma fracture, compared osteoporosis prevalence diagnosed by BMD alone and combined with VFA. In 139 men, mean age, weight and BMI of 68 years, 190 pounds and 27.9 kg/m^2, scans of the spine, hip, non-dominant forearm and lateral vertebral assessment images were obtained by one technologist using a GE Medical Systems Lunar Prodigy densitometer. Vertebral fractures were conservatively defined as being grade 2 or 3 (> 25% height reduction) using the Genant visual semi-quantitative method. We considered that height loss, BMD, age or standing occiput to wall distance (OWD) might be useful to define men in whom VFA is indicated. Of 1807 potentially evaluable vertebral bodies (T4-L4) 1436 (79%) were adequately visualized on VFA. Most non-evaluable vertebrae were from T4-T7; 91% of vertebral bodies from T8-L4 were adequately visualized. In these 139 men, grade 2 or 3 vertebral fractures were present in 47 (34%). Height loss of > 2 inches was associated with a greater ($p < 0.001$) likelihood of prevalent vertebral fracture on VFA. When reported height loss was 2.5 inches or greater, vertebral fracture was present in 52% (24/46). However, vertebral fractures were present in 26% (19/73) of men with height loss < 2 inches. Older men (age > 69 years) and those with low BMD (T-score < -1.5 at the spine or hip) were more likely ($p < 0.001$) to have fractures on VFA. Kyphosis was not a reliable predictor of vertebral fracture. Though 45% (13/29) of men with more than a 3 inch OWD had vertebral fractures, 25% (15/59) with no kyphosis (< 1 inch OWD) were found to have prevalent fracture on VFA. Fifty-two men reported having no prior fracture. In these men, VFA identified vertebral fracture in 23 increasing osteoporosis diagnosis from 39% with BMD alone to 78% using a T-score of < -1.5 plus VFA documented fracture.

In conclusion, VFA allows evaluation of the majority of vertebral bodies in men and identifies a substantial number with unappreciated fracture. As could be expected, older men (age > 69) and those with low BMD (T-score < -1.5) were more likely to have prior vertebral fracture. In this population, absence of height loss and kyphosis, defined by occiput to wall distance, do not preclude presence of vertebral fracture.

Disclosures: ***N. Vallarta-Ast****, None.*

F112

Fall Index Predicts Hip Fracture Independent of Bone Density and Hip Axis Length. K. G. Faulkner[1], W. K. Wacker*[1], C. Simonelli[2], P. K. Burke[3], S. Ragi[4], L. Del Rio[5]. [1]GE Healthcare, Madison, WI, USA, [2]HealthEast Clinics, Woodbury, MN, USA, [3]Osteoporosis Diagnostic and Treatment Center, Richmond, VA, USA, [4]4Centro de Diagnóstico e Pesquisa da Osteoporose do Espírito Santo, Vitoria, Brazil, [5]Densitometría Ósea, CETIR Centre Médic, Barcelona, Spain.

Femur BMD is a primary determinant of hip fracture risk. However, fracture risk also depends on patient age, height, weight, and factors such as bone structure and distribution. Femoral structural parameters, including hip axis length (HAL), cross sectional moment of inertia (CSMI) and cross sectional area (CSA) can be measured with newer bone densitometers. Fall Index (FI) combines density, structure (CSMI and CSA), age, height and weight to estimate the ability of a hip to withstand a fall on the greater trochanter. We compared femur BMD with CSMI, CSA and FI for assessing hip fracture risk.

DXA scans were obtained in 2406 women, 365 with prior hip fracture and 2041 controls using Lunar Prodigy (GE Healthcare) systems at 4 centers. The non-fractured femur was measured in fracture subjects. All scans were acquired and analyzed at the densitometry centers. Femur neck BMD and HAL were determined, as well as CSMI and CSA with the Lunar Hip Strength Analysis program. The FI is the ratio of a patient's estimated femoral strength (based on age, bone density and structure) and the expected force of a fall on the greater trochanter (based on height and weight). Larger FI values indicate greater femoral strength, corresponding to lower fracture risk. BMD, structure and FI measures were compared between fracture and control groups using an unpaired t-test, and logistic regression models were used to calculate odds ratios for hip fracture.

Age-adjusted femur neck BMD was significantly lower and HAL significantly higher in the fracture group vs. controls. After adjustment for BMD and HAL, neither CSMI nor CSA were significantly different between groups. However, FI was significantly lower in the fracture group, consistent with a reduced capacity to withstand a fall. Odds ratios by logistic regression were BMD 2.0, HAL 1.3, and FI 1.5 per standard deviation change in each measurement.

We conclude that the Fall Index and HAL are significant predictors of hip fracture, even after adjustment for BMD. Measurements of CSMI and CSA, which are based on BMD distribution, do not provide additional predictive power compared to BMD alone.

	Age	Height	Weight	Neck BMD	HAL	CSMI	CSA	FI
Fracture	71 yrs	156 cm	63.0 kg	0.722 g/cm^2*	103 mm*	8186	109 mm^2	1.34*
Controls	66 yrs	156 cm	64.0 kg	0. 812 g/cm^2	101 mm	8302	120 mm^2	1.56

*Significantly different than controls (p<0.0001)

Enzyme Immunoassay for Cathepsin K in Human Serum and Cell Culture Supernatants. G. Hawa*[1], N. Brinskelle-Schmal*[1], S. Maitzen*[1], M. Skoumal*[2], G. Kolarz*[2], W. Woloszczuk[1]. [1]Research & Development, Biomedica, Vienna, Austria, [2]Institut für Rheumatologie der Kurstadt Baden in Kooperation mit der Donauuniversität Krems & Rheumasonderkrankenanstalt der SVA der gewerblichen Wirtschaft, Baden, Austria.

Cathepsin K is a cysteine protease, which is highly expressed in Osteoclasts when they actively resorb bone. This enzyme has been shown to cleave a number of bone matrix proteins including collagen type I, II, and osteonectin. So it is widely accepted, that Cathepsin K plays an important role in bone remodelling, which is also supported by the finding, that Osteoclasts derived from Cathepsin K deficient mutant mice are predominantly mononuclear, do not form ruffled borders, and resorb bone poorly. Therefore Cathepsin K is an attractive target for the treatment of several diseases with pathologically elevated bone resorption like osteoporosis, rheumatoid arthritis and osteolytic bone metastasis. It also may become a new and highly specific biomarker of those diseases.

We have developed an ELISA for measuring Cathepsin K levels in human serum and cell culture supernatants. The calibration curve was set from 0-300pmol/l and the analytical detection limit was determined as 1.1pmol/l. The required sample volume was 50µl serum or cell culture supernatant. Intra- and Interassay CVs ranged from 4-6% and 6-8% respectively. Incubation was performed over night at room temperature. No cross-reactivity to the structurally related Cathepsins E,D,B and L was detected. The high homology of Cathepsin K across various species (mouse 86%, rat: 88%, pig: 97%, rabbit: 96%) should allow the use of this assay for studies in animal models for those diseases The assay was used to investigate serum samples from patients with rheumatoid arthritis and from a healthy control group. We found significantly elevated levels in rheumatoid arthritis (median 54.8 pmol/l). compared to the control group (median 8.7 pmol/l). We found no interference caused by rheumatoid factors. This data indicate, that as a specific marker enzyme for osteoclast activity, our Cathepsin K ELISA will be a valuable tool for bone research. Together with the determination of OPG and sRANKL it will add to our insights into the mechanism of bone resorption.

Prediction of Fracture Risk in 5195 Postmenopausal Women from Spain by Quantitative Ultrasound of the Calcaneus: 18 Months Interim Results from the ECOSAP Prospective Study. J. González-Macías[1], F. Marín[2], J. Vila*[3], D. Martín*[4], C. Alfonso*[5], P. Benavides*[6], J. Pozuelos*[7], F. Chavida*[8], J. Pérez*[9], J. Granados*[10]. [1]Internal Medicine, H. U. Valdecilla, Santander, Spain, [2]Medical Research, Eli Lilly and Company, Madrid, Spain, [3]IMIM, Barcelona, Spain, [4]C.S. Torredelcampo, Jaén, Spain, [5]C.S. San Andrés, Murcia, Spain, [6]C.S. Pumarín, Oviedo, Spain, [7]C.S. de la Paz, Badajoz, Spain, [8]C.S. Brihuega, Guadalajara, Spain, [9]C.S. Estación, Talavera, Toledo, Spain, [10]C.S. Guayaba, Madrid, Spain.

Bone quantitative ultrasound (QUS) is known to discriminate subjects with fracture history. Several prospective studies have also shown that QUS are predictive of osteoporotic fractures with a similar magnitude to DXA. ECOSAP is a 3-year prospective study to evaluate the ability of calcaneus QUS and several clinical risk factors of osteoporosis and fractures, to predict the non-vertebral fracture risk in women ≥ 65 years recruited in 58 Primary Care Centers in Spain. 5195 women aged 72.3±5.3 years (mean±SD) were assessed with a Sahara® equipment. Women were selected using non-probabilistic sampling of consecutive cases regardless of the reason for consultation. At baseline, 1042 women (20.1%) presented a history of fragility fracture in adulthood (>35 years)**.** We report here the results after 4705 women have completed the 18-month follow-up visit. During the mean 17.8 months follow-up, 194 non-osteoporotic fractures in 170 women were reported. A logistic regression analysis with QUS parameters as the dependent variable was performed. Independent variables included were all those with a p value < 0.15. The final model consisted of age, history of falls, prevalent fractures, and chronic airway disease (COPD + asthma). The hazard rates (and 95% CI) per SD decrease of each QUS parameter after adjusting for them are shown in the Table.

Type of fracture (number)	All non-vertebral (n=170)	Forearm (n=65)	Hip (n=23)	Humerus (n=28)
BUA	1.32 (1.11 ; 1.56)	1.54 (1.16 ; 2.04)	1.50 (0.95 ; 2.36)	1.32 (0.87 ; 1.99)
SOS	1.19 (1.04 ; 1.36)	1.34 (1.13 ; 1.59)	1.08 (0.73 ; 1.62)	1.14 (0.81 ; 1.61)
QUI	1.33 (1.12 ; 1.58)	1.67 (1.24 ; 2.25)	1.24 (0.79 ; 1.96)	1.34 (0.88 ; 2.04)
Estimated heel BMD	1.32 (1.11 ; 1.57)	1.64 (1.22 ; 2.21)	1.25 (0.79 ; 1.97)	1.34 (0.88 ; 2.06)
Estimated heel BMD (T-score)	1.30 (1.10 ; 1.53)	1.64 (1.24 ; 2.16)	1.32 (0.83 ; 2.04)	1.34 (0.90 ; 2.00)

Values are Hazard Rate (95% CI)

The interim results of the ECOSAP study show that QUS of the heel is a predictor of non-vertebral osteoporotic fractures in a cohort of elderly Spanish women.

Disclosures: ***J. González-Macías****, None.*

Bone Strength Is Regulated Predominantly by Genetic Loci that Regulate Bone Geometry. J. E. Wergedal[1], C. L. Ackert-Bicknell[2], S. Tsaih*[2], M. H. Sheng[1], W. G. Beamer[2], G. A. Churchill*[2], D. J. Baylink[1]. [1]JL Pettis VA Medical Center and Loma Linda Univ., Loma Linda, CA, USA, [2]Jackson Laboratory, Bar Harbor, ME, USA.

Bone strength is reduced in osteoporotic subjects to the extent that fractures begin to occur. Identifying the factors that can affect bone strength and potentially alter fracture incidence is very important. Previous studies have shown that bone geometry, bone density and bone quality are all important factors that affect bone strength. There is evidence that geometry and density are influenced by genetic mechanisms involving polygenic traits. We hypothesize that bone strength is regulated by genetic loci that influence bone geometry, density and quality. Inbred strains of mice are amenable to genetic analysis of these traits via the experimental design of quantitative trait loci (QTL) analysis. We have applied this approach to an F2 cross of the RF/J and NZB/B1nJ inbred mouse strains. These two strains differ widely in femur bending strength. The F2 progeny (737 mice) have been genotyped for 89 genome-wide markers and phenotyped for femur bending strength, cross sectional geometry, vBMD, material (m)BMD. QTL analysis was carried out with the Pseudomarker Package, version 1.02.

Table 1 Major QTL for bone strength, cross sectional geometry, and density.

Chrom.	Distance (cM)	Strength LOD	Geometry LOD	vBMD LOD	mBMD LOD
4	65	4.1	5.5	-	3.8
5	50	6.4	10.4	-	-
7	55	3.1	10.3	4.1	-
11	65	4.4	26.8	-	-
12	5	9.6	9.7	-	-

A total of 8 strength QTL were identified, and only one was not associated with a cross sectional geometry QTL. Four additional geometric QTL were found that were not associated with strength QTL. Of the strength QTL only 2 were associated with BMD QTL and those 2 were also associated with geometric QTL. There were 4 additional density QTL; and those were also associated with geometric QTL. Body weight QTL were also determined to test whether they were associated with strength QTL. Only 3 of the 8 strength QTL were associated with body weight QTL and only 2 of these 3 strength QTL had decreased significance when body weight was included as a covariate in the QTL analysis. Including body weight in the analysis did decrease 2 of the other strength QTL, but increased the significance of 2 of others. Conclusion: 1) Femur strength, cross sectional geometry and density are polygenic traits. 2) Bone Strength is regulated predominantly by genetic loci that regulate bone geometry. 3) Genetic regulation of bone strength is largely independent of body weight.

Whole-Genome Scan for Linkage to Bone Strength and Mineral Density in Inbred Rats. I. Alam[1], Q. Sun[1], L. Liu*[2], D. L. Koller[2], T. M. Fishburn*[3], M. J. Econs[3], T. Foroud[2], C. H. Turner[1]. [1]Orthopaedic Surgery, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA, [3]Medicine, Indiana University School of Medicine, Indianapolis, IN, USA.

Bone mineral density (BMD) and bone biomechanical properties are major determinants of osteoporosis. Genetic analyses in inbred mice and humans have identified several chromosomal regions linked to BMD, bone structure and biomechanics. However, the key genes that influence these phenotypes have not yet been identified. Rats are the most commonly used animal model for skeletal research. One of these rat strains, the Fischer (F344) has been shown to develop osteopenia similar to humans. Previously, we reported that compared to Lewis (LEW) rats, Fischer (F344) rats have significantly lower ($p<0.001$) bone strength and BMD both at the femur and spine. In this study, we seek to identify chromosomal regions that contain quantitative trait loci (QTLs) underlying variation in BMD, bone geometry and biomechanical properties in a sample of 595 F344 X LEW F2 rats. A genome screen was performed using 100 microsatellite markers at an average density of 20 cM. Skeletal phenotypes were measured by peripheral quantitative computed tomography (pQCT) and dual energy x-ray absorptiometry (DXA). Femoral and spinal biomechanical tests were performed using an MTS machine. Genetic marker maps were estimated from our own data and compared with published maps. These maps were then used to detect QTLs using interval mapping methods (MAPMAKER/QTL). Our results indicate that several chromosomal regions harbor QTLs for bone strength and BMD. The main QTLs and their synteny to a known QTL region in mice and human are summarized in the following Table.

Marker	Phenotype	LOD score	Mouse Synteny	Human Synteny
D1Rat136	Lumbar BMD	8.7	17, Whole body BMD and femoral structure	5q, Femur BMD and structure
D1Rat256	Femur BMD	7.4	17, Whole body BMD and femoral structure	5q, Femur BMD and structure
D2Rat67	Femur BMD Polar moment of inertia (Ip)	7.2 7.5	3, Femur BMD	1p, Whole body and lumbar BMD
D4Rat193	Polar moment of inertia (Ip)	7.5	6, Femur BMD and strength	3p, Femoral structure and spinal BMD
D5Rat159	Polar moment of inertia (Ip) Ultimate Force	8.3 6.9	4, Femur and lumbar BMD	1p, Whole body and lumbar BMD
D7Rat64	Polar moment of inertia (Ip)	10.9	10, Femoral structure and biomechanics	19p, Femoral structure

Our results provide evidence of new QTLs for bone strength and biomechanical properties as well as several QTLs syntenic to those previously identified in other species. These studies provide essential data for identification of genes that affect bone density and strength.

Interaction Between Polymorphisms of the Low Density Lipoprotein Receptor-Related Protein 5 (LRP5) Gene and Physical Activity on Bone Mineral Density (BMD): The Framingham Offspring Study. D. P. Kiel[1], A. G. Herbert*[2], S. L. Ferrari[3], L. A. Cupples*[4], D. Karasik[1], A. Imamovic*[2], J. Dupuis*[4]. [1]Heb Rehab Ctr for Aged, Boston, MA, USA, [2]Framingham Heart Study Genetics Lab, Boston Univ, Boston, MA, USA, [3]Div of Bone Diseases, Geneva Univ Hosp, Geneva, Switzerland, [4]Dept Statistics, Boston Univ Sch Pub Health, Boston, MA, USA.

Mutations in the LRP5 gene result in different single gene disorders with either high or low BMD. In mice, the LRP5 gene may be involved in bone adaptation to mechanical load, yet little information exists regarding the contribution of the LRP5 gene to BMD in the general population, nor the possibility of interaction between variants in this gene, physical activity, and BMD. Therefore, we genotyped 9 single nucleotide polymorphisms (selected tag SNPs to account for at least 80% of the common haplotypes for each of three LRP5 blocks previously identified) in LRP5 and tested for their association with hip (neck, troch, wards) and spine BMD in unrelated women and men from the Framingham Offspring Study. There were 695 men (mean age 62±9) and 747 women (61±9) in the sample. We hypothesized a priori that SNPs in LRP5 would be associated with BMD, especially in younger men (≤ 60 yrs of age). We coded SNP genotypes as the number of minor alleles (0,1,2) and used an additive model for genotype effect in combined sexes as well as within sex, in younger (age ≤60) males, and in pre- and post-menopausal women. From the 9 SNPs examined, two exonic missense mutations in H-W equilibrium (G2047A in exon 9 and C4037T in exon 18) yielded significant associations with BMD in men ≤ 60 yrs of age when using linear regression, adjusting for age, age squared, sex, wt, physical activity (using the Physical Activity Scale for the Elderly (PASE)), and in women, use of estrogen. Femoral neck BMD was lower the greater the number of A alleles in G2047A ($p=0.07$) and T alleles in C4037T ($p=0.01$) in males aged ≤ 60 years. Similar findings were observed for Wards BMD ($p<0.02$ both SNPs) and for spine BMD ($p=0.06$ C4037T only) in these males). The rs312016 intronic SNP in haplotype block 1 was associated with BMD at all hip sites in premenopausal women, with TT homozygotes having greater BMD than CC. There was also a significant interaction between exon18 T-allele count and PASE on spine BMD in males ($p=0.002$) such that the benefit of higher PASE values on BMD decreased with the number of T alleles.

We conclude that variation in two exonic missense mutations in the LRP5 gene was associated with BMD in men ≤ 60 yrs of age, and that the effect of these variants modifies the influence of physical activity on BMD. These findings support a role for the LRP5 gene as a contributor to BMD in the general population and potentially in the adaptation of bone to mechanical load.

Catechol-*O*-methyltransferase Is a Physiological Regulator of Longitudinal Bone Growth and Cortical Bone Dimensions both in Female Mice and in Pubertal Girls. A. Eriksson[1], M. Forsberg*[2], P. T. Männistö*[2], C. Ohlsson[3]. [1]Division of Clinical Pharmacology, Department of Internal Medicine, Göteborg University, Göteborg, Sweden, [2]Department of Pharmacology and Toxicology, University of Kuopio, Kuopio, Finland, [3]Center for Bone Research at the Sahlgrenska Academy, Department of Internal Medicine, Göteborg University, Göteborg, Sweden.

Estrogen is of vital importance for normal pubertal growth in humans as well as in mice. Catechol-*O*-methyltransferase (COMT) is a key enzyme in the degradation of estrogens. A functional polymorphism in the *Comt* gene (val158met) decreases the activity of the enzyme by 60-75%. We have previously shown that early pubertal girls who are homozygous for the low activity COMT genotype ($COMT^{LL}$) are taller and have an increased cortical thickness as well as an increased cortical BMC, and higher serum levels of bioavailable estrogens compared with girls homozygous for the high activity COMT genotype ($COMT^{HH}$). The aim of the present study was to investigate whether young female *Comt* gene disrupted ($COMT^{-/-}$) mice exhibit a similar bone phenotype as girls with the low activity $COMT^{LL}$ genotype.

Femurs of 70 days old female $COMT^{-/-}$ mice and wild type ($COMT^{+/+}$) littermates were analyzed using peripheral Quantitative Computerized Tomography. $COMT^{-/-}$ mice had longer femurs than wild type mice ($p<0.001$). Cortical thickness was increased by 7.0 % ($p<0.01$) in $COMT^{-/-}$ mice compared with wild type mice. This was due to a decreased endosteal circumference, while periosteal circumference did not differ between the two genotypes. Moreover, cortical volumetric BMD was increased by 3.7% in $COMT^{-/-}$ mice ($p<0.01$).

In conclusion, our results demonstrate that $COMT^{-/-}$ mice have a bone phenotype which is similar to that of young girls with the $COMT^{LL}$ genotype, characterized by an increased longitudinal bone growth and cortical thickness. Our findings indicate that in female mice as well as in early pubertal girls, COMT is an important regulator of growth velocity during puberty. However, further studies are needed to investigate the role of COMT genotype in adult stature and bone phenotype.

Osteoprotegerin Genetic Variants Are Associated with Both Susceptibility to Rheumatoid Arthritis and Rate of Joint Erosion. S. Steer*[1], L. J. Miles*[2], B. Lad*[1], J. Grumley*[1], a. National Repository*[3], M. A. Brown*[2]. [1]Kings College London, London, United Kingdom, [2]Botnar Research Centre, University of Oxford, Oxford, United Kingdom, [3]arc Epidemiology Unit, Manchester, United Kingdom.

Purpose: We have recently demonstrated that variation in the osteoprotegerin (OPG) gene influences bone density and serum OPG levels. OPG is known to have major effects on osteoclast activity and differentiation, as well as on T- and B-lymphocyte differentiation and activation. The aim of this study was to examine whether *OPG* sequence variation could influence either susceptibility to rheumatoid arthritis (RA) or the severity of erosive disease.

Methods: Eight haplotype-tag SNPs within *OPG* were genotyped in 295 RA affected sibling pair families from the arc National Repository, and in 300 Caucasian cases from London in whom Larsen scores and disease duration were available. Nonparametric linkage analysis was performed using MERLIN. TRANSMIT was used for single marker and two marker TDT analysis, with p-values calculated by bootstrap simulation. PHAMILY and PHASE were used to construct phase known/estimated haplotypes for the non-familial cases; only haplotypes with >90% certainty were analysed. ANOVA was used to test global association of markers and haplotypes with Larsen scores adjusted for gender and disease duration; Dunnett's post-hoc test was used to assess association of individual haplotypes where global association was observed.

Results: 'Nominal' linkage was detected across the locus with a multipoint LOD score of 1.3 ($P=0.007$). Association was noted with the single marker IVS2+4 ($P=0.003$), with over-transmission of the major allele (IVS2+4*1). Considering the haplotype of this marker with a neighbouring SNP, IVS2+1256, global association was observed $P=0.04$), with highly significant under-transmission of the haplotype IVS2+4*1/IVS2+1256*2 ($P=0.003$), and over-transmission of haplotype IVS2+4*1/IVS2+1256*1 ($P=0.02$). Association of a two-marker haplotype E1+9/E1-142 was also observed ($P=0.03$), with over-transmission of the major haplotype E1+9*1/E1-142*1 ($P=0.007$). The SNPs IVS2+4 and IVS2+1256 were also associated with disease severity as assessed by adjusted Larsen score. SNP IVS2+4 was globally associated with $P=0.02$, and the haplotype IVS2+4/IVS2+1256 with $P=0.05$. Posthoc tests showed that the under-transmitted haplotype IVS2+4*1/IVS2+1256*2 was associated with less erosive change than other haplotypes ($P<0.05$).

Conclusion: Genetic variation in *OPG* affects both susceptibility to and rate of erosive change in RA.

T Cells Suppress Physiological Bone Resorption In Vivo by Stimulating the B Cell Production of Osteoprotegerin. Y. Li*[1], G. Toraldo[2], H. Zhang[1], W. Qian*[1], R. Pacifici[1], M. N. Weitzmann[1]. [1]Division of Endocrinology & Metabolism & Lipids, Emory University School of Medicine, Atlanta, GA, USA, [2]Division of Bone & Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA.

Activated T cells secrete RANKL and TNF causing bone destruction in models of estrogen deficiency and rheumatoid arthritis. We have reported that nude mice, a model of T cell deficiency, are protected from ovariectomy induced bone destruction and that reconstitution of T cells restores bone loss. However, paradoxically nude mice also exhibit significantly decreased baseline bone mineral density (BMD), suggesting that the absence of T cells may also lead to bone destruction during physiological bone turnover. We have now examined physiological bone modeling in nude mice and elucidated a potential mechanism to explain the protective effects of T cells on bone mass under physiological conditions. Our data verifies decreased BMD and indices of bone mass in nude mice, and demonstrate the presence of enhanced numbers of osteoclasts in nude mouse tibias. Serum C-terminal telopeptide was significantly elevated in nude mice in the face of unchanged levels of serum osteocalcin. This data suggests that bone resorption is uncoupled from bone formation in nude mice leading to enhanced osteoclastic bone resorption. As T cells have been reported to stimulate the production of B cell osteoprotegerin (OPG), a potent inhibitor of osteoclastogenesis we investigated the production of OPG by bone marrow B cells. Our data shows that B cells are responsible for >40% of the total OPG produced by bone marrow under physiological conditions. Importantly, OPG production from purified B cells derived from nude mice was decreased by 3 fold relative to wild type mice. As T cells have been reported to stimulate OPG production by B cells, via T cell CD40 ligand interactions with the B cell CD40 receptor, we evaluated BMD in CD40 and CD40 ligand null mice. As expected, CD40 and CD40 ligand knock out mice displayed significantly decreased BMD and increased biochemical indices of bone resorption, concurrent with decreased B cell OPG secretion, although the magnitude of these changes was less than that observed in nude mice. Based on our data we hypothesize that B cells provide a critical reservoir of OPG in the bone marrow microenvironment and that this effect is upregulated by T cells, in part via a CD40-CD40 ligand dependent mechanism. This B cell derived OPG may serve to protect bone mass by neutralizing periodic increases in RANKL production in the bone marrow, a possible consequence of low grade T cell activation that occurs physiological in healthy humans and animals.

Placental Growth Factor Is Essential for Normal Fracture Healing in Mice by Affecting Inflammation, Angiogenesis and Mesenchymal Cell Development. C. Maes*[1], I. Stockmans*[1], K. Moermans*[1], R. Van Looveren*[1], N. Smets*[1], P. Carmeliet*[2], R. Bouillon[1], G. Carmeliet[1]. [1]Laboratory of Experimental Medicine & Endocrinology, KUL, Leuven, Belgium, [2]Center of Transgene Technology & Gene Therapy VIB, KUL, Leuven, Belgium.

It is generally accepted that signaling pathways regulating bone development are reactivated during fracture healing. In agreement, VEGF is important in both processes. Yet, some aspects of bone repair markedly differ from bone development, including its initiation by inflammatory and angiogenic responses to trauma and the source of mesenchymal progenitors. Particularly these aspects may be involved in failing repair, such as delayed or non-unions. Placental growth factor (PlGF), a homologue of VEGF, has no obvious role in development but is important during pathology as a mediator of inflammation and angiogenesis. Here we studied its role during bone repair. Histological analysis and quantitative real-time (q)RT-PCR revealed striking differences in the repair process between WT and PlGF-deficient (-/-) mice.

At post-fracture day (PFD) 13 the callus of WT mice was already mainly composed of woven bone, whereas PlGF-/- calluses contained massive hypertrophic cartilage (cartilage area of the callus, measured on safranin O staining: 2.1% ± 0.7 in WT versus 8.4% ± 1.7 in PlGF-/- mice, P<0.05, n=6-8). This type of impaired healing resembles a clinical delayed union. Molecular analysis at various time points by in situ hybridization and qRT-PCR revealed that the cartilage accumulation in PlGF-/- mice was due to both increased cartilage formation (increased collagen 2 and 10 and Ihh expression) and impaired cartilage resorption (reduced expression of MMPs). To further understand the causing mechanism, we studied the initial events of the repair process at PFD 2-3. Evidently, PlGF-/- mice showed an inadequate inflammatory reaction, with strongly reduced accumulation of CD45+ leukocytes in the callus and reduced expression of inflammatory cytokines. Concomitantly, the angiogenic reaction (CD31+ endothelial cell recruitment) was reduced. Surprisingly, PlGF-/- mice completely lacked the periosteal thickening seen in WT mice at PFD 3, and BrdU labeling revealed reduced proliferation of these mesenchymal progenitors (46% ± 8 of WT, P<0.01). Together, these defects in PlGF-/- mice resulted in impaired endochondral ossification at later stages, marked by imbalanced cartilage and bone formation with reduced invasion of osteoclasts and blood vessels (H&E, Von Kossa, TRAP, CD31 staining at PFD 8, 13, 21).

In conclusion, this study provides new insights in the mechanisms of fracture repair and may contribute to the development of new treatments for delayed/non-union types of fractures.

FGF23 plays crucial roles in maintaining phosphate and vitamin D metabolism in the physiological state, and enhanced action of FGF-23 was shown to cause several hypophosphatemic rickets/osteomalacia. The injection of recombinant FGF23 into mice lowered serum phosphate and 1,25-dihydroxyvitamin D [1,25D] levels, whereas treatment with anti-FGF23 neutralizing antibodies increased both serum concentrations of phosphate and 1,25D. In these experiments, serum 1,25D levels changed earlier than serum phosphate levels. Since 1,25D itself is known to be a potent regulator for phosphate metabolism, it has remained unclear whether FGF23 regulates serum phosphate by changing serum level of 1,25D. To address this issue, we established the vitamin D receptor (VDR) null mouse lacking exon 1 and evaluated the effect of recombinant FGF23 in those mice. Serum FGF23 levels in *Vdr* KO mice were not detectable at all, suggesting that the basal expression level of FGF23 appears to be regulated by a VDR dependent mechanism. Administration of recombinant FGF23 into 8-week-old *Vdr* KO mice further decreased serum phosphate and ameliorated the constitutionally elevated serum 1,25D level. These changes were accompanied by the reductions in sodium phosphate cotransporter type IIa (NaPi2a) protein in renal brush border membrane fractions and renal 25-hydroxyvitamin D-1alpha-hydroxylase (1aOHase) mRNA levels, as seen in the normal mice treated with FGF23. Thus, regulatory mechanisms for NaPi2a and 1aOHase by FGF23 are likely to be independent of the 1,25D/VDR system. On the other hand, the FGF23-induced increase in 24-hydroxylase (24OHase) mRNA levels already shown in normal mice was completely ablated in *Vdr* KO mice, indicating that the regulation of 24OHase mRNA by FGF23 depends on the 1,25D/VDR system. Therefore, these findings clearly indicate that FGF23 regulates phosphate and vitamin D metabolism by multiple signaling cascades involving VDR-dependent and -independent pathways.

A Novel Splicing Variant Transcript of the Renal Type IIa Sodium-Dependent Phosphate Cotransporter (NPT2a) Gene Is Positively and Negatively Regulated by 1,25-dihydroxyvitamin D_3 and Phex Cleavable Humoral Factors. H. Yamamoto, Y. Taketani, M. Tsuji*, T. Sato*, H. Arai*, E. Takeda. Department of Clinical Nutrition, Institute of Health Biosciences, University of Tokushima, Tokushima, Japan.

Decreased expression of the renal type IIa sodium-dependent phosphate cotransporter (NPT2a) has been shown in X-linked hypophosphatemic rickets (XLH) caused by mutations in the Phosphate-regulating gene with homologies to endopeptidases on X chromosome (Phex) gene, autosomal dominant hypophosphatemic rickets (ADHR) caused by mutations in the Fibroblast growth factor 23 (FGF-23). However, the repression mechanism of renal NPT2a gene expression in these disorders is unknown. During our efforts to understand the molecular mechanisms involved in regulatory factors, such as vitamin D, Phex and FGF-23 for the NPT2a gene expression, we identified a novel splicing variant transcript of the mouse NPT2a gene, Npt2a variant transcript 1 (Npt2a-v1), in addition to the previously known Npt2a variant transcript 2 (Npt2a-v2), characterized by the presence of alternative first exons (either exon 1A or exon 1B) that are spliced to exon 2 of the known transcript. Analysis of the chromosomal gene structure revealed the Npt2a gene is comprised of two promoters and 14 exons that, together with the 13 intervening introns, span approximately 17 kb. Real-time PCR analysis revealed that both renal Npt2a-v1 and Npt2a-v2 mRNAs expression in X-linked Hyp (hypophosphatemic) mice is decreased by 50% and 70% respectively when compared with normal littermates. On the other hand, abnormal metabolism of vitamin D has been also shown in XLH, ADHR. Therefore, we next examined the effects of $1,25(OH)_2D_3$ on the renal Npt2a variants expression in normal mice. Interestingly, renal Npt2a-v1 mRNA abundance was increased up to 4-folds following 48 h treatment with $1,25(OH)_2D_3$ (0.125μg/10g of diet), while renal Npt2a-v2 mRNA abundance was not changed. Furthermore, luciferase reporter assay showed that $1,25(OH)_2D_3$ or vitamin D analogs increased the transcriptional activity of Npt2a promoter including exons 1A and 1B in renal cell line, OK cells. These data suggest that a novel Npt2a variant transcript, Npt2a-v1 is positively and negatively regulated by $1,25(OH)_2D_3$ and Phex cleavable humoral factors and the differential regulation of these Npt2a gene promoters and splicing variant transcripts may have implications for understanding the various actions of phosphate regulating factors.

FGF-23 Mediated Internalization of the Type IIa Sodium Phosphate Co-Transporter (NaPi-2a) Requires the Scaffolding Protein, NHERF-1. M. D. Ruppe*, S. M. Jan de Beur. Endocrinology, Johns Hopkins Medical Institute, Baltimore, MD, USA.

FGF-23, a potent inhibitor of renal phosphate reabsorption, is central to several acquired and inherited renal phosphate wasting syndromes. FGF-23 exposure results in a down regulation of NaPi-2a RNA and protein expression in the proximal renal tubule. NaPi-2a co-localizes with PDZ containing proteins, including NHERF-1 (sodium-hydrogen exchange regulatory factor-1). This cytosolic scaffolding protein is thought to localize NaPi-2a to the apical membrane and mediate the rapid endocytic retrieval observed upon PTH stimulation. We hypothesized that FGF-23 inhibits phosphate reabsorption via internalization of NaPi-2a and that this is a NHERF-1 dependent process. To determine if FGF-23 promotes internalization of NaPi-2a from the membrane, we labeled OK cell surface proteins with biotin followed by incubation with PTH (10^{-7}M), FGF-23 (20 ng/mL) or untreated media for 30 minutes. Subsequently, cell surface biotin was removed with a membrane-stripping agent (TEPC). Whole cell lysates were prepared from both stripped and unstripped cells and immunoblotted with a NaPi-2a antibody. The signal intensity of the stripped versus the unstripped samples was compared to determine the proportion of internalized NaPi-2a cotransporters. Upon treatment with FGF-23, 86% of NaPi-2a was internalized compared to 67% in PTH treated cells and 5% in untreated cells. To investigate the role of NHERF-1 in FGF-23-mediated NaPi-2a internalization, we repeated the experiment with OKH cells, a subclone of OK cells known to have a markedly reduced level of NHERF-1. In these cells, NaPi-2a failed to internalize upon stimulation with neither FGF-23 nor PTH. To confirm the lysosomal processing of internalized NaPi-2a, OK and OKH cells were pre-treated with or without leupeptin (a lysosomal inhibitor) followed by 30 minutes of treatment with PTH (10^{-7}M), FGF-23 (20 ng/mL) or untreated media. After treatment, whole cell lysates were prepared and immunoblotted with a NaPi-2a antibody. Upon pretreatment with leupeptin, the decrement in NaPi-2a protein expression observed with PTH and FGF-23 was eliminated. In contrast, pretreatment with leupeptin had no effect on NaPi-2a expression in OKH cells suggesting that NaPi-2a does not undergo internalization and subsequent lysosomal degradation. Based on these observations, FGF-23 induces internalization of NaPi-2a from the renal apical membrane and subsequent lysosomal degradation in a process requiring NHERF-1. NHERF-1 may serve as the core for a multimolecular complex that integrates the receptors, ion transporters and signaling molecules important in FGF-23-mediated internalization of NaPi-2a.

Whole Genome Microarray Analysis of the *In Vivo* Effects of Single Effective Growth Hormone (GH) Dose on Gene Expression in Bones of GH-Deficient *lit/lit* Mice: Potential Involvement of Tbx3, a Novel Transcription Factor, in Mediating GH Effects in Bone. K. Govoni, S. Lee*, R. B. Chadwick*, H. Yu*, Y. Kasukawa, G. Linares*, D. J. Baylink, S. Mohan. JLP VAMC / Loma Linda Univ, Loma Linda, CA, USA.

The importance of GH in the development and maintenance of bone has been well established. GH effect on bone may be mediated via IGF-dependent and -independent mechanisms, however the molecular pathways remain to be established. To evaluate the major signaling pathways utilized by GH to mediate its effects on bone, we measured GH-induced changes in gene expression using Agilent microarray chips that contain 20,000 oligonucleotides. 4-wk old GH-deficient *lit/lit* mice were treated with GH (4 mg/kg body wt) or PBS (n = 6/group). 6 or 24 h after a single injection, bones were removed, RNA extracted and used for microarray. RNA from 2 animals was pooled and 3 pools per group were analyzed. After data normalization, analysis by Student's T-test determined that 393 and 633 genes showed significant changes in expression ($P < 0.01$) 6 and 24 h after GH treatment, of which over 50% represents cDNA clones with no assigned function. Approximately 75% of the genes up regulated by >2-fold at 6 h were also up regulated at 24 h. Consistent with the known effect of GH on the IGF axis, a number of GH responsive genes (IGF-I, IGF-II, BP-3 and BP-5) were significantly up regulated in the GH treated group, thus validating the microarray data. Of the known bone growth factor signaling pathways, IGF, BMP, and Wnt pathways are acutely regulated by GH treatment. For subsequent studies, we focused on Tbx3 because: 1) Tbx3 expression was increased more than 2-fold at both time points; 2) Tbx genes play an important role in limb development; and 3) Little is known about Tbx-3, a T-box containing transcription factor, except that mutations in Tbx3 result in human ulnar-mammary syndrome. After confirming microarray data with real time PCR (4.8 fold increase in Tbx3 expression at 24 h, $P < 0.01$), we found that GH treatment increased Tbx3 expression in MG63 and MC3T3-E1 cells ($P < 0.05$). Because GH effect on target gene expression is known to be mediated via stat5b, we pretreated MC3T3-E1 cells with TNFα which blocked GH-induced Tbx3 expression in MC3T3-E1 cells ($P < 0.05$). TNFα alone had no effect on Tbx3 expression. In conclusion, 1) GH caused acute change in the expression of signaling genes for IGF, BMP and Wnt signaling pathways. 2) Our findings that majority of the GH-induced genes in bone are not annotated suggest that many GH-induced signaling pathways and target genes remain to be discovered. 3) Our data demonstrate for the first time GH acutely regulates expression of Tbx3, which may act to mediate GH effects in bone.

Hypoxia Inhibition of Adipogenesis in Human Bone Marrow Stromal Cells Requires TGFβ/Smad Signaling. S. Zhou[1], S. Lechpammer*[1], J. Greenberger[2], J. Glowacki[1]. [1]Orthopedic Surgery, Brigham & Women's Hospital, Harvard Medical School, Boston, MA, USA, [2]University of Pittsburgh Medical Center, Pittsburgh, PA, USA.

Hypoxia (Hy) inhibits differentiation of murine preadipocytes, but it is not known whether Hy affects human marrow stromal cell (hMSC) differentiation nor whether there is a relationship between Hy and TGFß signaling in cellular differentiation. We tested the hypothesis that TGFß/Smad signaling mediates Hy's effects in hMSCs.

Early passage hMSCs (42-year-old woman) were cultured with adipocytogenic medium (MEM-α, 1% FBS-HI with insulin, dexamethasone, and 1-methyl-3-isobutylxanthine). Murine MSCs were established from $Smad3^{+/+}$ and $Smad3^{-/-}$ mice.

First, Western blot showed that treatment (16 h) of hMSCs with Hypoxia (2% O_2) or 15 μM of the hypoxia-mimetic deferoximine mesylate (DFO) induced hypoxia-inducible factor-1α (HIF-1α) protein. Macroarray and Northern blot analyses showed that Hypoxia (2 d) stimulated (relative to control) HIF-target genes, e.g. *VEGF* (210%), *PKM2* (310%) and *p21/Waf1/Cip1*, and inhibited adipocyte genes, e.g. *PPARγ, Adipsin* (43%), *C/EBPβ, INSR* (84%), and *LDLR*. DFO blocked the development of adipocytes at 3 w (38.8%, 20.4%, 1.0% vs. control at 2.5, 5.0, 15.0 μM respectively), and it prevented expression of adipocyte genes *PPARγ2* and *LPL*. Second, Hy up-regulated *TGFβ1* expression and many TGFß/Smad target genes, e.g. *βig-h3/TGFBI* by 383%, *PAI-1* by 686% (Northern and macroarray). Third, the direct effects of TGFß1 on adipocytogenesis were compared with Hy or its mimetic DFO. TGFß1 (1 ng/ml) decreased adipocyte number (1.4% vs. control) and adipocyte *PPARγ2* and *LPL* gene expression, and did not induce HIF-1α protein in hMSCs. Changes in adipogenic genes, e.g. *PPARγ, Adipsin, LPL, INSR*, induced by TGFß were similar to Hy-induced changes (macroarray and RT-PCR). Fourth, because these findings suggest that Hy or DFO actions are mediated by TGFß /Smad signaling, we tested effect of DFO on adipocytogenesis with mouse $Smad3^{-/-}$ MSCs. There were two notable differences in adipocyte development in stromal cells from $Smad3^{-/-}$ and $Smad3^{+/+}$ mice. First, there was more extensive (37-fold) adipocyte differentiation in $Smad3^{-/-}$ than $Smad3^{+/+}$ MSCs. The data suggest that Smad3 is a critical inhibitor of adipocyte differentiation. Second, there was less DFO inhibition in $Smad3^{-/-}$ (67.7% inhibition of adipocytogenesis) compared to in $Smad3^{+/+}$ (32.9%) MSCs.

In summary, hypoxia inhibits adipocyte differentiation in marrow stromal cells via activation of the TGFß/Smad signaling pathway and Smad3 is required for inhibition of adipocyte differentiation.

Loss of TIEG1 Results in Impaired TGFβ Regulated Gene Expression in Osteoblasts. M. Subramaniam[1], D. G. Monroe[1], G. Gorny*[1], K. Rasmussen*[1], M. Oursler[2], T. C. Spelsberg[1]. [1]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA, [2]Endocrinology, Mayo Clinic, Rochester, MN, USA.

TGFβ inducible early gene-1 (TIEG) is a Krüppel-like transcription factor which was originally cloned in our laboratory from human osteoblasts and plays an important role in mediating TGFβ effects in these cells. TIEG1 over expression in human osteosarcoma (MG63) cells mimics TGFβ treatment. Our laboratory has also demonstrated that TIEG over expression in human osteoblasts enhances Smad signaling by down-regulating negative feedback through inhibitory Smad7. In order to understand the biological functions of TIEG in bone development, we generated TIEG knockout mice. $TIEG^{-/-}$ mice appeared to be normal with typical breeding patterns. To examine the role of TIEG in osteoblast differentiation, we isolated neonatal calvarial osteoblasts from $TIEG^{+/+}$ and $TIEG^{-/-}$ mice and cultured them *in vitro*. Interestingly, osteoblasts derived from $TIEG^{-/-}$ mice display a retarded differentiation with the inability to produce mineralized nodules *in vitro*, and repressed expression of important osteoblast differentiation marker genes. To better understand the actions of TIEG in osteoblast cells, we performed Affymetrix microarray analysis on $TIEG^{+/+}$ and $TIEG^{-/-}$ calvarial osteoblasts treated with vehicle or $TGFβ_1$ for 24 hours to assess the full impact of the loss of TIEG on osteoblast function. When osteoblasts derived from $TIEG^{+/+}$ were treated with $TGFβ_1$, 403 genes were repressed compared to 149 genes repressed by $TGFβ_1$ treatment in $TIEG^{-/-}$ osteoblasts. Interestingly, the reverse pattern occurs with the induction of gene expression by $TGFβ_1$ with 138 induced in the $TIEG^{+/+}$ osteoblast and 260 in the $TIEG^{-/-}$ osteoblast. This change to the induction of more genes in the $TIEG^{-/-}$ mice is not unexpected, since TIEG is reported to be a general repressor of transcription with minor cases of gene induction. The results further demonstrate that 21% of the genes were commonly regulated by $TGFβ_1$ in osteoblast cells by both the genotypes, suggesting that $TIEG^{-/-}$ may not play a role in the modulation of all TGFβ regulated genes. Interestingly, 47% and 32% are regulated exclusively either in the $TIEG^{+/+}$ and $TIEG^{-/-}$ osteoblast cells respectively. Overall, the elimination of TIEG causes the loss of 126 genes that are regulated by $TGFβ_1$. In conclusion, we believe that loss of TIEG in osteoblasts results in perturbation of most (but not all) $TGFβ_1$ regulated genes which, in part, might explain the defective differentiation in osteoblasts involving mineralized nodule formation *in vitro* and reduced expression of important osteoblast-specific genes.

The Osteocyte-specific Antigen, E11, Is Responsive to Mechanical Loading in vitro and in vivo in Bone Distant from Maximal Strain. K. Zhang, K. Shiva*, L. Ye*, M. Dallas*, J. Feng, L. F. Bonewald. University of Missouri at Kansas City, Kansas City, MO, USA.

The earliest osteocyte-specific antigen as compared to osteoblasts is a membrane glycoprotein, E11/gp38, that appears to play a role in dendrite formation as the cells become embedded in osteoid. Although E11 is expressed in other tissues, it appears to be specifically post-translationally modified in osteocytes. To determine if mechanical loading could potentially affect dendrite formation, the regulation of E11 expression was examined both *in vitro* and *in vivo*. MLO-Y4 osteocyte-like cells respond to fluid flow shear stress at 4 and 16 dynes/cm^2 with an increase in E11 gene expression as determined by both northern analysis and gene arrays. To validate these *in vitro* observations, normal mice were used for immunohistochemical staining for E11 protein and for E11 gene expression, a mouse model in which the endogenous E11 promoter drives β-galactosidase expression was used. Compressive mechanical loads (-3.5 N, 30 sec, 2Hz), which induce bone formation, were applied to the right forearm of 3-month-old male mice (n=4). The mice were sacrificed at 4, 24, and 48 hrs after loading for Lac Z staining and at 24, 48, and 96 hrs for E11 immunostaining. The ulnae were fixed and cross-sectioned at 7 equidistant sections. Both positive and total osteocytes were counted for each section. At 4 hours after loading, there were significantly more LacZ(+) osteocytes at 5.5mm from the tip of the olecranon process (the elbow end) of loaded ulna than unloaded (4.8%±3.4% vs 1.4%±1.6%, p=0.02). There was no significant difference in other sections, including those with maximal strain, nor at 24 or 48 hours after loading. A significant increase in protein was observed at 24 hrs in the normal mice, not only in the 5.5mm section, but also in the 4.5 and 6.5mm sections.
In summary, increased E11 expression was observed in a level of the ulna that was subjected to lower, not maximal levels of strain. No significant differences were observed in areas of maximal strain. The majority of the positive osteocytes were near the bone surface, but mature osteocytes deep in the bone matrix also responded. If E11 is responsible for dendrite formation, embedded osteocytes can increase dendricity in response to strain. This raises the question of whether the osteocyte can modify and generate canaliculi when embedded in mineralized matrix.

Bone Matrix Strain Is Amplified at Osteocyte Lacunae in Cortical Bone. D. P. Nicolella[1], D. M. Moravits*[1], J. Lankford*[1], L. F. Bonewald[2]. [1]Materials Engineering, Southwest Research Institute, San Antonio, TX, USA, [2]Oral Biology, University of Missouri at Kansas City, Kansas City, MO, USA.

Mechanical factors affect bone remodeling such that increased mechanical demand results in net bone formation, whereas decreased demand results in net bone resorption. Previous studies suggest that osteocytes, due to their location within the bone matrix, are the best candidates for sensing mechanical stress. The most prominent of the proposed mechanical signals are stress-generated fluid flow forces acting on cells and bone matrix deformation itself. *In-vitro*, bone cells are more sensitive to fluid flow than to substrate stretch in terms of their production of NO, PGE_2, and osteopontin. Typical maximal *in-vivo* strains in humans have been measured, and found to range from around 1,200 μ (principal compressive strain) to about 1,900 μ (maximum shear strain). In these experiments, strains were measured on the surface of the bone using a strain gage that covered an area of several square mm, which encompasses thousands of bone cells. Therefore, the strains measured are averages over the total area covered by the gage and yield no information regarding local variations in the strain field that necessarily must result from naturally occurring microstructural inhomogeneities such as osteocyte lacunae. However, it is these average levels of mechanical strain that are typically used in cell culture experiments to investigate the effect of mechanical strain on bone cell function. Thus, the purpose of this study was to quantify osteocyte perilacunar strain relative to globally applied strain levels. We directly measured perilacunar bone matrix strain in bovine cortical bone using a digital stereoimaging technique. The bone specimens were loaded in a specially designed microscopy load frame to increasing levels of global mechanical strain while the microstructure was observed and digitally imaged at high magnification using an optical microscope. At all global strain levels, average perilacunar strains were significantly greater compared to the globally applied bone strain with strain concentration factors ranging from 1.5-4.5, which are consistent with both numerical and analytical estimates. Furthermore, local peak bone matrix strains reach up to ten times the globally applied strain indicating the possibility of local bone matrix damage. These results suggest that osteocytes embedded within lacuna in cortical bone may experience significantly higher strains due to matrix deformation than previously estimated from *in-vivo* strain gage studies and can be used to guide the application of substrate strain in *in-vitro* cell culture investigations.

The Mechanism for IGF-I Resistance Induced by Skeletal Unloading Is Specific for IGF-I and Mediated by Down Regulation of the Integrin Signaling Pathway. S. Nishida, Y. Wang, H. Z. ElAlieh*, B. P. Halloran, D. D. Bikle. Endocrine Unit, University of Calfornia, San Francisco and Veterans Affairs Medical Center, San Francisco, CA, USA.

Skeletal unloading leads to decreased bone formation and decreased bone mass. These results can be explained in part by a failure of IGF-I to activate its signaling pathways in unloaded bone. In previous studies we demonstrated that the resistance to IGF-I was caused by its failure to activate its receptor. To determine whether this resistance is specific for IGF-I or common to all skeletal growth factors acting through receptor tyrosine kinase mechanisms, we compared the effect of IGF-1 and PDGF in a rat model using hindlimb suspension. We evaluated the response of osteoprogenitor cells isolated from the tibia and femur of suspended and control rats to IGF-I and PDGF treatment in vitro with respect to activation to IGF-I and PDGF signaling pathways, respectively. IGF-I (10ng/ml) did not increase bone marrow osteoprogenitor (BMOp) cell proliferation in bone marrow stromal cells (BMSC) taken from unloaded bone, whereas PDGF (1ng/ml) was fully effective. The ability of IGF-I and Des-IGF-I, which has little affinity for IGFBPs, to stimulate IGF-I receptor phosphorylation was blocked in BMSC from unloaded bones but not the ability of PDGF to stimulate PDGF receptor phosphorylation. Integrins are likely to serve as mechanical sensors in bone, and integrin activation is known to augment growth factor signaling. In recent studies we found that unloading resulted in decreased integrin expression. In this study we found that skeletal unloading reduced the activation (phosphorylation) of focal adhesion kinase (FAK), an important mediator of integrin signaling, without affecting its protein level. Echistatin, an inhibitor of integrin signaling, blocked IGF-I stimulated BMOp cell proliferation and IGF-I receptor phosphorylation but was much less effective in blocking these actions of PDGF. Our results indicate that the mechanism by which skeletal unloading leads to IGF-I resistance is specific for IGF-I, involves integrin signaling, and has little impact on the anabolic response to PDGF. These results suggest that PDGF, and, possibly other growth factors may be of clinical use in preventing and /or treating bone loss during immobilization and other forms of skeletal unloading.

Global Analysis of 22,000 Genes in the Bones Reveals Involvement of Several Novel Genes/ESTs and Pathways in Mediating the Anabolic Response of Mechanical Strain in Mice *In Vivo*. W. Xing, D. J. Baylink, C. Kesavan*, H. Yu*, R. B. Chadwick, Y. Hu*, R. Rajkumar*, S. Mohan. JLP VAMC / LLU, Loma Linda, CA, USA.

To clarify the mechanisms and identify the genes responsible for mediating the effects of mechanical loading on osteogenesis, we evaluated differential gene expression on a global basis in the tibias of 10-wk old C57BL/6J (B6) females after 4 days of 4-point bending. We chose 4 point bending as a loading regimen based on our findings that it produces a robust bone anabolic response (15% increase in BMD after 2 wks, P<0.001) compared to other forms of loading in B6 mice. The right tibias of the mice were loaded at 9N, 2Hz for 36 cycles per day and the left tibias of the same mice were used as unloaded controls. RNA from the tibias harvested 24 hrs after last stimulation was subjected to oligonucleotide microarray-based analysis of 22,000 mouse genes. In total, 1074 genes/ESTs were significantly up- or down-regulated (N=5, t-test: p<0.05), of which, 741 are known and can be characterized into 120 biological processes. As expected, genes related to biological processes such as extracellular matrix synthesis, cell growth, cell adhesion, immune response and proteolysis were increased, thus validating the microarray data. Functional annotation of known genes and unknown genes/ESTs based on functional motifs revealed several interesting and unique findings: 1) Of the known genes, 27 exhibit kinase activity (e.g.. CDK2,PTK2, CDC42) and 34 exhibit receptor activity (e.g. PDGF, BMP, toll-like). These findings suggest that multiple pathways are stimulated in this large response to loading in bone. In this regard, several growth factor genes (e.g. pleiotrophin, osteoclycin, PDGFα, inhibinβ, IL25, nephroblastoma overexpressed gene) that have not been previously implicated in mechanical loading pathway have been identified as mediators of mechanical stress; 2) Of the 1074 significantly expressed genes, 31% express EST clones, some of which contain functional domains such as LIM, cysteine-rich protein and leucine-rich repeats, which are characteristics of motifs found in transcription factors, suggesting that future studies on these ESTs are essential for complete understanding of the molecular pathways for mechanical loading; 3) Pathway analysis revealed involvement of both well known (Integrin, Wnt, Calcium channels) and less known (Orphan GPCR, small ligand GPCR, apoptosis) pathways in mediating the effects of loading in bone. Conclusions: 1) This is the first study to examine the in vivo effect of mechanical loading on differentially expressed genes in the whole genome; 2) We have identified a number of novel genes, ESTs and pathways that have not been previously implicated to play a role in mechanical loading.

In-vivo Site-Specific Correlation of Dentin Matrix Protein 1 (DMP1) and Matrix Extracellular Phosphoglycoprotein (MEPE) Gene Expression: Effect of Overload. J. Gluhak-Heinrich*[1], S. P. Kotha*[2], L. F. Bonewald*[2], M. B. Schaffler*[3], S. E. Harris*[4]. [1]Ortho., Univ. of TX Health Sci. Ctr at San Antonio, San Antonio, TX, USA, [2]Oral Biol., Univ. of MO at Kansas City, Kansas City, MO, USA, [3]Orthopedics, Mount Sinai School of Medicine, New York, NY, USA, [4]Perio., U of TX Health Sci Ctr at San Antonio, San Antonio, TX, USA.

Osteocytes are thought to play critical roles in translating mechanical stimuli into signals that regulate mineralization, bone formation and resorption. In response to mechanical loading, we have previously shown increased gene expression of an acidic glycoprotein, DMP1, which may function to modulate mineralization. Another sibling protein that modulates and organizes the mineralization process, MEPE, may also play a role in osteocyte function. We sought to determine if there is a site-specific correlation between DMP1 and MEPE gene expression in normal bone and in bone subjected to overload. We used the rat ulnae fatigue model to mechanically stimulate osteocytes and correlate the magnitude of DMP1 to that of MEPE gene expression. After loading, (20 N, 4 Hz, 30% stiffness loss), expression of DMP1 and MEPE mRNA was assessed at day 1 and day 2 by quantitative in situ hybridization using P32 labeled RNA probes. Transverse cross-sections of control and loaded bones were analyzed from the mid-shaft and both proximally and distally in 0.75mm sections. Each section was divided into 100-150 segments. Gene expression in each segment was normalized by the number of osteocytes in that area. DMP1 and MEPE gene expression in loaded bones were compared to an equivalent segment in control bone and with each other. The results indicate that maximum increases in DMP1 and MEPE gene expression occurred at a section that was about 2-3mm distal to the ulnar mid-shaft. In these sections, the in-plane magnitudes of DMP1 and MEPE gene expression per osteocyte in the loaded ulnae were 1.9 and 3.2 times higher than in the control ulnae. The magnitude of changes in DMP1 and MEPE expression per osteocyte due to loading were similar indicating the same number of increased mRNA molecules after loading ($r2 = 0.67$; $p<0.001$). There were numerous segments with differential expression, where there was a larger increase in expression of DMP1 than MEPE. When combining data of both the loaded and control bone, DMP1 expression was highly correlated with MEPE ($r2 = 0.56$; $p<0.001$). Our results suggest that in response to loading, osteocytes may alter their microenvironment by causing site-specific changes in mineralization through increases in DMP1 and MEPE expression. These modifications could then alter the dynamics of fluid flow through bone with important implications for osteocyte survival, bone formation and resorption.

Changes in Vigorous Physical Activity Predict Bone Mineral Content in Young Children: The Iowa Bone Development Study. K. F. Janz*[1], S. M. Levy[2], T. L. Burns*[3], J. C. Torner*[4], M. C. Willing[5], J. M. Gilmore*[2], T. A. Marshall*[2]. [1]Health and Sport Studies, University of Iowa, Iowa City, IA, USA, [2]Preventive and Community Dentistry, University of Iowa, Iowa City, IA, USA, [3]Program in Public Health Genetics, University of Iowa, Iowa City, IA, USA, [4]Epidemiology, University of Iowa, Iowa City, IA, USA, [5]Pediatrics, University of Iowa, Iowa City, IA, USA.

Longitudinal observational studies during childhood have the potential to define the natural history of bone development and may provide insight into the prediction of future bone health. To examine whether changes in everyday physical activity predict bone mineral content (BMC, g) and accrual, we assessed physical activity (PA, min/d) and BMC at age 5.3 yr (SD $\pm$ 0.4) and again at age 8.6 yr (SD $\pm$ 0.6) (3-yr interval) in a cohort of Iowa children. PA was measured using whole-day accelerometry (MTI uniaxial) and described as frequency of sedentary, moderate, and vigorous movement. BMC of the hip, spine, and whole body was measured with a Hologic 2000 DXA. Associations were examined using partial correlation coefficients, stepwise linear regression, and general linear models. Age, gender, and body size were included as covariates. Change in BMC analyses also included adjustment for baseline BMC.

Partial Correlation Coefficients

p<0.01 unless NS=not significant		Hip BMC	Spine BMC	Whole Body BMC
* Baseline n=430	Vigorous PA	0.29*	0.20*	0.17*
** Follow-up n=454	Vigorous PA	0.22*	0.12*	0.14*
***Change n=342	Vigorous PA	0.13*	NS	0.14*

* Baseline BMC and PA, controlling for sex and baseline age, weight, height.
** Follow-up BMC and PA, controlling for sex and follow-up age, weight, height.
***Follow-up BMC (adjusted for baseline BMC) and change in PA, controlling for sex and baseline age, weight, height, and change in age, weight, height.

Vigorous PA was consistently and positively associated with BMC, whereas sedentary and moderate PA were not. Vigorous PA explained 1.4 to 8.2% of the variance in BMC ($p<0.05$), except change in spine BMC ($p\geq0.05$). Children who increased their vigorous activity, on average, by 8 min/d between baseline and follow-up had a follow-up whole body BMC that was 2% greater than less active peers. Even without targeted bone loading or extraordinary amounts of PA, young children who engage in vigorous PA are likely to have more BMC and likely to accrue more BMC than peers. Results are potentially important since observational studies are needed for public health recommendations that set realistic levels of exercise for children based on potential benefits.

Estrogen Does Not Modulate the Sensitivity of the Bones to Mechanical Loading. I. Pajamaki*[1], H. Sievanen*[2], P. Kannus*[1], T. Vuohelainen*[1], T. L. N. Jarvinen[1]. [1]Department of Orthopaedics and Traumatology, University of Tampere, Tampere, Finland, [2]UKK Institute, Tampere, Finland.

Estrogen, the primary non-mechanical regulator of the female skeleton, is believed to have a permissive role on the osteogenic effects of mechanical loading. In essence, it has been proposed that the mechanical loading-induced osteogenic response is dependent either on oestrogen or ER-α. To determine whether estrogen and loading are indeed coupled in the regulation of skeletal integrity, we first subjected 30 three-week-old female rats either to sham-operation (E^+) or ovariectomy (E^-). We then removed loading from the left hind limb of each rat by cast immobilization (L^-), while the right limb served as a non-immobilized control (L^+). After an 8-week period of unloading, a comprehensive analysis of the femoral neck of both limbs was carried out using peripheral quantitative computed tomography and mechanical testing.

As readily evident in the figure below, the bone mineral content (BMC: -42% in E^+ and -35% in E^-, both $p<0.001$) and cross-sectional area (CSA: -46% in E^+ and -40% in E^-, both $p<0.001$) were significantly reduced in the immobilized legs in both estrogen-replete (E^+) and -deplete (E^-) rats (**A-B**). Similarly, a profound decrease was observed in the fracture load of the immobilized legs in the E^+ (Fmax: -25%, $p=0.002$) and the E^- (-35%, $p<0.001$) groups, respectively (**C**). Despite the apparent stimulatory effect of estrogen on BMC ($p=0.025$ for the interaction, **B**), there was no difference between the estrogen-replete (E^+) and -deplete (E^-) rats in the CSA or Fmax (**A** and **C**).

The results of this study show that despite an apparent modulatory effect of estrogen on the mechanical loading-induced bone mass accrual, estrogen had no effect on fracture load, and accordingly, the skeletal sensitivity to mechanical loading. This finding actually emphasizes the importance of choosing the most appropriate final outcome - bone strength - for analysis, instead of only measuring some surrogates or determinants of bone strength.

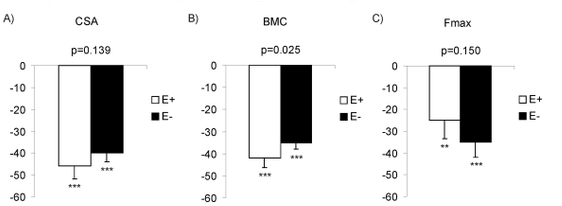

Figure: The unloading-induced reduction in the (A) total cross-sectional area (CSA), (B) the bone mineral content (BMC), and (C) the fracture load (Fmax) of femoral neck in estrogen-replete (E+, blank bars) and estrogen-deplete (E-, solid bars) rats. Bars represent percent (%) deficit of the unloaded group compared with the contralateral, normally loaded control group. Significant differences between unloaded and control limb are indicated: **p<0.01, ***p<0.001.

Sympathetic Nervous System Is Involved in Both Unloading -Induced Suppression of Bone Formation Rate and Unloading-Induced Enhancement in Osteoclast Surface in Vivo. H. Kondo[1], K. Tsuji[1], K. Kitahara[1], S. R. Rittling[2], A. Nifuji[1], D. T. Denhardt[3], S. Takeda[1], G. Karsenty[4], M. Noda[1]. [1]Molecular Pharmacology, Tokyo Medical and Dental University Medical Research Institute, Tokyo, Japan, [2]Cell Biology and Neuroscience, Rutgers University, Piscataway, NJ, USA, [3]Cell Biology and Neuroscience, Rutger University, Piscataway, NJ, USA, [4]Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA.

Unloading in bed ridden patients decreases bone mass and causes osteoporosis which is a major problem in the modern aging society. However, the mechanisms underlying such unloading-induced bone loss have not been yet fully understood. Sympathetic nervous system has been reported to suppress bone formation. This paper examines whether sympathetic nervous system is involved in alteration of the bone formation activity as well as bone resorption activity in mice subjected to tail suspension (TS). We conducted TS experiments using adult mice treated with vehicle or antagonist or agonist of β-adrenergic receptors. In vehicle treated control mice, TS reduced mineral apposition rate (MAR) as well as bone formation rate (BFR) as reported previously. Propranolol (PRO), a β-adrenergic blocker, treatment blocked the TS-inducded suppression of MAR and BFR, corresponding to the PRO blockage against TS-induced suppression on cancellous bone volume (BV/TV). Another β-adrenergic antagonist, Guanethidine sulfate (GS), which depletes storage of norepinephrine, also blocked the TS-induced suppression of MAR and BFR, again corresponding to the GS block of TS-induced bone loss. Isoproterenol (ISO), a β-agonist, treatment by itself reduced MAR and BFR in loaded group, similarly to the TS-induced suppression. In the presence of ISO, TS failed to further suppress BFR and MAR, corresponding to the failure of TS to further suppress BV/TV when ISO was administered. Bone marrow cells (BMCs) were taken after TS of mice treated with PRO in vivo and cultured. Nodule formation (NF) was suppressed by TS. In contrast, PRO treatment in vivo blocked the TS-induced suppression of NF levels. Osteoclast surface (OcS) in these mice was increased by TS in vehicle treated mice while this TS enhancement was blocked by the treatment with PRO during TS. GS treatment also blocked TS-induced increase in OCs. ISO treatment in vivo increased osteoclasts development in BMCs culture in loaded group, similarly to TS. After ISO treatment, there was no further increase in osteoclast development even after TS. These observations indicated that both TS suppression of osteoblastic activity as well as TS enhancement in osteoclastic activity in vivo are both mediated through β-adrenergic pathway.

Insulin-like Growth Factor II (IGF-II) Induces Apoptosis in Osteoblasts. W. Zhang, M. McCarthy*, H. Zhang, G. Gronowicz. Orthopedic Surgery, Uconn Health Center, Farmington, CT, USA.

Insulin-like growth factor II (IGF-II) is an important growth factor produced in bone and is more prevalent in human osteoblasts than IGF-I, but its function in bone metabolism is not well known. In this study, the ability of IGF-II to modulate apoptosis was investigated in primary osteoblast cultures. At 72 h of culture, 0.01, 0.1 and 1.0 nM IGF-II produced a dose-dependent increase in apoptosis assayed by TdT-mediated dUTP-biotin nick end labeling (TUNEL) and was confirmed with acridine orange/ethidium bromide staining in primary murine osteoblast cultures. A maximal increase of 5.0-fold above control was found with 1 nM IGF-II. A time course of treatment with 0.1 nM IGF-II demonstrated a significant increase in apoptosis compared to vehicle-treated cells by 48 h. IGF-II-induced apoptosis could not be inhibited by a blocking antibody to the IGF-I receptor during 72h of treatment with 0.01, 0.1, or 1 nM of IGF-II. Primary human osteoblast cultures demonstrated a similar dose-dependent increase in apoptosis with IGF-II treatment, with a 4-5 fold maximal increase in apoptosis after 72h treatment with 1.0 nM IGF-II. No significant effect of IGF-II was found on proliferation in murine osteoblast cultures. Western blot analysis demonstrated that IGF-II decreased Bcl-2 protein levels but not Bax resulting in a significant reduction in the Bcl-2/Bax ratio. To determine if overexpression of Bcl-2 could block IGF-II-induced apoptosis, osteoblasts were isolated from a transgenic mouse that overexpresses human Bcl-2 in bone through a construct utilizing the 2.3 kb promoter region of the Type I collagen gene linked to a 1.8kb region of human Bcl-2 cDNA (Col2.3Bcl-2). At 72h, IGF-II significantly increased apoptosis in a dose-dependent manner in the osteoblast cultures from the wild type littermates. In osteoblasts from Col2.3Bcl-2 mice, no significant effect on apoptosis was found with 0.01, 0.1 or 1.0 nM IGF-II. Western blot analysis of Bcl-2 and Bax levels demonstrated a transient decrease in the Bcl-2/Bax ratio at 24 h with no decrease in the ratio at 48 h or 72 h. Thus, IGF-II appears to promote osteoblast apoptosis, and overexpression of Bcl-2 is able to block IGF-II-induced apoptosis.

Identification of the Spliced Variant of CAPRI as a Critical Regulator of RANKL Shedding. A. Hikita*[1], H. Yasuda[2], K. Nakamura[1], H. Oda[1], S. Tanaka[1]. [1]Department of Orthopaedic Surgery, The University of Tokyo, Tokyo, Japan, [2]Institute of Medical Science, The University of Tokyo, Tokyo, Japan.

Accumulating evidence has demonstrated an essential role of RANKL (receptor activator of NF-kappa B ligand) in osteoclast differentiation and activation. RANKL is made as a membrane-anchored precursor, which is released from the plasma membrane by enzymatic shedding. However, the molecular mechanism and physiological/pathological importance of RANKL shedding have not been clarified yet.

To identify essential molecules for RANKL shedding, we constructed an assay system for expression screening. Plasmids encoding SEAP (secreted placental alkaline phosphatase) fused with partial cDNA of mouse RANKL containing stalk region was constructed, and co-transfected to 293T cells together with subpools of cDNA library of ST2 cells. RANKL-shedding activity was detected as AP activity in the supernatant, and positive subpools were partitioned into smaller subpools, and positive clones were sequenced.

One of the positive clones we identified was the splice variant of CAPRI (Ca^{2+}-promoted Ras inactivator), a novel member of RAS-GAP (GTPase-activating protein) which .is activated in response to Ca^{2+} stimuli and suppresses Ras activity. The splice variant (ΔCAPRI) lacks GAP-related domain, indicating that it works in a dominant negative fashion. ΔCAPRI expression was detected in primary osteoblasts, and overexpression of ΔCAPRI efficiently induced RANKL shedding as does activated mutant of Ras, while wild type CAPRI did not stimulate RANKL shedding. Stimulation with Ca ionophore induces the membrane translocation of wild type CAPRI, while ΔCAPRI remains at the cytoplasm. These results indicate the regulatory action of Ras pathways in RANKL shedding, and CAPRI-ΔCAPRI is a critical modulator of Ras activity.

In conclusion, we established an efficient assay system to identify the molecules involved in RANK shedding, and found that CAPRI-ΔCAPRI system is a critical regulator.

Androgens Inhibit Osteoclast Activity In AR-Transgenic Mice Through Reductions In RANKL/OPG Ratio. K. Wiren[1], A. Toombs*[1], V. Kasparcova*[2], S. Harada[2], X. Zhang[1]. [1]VA Medical Center, Oregon Health & Science Univ, Portland, OR, USA, [2]Merck Research Laboratories, West Point, PA, USA.

Our appreciation of the physiological functions of androgens has been changing. We recently characterized transgenic mice with AR overexpression in the osteoblast lineage under control of type I collagen promoter (col3.6 AR-transgenic mice), demonstrating proof of principle for the specific importance of androgen transactivation of AR directly in bone. Static and dynamic histomorphometric analysis in male AR-tg mice revealed site-specific effects on bone formation consistent with an anti-resorptive response. Characterization of gene expression by quantitative RT-PCR (qRT-PCR) in RNA isolated from tibial mid-diaphysis demonstrated reduced expression for osteoclastic genes including cathepsin K, RANKL and TRAP, while OPG expression was increased in males. Increased OPG serum levels were also observed. Since these results suggest osteoblast lineage-mediated inhibition of osteoclast activity, we characterized androgen control of osteoclastogenesis using a coculture system with monocytic RAW 264.7 cells as osteoclast precursors and col3.6 AR-MC3T3 cultures as a model of enhanced androgen responsiveness for osteoblasts. Cultures were treated with vehicle, 10^{-8}M DHT or soluble recombinant RANKL (50 ng/ml) alone, or DHT and sRANKL in combination. TRAP+ multinucleated cells containing 3 or more nuclei were considered formation of osteoclast-like cells. After 7 days, DHT inhibited osteoclast formation over 50% (P<0.001). The effects of DHT were abrogated with coadministration of sRANKL. The response in coculture with control ß-gal MC3T3 (no AR overexpression) demonstrated the same pattern but with reduced androgen efficacy. To evaluate the stage of osteoblast differentiation mediating androgen inhibition of osteoclastogenesis, OPG and RANKL mRNA was assayed using qRT-PCR at day 5 (proliferating preosteoblasts) and day 25 (osteocytic) colAR-MC3T3 cells, and with the osteocyte-like cell line MLO-Y4 (transiently transfected with an AR expression construct). Consistent with the effects in vivo, DHT inhibited RANKL but stimulated OPG gene expression in MLO-Y4 cells and day 25 colAR-MC3T3 osteoblastic cells. In contrast, in day 5 proliferating osteoblasts RANKL expression was undetectable while OPG expression was inhibited. These results demonstrate that inhibition of osteoclastogenesis occurs primarily by suppression of RANKL and/or elevation of OPG in mature osteoblasts. Collectively, these findings demonstrate that androgen signaling through the AR in bone directly influences osteoblast-osteoclast signaling and offers valuable insight into the role of androgen in bone homeostasis.

Transgenic Expression of Constitutively Active Mutant Estrogen Receptor-alpha (CAMERA) in Osteoblasts Leads to Increased Trabecular Bone Mass. N. Quibria*[1], R. Fajardo*[2], J. deSilva*[2], J. M. Alexander[3]. [1]ACCESS Program, University of California, Los Angeles, CA, USA, [2]Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center, Boston, MA, USA, [3]Physiology Department, Tufts University, Boston, MA, USA.

This study examines targeted expression of a **c**onstitutively **a**ctive **m**utant **e**strogen **r**eceptor-**a**lpha [CAMERA] in osteoblasts and its developmental effects on bone formation and phenotype in transgenic Swiss-Webster mice. Using cell-based gene activity assays, we characterized human ERα point mutations that result in nearly 100% constitutive transcriptional activity of ERα in the absence of hormone. After *in vitro* characterization, the CAMERA structural gene was cloned downstream of a 1.3 kb 5' flanking region of the mouse osteocalcin (mOC) gene to target its expression to osteoblasts. Transgenic Swiss-Webster lines expressing the mOC/CAMERA transgene were established, and their bone mineral density and structure were investigated using Piximus and microCT analysis, respectively. Both analytical methods demonstrated that transgenic females have significantly higher bone densities than age-matched non-transgenic Swiss-Webster mice. Piximus scanning documented consistent increases in overall BMD compared with non-transgenic females at both the femur (mean 22% increase) and lumbar spine (mean 24% increase). A microCT analysis revealed that trabecular BV/TV was dramatically increased in transgenic females (mean, 93% Tb BV/TV) compared to non-transgenic females (mean, 27% Tb BV/TV). At the femoral diaphysis, transgenic animals had significantly greater cortical thickness (mean Ct.Th, 0.380mm) compared to wildtype controls (mean Ct.Th, 0.230mm). Furthermore, transgenic females exhibited endosteal trabecular bone formation at the mid-shaft that resulted in dramatic increases in endosteal bone volume (mean, 70% endosteal BV/TV) compared to wildtype females who have no trabecular bone at the mid-shaft. To investigate the ability of the CAMERA transgene to protect against hormone deficient bone loss, transgenic females were ovariectomized (OVX) at 12 weeks of age, and bone parameters were examined 4 weeks later at 16 weeks of age. Despite the obvious developmental effects of the CAMERA transgene on overall bone density and structure, transgenic animals were only partially protected against post-OVX bone loss. Trabecular BV/TV in transgenic females decreased 55% after 4 weeks post-OVX compared to a 73% trabecular bone loss in wildtype females. We continue to evaluate this transgenic line for new insights regarding the mechanisms of action of ERα on bone physiology and post-OVX bone loss.

Wnt3a Regulates Induction of Id1 gene Expression by Bone Morphogenetic Protein 2 in Osteoblastic Differentiation. A. Nakashima*[1], T. Katagiri[2], M. Tamura[1]. [1]Department of Biochemistry and Moleculer Biology, Graduate School of Dental Medicine, Hokkaido University, Sapporo, Japan, [2]Division of Pathophysiology, Research Center for Genomic Medicine, Saitama Medical School, Hidaka, Japan.

It has been shown that loss of function of the Wnt corecepter, LRP5, in both humans and mice leads to decreased bone formation and bone mass, and a point mutation in this gene results in high bone mass, indicating the crucial role that Wnt/LRP5 signaling plays in bone formation. However, the exact signaling mechanisms by which Wnt members regulate bone formation remain to be elucidated. In this study, we examined a potential role for Wnt/LRP5 in osteoblast differentiation and functional cross-talk of bone morphogenetic protein (BMP) 2. To assess the functional contribution of Wnt, we generated a C2C12 cell line overexpressing Wnt3a, Wnt5a or the activated form of β-catenin and treated these cells with BMP2 for 24 h. The Id1 mRNA level induced by BMP2 decreased in the stable Wnt3a-expressing cells. In contrast, Wnt5a did not alter the Id1 mRNA level induced by BMP2. We show that this suppression is mediated by a 29-bp GC rich region of the BMP2-response element (BRE) of the human Id1 gene promoter. A novel interaction between Smad1, 4 and Tcf1 in the BRE was identified and found to be crucial for Wnt-mediated suppression of the BMP2 response in C2C12 cells. Overexpression of Dkk1 or the truncated secretary form of LRP5 inhibits this suppression, whereas Dkk2, Dkk3 or Dkk4 did

not alter the suppression. In contrast, neither Smad1, Smad4 nor BMP2 up-regulated activated β-catenin-induced Tcf-1-dependent transcriptional activity. Nevertheless, Smad4 lead to activation of Tcf-1 dependent transcriptional activity in C2C12 cells. These results identify a novel mechanism by which Wnt/LRP5 regulates the BMP2-response in osteoblastic differentiation, and is the first study linking Id1 expression to Wnt/β-catenin signaling. Thus, these results demonstrate the link between Wnt and BMP signaling in osteoblastic differentiation.

C/EBP Homologous Protein (CHOP, Ddit3) Interacts with Smads and Enhances Smad and Wnt Signaling. R. C. Pereira, V. Deregowski, S. Rydziel, E. Canalis. Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA.

CCAAT/enhancer binding proteins (C/EBPs) play important roles in cell fate and gene regulation. C/EBP homologous protein (CHOP, Ddit3) forms heterodimers with classic C/EBPs, preventing their binding to target DNA sequences, but CHOP can also interact with additional transcription factors. We demonstrated that CHOP suppressed adipogenesis and induced osteoblastogenesis by enhancing the effect of bone morphogenetic protein (BMP)-2. To assess mechanisms involved in the induction of osteoblast differentiation by CHOP, we examined its effect on BMP and Wnt signaling pathways in permanently transduced ST-2 cell lines overexpressing CHOP under the control of the CMV promoter. CHOP overexpression did not modify the basal activity of a transiently transfected BMP-responsive 12xSBE-Oc-pGL3 construct, containing 12 repeats of a Smad binding site directing luciferase expression. However, CHOP amplified markedly the effect of BMP-2 on the activity of the construct and the effect of BMP was 6 fold greater in the presence than in the absence of CHOP. Transfections of mutant Smad 1 or 5 constructs with dominant negative properties, significantly decreased the effect of CHOP on BMP-2 induced transactivation of 12xSBE-Oc-pGL3 construct. BMP-2 induced Smad 1/5/8 phosphorylation, but CHOP overexpression did not modify the level of phosphorylated Smad 1/5/8 in control or BMP-2 treated cells. However, co-immunoprecipitation experiments in nuclear extracts from CHOP overexpressing cells transfected with Smad 1 and 5 expression constructs and treated with BMP-2 revealed that Smad 1/5 associated with CHOP. Although BMPs can activate mitogen activated protein (MAP) kinases in osteoblastic cells, BMP-2 had no significant effect on the phosphorylation of the MAP kinases ERK, p38 or JNK, and these were not modifed by CHOP. Furthermore, CHOP overexpression did not modify the transactivation of a construct in which seven AP-1 recognition sequences direct the expression of luciferase, confirming no involvement of the MAP kinase pathway. The results indicate that BMP modulates osteoblastic differentiation via the Smad signaling pathway and that CHOP associates with Smads enhancing their interactions with DNA recognition sequences. CHOP overexpression also increased the activity of the Wnt/ß-catenin pTOP-FLASH responsive construct, containing 3 copies of the Lef 1/Tcf4 binding sequences, by 3 fold. In conclusion, CHOP interacts with Smad 1/5 and enhances osteoblastic differentiation by sensitizing the BMP/Smad and the Wnt/ß-catenin signaling pathways, but not the MAP kinase pathway.

Discovery of Genomic Sites Occupied by RUNX2 in Living Osteoblasts. A. Barski[1], S. K. Pregizer*[1], B. Frenkel[2]. [1]Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA, USA, [2]Orthopaedic Surgery, University of Southern California, Los Angeles, CA, USA.

The transcription factor Runx2 is considered a master gene for osteoblast differentiation. Although some transcriptional targets for Runx2 are known, it is believed that the osteogenic action of Runx2 requires additional target genes. However there is no established method for unbiased discovery of genomic sites directly occupied by transcription factors of interest. Therefore, we developed a novel approach, Chromatin Immunoprecipitation (ChIP) Display (CD), which allowed us to identify several novel Runx2 target genes. The CD technique was successfully employed with a robustly mineralizing MC3T3-E1 osteoblastic subclone. Cells were subjected to ChIP with Runx2 antibodies, resulting in a precipitate containing Runx2 targets, but also the inevitable vast excess of non-specifically co-precipitated DNA. This background makes problematic identification of Runx2 targets by direct cloning of immunoprecipitated fragments. To overcome this obstacle, fragments containing Runx2 targets were effectively concentrated using restriction digestion with *Ava*II, which brought all the fragments representing any one target to a unique size. Furthermore, following linker ligation, the immunoprecipitated DNA fragments were PCR amplified in distinct families, segregated based on the identity of two nucleotides in the vicinity of the *Ava*II sites at the ends of each fragment. This results in improved signal-to-background ratio for each target because all fragments containing any given target are amplified within its respective family, while all other DNA fragments, mostly background, are scattered between different families. Indeed, upon gel electrophoresis, fragments representing true Runx2 target genes formed distinct bands. In contrast, the non-specifically precipitated DNA resulted in a background smear formed by fragments of diverse sizes. Bands of interest were excised, and the DNA fragments were identified by sequencing and comparison to genomic databases. Our initial CD experiments identified several novel Runx2 targets, including both well known and novel genes i.e. the transcription factors Fli1 and Runx3 and less well-known genes ORP8 and a novel EST homologous to the DYRK1 kinase. These genes were confirmed as Runx2 targets using conventional ChIP assay. Promoter-reporter assays and RNA analysis of BMP-2-treated cells further establish ORP8, a member of the oxysterol-binding protein family, as a functional Runx2 target. In principle, CD can facilitate the discovery of novel target genes for any DNA binding protein.

Smad1 Binding to the Dlx5 Promoter Is Responsible for the BMP-2-Induced Dlx5 Expression. H. Park*[1], Y. Kim*[1], B. Kim*[1], H. Shin[2], J. Cho*[1], H. Ryoo[1]. [1]Department of Biochemistry, School of Dentistry and Skeletal Disease Genome Research Center, Kyungpook National University, Daegu, Republic of Korea, [2]Department of Oral Pathology, School of Dentistry, Kyungpook National University, Daegu, Republic of Korea.

Bone morphogenetic protein (BMP)-2, a member of transforming growth factor (TGF) β superfamily, is well known by its ability to induce ectopic bone formation *in vivo* and osteoblastic transdifferentiation from non-skeletal cells *in vitro*. Our previous results indicated that Dlx5 is an indispensable regulator of BMP-2-induced transdifferentiation in myoblastic C2C12 cells. However, little is known about the molecular mechanism by which BMP-2 regulates Dlx5 promoter. In this study, to identify BMP responsive elements (BRE), we established a series of 5' deletion constructs of the mouse Dlx5 promoter region; Dlx5P-3kb, Dlx5P-2kb, Dlx5P-1kb, Dlx5P-0.9kb, and Dlx5P-0.2kb which contain the -2935, -1928, -965, -774, and -94 to +123 region of the mouse Dlx5 promoter, respectively. BMP-2 treatment or cotransfection of the Smad1 expression vector with the promoter deletion constructs to C2C12 cells indicated that BMP response region is between +47 to +61 nucleotide of the Dlx5 transcription initiation site. By sequence analysis, we identified Smad1 binding consensus motifs (5'GCCGNCGC3') in the region. Site directed mutagenesis of the Smad1 binding consensus motifs in Dlx5P-1kb resulted in a complete abrogation of the BMP2- or Smad1- induced promoter activation. Furthermore, gel mobility shift assays indicated that the putative binding sites effectively interact with Smad1 as sequence specific manners. These results indicated that BMP-2 activated Smad1 mediates the transcription of Dlx5 through the direct binding to the cognate cis-acting element in Dlx5 promoter.

Selective *Runx*2-II Deficiency Differentially Affects Endochondral, Cortical and Intramembranous Bone Formation in Adult Mice. Z. Xiao[1], H. Awad*[2], S. Liu[1], F. Guilak*[2], L. D. Quarles[1]. [1]Internal Medicine/Kidney Institute, University of Kansas Medical Center, Kansas City, KS, USA, [2]Orthopaedic Surgery, Duke University Medical Center, Durham, NC, USA.

The *Runx*2 gene transcribes the "bone-related" *Runx*2-II and *Runx*2-I isoforms that differ only in their N-termini. *Runx*2 is essential for osteoblast differentiation. Homozygous mice lacking both isoforms die at birth and lack a mineralized skeleton. In contrast, selective deletion of the *Runx*2-II isoform results in a less severe skeletal phenotype in newborn mice characterized by a greater impairment of endochondral bone formation compared to the mild defects in intramembranous and cortical bone formation. In this study we determined the post-natal effects of selective *Runx*2-II deficiency. We performed bone mineral density (BMD), micro-computer tomography (μCT), and 3-point bending biomechanical testing of femurs as well assessed biochemical markers in wild-type (WT), *Runx*2-II heterozygous ($^{+/-}$) and null ($^{-/-}$) mice up to 24-weeks of age. WT mice exhibited an age-dependent increase in bone mass due to an increase in cortical bone (BV/TV% 21.2±1.4 vs 14.5±1.2, Ct.Th 0.18±0.01 vs 0.24±0.01 mm and BMD 0.061±0.001 vs 0.086±0.001 g/cm^2 at 6 and 24 weeks, respectively). These changes were associated with reduced osteoclastic and osteoblastic markers (deoxypyridinoline (DPD) 126±11 vs 34±3 ηmol/mmol creatinine, osteocalcin (Osc), 451±51 vs 114±10 ηg/ml at 6 and 24 weeks, respectively). There were also significant age-dependent increases in bending strength (Fmax) and flexural rigidity (EI) of femurs in WT mice (Fmax, 25.1±5.4 vs 37.8±6.4 N; EI, 125.2±32.2 vs 242.2±44.0 at 6- and 24-weeks, respectively). *Runx*2-II $^{-/-}$ mice did not survive past 8 weeks, whereas survival in *Runx*2-II$^{+/-}$ was identical to WT littermates. Compared to WT mice, 6-week-old *Runx*2-II $^{+/-}$ had reduced BV/TV% (14.8±1.4), Ct.Th (0.16±0.01mm) and BMD (0.057±0.001 g/cm^2), but no difference in DPD or Osc, whereas *Runx*2-II $^{-/-}$ had severe reductions in BV/TV% (7.1±1.7), Ct.Th (0.11±0.01), and BMD (0.037±0.002) associated with reduced Osc (107±56) but not DPD (121±24). These changes were associated with significant reductions in Fmax (18.7±3.3 and 8.1±2.7 N) and EI (89.2±16.1 and 27±8) in *Runx*2-II $^{+/-}$ and *Runx*2-II $^{-/-}$ mice, respectively. Although 24-week-old *Runx*2-II $^{+/-}$ mice had persistently reduced BV/TV%, Osc levels and impaired mechanical strength, these mice normalized both femoral Ct.Th and BMD. These studies suggest that *Runx*2-II has differential effects on trabecular and cortical bone formation, possibly reflecting a site-specific function of *Runx*2-II in osteoblasts derived from sites of endochondral ossification.

Increase of Bone Mass in Dominant-Negative Runx2 Transgenic Mice. T. Komori[1], T. Furuichi*[1], R. Fukuyama*[1], T. Fujita[2], S. Toyosawa*[3], K. Yamana*[4], N. Kanatani*[1]. [1]Department of Developmental and Reconstructive Medicine, Nagasaki University, Nagasaki, Japan, [2]Department of Pharmacology, Setsunan University, Hirakata, Japan, [3]Department of Oral Pathology, Osaka University, Osaka, Japan, [4]Teijin Institute for Biomedical Research, Teijin Ltd., Hino, Japan.

Runx2-deficient mice completely lack osteoblasts, demonstrating that Runx2 is an essential transcription factor for osteoblast differentiation. Further, previous in vitro and in vivo studies showed that Runx2 plays an important role in the expression of major bone matrix protein genes. As Runx2-deficient mice die after birth, the role of Runx2 in postnatal bone development remains to be clarified. We pursued this issue using dominant negative (dn)-Runx2 in vitro and in vivo. Adenoviral introduction of dn-Runx2 into primary calvarial cells and into C2C12 cells that were stimulated with BMP-2 inhibited early osteoblast differentiation. However, adenoviral introduction of dn-Runx2 into primary calvarial cells and MC3T3-E1 cells, both of which had been cultured for 10 days after confluence for their maturation, and into MLO-A5 cells did not inhibit Col1a1 and osteocalcin expression. We generated transgenic mice that expressed dn-Runx2 under the control of 2.3 kb mouse Col1a1 promoter. Further, the dn-Runx2 transgenic mice were mated with Runx2 transgenic mice under the control of Col1a1 promoter, which showed osteopenia with fractures and drastic reduction in osteocytes (J. Cell Biol. 155: 157, 2001). Runx2/dn-Runx2 double transgenic mice showed no fracture, and a large number of osteocytes were observed. In dn-Runx2 transgenic mice, the number of osteoblasts was reduced and the parameters for osteolysis were normal in bone morphometric analysis, and the osteoblasts expressed normal levels of major bone matrix protein genes. However, the trabecular bone gradually increased during aging. Further, the trabecular bone was highly mineralized and urinary deoxypyridinoline was significantly decreased. Moreover, the bone in dn-Runx2 transgenic mice was conserved after ovariectomy. These findings indicate that dn-Runx2 induces terminal differentiation of osteoblasts, decreases the number of osteoblasts, and suppresses osteolysis. Thus, Runx2 plays an important role in maintaining the number of osteoblasts, but Runx2 is not essential for the regulation of expression of major bone matrix protein genes. Further, our findings indicate that Runx2 is responsible for the high bone turnover in estrogen deficiency. All experiments were reviewed and approved by the Osaka University Medical School Animal Care and Use Committee.

Dissection of PTH-induced Signaling Network in Osteoblastic Cells Using a Novel Bioinformatics Approach. X. D. Chen, S. A. Stewart*, S. C. Manolagas, R. L. Jilka. Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

The anabolic effect of intermittent PTH is due at least in part to attenuation of osteoblast apoptosis. As little as 1h of PTH is sufficient to induce survival signaling in cultured osteoblastic cells, which is abolished by inhibition of RNA and protein synthesis. Earlier work demonstrated that PTH inhibition of apoptosis requires an increase in the synthesis of the anti-apoptotic protein Bcl-2. Here, we used global gene expression profiling to more fully appreciate the changes in gene expression underlying the anti-apoptotic effect of PTH. The level of 12,488 transcripts in osteoblastic OB-6 cells was quantified with Affymetrix U74A chips under basal conditions (0 time), and after addition of 50 nM PTH for 30 or 60 minutes. Triplicate cultures were analyzed. Significance Analysis of Microarray, and t-test comparison of changes in single transcripts (0 vs 30, 0 vs 60, 30 vs 60), indicated significant changes in the expression of 1984 genes with a false discovery rate of <5%. Using PathwayAssistant, a database of several thousand proteins and information on the relationships among them, we conducted an unbiased search for those PTH-regulated genes that have a biological relationship with at least one other PTH-regulated gene in an effort to visualize components of the interconnected signaling cascade affected by the hormone. We identified 440 such genes, which were then mapped onto 44 established signaling cascades. We found that the pathways most affected by PTH are highly interconnected and are involved in the control of cell cycle and apoptosis. They include FAS/death domain, MAPK-ERK, p53, caspase, integrin signaling, mitochondrial control of apoptosis, G-protein, PI3/PI4-kinase, Rb, SAP-JNK, Cx43, Rb, PTEN, p38. The PTH-regulated genes that most frequently appear in the 44 pathways were *Jun*, *MAPKK3*, *AKT1*, *c-fos*, *p53*, and *ADPRT,* which were up-regulated; *Fyn* and *FADD* were down-regulated. These 8 genes have direct links to 144 of the 440 PTH-regulated genes. These 144 genes thus represent highly connected co-regulated factors, some of which are potentially involved in the anti-apoptotic effect of PTH. Among these genes are the anti-apoptosis factor survivin and integrin-linked kinase. This unbiased bioinformatics approach has thus identified new candidates for the key PTH-regulated pro-survival genes. Moreover, hierarchical clustering revealed unique dynamic expression patterns of PTH-regulated genes, and provided an outline of the interconnected signaling cascade involved in control of cell behavior by short-term exposure to the hormone.

Interactions between Twist and Fibroblast Growth Factor Receptor 2 Controls Osteoblast Gene Expression in the Saethre-Chotzen Syndrome. H. Guénou*, K. Kaabeche*, S. Le Mée*, P. J. Marie. Laboratory of Osteoblast Biology and Pathology, Inserm U606, Paris, France.

Genetic mutations of the Twist gene, a bHLH transcription factor, induce premature fusion of cranial sutures in the Saethre-Chotzen syndrome (SCS). We previously showed that Twist haploinsufficiency in SCS induces marked alterations in osteoblast differentiation and survival. In this study, we investigated the role of fibroblast growth factor receptor 2 (FGFR2) in the abnormal expression of osteoblast differentiation genes induced by bHLH deletion in Twist. Cranial osteoblasts from a SCS patient with a Y103X mutation in Twist showed decreased Twist dosage associated with decreased Runx2, osteocalcin (OC) and bone sialoprotein (BSP) mRNA, compared to normal osteoblasts. This phenotype in Twist mutant osteoblasts was associated with decreased FGFR2 mRNA levels (C-terminal, N-terminal and intramembranous domains). EMSA analysis in nuclear extracts from Twist mutant osteoblasts showed specific reduction of Runx2 binding to the FGFR2 promoter, suggesting that the reduced Runx2 expression in mutant osteoblasts results in decreased FGFR2 levels. Transfection of Twist mutant osteoblasts with a dominant-negative (DN) FGFR2 vector decreased Runx2, OC and BSP expression compared to empty vector, indicating that FGFR2 signaling upregulates Runx2 and downstream targets in mutant cells. Transfection of Twist mutant osteoblasts with Twist cDNA rescued FGFR2 mRNA levels, and corrected Runx2, OC and BSP mRNA expression. We conclude that 1) Twist haploinsufficiency induced by bHLH deletion causes reduced FGFR2 mRNA; 2) this effect may contribute to the reduced Runx2, OC and BSP mRNA expression in Twist mutant osteoblasts; 3) the reduced Runx2 expression induced by Twist haploinsufficiency may conversely contribute to downregulate FGFR2 in Twist mutant cells.This provides novel genetic evidence for positive interactions between Twist and FGFR2, and for reciprocal interactions between Runx2 and FGFR2 in human osteoblasts. This indicates that Twist haploinsufficiency can alter osteoblast differentiation gene expression by multiple mechanisms in the Saethre-Chotzen Syndrome.

Characterization of Stromal/Preosteoblast Cells from Heat Shock Factor-2 (HSF-2) Null Mice. H. Kajiya[1], M. Ito[1], H. Ohshima*[2], S. Kenmotsu*[2], I. J. Benjamin*[3], W. L. Ries[4], S. V. Reddy[1]. [1]Medicine/Hematology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Division of Anatomy and Cell Biology of the Hard Tissue, Niigata University, Niigata, Japan, [3]Internal Medicine, University of Texas Southwestern Medical Center at Dallas, Dallas, TX, USA, [4]Pediatrics, Medical University of South Carolina, Charleston, SC, USA.

RANK Ligand (RANKL) is a critical osteoclastogenic factor that is expressed on marrow stromal/osteoblast cells. We previously cloned a 2 Kb hRANKL promoter region and identified functional heat shock factor-2 (HSF-2) responsive motifs (HSE) in the promoter. We also demonstrated that b-FGF induced HSF-2 nuclear localization and binding to the RANKL promoter region in stromal/preosteoblast cells. These data suggested that HSF-2 is a down-stream target of b-FGF to induce RANKL expression in stromal/osteoblast cells, and that HSF may play an important role in modulating RANKL gene expression in the bone microenvironment. In the present study, we characterized HSF-2 null mice bone marrow derived stromal/preosteoblast cells for RANKL expression and their capacity to support osteoclastogenesis. Western blot analysis demonstrated that b-FGF (4 ng/ml) treatment (3 days) of HSF-2 (-/-) stromal/preosteoblast cells did not induce RANKL expression. In contrast, b-FGF induced a 10-fold increase in RANKL expression in cells derived from wild type littermates. Furthermore, basal RANKL expression was decreased three fold in HSF-2 -/- stromal/preosteoblast cells compared to wild type littermates. Wild type mouse bone marrow derived spleen cells cocultured with HSF-2 -/- mice stromal/preosteoblast cells in the presence of dexamethasone (10^{-9} M) and b-FGF (40 ng/ml) did not form osteoclasts. In contrast, cocultures using wild type stromal/preosteoblast cells formed significant numbers of osteoclasts. Interestingly, micro CT analysis of HSF-2 null mice long bones demonstrated that the trabecular bone was thin and decreased. Electron microscopic studies showed that although osteoclasts of HSF2-/- mice were in direct contact with the bone surface, ruffled borders are poorly developed compared to osteoclasts from wild type littermates. These data further suggests that HSF-2 modulates osteoblast and osteoclast function in the bone microenvironment and thus plays an important role in bone remodeling.

Runx2 Acts as a Negative Regulator of the Repressive Activity of the Basic Helix Loop Helix Factor Hes-1 on $1,25(OH)_2D_3$ Induced Osteopontin Transcription. Q. Shen*, S. Christakos. Biochemistry, Graduate School of Biomedical Science-New Jersey Medical School, Newark, NJ, USA.

Osteopontin (OPN), a glycosylated phosphoprotein that binds calcium, is present in bone extracellular matrix. OPN deficient mice are resistant to PTH induced bone resorption, indicating a requirement for OPN in bone remodeling. In osteoblastic cells the transcription of OPN is stimulated in response to $1,25(OH)_2D_3$ and we previously reported functional cooperation between Runx2 and the vitamin D receptor (VDR) in the regulation of OPN transcription. We now report that the helix loop helix factor Hes-1, a mammalian counterpart of the Drosophila Hairy and Enhancer of split proteins, which is expressed in osteoblastic cells, is involved in $1,25(OH)_2D_3$ and Runx2 mediated regulation of osteopontin transcription. Studies were initially done in COS-7 cells transfected with the mouse OPN promoter (-777/+79) and Hes-1 and VDR expression vectors. With increasing amounts of Hes-1 DNA transfected (10 -200 ng), the $1,25(OH)_2D_3$ dependent induction of OPN transcription was steadily repressed to control levels. In COS-7 cells these concentrations of Hes-1 did not significantly affect the basal level of OPN promoter activity. Cotransfection of Runx2 in COS-7 cells reversed the inhibition by Hes-1. In ROS 17/2.8 cells, that contain endogenous Runx2, transfection of Hes-1 (10 - 100 ng) resulted in a dose dependent enhancement of both basal and $1,25(OH)_2D_3$ induced transcription (the maximal enhancement was 4.7 ± 0.1 fold). The enhancement of the induction of OPN transcription by Hes-1 in ROS cells was inhibited in a dose dependent manner by AML-1/ETO, which acts as an inhibitor of Runx2 and has also been reported to recruit histone deacetylase.

Sodium butyrate (2mM), which acts in part as a histone deacetylase inhibitor, was able to partially rescue the inhibition by AML-1/ETO of Hes-1 induced OPN transcription, suggesting the involvement of both histone deacetylase dependent and independent mechanisms. Immunoprecipitation assays using ROS 17/2.8 cells coexpressing Hes-1 and Runx2 indicated that Hes-1 and Runx2 interact and that $1,25(OH)_2D_3$ (10^{-8} M, treatment for 24h) can enhance this interaction. Taken together, our studies show that Hes-1 can potentiate both basal and VDR mediated OPN transcription in the presence of Runx2 and Runx2 can act as a negative regulator of the inhibitory activity of Hes-1. These findings define new mechanisms and functional interactions that are involved in the regulation of OPN and may therefore affect the process of bone remodeling.

Expression of MINT, the Msx2 Interacting Nuclear Matrix Target Protein, Is Upregulated with Osteogenic Commitment of Murine Mesenchymal Progenitors. O. L. Sierra, S. L. Cheng, J. S. Shao*, A. P. Loewy*, D. A. Towler. Bone & Mineral Diseases, Washington University School of Medicine, St Louis, MO, USA.

The transcription factor Msx2 is required for craniofacial bone formation and normal cerebellar development. The gain - of - function Msx2 variant, Msx2(P148H), causes Boston-type craniosynostosis, and enhances the osteogenic differentiation of mesenchymal progenitors -- exhibiting markedly enhanced synergy with BMP2. Detailed mechanistic studies indicate that Msx2 promotes early osteogenic commitment by augmenting paracrine Wnt/Dkk signals; stable expression of Msx2 in uncommitted mesenchymal progenitors enhances Wnt3a and Wnt7a expression, but suppresses Dkk1 expression. However, also Msx2 suppresses late phenotypic markers such as osteocalcin by targeting a specific nuclear matrix protein, MINT, that organizes a multiprotein osteocalcin promoter complex containing Runx2. In situ hybridization studies confirm expression of MINT in neonatal craniofacial bone and in cerebellar Purkinje cells, two tissues dependent upon Msx2 action. RNAi directed towards MINT selectively inhibits osteocalcin gene expression in MC3T3E1 calvarial osteoblasts.. Since *spen* -the Drosophilan ortholog of MINT- is required for *wingless* (Wg) signaling in fly eye development, we studied the expression and regulation of MINT during the osteogenic commitment of C3H10T1/2 mesenchymal progenitors -- a process regulated by paracrine Wnt signals. Uncommitted C3H10T1/2 cells grown in vitro for 5 days in the presence of beta-glycerolphosphate and ascorbic acid led to a 260-fold increase of alkaline phosphatase mRNA abundance. This osteogenic commitment C3H10T1/2 is dependent upon endogenous Wnt signaling; treatment with recombinant Dkk-1 (1 ug/mL) for 5 days decreased alkaline phosphatase by 50% ($p < 0.05$). We next studied the expression of MINT over this same time frame. With osteogenic commitment of C3H10T1/2 cells, MINT mRNA was increased 3-fold ($p < 0.05$) as quantified by fluorescence RT-PCR. By contrast, no significant change in Msx2 expression was noted. Unlike committed MC3TE1 cells, MINT siRNA had little effect on basal OC expression. However, MINT siRNA significantly enhanced the antagonistic actions of Dkk1 on OC expression in during commitment of C3H10T1/2 cells to the osteogenic lineage ($p < 0.05$). Dkk1 treatment had no effect on endogenous MINT mRNA accumulation. Thus, these data suggest that MINT participates in the control of osteoblast gene expression, potentially regulating stage-specific responses to paracrine Wnt/Dkk signaling.

1,25-Dihydroxyvitamin D Downregulates PHEX Gene Expression in Osteoblasts via Repression of a 110 kDa Positive Transfactor that Binds to a Polyadenine Element in the Promoter. E. R. Hines*[1], O. I. Kolek*[1], M. D. Jones*[2], S. H. Serey*[1], N. B. Sirjani*[1], P. R. Kiela*[1], P. W. Jurutka[3], M. R. Haussler[3], J. F. Collins*[1], F. K. Ghishan*[1]. [1]Pediatrics and Steele Memorial Children's Research Center, University of Arizona College of Medicine, Tucson, AZ, USA, [2]Orthopedic Surgery, University of Arizona College of Medicine, Tucson, AZ, USA, [3]Biochemistry & Molecular Biophysics, University of Arizona College of Medicine, Tucson, AZ, USA.

The PHEX gene, mutated in X-linked hypophosphatemic rickets, encodes an endopeptidase expressed in osteoblasts that inactivates an uncharacterized peptide hormone, phosphatonin, which suppresses bone mineralization as well as renal phosphate reabsorption and vitamin D bioactivation. We demonstrate that 1alpha,25-dihydroxyvitamin D (1,25D), the active renal vitamin D metabolite, decreases both mineralization (measured by calcein staining of calcium phosphate) and PHEX mRNA (monitored by real time PCR) in the rat osteoblastic cell line, UMR-106. 1,25D also represses PHEX expression in mouse calvaria, in vivo. Promoter/reporter construct analysis of the murine PHEX gene in transfected UMR-106 cells localized the repressive effect of 1,25D to the -133 to -74 region, and gel mobility shift experiments revealed that 1,25D treatment of the cells diminished the binding of a nuclear protein(s) to a stretch of 17 adenines from -116 to -100 in the proximal PHEX promoter. Either overexpression of a dominant negative vitamin D receptor (VDR) or deletion of this sequence of 17 A-T base pairs abolished the repressive effect of 1,25D by attenuating basal promoter activity, indicating that this region mediates the 1,25D response and is involved in basal transcription. Southwestern blot analysis and DNA affinity purification show that an unidentified 110 kDa nuclear protein recognizes the poly A element. Because 1,25D-liganded VDR neither binds to the polyadenine region of the PHEX promoter nor directly influences the association of the 110 kDa transfactor, we propose that 1,25D indirectly decreases PHEX expression via VDR-mediated repression of this novel transactivator. Thus, we have identified a cis-element required for PHEX gene transcription that participates in negative feedback control of PHEX expression and thereby potentiates the actions of phosphatonin. We conclude that although 1,25D-VDR indirectly promotes bone mineralization by inducing intestinal calcium and phosphate absorption, the direct action of the hormone-receptor complex on bone is to limit osteoblastic mineralization. One mechanism whereby 1,25D suppresses mineralization appears to involve amplification of the autocrine effect of phosphatonin as a result of PHEX repression.

Notch1 Overexpression Impairs Osteoblastogenesis Exclusively by Downregulating Wnt Signaling. V. Deregowski, E. Gazzerro, L. Priest*, E. Canalis. Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA.

Notch is a family of transmembrane receptors that mediate signaling mechanisms controlling cell fate decisions. Notch activation requires a regulated intramembranous proteolytic cascade leading to the release of Notch intracellular domain (NotchIC) and its nuclear translocation. Overexpression of NotchIC in ST-2 stromal cells depresses osteoblastogenesis and the response to bone morphogenetic protein 2 (BMP) and enhances adipogenesis. The mechanisms involved are not known, but interactions between Notch1 and Wnt/β-catenin may explain the effects observed, since they have opposite effects on cell differentiation and fate. NotchIC overexpression in stromal cells opposes Wnt/β-catenin signaling, decreasing the activity of the Wnt/β-catenin responsive construct, pTOPFLASH, containing Tcf4/Lef1 binding sequences upstream of the luciferase gene, by 50%. NotchIC overexpression induced low density lipoprotein receptor (LRP) 1 mRNA, providing a mechanism for Wnt downregulation since LRP-1 interacts with the Wnt receptor Frizzled to repress Wnt binding and signaling. Moreover, NotchIC overexpressing cells expressed lower β-catenin levels by Western blot analysis. In accordance, transfection of a stable mutant β-catenin expression construct rescued the inhibitory effect of NotchIC on transfected pTOPFLASH constructs. To exclude additional mechanisms involved in the inhibition of osteoblastogenesis by NotchIC, we explored whether Notch1 modified the BMP dependent Smad or mitogen activated protein (MAP) kinase signaling pathways. BMP-2 induced phosphorylation of Smad 1/5/8 and enhanced the transactivation of a transiently transfected BMP-responsive 12xSBE-Oc-pGL3 construct, containing 12 repeats of a Smad binding site directing luciferase expression, but NotchIC overexpression did not modify the level of phosphorylated Smad 1/5/8 or the transactivation of the 12xSBE construct in control or BMP-2 treated cells. BMPs had no significant effect on the phosphorylation of the MAP kinases ERK, p38 or JNK, or on the transactivation of a transfected construct containing seven AP-1 binding site repeats directing luciferase expression, in either control or NotchIC overexpressing cultures. These results indicate that whereas NotchIC overexpression prevents BMP-2 induced osteoblastogenesis, it does not inhibit Smad or MAP kinase signaling pathways, but it impairs Wnt/β-catenin signaling, possibly by inducing LRP-1. This also suggests that maintaining Smad/MAP kinase signaling is not sufficient for BMP-2 dependent osteoblastogenesis.

Mesenchymal Cells Derived from Human Embryonic Stem Cells Differentiate into Bone Forming Osteoblasts. N. K. Shevde[1], J. A. Fretz*[1], L. Crandall*[2], J. A. Thomson*[3], J. W. Pike[1]. [1]Biochemistry, University of Wisconsin- Madison, Madison, WI, USA, [2]WiCell Research Institute, Madison, WI, USA, [3]NPRC/Anatomy, University of Wisconsin- Madison, Madison, WI, USA.

Self-renewing mesenchymal stem cells (MSCs) give rise to a variety of differentiated cell types including adipocytes, chondrocytes, myoblasts, and bone-forming osteoblasts. Thus, MSCs have an enormous therapeutic potential for restoring tissues damaged through injury or disease, and, in the context of bone, may be particularly useful in orthopedic/dental transplants, fracture healing, and skeletal regeneration and repair. Accordingly, isolated bone marrow-derived MSCs have been developed for these applications and have been shown to restore bone *in vivo* in a variety of animal models. We describe here the production of MSCs from human embryonic stem cells (hES) that are capable of forming bone *in vitro*. Totipotent hES cells (H9 and H11 cell lines) routinely maintained in the undifferentiated state on feeder layers of mouse embryonic fibroblasts (MEFs) were allowed to undergo progression and differentiation over a period of 10 to 12 days to form embryoid bodies (EBs). EBs were then disaggregated using trypsin and the isolated cells cultured for an additional 10-14 days in Mesencult medium containing 15% pre-tested FBS. Cells produced in this manner exhibited a sustained high proliferative capacity and a spindle-shaped morphology typical of MSCs. RT-PCR analysis of RNA derived from hES, EBs, and MSC populations revealed a dramatic suppression of Oct4 and BMP7 expression during the progression of hES cells to EBs, and an upregulation of the transcription factor genes Runx2, Msx2 and Dlx5 during the progression of EBs to MSCs. Osteocalcin RNA was undetectable in each of these cell culture populations. To assess the ability of these MSCs to differentiate into bone forming osteoblasts, cells were cultured in DMEM/F12 containing 10% FBS, 50μg/ml fresh ascorbic acid, 5mM β-glycerophosphate and steroids for periods up to 21 days, and then evaluated for the presence of calcified bone nodules using von Kossa staining. Almost all of the cultures showed significant bone nodule formation. RT-PCR analysis of phenotypic markers for authentic osteoblasts confirmed the expression of both osteopontin and osteocalcin. Current experiments are focused on evaluating the bone forming ability of these cells *in vivo*. Our studies demonstrate that hES cells can be induced to produce MSCs capable of further differentiation into functional bone-forming osteoblasts. Thus, hES cells may represent an inexhaustible source of MSCs with therapeutic potential for specific skeletal indications.

Inhibitory Action of N-Cadherin on Osteoblast Differentiation. C. Lai-Huang, C. Liu*, S. Cheng, G. Mbalaviele, R. Civitelli. Bone and Mineral Diseases, Washington University in St. Louis, St. Louis, MO, USA.

We have previously shown that targeted expression of a dominant negative truncated form of N-cadherin (Ncad) delays acquisition of peak bone mass in mice and retards osteoblast differentiation, most likely by interfering with β-catenin signaling. To gain insights on the specific role of Ncad in bone, we used heterozygous Ncad null mice (homozygous loss of Ncad is embryonically lethal), since $Ncad^{+/-}$ calvarial cells express lower abundance of Ncad protein relative to wild type ($Ncad^{+/+}$) cells. Whole body bone mineral density (BMD) by DEXA was not significantly different between $Ncad^{+/-}$ and $Ncad^{+/+}$ littermates up to 8 months of age, implying that a single allele of Ncad is sufficient for bone mass development and maintenance. However, while 4-month-old $Ncad^{+/+}$ mice rapidly (within 3-4 weeks) lost about 8% of baseline BMD following ovariectomy (OVX), bone loss was surprisingly far slower and less pronounced (about -2% at 3 weeks and -4% at 6 weeks post-OVX) in $Ncad^{+/-}$ mice. Since Ncad is expressed in osteoblasts but not in osteoclasts, we characterized the function of $Ncad^{+/-}$ osteoblasts in vitro. Intriguingly, development of calcified nodules was faster and more intense in calvarial cells isolated from $Ncad^{+/-}$ mice relative to $Ncad^{+/+}$ cells, in the presence of ascorbic acid and β-glycerophosphate. Similarly, bone marrow stromal cells from heterozygous mice developed ~40% more alizarin red positive colony forming units than cells from wild type mice, although the difference disappeared after 4 weeks of culture. In 2-week calvarial cultures, alkaline phosphatase activity was 5-fold higher in $Ncad^{+/-}$ relative to $Ncad^{+/+}$ cells. Consistent with an inhibitory role on osteoblast differentiation, Ncad expression (mRNA and protein) was progressively down regulated with differentiation in $Ncad^{+/+}$ calvarial cells. Ncad protein was barely detectable after 3 weeks in mineralizing medium, while cadherin-11 abundance remained unchanged. Interestingly, cell-cell adhesion (tested immediately after reaching confluence) was decreased >30% among heterozygous calvaria cells, as was cell proliferation (pre-confluence), relative to wild type cells. However, the abundance of whole cell β-catenin was not different between $Ncad^{+/+}$ and $Ncad^{+/-}$ cells. These data suggest that Ncad functions as an inhibitor of osteogenic differentiation by preventing cells from progressing through the late stages of osteoblast development, presumably via stabilization of cell-cell adhesion and perhaps reduction of the osteoprogenitor pool. Partial release from this inhibition may be involved in the attenuated bone loss following OVX in $Ncad^{+/-}$ mice.

Disclosures: ***R. Civitelli****, None.*

The Transcription Factor C/EBPα Isoform p30 Promotes Osteoblastogenesis but Inhibits Adipogenesis Contrary to C/EBPα. M. Ueda*, K. Hata*, F. Ikeda, T. Matsubara, S. Ebisu*, R. Nishimura, T. Yoneda. Osaka Univ Grad Sch Dent, Suita, Japan.

Evidence has accumulated that the undifferentiated mesenchymal progenitor cells in bone marrow give rise to both adipocytes and osteoblasts. The transcription factor CCAAT/enhancer-binding protein α (C/EBPα) is known to play a crucial role in adipogenesis. Formation of mature adipocytes was profoundly diminished in C/EBPα-deficient mice. However, little is known about its role in the mesenchymal cell differentiation to osteoblasts. Here, we investigated the role of C/EBPα in osteoblastogenesis as well as adipogenesis using the multipotent mesenchymal cell line C3H10T1/2. Treatment of C3H10T1/2 cells with BMP2 induced C/EBPα expression along with osteoblast differentiation. Of note, we also observed strong expression of C/EBPα isoform p30, which lacks the transcription activation domain, in BMP2-treated C3H10T1/2 cells. These results suggest that C/EBPα and its isoform p30 are involved in osteoblastogenesis. To clarify the role of C/EBPα and p30 in osteoblastogenesis, C/EBPα or p30 were overexpressed in C3H10T1/2 cells using an adenovirus system. Overexpression of C/EBPα induced osteoblast differentiation and enhanced osteoblastogenic effects of BMP2. On the other hand, overexpression of p30 showed marginal induction of osteoblast differentiation. However, p30 markedly augmented BMP2-promoted osteoblastogenesis as C/EBPα did. To understand the molecular mechanism underlying the osteoblastogenic activity of C/EBPα and p30, interactions of C/EBPα or p30 with Runx2 were examined. Overexpression of C/EBPα or p30 stimulated the osteoblastogenic effects and transcriptional activity on the osteocalcin gene promoter of Runx2. Moreover, co-immunoprecipitation experiments revealed a physical association of C/EBPα or p30 with Runx2. Next, the role of C/EBPα and p30 in adipogenesis was examined. Overexpression of C/EBPα induced adipogenesis and PPARγ expression and enhanced BMP2-promoted adipogenesis in C3H10T1/2 cells. Of interest, p30 alone exhibited no effects on adipogenesis. However, it markedly inhibited adipogenesis induced by BMP2 or C/EBPα and suppressed C/EBPα-induced PPARγ expression in a dominant-negative fashion. In conclusion, our results suggest that C/EBPα and its isoform p30 promote osteoblastogenesis through physical and functional association with Runx2. However, p30 exhibits inhibitory effects on adipogenesis contrary to C/EBPα which stimulates adipogenesis. P30 isoform may be a key transcriptional regulator that promotes osteoblastogenesis and inhibits adipogenesis and a potential molecular target in design of therapeutic agents for osteopenia and obesity.

Inhibition of Wnt Signaling by DKK-1 Decreases Osteoblast Differentiation via Mechanisms Dependent on Transcriptional Repression of FRA-1. A. K. Chesterfield*, J. Rohrbach*, V. Easwaran*, D. Ebert*, P. Stevens*, D. Cody*, Y. O. Taiwo, A. Houghton, G. Sabatakos. Skeletal Research, Procter and Gamble Pharmaceuticals, Mason, OH, USA.

Signaling through the canonical Wnt pathway has a dramatic effect on bone mass as has been demonstrated by the low and high bone mass phenotypes of LRP5 mutations. Dkk-1 is an inhibitor of the Wnt pathway by antagonizing LRP5/6 activity. The aim of this study was to explore the mechanism by which Dkk-1 regulates Wnt target gene function that is essential for osteoblast differentiation. For this we generated stable transfectants of Dkk-1 and of a mutant Dkk-1 C220A in C2C12 cells. Cells overexpressing Dkk-1 demonstrated a significant reduction in alkaline phosphatase activity in response to BMP-2. Unexpectedly, overexpression of the C220A mutant inhibited BMP-2-induced differentiation to a greater extent than wild type Dkk-1. In addition, the mRNA levels of the osteoblast markers osterix and alkaline phosphatase were also significantly decreased by both Dkk-1 and C220A overexpression, and these effects were Runx2 independent. Using co-immunoprecipitation studies with the C-terminal of LRP5 we showed that these effects could be due to interactions with LRP5. In the absence of BMP-2 only wild type Dkk-1 interacted with the C-terminal domain of LRP5, whereas, in the presence of BMP-2 both wild type and C220A interacted with LRP5. Having demonstrated the regulatory role of Dkk-1 in BMP-2 induced osteoblast differentiation we investigated whether these events could be mediated through Fra-1. Using EMSA analysis with a Lef/TCF site from the Fra-1 promoter we confirmed that in the presence of BMP-2 complex formation was increased in cells overexpressing both Dkk-1 and the C220A mutant, thus indicating that the inhibitory effect of Dkk-1 or the C220A mutant could be mediated by interactions on the Lef/TCF site of the Fra-1 promoter. However, western blot analysis revealed no change in Fra-1 protein levels in cells overexpressing either Dkk-1 or the C220A mutant, suggesting that Dkk-1 signaling affects transcriptional activity but not abundance of Fra-1. To determine the mechanism of transcriptional regulation of the Fra-1 promoter by Dkk-1, we performed co-tranfections of Dkk-1 with a Fra-1 luciferase reporter containing a trimerized TCF-binding site. Dkk-1 inhibited the Wnt3a-induced luciferase activity demonstrating that the inhibitory effect of Dkk-1 on osteoblast differentiation could be mediated by transcriptional repression of Fra-1. In conclusion, our data demonstrate that Dkk-1 and the C220A mutant are inhibitors of osteoblast differentiation and that the inhibitory effect is mediated by repression of Fra-1 activity at the transcriptional level.

Genomic Occupancy and Chromatin Organization of the Runx2/Cbfa1 Gene P1 Promoter, Which Regulates Its Bone-Specific Expression in Osteoblasts. H. Hovhannisyan*, C. J. Lengner, J. Shen*, J. B. Lian, G. S. Stein, J. L. Stein*, A. J. van Wijnen. Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA.

The essential biological function of the Runx2 transcription factor in skeletal development and the physiological responsiveness of Runx2 gene expression to osteoblast-related anabolic and catabolic factors have become conclusively established concepts in bone cell biology. However, the exact molecular mechanisms that control transcription of Runx2 in mesenchymal cells to support its skeletal gene regulatory function remain to be established. To characterize bona fide promoter elements, we analyzed the regulatory organization of the P1 promoter in intact cells using DNaseI hypersensitivity and chromatin immuno-precipitation (ChIP) assays, as well as LM-PCR assisted genomic DNaseI footprinting. We find that there is only a single DNaseI hypersensitive region (DHS) within 15 kB of the P1 transcriptional start site. At higher resolution this region resolves into several discrete sites located between -0.4 and 0.0 kB which contain the key elements required for basal Runx2 transcription in osteoblasts (as defined by transient transfections with reporter genes). ChIP assays reveal that the DHS of the basal promoter interacts with acetylated histones H3 and H4, reflecting its open chromatin conformation, and the Runx2 protein itself, which we have shown auto-regulates its own promoter. Genomic DNase I footprinting with a panel of mesenchymal cell lines indicates that the DHS region encompasses several in vivo protein/DNA interaction sites (e.g., AP1 binding site at -0.4 kB, an HLH/E-box at -0.1 kB, and Runx2 motifs in the 5'UTR), which are occupied in the endogenous Runx2 P1 promoter within the intact cell. Occupancy of the HLH/E-box, which overlaps with a Runx2 motif, is also observed in Runx2 null cells, as well as in non-osseous cells where Runx2 gene expression is virtually undetectable. We propose a model in which the DHS region (i.e., the first 0.4 kB of the P1 promoter) interacts with HLH factors to repress Runx2 transcription prior to osteoblast lineage commitment. This model invokes putative long-distance control elements (beyond the 15 kB region we examined here) for the BMP2 responsive and bone-tissue specific induction of Runx2.

Structure-Function Analysis of SFRP-1 for its Wnt Antagonist Function. R. A. Bhat, B. Stauffer*, P. V. Bodine. Women's Health and Bone, Wyeth Research, Collegeville, PA, USA.

Wnts are secreted glycoproteins that mediate fundamental biological processes like embryogenesis, organogenesis and tumorigenesis. Many extracellular proteins control Wnt signaling including Wnt inhibitory factor, secreted frizzled related proteins, cerberus and dickkopfs. These proteins either bind to Wnt directly or interact with frizzled receptor or with low-density lipoprotein-receptor related protein (LRP) to modulate Wnt signaling. Recent studies from our group have shown that secreted frizzled related protein-1 (SFRP-1) is an important regulator of osteoblast survival, and the targeted disruption of SFRP-1 in mice led to decreased osteoblast and osteocyte apoptosis and increased trabecular bone formation. SFRP-1 is a secreted glycoprotein of ~35 KD and contains two cysteine rich domains. The amino-terminal Cysteine Rich Domain (CRD) contains 10 cysteines involved in 5 disulphide bridges and is homologous to the CRD domain of Frizzled receptors (FZD). The CRD domain can bind to both the Wnt and the FZD receptor and interfere with Wnt signaling. The carboxyl half of the SFRP-1 contains 6 cysteine residues and is homologous to netrin domains and also contains a hyaluronan-binding region. The present study was focused on identifying the functional domains of SFRP-1 and the structural requirements that are necessary for its Wnt inhibitory function. Several mutants of SFRP-1 were generated and tested by transient transfection in human osteosacrcoma cell line, U2OS, for their ability to inhibit Wnt -3 mediated upregulation of an optimized TCF-Luciferase reporter. Chimeras of SFRP-1 and SFRP-3 were generated by switching their netrin domains and tested for their ability to antagonize Wnt function. Deletion mutants of CRD domain showed reduced Wnt inhibitory activity and deletion of amino acids 71-163 resulted in total loss of Wnt antagonist function. These results indicate that the CRD domain of SFRP-1 is critical for its Wnt inhibitory function. The SFRP-1/SFRP-3 chimera showed a loss of about 30% Wnt inhibitory activity compared to SFRP-1, and SFRP-3/SFRP-1 chimera gained about 40% of the Wnt inhibitory function compared to SFRP-3. These studies from the chimeras have indicated that the netrin domain is necessary for optimal Wnt inhibitory function and may be involved in proper folding of the molecule. Mutation of the hyaluronan binding region of SFRP-1 resulted in about 35% loss of Wnt antagonistic function, suggesting that the SFRP-1 protein may interact with the matrix that results in efficient Wnt inhibition, probably by increasing the local concentration of SFRP-1. The mutational studies clearly demonstrate the interaction of several functional domains in SFRP-1 for the optimal Wnt antagonist function.

Importance of Human Dkk1 C-terminal 21 Amino Acids and Glycosylation for Its Function as an Antagonist of LRP5/6-Wnt-TCF-Signaling. B. M. Bhat[1], H. Lam*[1], V. E. Coleburn*[1], A. Anisowicz*[2], K. M. Allen*[2], P. Yaworsky*[3], F. J. Bex[1]. [1]Women's Health & Bone, Osteoporosis Group, Wyeth Research, Collegeville, PA, USA, [2]Human Genetics, Oscient Pharmaceuticals Corporation, Waltham, MA, USA, [3]Genomics, Wyeth Research, Cambridge, MA, USA.

Human Dickkopf 1 (Dkk1) is an inhibitor of canonical Wnt signaling by interacting with trans-membrane receptors LRP5/6 and Kremens. Members of the Dkk family contain two conserved cysteine-rich (Cys-1 & Cys-2) domains separated by variable-length spacer regions and show greater than 50% aa homology at the C-terminal region. The importance of Cys-2 to functional activity was shown when expression of this region alone retained Wnt signaling inhibitory activity and by the ability of a single C220A mutation in the Cys-2 region of the full-length protein to abolish its inhibitory activity. Opposing activity between the N-terminal Cys-1 domain region and the C-terminal Cys-2 region on Wnt signaling has been reported. To further investigate the structural requirements for Dkk1 activity, we tested the functional consequences in a Wnt3a TCF reporter assay of deletion constructs of Dkk1 that retained either one or both Cys-domains, but had the N-terminal 97aa or C-terminal 21aa removed. Most interestingly, the construct lacking C-terminal 21 aa lost TCF inhibitory activity even though it contained both Cys-domains. Moreover, expression of Kremen-2 enhances wild type Dkk1-mediated inhibition, but cannot reverse the lost functionality of Dkk1 that lacks the C-terminal 21aa. Since this 21 aa region contains a putative N-glycosylation site, it was hypothesized that the glycosylation of Dkk1 could also be necessary for its inhibitory function. When Dkk1-transfected 293A cells were treated with tunicamycin (N-glycosylation inhibitor), Western blot analysis of the conditioned medium (CM) showed a downward mobility shift of Dkk1 (~45kD to ~35kD) suggesting a loss of glycosylation. Importantly, the tunicamycin treated CM showed significantly reduced Wnt-TCF-inhibitory activity as compared to that of the control CM. The importance of Dkk1 glycosylation to its function was further substantiated when we observed 5-10 fold lower Wnt-TCF inhibitory activity in insect cell-derived Dkk1, which lacked proper glycosylation, as compared to that produced by mammalian cells (293A). These results indicate that in addition to conserved Cys-2 domain, the C-terminal 21 aa are essential for the inhibitory function of Dkk1. They also suggest that only properly glycosylated Dkk1 can fully inhibit the Wnt-TCF signal, presumably as a result of improved interaction with LRP5/6 and Kremen-2.

Global Application of Expression Profiling Reveals Potential Involvement of the Wnt, IGF-I, Estrogen Receptor (ER), and BMP/TGFβ Pathways in C57BL/6J (B6) but not C3H/HeJ (C3H) Mouse Osteoblasts in Response to Fluid Shear Stress. K. H. W. Lau, S. Kapur, D. J. Baylink. Musculoskeletal Disease Center, Jerry L. Pettis Mem VAMC, Loma Linda, CA, USA.

Our previous studies indicate that, while B6 inbred mice responded to in vivo mechanical loading with an increase in bone formation; C3H mice showed no such response. In this study, we tested the hypothesis that this inbred mouse differential response would be present in vitro in response to shear stress. We found that a steady fluid shear stress of 20 dynes/cm^2 for 30 min, while significantly increased (by 2-fold, $p<0.001$) thymidine incorporation and ALP specific activity in B6 osteoblasts (ob), had no effects on either parameter in C3H ob, confirming that osteogenic responses to mechanical strains are genetically regulated. We next applied global gene expression profiling 4 hr after the 30-min shear stress in an attempt to identify signaling pathways to account for the differential shear stress response in ob from these 2 inbred strains of mice. RNAs isolated from C3H and B6 ob (4 replicates each) were analyzed by microarray with our in-house chips (containing 5,500 gene fragments). Paired t-test and Lowess normalization were performed with Genespring software and gene expression changes defined as significant if $p<0.05$. The expression of 672 genes in B6 ob and 477 genes in C3H ob was altered in response to the shear stress. 515 genes were affected only in B6 ob. Preliminary grouping (according to gene functions or pathways) of known mouse genes that were affected only in B6 ob revealed that (consistent with an anabolic response) genes involved in proliferation and energy metabolism were upregulated. Several genes of the IGF-I (IGFBP-5, IGF-IR, MKK3, Big MAPK1, c-Fos, c-Jun) and ER (ERα, NCOA1) pathways were upregulated only in B6 ob. Moreover, several genes of the BMP/TGFβ pathways (BMP-4, TGFβ1, TGFβ2, BMP2/4 receptor, Mef2, Dlx-1, Necdin) and the Wnt pathway (Wnt-5a, Lef-1, β-catenin) were also upregulated in B6 but not C3H ob. Regarding the Wnt pathway, the upregulation of gene expression of Wnt-5a, Lef-1, LRP-5, and β-catenin in B6 but not C3H ob was confirmed by real-time PCR and western blots. Importantly, endostatin (a potent inhibitor of wnt pathway) abolished the upregulation of β-catenin gene expression and blocked the shear stress-induced proliferation in B6 ob. In summary, the robust mitogenic response to steady shear stress in B6 but not C3H ob was associated with significant increased gene expression in the IGF, ER, BMP/TGFβ, and Wnt pathways. The differential regulation in these anabolic pathways could contribute to the good and poor response, respectively, in the B6 and C3H mice to fluid shear stress.

Essential Role for Siah1a, but not Siah2, Ubiquitin Ligase in Bone Growth and Remodeling. N. A. Sims[1], I. J. Frew*[2], J. M. W. Quinn[3], C. R. Walkley*[2], R. A. Dickins*[2], L. E. Purton*[2], D. D. L. Bowtell*[2], M. T. Gillespie[3]. [1]Department of Medicine at St. Vincent's Hospital, The University of Melbourne, Melbourne, Australia, [2]Peter MacCallum Cancer Institute, Melbourne, Australia, [3]St. Vincent's Institute, Melbourne, Australia.

The seven in absentia homolog (Siah) proteins function as E3 ubiquitin ligases to target degradation of diverse protein substrates. Mice have three homologous Siah proteins: Siah1a, 1b and Siah2. Siah1a and b differ by only 6 of their 282 amino acids, while Siah2 contains an extended N-terminal region. Given the tightly controlled process of proteasomal degradation of proteins in the Wnt pathway, we predicted that deficiencies in Siah (Siah1a and Siah2 null mice) may reveal physiological roles of these proteins in bone metabolism in vivo, and have analyzed adult Siah1a and Siah2 null (KO) mice by histomorphometry and ex vivo cell cultures.

Siah2KO mice are largely phenotypically normal, and while trabecular and cortical structure and bone turnover are normal, Siah2KO bone marrow produced more osteoclasts in vitro than wild-type bone marrow when stimulated with RANKL, indicating a role for Siah2 in regulating osteoclastogenesis, which is corrected by compensatory mechanisms in vivo.

Siah1aKO mice, however, are growth-retarded and exhibit early lethality. These mice also exhibit a striking osteopenia: trabecular bone volume was half that of wild type mice in both males and females. This osteopenia was associated not only with a low level of bone formation, including low osteoblast numbers and osteoid volume, but also a high level of bone resorption (osteoclast numbers were more than double wild type levels). While ex vivo osteoblast colony formation from Siah1aKO mice was normal, mineralization from these cells was elevated, and may explain the reduction in osteoid volume seen in vivo. In contrast, haematopoietic osteoclast progenitor numbers were normal in Siah1aKO mice and ex vivo osteoclast formation occurred at wild type levels. Furthermore, adoptive transfer of Siah1aKO bone marrow into wild type mice failed to generate osteopenia or elevated osteoclast numbers.

These findings suggest that, unlike Siah2, Siah1a is clearly essential for normal bone metabolism in vivo, yet the bone defect in Siah1a mutant mice is not the result of cell-autonomous requirements for Siah1a in either osteoblast or osteoclast formation.

OPPG and HBM Disease-causing Missense Mutations in LRP5 Have Opposite Effects on Wnt Signaling. M. Ai*, D. Schelling*, M. L. Warman*. Genetics, Case Western Reserve University, Cleveland, OH, USA.

Low-density-lipoprotein receptor Related Protein 5 (LRP5) plays a critical role in regulating bone mass. Nonsense, frameshift, and missense mutations in the gene cause the autosomal recessive disease osteoporosis-pseudoglioma syndrome (OPPG), which is characterized by reduced bone mass. Other missense mutations have been associated with dominantly inherited high bone mass (HBM) phenotypes. How missense mutations in the same gene cause opposite skeletal phenotypes is the subject of this study.

At least one function of LRP5 is as a co-receptor of Wnt ligand in the canonical signaling cascade. We tested 6 OPPG-causing missense muteins (S356L, T390K, G404R, D434N, G520V, G610R) and 7 HBM-causing missense muteins (D111Y, G171R, G171V, A214T, A214V, A242T, T253I) for their ability to transduce Wnt signaling in 293T cells using the TopFlash reporter assay. Wild-type LPR5, when co-transfected with v5-tagged Wnt1 (Wnt1-v5) yielded a 4-fold increase in luciferase activity compared to transfection with Wnt1-v5 alone. The OPPG-causing muteins S356L, T390K, and G520V completely abolished the response to Wnt1-v5, while G404R, D434N, and G610R reduced the response by >50%. Cell surface labeling studies suggest that some of the OPPG-muteins affect protein folding and transport to the cell surface, whereas others may affect Wnt1 binding or interaction with frizzled co-receptors. None of the 7 HBM-causing muteins demonstrated constitutive activity in the absence of Wnt1-v5 ligand. When compared to wild-type LRP5, each of the individual HBM-causing muteins caused modestly or moderately higher (5-35%) luciferase induction in the presence of Wnt1-v5. Also, we found that exogenously applied DKK1 was >50% less effective in inhibiting Wnt1-v5 signaling via the HBM-causing muteins compared to wild type LRP5. This result supports a similar observation made by Boyden et al (N Engl J Med, 2002, 346(20), 1513-1521) for the mutein G171V. Surprisingly, despite the ability of DKK1 to inhibit Wnt1-v5 signaling via LRP5, we could not detect a direct interaction between DKK1 and LRP5 by either co-immunoprecipitation or cell surface labeling. This suggests either that the mechanism of inhibition is more complex than a simple two-protein interaction or that another DKK family member with higher affinity for LRP5 is the primary regulator of signaling in bone. In conclusion, we find that OPPG-causing LRP5 missense muteins have completely or markedly reduced ability to transduce Wnt1-v5 signaling in 293T cells. HBM-causing muteins are not constitutively active, but have slightly increased responsiveness to Wnt1-v5, and are less inhibited by DKK1 compared to wild-type LRP5.

Characterization of Protein-Protein Interactions of Lrp5/6 with Dkk-, Sclerostin- and Kremen-Proteins. H. Glantschnig*[1], P. D. Zuck*[1], V. Kasparcova*[1], H. Zhang*[1], F. J. Hess*[2], L. P. Freedman*[1], S. Harada[1]. [1]Molecular Endocrinology & Bone Biology, Merck & Co.,Inc., West Point, PA, USA, [2]Molecular Neurology, Merck & Co.,Inc., West Point, PA, USA.

Gain of function mutations of LRP5 have defined Wnt/LRP signaling as regulator of bone mass accrual throughout life. LRP5 and LRP6 are cell surface co-receptors for Wnt and Dickkopf (Dkk) proteins, and ligand binding to LRP5/6 modulates the Wnt-signaling pathway. We have found earlier that Dkk-1, like Sclerostin, is expressed predominantly in adult bone. Internalization of LRP5/6 receptors, triggered by Kremen proteins and Dkk, has been proposed as a mechanism to down-regulate Wnt/LRP mediated signaling.

To further define the mechanism of ligand binding to LRP/Kremen receptors, we have established a cell-based ligand-binding assay. Dkk-1, Dkk-4, Soggy, and Sclerostin-proteins were fused to GFP and binding was observed to cells over-expressing LRP5/6 or Kremen2 proteins. Protein-interaction of LRPs and Kremen2 protein were studied by chemical cross-linking and co-immuno-precipitation. Taqman analysis was performed to measure Kremen transcripts in bone.

We find that, in the cell system used, ectopic Dkk-1, Dkk-4, and Sclerostin but not Soggy, bind to LRP5/6. We find that Kremen2 transcripts are highly expressed in bone tissue, and although Kremen2 showed little specific in-vitro binding of Dkk on its own, Kremen2 effectively cooperates with over-expressed LRP5/6 for Dkk binding. LRPs and Kremen2 were found to be associated on the cell surface of double-transfected cells. Interestingly, the complex containing LRP5/6 and Kremen2 on the cell surface was preformed, independently of ectopically added Dkk-1. Further, LRP/Kremen2 complex formation was not affected by LRP5G171V or LRP6G158V substitutions. More importantly, Dkk-1 as well as Sclerostin binding to LRP6G158V is diminished, and this defect extends to functionally affect the cooperativity seen for LRP/Kremen2.

HBM-mutations in LRPs result in reduced cell surface binding of ligands in vitro. This might result in a failure of LRPs to cooperatively interact with Kremen2 for ligand binding and a failure to efficiently remove the LRP/Kremen complex from the cell surface

Hypoxia Inducible Factor-1 and Inducible Nitric Oxide Synthase are Involved in the Inhibition of Osteoblast Differentiation during Modeled Microgravity. M. Zayzafoon, V. E. Meyers, T. L. Clemens, J. M. McDonald. Department of Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

Spaceflight, prolonged disuse and aging are known to induce bone loss due, in part, to decreased osteoblastic differentiation. We have previously shown that osteoblastic differentiation of human mesenchymal stem cells (hMSC) is suppressed after 7 days of culture in modeled microgravity (MMG) while adipocytic differentiation is induced (*Endocrinology* 145:2421-2432). We are also showing at this meeting that MMG alters the actin cytoskeleton in hMSC. The purpose of this study is to examine the effects of MMG on the expression of inducible nitric oxide synthase (NOS2) in order to elucidate the mechanism by which MMG suppresses osteoblastogenesis. It is known that the expression of NOS2 is modulated in response to changes in the actin cytoskeleton. Here we show that exposure of hMSC to MMG for 3 hours increases NOS2 protein expression with plateau at 24 hours. NOS2 is known to be regulated by several transcription factors including the hypoxia inducible factor-1 alpha (HIF-1 alpha). Using Western blotting we show that HIF-1 alpha is acutely increased after 30 minutes of MMG and remains elevated for 7 days. In addition, EMSA demonstrated that MMG increases the DNA binding activity of the hypoxia response element (HRE). Surprisingly, this increase in HIF-1 expression and binding activity were not due to hypoxia. The use of the rotary cell culture system (RCCS), used to simulate microgravity, does not alter pCO2, pO2 or pH. MMG does not alter oxygenation parameters; pO2 (140.8 ± 4.9 mmHg in gravity and 150.4 ± 3.6 mmHg in MMG) and pCO2 (26.9 ± 1.3 mmHg in gravity and 25.3 ± 0.6 in MMG). In addition, MMG using the RCCS did not cause acidosis, as the medium's pH remained constant throughout the study (7.61 ± 0.02). Based upon our previous and recent findings, we propose a novel mechanism by which disruption of the actin cytoskeleton, as seen in microgravity or prolonged disuse, induces normoxic upregulation of HIF-1 alpha and NOS2. The resulting increase in nitric oxide inhibits osteoblastogenesis and induces adipogenesis. These findings may ultimately assist in developing novel anabolic therapy for various forms of osteoporosis.

Leptin Treatment Decreases Bone Marrow Adipocyte Number and Increases Endosteal Bone Formation in Leptin-Deficient Ob/Ob Mice. M. Hamrick[1], H. Choi*[2], D. Hartzell*[2], C. Pennington*[1], M. A. Della-Fera*[2], C. A. Baile*[2]. [1]Cellular Biology & Anatomy, Medical College of Georgia, Augusta, GA, USA, [2]Animal & Dairy Science, University of Georgia, Athens, GA, USA.

The limb bones of leptin-deficient ob/ob mice are known to show lower bone mass, density, and cortical thickness than the limb bones of normal mice. The low bone mass observed in the appendicular skeleton of ob/ob mice is also associated with a marked increase in marrow adipocyte number. Increased marrow adipogenesis has been implicated in the pathogenesis of osteoporosis because mesenchymal progenitor cell populations are directed towards the adipocyte lineage rather than the osteoblast lineage. We tested the hypothesis that leptin treatment increases osteogenesis and decreases marrow adipogenesis by treating leptin-deficient, ob/ob mice with leptin using two different doses of leptin: 2.5μg leptin per day and 10 μg leptin per day. One group of normal mice and one group of ob/ob mice were treated with saline (vehicle) as controls. At the age of 15 weeks mice were implanted with Alzet osmotic pumps for subcutaneous delivery of treatment solutions for 14 days at a delivery rate of 0.25 μl/h. Mice were injected with tetracycline (20 mg per kg body weight) 6 days before the end of the experiment and then with demeclocycline (same dosage as above) one day before the end of the experiment to label bone forming surfaces. The right femur was decalcified, embedded in paraffin, sectioned, and stained with hematoxylin and eosin to visualize adipocytes. The left femur was embedded in methyl-methacrylate and sectioned for visualization of fluorochrome labels. Results indicate that both doses of leptin decreased the number marrow adipocytes by more than 20% (P<.05) compared to PBS-treated ob/ob mice. Both doses also significantly (P<.05) increased the percentage of labeled bone forming endosteal surface by more than 30% compared to PBS-treated ob/ob mice. We conclude that leptin treatment can eliminate bone marrow adipocytes in leptin-sensitive animals and, furthermore, that elimination of marrow adipocytes has positive effects on bone formation.

Structure/Activity Analyses of β-catenin in Osteoblast Differentiation. V. S. Salazar*, J. P. Stains, G. Mbalaviele, R. Civitelli. Bone and Mineral Diseases, Washington University in St. Louis, St. Louis, MO, USA.

Although the Wnt/β-catenin signaling system is now recongnized as a critical regulator of bone formation, the mechanisms by which β-catenin, a ubiquitous transcription factor, provides tissue-specific cues remain unknown. We have previously reported that a transcriptionally active N-terminal truncated β-catenin (ΔN151) enhances osteoblast differentiation induced by BMP-2 in mesenchymal stem cells, but it is inactive by itself. Since endogenous β-catenin has functions beyond transcriptional activity (e.g. modulating cell structure and cell-cell adhesion), and since ΔN151 lacks many important protein-interaction sites (e.g. α-catenin), we asked whether alternative mutants could have different activity. Using retroviral vectors (pLNCX2), we expressed two other transcriptionally active β-catenin mutants, *mut*GSK3β (full length β-catenin with S33A, S37A, T41A, S45A mutations) and ΔN90, with >90% transduction efficiency in multipotent mesenchymal C3H10T1/2 or C2C12 cells. Similar to ΔN151, *mut*GSK3β and ΔN90 had negligible effects on osteogenic differentiation, but all mutants synergized with BMP-2 (100 ng/ml) to stimulate alkaline phosphatase activity (1.8-, 1.6-, 2.5- fold above BMP-2 alone in C3H10T1/2; 1.8-, 1.3-, 2.5-fold in C2C12 cells, respectively). Thus, interference with cell-cell adhesion or with α-catenin binding is not responsible for the osteogenic action of β-catenin. While all 3 mutants stimulated Tcf/Lef transcriptional activity, their relative potency did not correlate with their ability to stimulate cellular differentiation: *mut*GSK3b was the most powerful in activating a Tcf/Lef-luciferase reporter system (2.5-fold), whereas ΔN90 induced the highest degree of synergism with BMP-2 on alkaline phosphatase activity in both cell lines. Although Tcf/Lef transcriptional activity is not sufficient to drive differentiation, in C3H10T1/2 lysates both Tcf-4 and β-catenin co-immunoprecipitate with Smad4, suggesting that Tcf/Lef factors may participate in β-catenin osteogenic signaling. Interestingly, exposure to BMP-2 results in a rapid (within 10 min.) dephosphorylation of endogenous β-catenin, an event required for β-catenin transcriptional activity,

and this correlates to increased β-catenin/Smad4 interaction, as evidenced by co-immunoprecipitation analysis. Collectively, these data support the notion that β-catenin is not sufficient to induce osteogenesis (insufficient activator). Rather, it is direct interactions between β-catenin, downstream components of the canonical β-catenin system, and tissue-specific transcription factors, which drives mesenchymal cell differentiation towards the osteogenic lineage.

Functional Interaction of Dynamin with the Cbl-Src-Pyk2 Signaling Complex in Osteoclasts Regulates Podosome Turnover and Bone Resorption. A. Bruzzaniti, L. Neff*, A. Sanjay, O. Destaing, P. De Camilli*, R. Baron. Yale University School of Medicine, New Haven, CT, USA.

Podosomes are highly dynamic actin-rich structures that mediate osteoclast (OC) attachment and migration. Following integrin engagement, Src forms a tri-molecular signaling complex with c-Cbl and Pyk2. Signaling from this complex is essential for cell migration, and deletion of either molecule leads to disruption of the podosome ring and decreased OC migration and/or resorption. Dynamin, a GTPase essential for endocytosis, is also involved in actin cytoskeleton remodeling. We previously showed that dynamin and dynK44A (a dynamin GTP-binding mutant) are localized to podosomes and that dynK44A slows actin turnover in podosomes relative to wild type dynamin (Ochoa, JCB, 2000). Thus, we hypothesized that dynamin regulates podosome turnover by modulating signaling downstream of integrins, possibly by interacting with the Cbl-Src-Pyk2 complex. Our results show that dynamin is enriched in the podosome ring of OCs and at steady state, is often restricted to the inner edge of the actin ring where podosomes may disassemble. Phosphorylation by Src is known to increase dynamin's basal GTPase activity and in Src-/- osteoclasts, which exhibit disrupted actin ring formation and decreased podosome turnover (Sanjay, JCB, 2001), dynamin failed to localize to podosomes, suggesting that Src-catalyzed phosphorylation of dynamin may promote podosome disassembly. OCs infected with dynamin adenovirus resorbed more when plated on dentin, while resorption was decreased in dynK44A-infected OCs, revealing a GTP-dependent role of dynamin in bone resorption, consistent with the reduced podosome turnover observed in dynK44A over-expressing cells. Immunoprecipitation studies demonstrated a GTPase-independent association of dynamin with both Cbl and Pyk2. Activated Src destabilized the association of dynamin with Cbl, while kinase-inactive Src stabilized dynamin-Cbl binding. Furthermore, a Cbl mutant that binds poorly to Src was constitutively bound to dynamin, confirming that the kinase activity of Src regulates the stability of the dynamin-Cbl complex. In contrast to Src, Pyk2 enhanced dynamin-Cbl association. Moreover, dynamin, but not dynK44A, decreased Pyk2 autophosphorylation at Tyr402, the docking site for the Src SH2 domain, potentially disrupting Src-Pyk2 interaction and negatively affecting recruitment and signaling from this integrin-induced complex at adhesion sites. These studies demonstrate a functional role for dynamin in actin remodeling in osteoclast podosomes and bone resorption, and suggest that this regulation occurs through dynamin's interaction with the Cbl-Src-Pyk2 signaling complex.

c-Fms Y559 Is Required, but not Essential, for Formation of a Multimeric Complex which Controls M-CSF-dependent Motility in OCs. R. Faccio[1], S. Takeshita[2], J. Chappel*[2], G. Colaianni*[1], S. L. Teitelbaum[2], F. P. Ross[2]. [1]University of Bari, Italy and Washington University, St Louis, MO, USA, [2]Washington University, St Louis, MO, USA.

While M-CSF is known to induce cytoskeletal reorganization in macrophages and osteoclasts (OCs) by activation of PI3K and c-Src, the detailed mechanisms remain unclear. We have established a system to identify the role of individual tyrosine (Y) residues in signal transmission by the M-CSF receptor, c-Fms. Despite the fact that wortmannin, a potent inhibitor of PI3K activity, blocks M-CSF-induced OC motility, we find that mutation of Y721, the PI3K binding site of c-Fms, to phenylalanine (F) fails to affect cytoskeletal remodeling or actin ring formation, raising the question of how PI3K modulates the OC cytoskeleton. Surprisingly, mutation of c-Fms-Y559, which we show binds Src, to phenylalanine (F), blocks all the above actin-dependent processes and also fails to activate the Rho-GTPases. We find that PI3K binds c-Fms not only through the canonical c-Fms-Y721, but also indirectly at the level of c-Fms-Y559, via association with Cbl and Src, in a Src kinase dependent manner. Interestingly, several members of the Src Family bind directly c-Fms-Y559 and form a complex with Cbl and PI3K, even in Src-/- OCs, explaining the mechanism by which M-CSF rescues motility in these mutant cells. To better understand how c-Fms-Y559 controls actin reorganization and cell motility, we generated mutants in which selected Y residues are added back to a c-Fms receptor where the existing 7Ys are all mutated to F. While the single add-back mutant c-Fms-Y559 has no effect, the double add-back mutant Y559/Y697, the latter a putative binding site for Grb2, promotes 50% increase in cell migration compared to WT c-Fms, and induces formation of the Src/Cbl/PI3K complex. Grb2 is also recruited to this complex, via binding to Cbl, in a process dependent on M-CSF and blocked by the Src Family kinase inhibitor PP2. Finally, the add-back mutant Y721, in combination with Y559 and Y697, but not alone, maximally rescues osteoclast migration. The mechanism of this event involves recruitment of a second complex between PI3K and Src to Y721. In summary, we have dissected initial steps in a signaling cascade involved in M-CSF induced-actin dynamics. M-CSF, by binding its receptor c-Fms, initiates a series of phosphorylation events resulting in formation of multimeric complexes with Src/Cbl/PI3K/Grb2 via Y559 and Y697, and between PI3K and Src at the level of Y721, which are required for osteoclast motility.

Bone Morphology of the Super *op/op* Mice, M-CSF and VEGFR-1 Tyrosine Kinase Domain Deficient Mice. S. Niida[1], K. Ikeda[1], M. Shibuya*[2]. [1]Bone and Joint Disease, National Center for Geriatrics and Gerontology, Obu, Japan, [2]Institute of Medical Science, University of Tokyo, Tokyo, Japan.

Vascular endothelial growth factor receptor-1 (flt-1/VEGFR-1) is a high-affinity tyrosine kinase (TK) receptor for VEGF, and regulates angiogenesis and functions of monocyte/macrophage lineage cells including osteoclasts. We demonstrated that VEGF and placenta growth factor (PlGF) can substitute for macrophage colony-stimulating factor (M-CSF), an essential cytokine for osteoclastogenesis, to recruit osteoclasts in CSF-1-deficient osteopetrotic (*op/op*) mice. In order to clarify how M-CSF and VEGF signalings interact in bone morphogenesis and to determine which VEGF receptor, VEGFR-1 or VEGFR-2, is responsible for osteoclast formation, we introduced VEGFR-1-signaling deficient mutation (*flt-1TK-/-*) into *op/op* mice. The double mutant (*op/opflt-1TK-/-*) mice, we call them super *op/op* mice in this abstract, show severe osteopetrosis due to a lack of osteoclasts. However, super *op/op* mice could not recruit enough osteoclasts in the bone, whereas in the *op/op* mice osteoclasts were progressively increased in an endogenous VEGF-dependent manner. Administration of VEGF-E, a VEGFR-2-specific ligand, efficiently rescued osteoclastogensis in the super *op/op* mice, whereas PlGF, a VEGFR-1-specific ligand, did not. Administration of VEGF-A, which binds to both VEGFR-1 and -2, induced osteoclast formation in the super *op/op* mice. These results were confirmed in osteoclast formation assays *in vitro* of spleen cells cocultured with OP9 cells (established from *op/op* mice and used as a feeder). These results indicate that osteoclast precursors alos express VEGFR-2 in the super *op/op* mice. Furthermore, the super *op/op* mice exhibited deformation of cartilage structure in the growth plate. Taken together with the previous report that VEGF is involved in cartilage remodeling at growth plate, it was suggested that signaling through VEGFR-1 tyrosine kinase plays a predominant role with M-CSF function for osteoclast formation and cartilage growth.

CSF-1-Dependent Rac-1 Interaction With the Coatomer Protein, Delta-COP in Osteoclasts: A Novel Cellular Role for Rac. K. Yu*, X. Zhao*, K. Insogna. Internal Medicine, Yale University School of Medicine, New Haven, CT, USA.

Rac-1 is a member of the family of small GTPases with prominent effects on the actin cytoskeleton. In osteoclasts, Rac-1 is required for CSF-1-induced cytoskeletal remodeling. To explore other metabolic pathways in osteoclasts where Rac plays a role, we undertook a yeast two-hybrid screen using the Clontec Matchmaker-3 system with wild-type Rac-1 as bait and a cDNA library prepared from osteoclast-like cells (OCLs) as prey. OCLs were prepared by co-culturing murine bone marrow and calvarial osteoblasts. RNA isolated from these cells was highly enriched for c-src, cathepsin K and calcitonin receptor transcripts. Five clones were identified in an initial mating assay screen of the OCL library, which contained 8.6X105 transformants. A Y2H assay using co-transformation confirmed that 3 of the five clones expressed Rac-interacting proteins. One of these encoded delta-COP, a member of the coatomer-I (COP I) family of proteins that coat transport vesicles involved in retrograde transport of proteins from Golgi to endoplasmic reticulum (ER). These retrograde transport vesicles recycle resident ER proteins back to the ER that have arrived at the Golgi as part of COP II-coated cargo vesicles. Deletion of delta COP is lethal in yeast. By RT-PCR we found that the transcript for delta-COP is highly expressed in OCLs. The cDNA for delta-COP was translated and radiolabeled using rabbit reticulocyte lysates and 35S-methionine, and the radiolabeled protein used in an in vitro pull down assay with GST-Rac. This experiment confirmed direct interaction of delta-COP and Rac. Immunoprecipitates of delta-COP prepared from lysates of p-zen cells (mouse fibroblasts expressing the CSF-1 receptor, c-fms) demonstrated CSF-1-dependent co-immunoprecipitation of Rac-1 and delta-COP that was maximal at 2 minutes. We repeated this experiment in lysates prepared from OCLs treated either with vehicle or CSF-1 for 2 minutes. As in p-zen cells, Rac co-immunoprecipitated with delta-COP after 2 min. of treatment with CSF-1. Confocal microscopy demonstrated co-localization of Rac-1 with TGN38, a trans-Golgi-specific protein. As far as we are aware, this is the first report to describe a potential role for Rac in early vesicular transport. It is also the first evidence that Rac can interact with a COP I protein, in this case delta-COP, and that this interaction is regulated by a growth factor. Given the known importance of Rac in regulating the osteoclast cytoskeleton and the importance of the cytoskeleton for Golgi function, it is possible that co-ordination of vesicular transport and actin dynamics in these cells is achieved, in part, through the interaction of Rac-1 and COP I proteins such as delta COP.

NF-kappa B and p38 MAPK Cross-talk Is Critical for Osteoclast Differentiation. C. Menaa[1], M. Corr*[2], C. Froelich*[1], S. Sprague[1]. [1]Evanston Northwestern Healthcare, Northwestern University, Evanston, IL, USA, [2]Evanston Northwestern Healthcare, Evanston, IL, USA.

RANKL is the key cytokine that regulates osteoclast (OC) differentiation. RANKL binds to its receptor, RANK, which then mediates the activation of NF-κB and various MAP kinases, in particular, p38 MAPK and JNK. The role of NF-κB and JNK in OC biology have been demonstrated by *in vivo* studies using knock-out mice. In, *in vitro* studies utilizing specific inhibitors, a regulatory role of the p38 MAPK has been demonstrated. Additional *in vitro* studies have demonstrated that NF-κB and p38 are regulated by both activators and inhibitors of OC formation suggesting cross-talk between these two signal pathways. However, at what step of OC formation and whether the activation of these signaling pathways is synchronized are not known. In order to differentiate the role of the p38 MAPK, we first developed stable cell lines of an OC precursor (RAW 264.7) which over-express dominant negatives (DN) of the upstream kinases regulating p38 MAPK, KK6 and KK3. While the *in vitro* assay demonstrated that the DNs block the effect of immuno-precipitated KK6 or KK3 on p38 MAPK, OC formation was not affected. Moreover, CFU-GM isolated from knock-out mice (KK3 -/- and KK6 -/-) show no difference to response to RANKL compared to the wild type. Equally important, double transfected cells, which over-expressed both the DN of KK6 and KK3, were still capable to form OC in response to RANKL. These findings suggest that an alternative pathway might account for the critical role of p38 MAPK during OC formation. However, the inhibition of NF-κB activity by over-expression of the super-repressor IκB mutant, totally blocked OC formation in response to RANKL. This effect was due to a shift in RAW cell differentiation pathway, rather than to an absolute reduction in numbers of OC precursors, which could be related to either an inhibition in their proliferation or an increase cell death. More importantly, this effect was not due to an impaired RANK receptor but rather to a specific effect of NF-κB, because the IκB super-repressor does not block RANKL stimulating NF-ATc1. Further analysis demonstrated that the p38 MAPK activation was impaired suggesting that the inhibitory effect of NF-κB on OC formation might be due to the inhibition of p38 MAPK. In summary, these data demonstrated that NF-κB is critical for OC differentiation even during the over-expression of NF-ATc1 and that p38 MAPK may mediate this effect. In conclusion, these results collectively suggest that the cross-talk between NF-κB and p38 MAPK is essential for osteoclastogenesis. Thus, our data provide new insight on how multiple signaling pathways of RANKL are synchronized.

Modulation of NFAT2 by TLR Signaling in RANKL-Stimulated RAW264 Cells. T. Ogawa*[1], T. Hirouchi*[1], N. Ishida*[1], K. Yogo*[1], T. Kimura*[2], M. Matsumoto*[3], T. Seya*[3], T. Takeya*[1]. [1]Graduate School of Biological Sciences, Nara Institute of Science and Technology, Ikoma, Nara, Japan, [2]Research Division, Sumitomo Pharmaceuticals Co., Ltd., Konohana, Osaka, Japan, [3]Department of Immunology, Osaka Medical Center for Cancer and Cardiovascular Diseases, Higashinari, Osaka, Japan.

Osteoclasts are formed by fusion of mononuclear precursor cells derived from colony-forming unit granulocyte macrophages (CFU-GM) and branch from the monocyte-macrophage lineage during an early stage of the differentiation process. We previously elucidated the key role of a transcription factor, NFAT2, in the progression to multinucelated cell formation using an *in vitro* differentiation system consisting of the murine monocytic cell line RAW264 and recombinant RANKL. Toll-like receptors (TLRs) have been shown to affect bone metabolism, besides affecting the activation of macrophages and monocytes. Here we report that signaling through TLR 2, 3 and 4 downregulates *NFAT2* at the transcriptional level and suppresses the progression to multinucleated cell formation.

LPS and poly (I:C), triggers of TLR4 and TLR3 activation, respectively, induced *IFN*-ß in RAW264 cells, and conversely, ectopic administration of *IFN*-ß mimicked the effects of LPS and poly (I:C). Neutralizing antibody against IFN-ß suppressed the inhibitory effect of ectopically expressed IFN-ß, but did not cancel the effects of LPS, suggesting the existence of *IFN*-ß-dependent and -independent signaling cascades. In fact, MALP2, a TLR2 ligand, caused the same effects as LPS and poly (I:C), but its activity could be exerted without inducing *IFN*-ß. We found that c-Fos is a component of the AP-1 complex that binds to the *NFAT2* promoter in RANKL-stimulated RAW264 cells, and that IFN-ß as well as the TLR ligands downregulated c-*fos* mRNA. Furthermore, sustained activation of ERK was observed in the TLR ligand- and IFN-ß-treated cells, and PD98059, a specific inhibitor of MEK, restored c-Fos and NFTA2 expression and diminished the inhibitory effects of TLR ligands and IFN-ß.

Together, these results suggest that signaling cascades lying downstream of TLR2, 3 and 4 convergently activate ERK through IFN-ß-dependent and -independent pathways in RAW264 cells and downregulate the signaling from RANK to c-*fos* and *NFAT2*. TLRs, therefore, seem to regulate the balance of immune responses and bone metabolism during acute attacks of vertebrate hosts by various microbes by activating monocyte/macrophages on one hand and suppressing osteoclastogenesis on the other hand.

ITAM-mediated Costimulatory Signals Cooperate with RANKL for Osteoclastogenesis. T. Koga*[1], M. Inui*[2], A. Suematsu*[1], T. Taniguchi*[3], T. Takai*[2], H. Takayanagi[1]. [1]Department of Cellular Physiological Chemistry, Tokyo Medical and Dental University, Tokyo, Japan, [2]Department of Experimental Immunology, Institute of Development, Aging and Cancer, Tohoku University, Sendai, Japan, [3]Department of Immunology, Tokyo University, Tokyo, Japan.

We previously reported that RANKL-induced NFATc1 is a master transcription factor for regulating terminal differentiation of osteoclasts. However, it remains unclear how RANKL activates Ca^{2+} signals that lead to induction of NFATc1. In the immune system, DAP12 and FcRγ, which bear immunoreceptor tyrosine-based activation motif (ITAM), are shown to be important for Ca^{2+} signaling. This prompted us to analyze the role of ITAM in osteoclast differentiation. In the osteoblast-free culture system, osteoclastogenesis induced by RANKL/M-CSF in the bone marrow monocyte/macrophage lineage cells (BMMs) derived from DAP12-deficient mice was severely blocked. However, in coculture system with osteoblasts, the impairment of osteoclastogenesis in DAP12-deficient BMMs was efficiently recovered. In addition, DAP12-deficient mice contained a normal number of osteoclasts *in vivo*. These results suggest that osteoblasts can stimulate the pathway that compensates for the loss of DAP12-mediated ITAM signal. Among ITAM-harbouring adaptors, we found that FcRγ was also abundantly expressed in osteoclast precursor cells. Considering the possibility that DAP12 and FcRγ compensate for each other, we generated the double knock out (DKO) mice of DAP12 and FcRγ. *In vitro* osteoclastogenesis in precursor cells derived from DKO mice was completely blocked in both systems of RANKL/M-CSF and coculture with osteoblasts. Importantly, DKO mice exhibited severe osteopetrosis due to impaired osteoclast differentiation, indicating that DAP12 and FcRγ are essential for osteoclast differentiation *in vivo*. We analyzed DAP12- or FcRγ-associating immunoreceptors in osteoclast precursor cells and identified TREM-2 and SIRP-β1; OSCAR and PIR-A, which associated with DAP12 and FcRγ, respectively. Stimulation of these receptors accelerated RANKL-induced osteoclast differentiation. We found that Ca^{2+} oscillation and NFATc1 expression was impaired in RANKL-stimulated DKO cells, and that osteoclastogenesis in these cells was rescued by the ectopic expression of NFATc1, suggesting that ITAM signaling through these receptors is critical for Ca^{2+} signals and NFATc1 induction during osteoclastogenesis. Thus, ITAM-dependent costimulatory signals activated by multiple immunoreceptors are indispensable for the maintenance of bone homeostasis. This indicates that RANKL and M-CSF are not sufficient to activate signals required for osteoclastogenesis.

CD44 Intracellular Domain Stimulates Osteoclastogenesis in a Presenilin-dependent Manner. W. Cui*[1], C. Chalouni*[2], J. Zhang*[1], H. Ke[3], A. Vignery[1]. [1]Orthopaedics, Yale School of Medicine, New Haven, CT, USA, [2]Cell Biology, Yale School of Medicine, New Haven, CT, USA, [3]Metabolism, Pfizer Global Research and Development, Groton, CT, USA.

Presenilins (PS1 and 2) belong to an enzymatic complex that cleaves the intracellular domain of Alzheimer Precursor Protein (APP) after its extracellular domain has shed. Mutations in PS have been associated with Alzheimer Disease. While PS1 and PS2 share over 60% identity, only PS2 expression is regulated. In addition, PS1 deletion is associated with major skeletal defects. We identified PS2 as a transcript transiently induced in fusing macrophages using oligonucleotide microarray. As we previously reported, CD44 is a transmembrane protein the expression of which is highly but transiently induced in macrophages at the onset of fusion. CD44, like APP, sheds its extracellular domain. We therefore set out to investigate whether PS plays a role in osteoclastogenesis, and if so, whether it targets CD44. DAPT and DupE, two potent inhibitors of PS, dose-dependently inhibited fusion of pre-osteoclasts without affecting PS expression. To next investigate whether PS targets CD44, we engineered fusion proteins lacking CD44 extracellular domain (DE-CD44) tagged with myc or GFP inserted in the retroviral vector MigR1. Using confocal microscopy, we found DE-CD44-GFP transiently expressed in pre-osteoclasts localized in both the plasma membrane and the nucleus. This was confirmed by subcellular fractionation studies that revealed the presence of a lower molecular weight form of CD44 in the nuclear fraction. In contrast, DAPT and DupE treatment of these cells confined DE-CD44 localization to the plasma membrane. To investigate the role of CD44 intracellular domain (ICD), we engineered a fusion protein containing CD44-ICD tagged with myc. CD44-ICD-myc transiently expressed in pre-osteoclasts potentiated their fusion into TRAP+ multinucleated osteoclasts. In addition, CD44-ICD-myc rescued fusion in cells treated with DAPT. MigR1 containing myc alone had no effect. To initiate an investigation on the mechanism by which CD44-ICD promotes fusion, pre-osteoclasts were transiently transfected with CD44-ICD together with promoter-linked luciferase reporter genes. CD44-ICD strongly activated NFkB and SRE, and modestly AP-1, but not NFAT. We next subjected 8 month old female mice deficient in CD44 and age-sex matched wild types to pQCT analysis. CD44-/- demonstrated a 1.5 fold higher total bone density, and 2 fold higher trabecular bone density than controls. Together, our data suggest that the intracellular domain of CD44 stimulates osteoclastogenesis by virtue of altering gene transcription in a presenilin-dependent manner.

Multiple RANK Cytoplasmic Motifs Play Distinct Roles in Osteoclast Differentiation, Function and Survival. W. Liu*, D. Xu*, X. Feng. Pathology, Univ. of alabama at birmingham, Birmingham, AL, USA.

Osteoclasts differentiate from mononuclear cells of monocyte/macrophage lineage upon the stimulation of two critical factors: M-CSF and RANKL. RANKL, a member of the TNF superfamily, exerts its effects through its receptor RANK which is expressed on osteoclast precursors and mature osteoclasts. Since the unraveling of the RANKL/RANK system, it has been established that the RANKL/RANK system plays an important role in osteoclast differentiation, function and survival. As a member of the TNF receptor superfamily, RANK mediates intracellular signaling by recruiting signaling molecules such as TRAFs. The previous data have shown that the RANK possesses three functional RANK motifs (Motif 1: PFQEP$^{369-373}$; Motif 2: PVQEET$^{559-564}$ and Motif 3: PVQEQG$^{604-609}$ in its cytoplasmic domain that are capable of promoting osteoclast formation. In addition, Motif 1 is less potent than Motif 2 and Motif 3 in stimulating osteoclast formation. In the present study, we investigated the role of the three RANK cytoplasmic motifs in osteoclast function and survival. The bone resorption assays demonstrated that all these motifs are able to mediate bone resorption. However, our data indicated that Motif 1 plays a predominant role in modulating the survival of mature osteoclasts. Notably, while Motif 1 is not very potent in promoting osteoclast formation, it plays an important role in osteoclast survival. Thus, these three RANK motifs play distinct roles in osteoclast differentiation and survival. RANK has been shown to activate NF-κB/IκB and three MAPK (JNK, ERK and p38) pathways in osteoclasts. So, we examined the role of the RANK motifs in the activation of these signaling pathways. Our signaling studies demonstrated that these functional RANK motifs activate different intracellular signaling in osteoclasts. All three RANK motifs were able to activate IκB/NF-κB pathway. Moreover, our data showed that Motif 1 could also significantly activate all three MAPK pathways: JNK, ERK and p38. In contrast, Motif 2 only induced p38 activation and Motif 3 did not activate any of MAPK pathways. In summary, the identification of these functional RANK cytoplasmic motifs not only revealed the complexity of the RANK signaling in osteoclast formation, function and survival but also laid a foundation for further delineating downstream RANK signaling pathways in osteoclasts. Moreover, these RANK motifs themselves represent potential therapeutic targets for bone disorders such as osteoporosis.

In Vivo Characterization of β_3 Integrin $S^{752}P$ and $Y^{747}F/Y^{759}F$ Mutants in Ovariectomy-induced Bone Loss. H. Zhao, F. P. Ross, S. L. Teitelbaum, D. V. Novack. Departments of Pathology and Medicine, Washington University School of Medicine, St. Louis, MO, USA.

$\alpha_v\beta_3$ integrin, the most abundant integrin expressed in osteoclasts, plays a fundamental role in osteoclastic bone resorption. We have previously performed an in vitro structural-functional analysis of the β_3 integrin cytoplasmic domain mediating osteoclast function, using retroviral transduction of $\beta_3^{-/-}$ osteoclast precursors . Of a series of human β_3 integrin constructs bearing point mutations known to effect β integrin function, only one, $S^{752}P$, representing a mutation seen in Glanzmann's thrombasthenia, failed to rescue $\beta_3^{-/-}$ osteoclast function. Although Y^{747} and Y^{759} are essential for platelet function, the $Y^{747}F/Y^{759}F$ mutant behaved like β_3^{WT}. We previously demonstrated that $\beta_3^{-/-}$ mice are protected from ovariectomy-induced bone loss. In the current experiments we characterize the role of these β_3 mutants, in vivo, using the ovariectomy model, combined with transplantation of lentiviral-transduced bone marrow. Whole bone marrow cells were collected from $\beta_3^{-/-}$ female donor mice and transduced overnight with lentiviral vectors harboring human β_3^{WT}, β_3^{S752P}, or $\beta_3^{Y747F/Y759F}$, then tail-vein injected into irradiated $\beta_3^{-/-}$ female recipient mice. Five weeks later, baseline measurement of bone mineral density (BMD) was performed by DEXA, and the mice were ovariectomized. One-month after the operation BMD was again measured by DEXA, at the time of sacrifice. At this point, two months post-transplantation, approximately 40%-50% of bone marrow cells expressed the human β_3 constructs, as demonstrated by flow cytometry, with equivalent levels of surface expression. Bone marrow macrophages were also isolated and incubated with MCSF and RANKL for 5 days to generate osteoclasts. β_3^{WT} and $\beta_3^{Y747F/Y759F}$ but not β_3^{S752P} expressing osteoclasts had normal cell spreading and formed actin-rings on dentin. Most importantly, β_3^{S752P} transplanted mice, like $\beta_3^{-/-}$ mice, were protected from bone loss induced by estrogen deficiency, compared to β_3^{WT} and $\beta_3^{Y747F/Y759F}$ transplanted mice. Specifically, ovariectomy resulted in a 4% or 2.5% loss in whole body BMD in $\beta_3^{-/-}$ mice transduced with β_3^{WT} and $\beta_3^{Y747F/Y759F}$, respectively, while $\beta_3^{-/-}$ mice transduced with β_3^{S752P} showed a 2% gain ($p<0.01$). BMD loss was 10% in the lumbar vertebrae with β_3^{WT} and $\beta_3^{Y747F/Y759F}$, but only 2% with β_3^{S752P} ($p<0.01$). Isolated tibial BMD was 0.049 g/cm^2 for β_3^{WT}, 0.052 g/cm^2 for $\beta_3^{Y747F/Y759F}$, and 0.058 g/cm^2 for β_3^{S752P} ($p<0.01$). In summary, we have used a lentiviral transduction strategy to introduce various human β_3 integrin constructs into $\beta_3^{-/-}$ mice, demonstrating that S^{752}, and not $Y^{747/759}$, is critical for osteoclast function in vivo.

Further Characterization of Human Osteoclast Inhibitory Peptide-1 (OIP-1/hSca) Gene Expression. M. Ito[1], H. Kajiya[1], N. Kawanabe*[1], N. Kurihara[1], T. L. Johnson-Pais*[2], J. J. Windle*[3], S. V. Reddy[1]. [1]Medicine-Hematology/Oncology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Pediatrics, University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [3]Human Genetics, Virginia Commonwealth University, Richmond, VA, USA.

We have previously identified and characterized osteoclast inhibitory peptide-1 (OIP-1), a member of Ly-6 gene family. Although previous studies have determined the chromosomal localization and partial characterization of the OIP-1 gene 5'-flanking region, the promoter activity and mechanisms of gene regulation remain to be elucidated. Therefore, in the present study we isolated a human BAC genomic clone containing the OIP-1 gene and sequence analyzed 2 Kb 5'-flanking region for transcriptional factor binding motifs and promoter activity. We identified motifs with significant identity (>85%) for transcription factors SP-1, SRY, c-Myc, c-Myb, GATA-2, AP-2, AP-4 and ADR1 in the OIP-1 gene promoter region. IFN-gamma treatment of RAW264.7 cells transfected with OIP-1 gene promoter-luciferase reporter plasmids demonstrated a significant (4 fold) enhancement of OIP-1 gene promoter activity. In order to assess the effects of constitutive over-expression of OIP-1 on osteoclast differentiation, we stably expressed OIP-1 in RAW264.7 cells and clonal cell lines were established. OIP-1 expression in RAW264.7 cells significantly inhibited osteoclast differentiation compared to mock transfected cells stimulated with RANKL. We further examined OIP-1 binding to RAW 264.7 cells using FACS analysis. Fluorescein conjugated OIP-1 c-peptide demonstrate a low affinity binding (<30%) to these cells. These data may suggest presence of a low affinity binding surface receptor or membrane protein partner. To further determine the in vivo effects of OIP-1, we have developed transgenic mice in which OIP-1 expression was targeted to cells of osteoclast lineage using the mouse TRAP gene promoter and identified three founder mice (two males and one female), which express OIP-1. RANKL stimulation of OIP-1 mice derived bone marrow cells resulted in significantly decreased osteoclast formation compared to wild type littermates. Furthermore, OIP-1 transgenic mice bones demonstrated an osteopetrotic phenotype. These data suggest that OIP-1 is an important physiologic regulator of osteoclast development and bone resorption in vivo.

Recruitment of Csk to Lipid Rafts by Cbp/PAG Is Critical to the Regulation of c-Src Activity in Osteoclasts. T. Matsubara[1], F. Ikeda[1], K. Hata*[1], F. Ichida*[1], M. Okada*[2], R. Nishimura[1], T. Yoneda[1]. [1]Dept Biochem, Osaka Univ Grad Sch Dent, Osaka, Japan, [2]Oncogene Res, Res Inst for Microbial Diseases, Osaka, Japan.

A tyrosine kinase c-Src is essential for the formation of actin rings and ruffled borders and subsequent bone resorption in osteoclasts. c-Src activity is negatively regulated by Csk. Despite that Csk is ubiquitously expressed, c-Src activity is characteristically increased in osteoclasts compared with other cells, suggesting the presence of yet-unidentified specific mechanism for elevated c-Src activity in osteoclasts. Recently, Csk binding protein Cbp/PAG has been identified and found to recruit Csk to lipid rafts on cell membrane where c-Src and Csk harmoniously control actin organization. However, it is currently unexplored whether Cbp/PAG plays a role in the regulation of c-Src and Csk function and ultimately bone resorption in osteoclasts. To determine subcellular localization of c-Src and Csk in osteoclasts, lipid rafts were isolated from osteoclast-like cells formed in RAKL-treated spleen cultures by successive fractionation by Triton X-100 and n-octyle-D-glucoside treatment. Western analysis demonstrated that c-Src was localized in lipid rafts and highly activated. In contrast, Csk expression in lipid rafts was not detected, although its expression in unfractionated osteoclasts was equivalent to other tissues or cells including lung, liver and macrophages. To examine whether Cbp is involved in decreased Csk expression in lipid rafts, we determined Cbp expression in osteoclasts. Interestingly, Cbp expression in osteoclasts was much lower than other tissues or cells. In addition, co-immunoprecipitation experiments showed that the amount of Csk bound to Cbp was profoundly decreased in osteoclasts. Consistent with these observations, Cbp expression was markedly down-regulated in osteoclast-like cells formed in soluble RANKL-treated spleen macrophages or RAW-D cells, while c-Src activity was up-regulated. To validate the relationship between Cbp expression and Csk recruitment to lipid rafts, we introduced Cbp in osteoclasts using adenovirus technology. Cbp introduction caused physical association between Csk and Cbp and recruitment of Csk to lipid rafts in a Cbp concentration-dependent manner and profoundly suppressed c-Src activity. More importantly, Cbp markedly inhibited actin ring formation in osteoclasts and blocked pit formation on dentine slices by these osteoclasts. In conclusion, our results suggest that increased c-Src activity in osteoclasts is attributable to decreased Cbp expression, leading to impaired recruitment of Csk to lipid rafts. Cbp/Csk/c-Src cascade may be a critical signaling pathway involved in osteoclastic bone resorption.

Osteopetrosis in Pyk2 -/- Mice Is Due to an Autophosphorylation-dependent Cell Autonomous Defect in Actin Organization and Bone Resorption. A. Sanjay[1], H. Henn*[2], L. Neff*[1], N. Sims[1], K. Aoki[1], T. Miyazaki[1], J. Schlessinger*[2], R. Baron[1]. [1]Orthopaedics & Rehabilitation, Yale University School of Medicine, New Haven, CT, USA, [2]Pharmacology, Yale University School of Medicine, New Haven, CT, USA.

Pyk2 is a member of the focal adhesion kinase (FAK) family of non-receptor tyrosine kinases and like Src, it is highly expressed in podosomes in osteoclasts. Like Src, Pyk2 is phosphorylated in response to adhesion-induced integrin stimulation, but in a calcium-dependent manner. Pyk2 is characterized by a centrally located kinase domain which autophosphorylates tyrosine 402. The Src SH2 domain binds to the autophosphorylated tyrosine 402 of Pyk2, and we have previously established that this recruitment of Src to the activated integrin complex is necessary for osteoclastic bone resorption. Pyk2$^{-/-}$ mice are osteopetrotic and the osteopetrotic effects of deleting Pyk2 and Src are additive. The present study aimed to identify the molecular mechanisms by which Pyk2 regulates bone resorption. Mix-and-match experiments co-culturing bone marrow and osteoblasts from wild type and Pyk2$^{-/-}$ mice demonstrated that the defect is cell autonomous to the osteoclast lineage. Analysis of the cytoskeleton demonstrated that Pyk2$^{-/-}$ osteoclasts failed to form an actin ring. The podosomes were instead organized as dense clusters or in multiple small rings. In addition, the cells failed to form a proper ruffled border and the localization of the proton pump was altered. In vitro, osteoclasts derived from Pyk2$^{-/-}$ cultures showed decreased bone resorption activity with shallow pits. To determine the molecular mechanisms of Pyk2 function in osteoclasts, we then examined the effects of adenovirus-driven expression of wild type Pyk2 and kinase-dead and Y402F mutants of Pyk2 on the actin cytoskeleton and bone resorption. Reconstitution of Pyk2-deficient cells with wild type Pyk2 or kinase-dead Pyk2 resulted in full rescue of the altered actin phenotype, while in wild type osteoclasts they did not affect bone resorption. In contrast, expression of the Y402F mutant failed to rescue Pyk2$^{-/-}$ osteoclasts while its expression in wild type cells resulted in smaller cells with disrupted actin rings and decreased bone resorption. Thus, the osteopetrotic phenotype of Pyk2$^{-/-}$ mice is due to a cell autonomous defect in osteoclasts that affects the organization of podosomes, the actin ring and bone resorption and is due at least in part to the lack of Src recruitment to adhesion sites by Pyk2 autophosphorylation at Y402.

The IKK Inhibitor, NEMO-binding Domain Peptide, Blocks Osteoclastogenesis and Bone Erosion in Inflammatory Arthritis. S. Dai*, T. Hirayama*, S. Abbas*, Y. Abu-Amer. Orthopaedics and Cell Biology & Physiology, Washington University School of Medicine, Saint Louis, MO, USA.

Activation of the transcription factor NF-kB leads to expression of ample genes that regulate inflammatory and osteoclastogenic responses. In this regard, gene targeting studies have shown that members of the NF-kB family are obligatory for osteoclastogenesis, and mediate inflammatory processes. Activation of NF-kB requires induction of IkB kinase (IKK) complex that phosphorylates the NF-kB inhibitory protein IkB and leads to its dissociation form the NF-kB complex, thus permitting nuclear translocation of NF-kB. The IKK complex contains several factors primarily IKK-alpha, IKK-beta, and the regulatory kinase IKK-gamma, also known as NEMO. IKK activity is utterly dependent on the integrity of NEMO and entails recruitment of this kinase through its binding to carboxyl-terminal region of the IKK-alpha and IKK-beta, termed NEMO-binding domain (NBD). In this regard, recent studies have shown that a cell-permeable NBD peptide blocks association of NEMO with the IKK complex, inhibits cytokine-induced activation of NF-kB, and ameliorates inflammatory responses. Given the pivotal role of cytokine-induced NF-kB in osteoclastogenesis and inflammatory bone loss, we deduced that cell-permeable TAT-NBD peptide may hinder osteoclastogenesis and bone erosion in inflammatory arthritis. Using NBD peptides, we show that wild type, but not mutant, NBD blocks recruitment of NEMO to IKK-alpha and IKK-beta as reflected by diminished TNF activation of IKK-alpha and by comprehensive inhibition of IKK-beta activation measured by in vitro kinase activity assays. Consistent with the crucial role of IKKs as activators of NF-kB, and the pivotal role of NF-kB in osteoclastogenesis, wild type NBD inhibition of IKK-alpha and IKK-beta led to reduced TNF-induced promoter and DNA-binding activities of NF-kB and to inhibition of cytokine-induced osteoclast formation by macrophages. NF-kB is considered a key regulator of osteolytic and inflammatory responses. To test their effect in vivo, wild type and mutant TAT-NBD peptides were administered into mice prior to induction of inflammatory arthritis. Our findings indicate that wild type NBD efficiently blocks in vivo osteoclast recruitment, inhibits focal bone erosion, and ameliorates inflammatory responses in the joints of arthritic mice. The mutant NBD failed to execute these functions. These results provide strong evidence that IKKs are potent regulators of cytokine-induced osteoclastogenesis and inflammatory arthritis. More importantly, blockade of NEMO assembly with the IKK complex is a viable strategy to avert inflammatory osteolysis.

Calcineurin Is Necessary for Osteoclastogenesis. L. Sun[1], Y. Peng*[1], J. Iqbal*[1], G. Rajendren*[1], B. Moonga[1], O. Adebanjo*[1], E. Abe[1], H. C. Blair[2], A. Zallone[3], S. Epstein[1], M. Zaidi[1]. [1]Medicine, Mt. Sinai School of Medicine and the Bronx VA GRECC, New York, NY, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]University of Bari, Bari, Italy.

We demonstrate that dephosphorylation of the transcription factor NFATc1 by the Ca^{2+}-activated phosphatase calcineurin is required for osteoclast formation. Specifically, we show that (a) calcineurin A$\alpha^{-/-}$ progenitors display reduced osteoclastogenesis, (b) the calcineurin inhibitors cyclosporine A (CsA) and tacrolimus (FK506) inhibit osteoclast differentiation, (c) calcineurin over-expression, as a TAT fusion protein, stimulates NFATc1 expression, (d) calcineurin dephosphorylates NFATc1, and (e) dominant-negative and constitutively-active NFATs, respectively, inhibit and enhance osteoclast differentiation. Immune labeling localized calcineurin to osteoclasts both *in vivo* and *in vitro*. Real time PCR showed that the calcineurins Aα, Aβ, Aγ, B1, and B2 remained constant during osteoclastogenesis. However, NFATc1 expression increased up to 10-fold at days 3 and 5, while NFATc2 showed a 5-fold decrease at day 5. NFATs c3 and c4 showed no change. Parallel cross-linking, immunoprecipitation, and phosphatase assays determined that NFATc1 bound to, and was dephosphorylated by calcineurin Aα. That calcineurin was required for osteoclastogenesis was established by the 50% reduction in osteoclast formation noted in calcineurin A$\alpha^{-/-}$ bone marrow cell cultures and in cultures treated with CsA or FK506. In separate experiments, TAT-calcineurin Aα over-expression in RAW-C3 cells enhanced NFATc1, and to a lesser extent NFATc2 expression. Inhibiting the expression of specific calcineurin isoforms through anti-target (Aα, Aβ, Aγ or B1) U1 vectors resulted, in every case, in a marked reduction in NFATc1 expression. TAT-calcineurin Aα increased osteoclast differentiation markers, notably TRAP and β3. Co-expression of TAT-calcineurin Aα with dominant-negative NFAT significantly attenuated this induction, establishing that NFAT was downstream of calcineurin. Finally, constitutively active NFAT stimulated TRAP and β3 expression by up to 8-fold, confirming a direct effect of NFAT on osteoclast differentiation. Taken together, the results demonstrate that an intact calcineurin-NFAT axis is a requirement for full osteoclastogenesis.

An Osteoclastic Protein-Tyrosine Phosphatase (PTP-oc) Regulates Osteoclast Activity In Part By Decreasing Osteoclast Apoptosis Through c-Src-Dependent Activation of NFκB. K. H. W. Lau, M. Amoui, D. J. Baylink. Jerry L. Pettis Mem VAMC, Loma Linda, CA, USA.

Our previous studies have indicated that PTP-oc plays an important regulatory role in osteoclast (Oc) activity. The present study sought to determine the mechanism whereby PTP-oc regulates Oc activity by evaluating the effects of overexpression of wild-type (WT) or phosphatase-dead (PD) PTP-oc on Oc or precursors. We have shown that Oc-like cells derived from RAW264.7 clones stably overexpressing WT-PTP-oc showed 2- to 3-fold increases, while Oc-like cells derived from stable clones expressing PD-PTP-oc had a significant > 50% reduction in resorption activity, suggesting that these clones can be used to investigate the mechanism whereby PTP-oc regulates Oc activity. Since c-src has an essential role in Oc activity and since c-src is regulated negatively by tyr-527 phosphorylation (PY527), we tested the hypothesis that PTP-oc acts to dephosphorylate c-src PY-527, leading to c-src activation and increased Oc activity. The rationale for this hypothesis was that we had previously shown that WT-PTP-oc overexpressing clones showed significant reduction, whereas PD-PTP-oc expressing clones had elevation, in c-src PY527. The Oc-like cells derived from WT-PTP-oc overexpressing clones appeared to have a longer life span than control Oc-like cells. Because an increase in the life span of Oc could increase their overall resorption activity, we sought to test the hypothesis that PTP-oc regulates Oc activity in part by reducing the apoptosis of Oc. Because the NFκB pathway (activated by phosphorylation and degradation of IκB) has anti-apoptotic functions in Oc, and because IκB can be phosphorylated by c-src in Oc, we tested the effects of PTP-oc overexpression on NFκB activation. We found that WT-PTP-oc overexpressing clones showed a significant decrease (30-70%) in cellular IκB level with a corresponding increase (50-100%, $p<0.01$) in NFκB activation. Conversely, PD-PTP-oc expressing clones exhibited a 50-75% ($p<0.01$) increase in cellular IκB and a 25-50% reduction in NFκB activation. Moreover, WT-PTP-oc overexpressing clones showed a 2- to 4-fold ($p<0.001$) decrease, whereas PD-PTP-oc expressing clones had an increase (50% to 2-fold, $p<0.001$), in apoptosis. Consistent with the premise that the increased IκB degradation was mediated through PTP-oc-induced c-src activation, we found that overexpression of the K295S-inactive c-src mutant in PTP-oc overexpressing clones led to several-fold increases in cellular IκB level. In conclusion, these findings are entirely consistent with the position that PTP-oc activates Oc activity in part by decreasing Oc apoptosis through the PTP-oc-mediated c-src-dependent activation of the NFκB pathway.

SHIP Negatively Regulates M-CSF Stimulated Proliferation of Osteoclast Precursors via Altering the Akt-GSK-3β - cyclin D Pathway. P. Zhou[1], S. L. Teitelbaum[1], N. Namba*[2], C. D. Helgason*[3], R. K. Humphries*[3], G. Krystal*[3], F. P. Ross[1], S. Takeshita[1]. [1]Pathology, Washington University, St. Louis, MO, USA, [2]Padiatrics, Okayama University, Okayama, Japan, [3]Terry Fox Laboratory, BC Cancer Agency, Vancouver, BC, Canada.

SHIP, an SH2-containing inositol-5-phosphatase, negatively regulates phosphatidylinositol-3-kinase (PI3-K)-initiated signaling by dephosphorylating phosphatidylinositol-3, 4, 5-triphosphate. SHIP is essential for normal bone homeostasis as knock out mice contain increased numbers of hyper-resorptive osteoclasts leading to osteoporosis. SHIP null osteoclast precursors, in the form of bone marrow macrophages, undergo robust osteoclastogenesis in response to both macrophage colony-stimulating factor (M-CSF) and receptor activator of nuclear factor-κ B ligand (RANKL) *in vitro*. Here we characterize the mechanism involved in the negative regulation of osteoclast differentiation by SHIP. We find that inhibition of M-CSF dependent osteoclast precursor proliferation by SHIP contributes to the ability of the lipid phosphatase to suppress osteoclastogenesis. We show that *SHIP*$^{-/-}$ osteoclast precursors exhibit a hyperproliferative response to M-CSF. This accelerated proliferation correlates with advanced and elevated accumulation of D-type cyclins and subsequently hyperphosphorylation of the retinoblastoma (Rb) protein in *SHIP*$^{-/-}$ osteoclast precursors compared to wild type cells. Analysis of M-CSF signaling reveals that SHIP suppresses activation of Akt but not ERK. Consistent with elevated active Akt in *SHIP*$^{-/-}$ osteoclast precursors, inactivation of GSK-3β , a process primarily regulated by Akt-induced phosphorylation, is also enhanced in these cells. Inhibition of PI3-K activity by the specific inhibitor, LY294002, abrogates M-CSF induced Akt activation, GSK-3β phosphorylation and D-type cyclin expression, and also dose dependently blocks osteoclast precursor proliferation at doses that have no affect on cell viability. Reconstitution of SHIP expression in *SHIP*$^{-/-}$ osteoclast precursors via retrovirus corrects their enhanced Akt activation, proliferation and osteoclastogenesis. Retroviral expression of SHIP mutants lacking phosphatase activity, or the N-terminal SH2 domain or the C-terminal 163 amino acids in *SHIP*$^{-/-}$ osteoclast precursors fails to rescue enhanced osteoclastogenesis, documenting the requirement of these domains in SHIP-regulated osteoclast precursor proliferation and osteoclastogenesis. These studies establish a critical role of the PI3-K->SHIP->Akt->GSK-3β pathway in M-CSF induced osteoclastogenesis.

Clinically-Defined Frailty Is Associated with Lower Hip Bone Mineral Density and a Greater Rate of Decline in Hip Bone Mineral Density in Older Women: Data from the Study of Osteoporotic Fractures. J. K. Tracy*[1], M. C. Hochberg[2], J. Cauley[3], K. Ensrud[4], T. Hillier*[5]. [1]Epidemiology, University of Maryland, Baltimore, MD, USA, [2]Medicine and Epidemiology, University of Maryland, Baltimore, MD, USA, [3]Epidemiology, University of Pittsburgh, Pittsburgh, PA, USA, [4]Medicine, University of Minnesota, Minneapolis, MN, USA, [5]Medicine, Kaiser Permanente, Portland, OR, USA.

To determine whether the clinical syndrome of frailty is associated with lower bone mineral density (BMD) in older women, we evaluated data from 7809 white women aged 67 years and above (mean [SD] 73.6 [5.1] years) who completed their second clinic visit (V2) between 1988-1989 and had BMD measured by DXA (Hologic QDR-1000, Waltham, MA). Women were categorized into three groups (frail, pre-frail, not frail) based on a phenotypic definition that includes the elements of weight loss, weakness, poor endurance and energy, slowness and low physical activity (J Gerontol 2001;56A:M146-56). 629 (8.1%) women were categorized as frail (3 or more features), 4987 were pre-frail (1 or 2 features) and 2193 were not frail (no features). Frail women were significantly older, shorter and lighter and more likely to have had a prior fracture than both pre-frail and not frail women. Frail women had lower total hip and femoral neck BMD (P < .001); however, lumbar spine BMD did not differ by frailty group (Table 1). These results were unchanged after adjustment for age. To determine whether frail women had a greater rate of decline in total hip BMD, we evaluated data from the subgroup of 5657 women who had BMD measured by DXA at both V2 and V4, a mean of 3.5 years apart. Frail women had a greater rate of decline in total hip BMD, even after adjustment for age and weight (P = .001) (Table 2). These results demonstrate that the clinical syndrome of frailty is associated with both lower hip BMD and a greater rate of decline in hip BMD in older women. Further analyses will explore whether frailty is an independent risk factor for hip fracture among older women.

Table 1. Mean (SD) BMD (gm/cm2) by frailty group

Site of BMD	Frail	Pre-frail	Not frail
Total Hip	0.73 (.14)	0.75 (.13)	0.77 (.13)
Femoral Neck	0.62 (.11)	0.65 (.11)	0.66 (.11)
Lumbar Spine	0.85 (.17)	0.86 (.17)	0.86 (.17)

Adjusted rate of change (%/year) in Total Hip BMD by Frailty Group (mean [95% confidence intervals])

Frail	Pre-frail	Not frail
-0.79 (-0.93, -0.64)	-0.59 (-0.63, -0.54)	-0.52 (-0.58, -0.49)

The Relation between Dietary Vitamin A and Bone Mineral Density in a Multi-ethnic Cohort of Midlife Women. M. Huang*[1], A. Karlamangla*[1], C. Crandall[2], B. Sternfeld*[3], C. Luetters*[1], G. Block[4], G. A. Greendale[1]. [1]Department of Medicine/Division of Geriatrics, University of California, Los Angeles, Los Angeles, CA, USA, [2]Div of Gen Int Med and Health Svcs Res, University of California, Los Angeles, Los Angeles, CA, USA, [3]Dept of Epidemiology and Biostatistics/Div of Research, Kaiser Permanente, Oakland, CA, USA, [4]Division of PH Biology & Epidemiology, University of California, Berkeley, Berkeley, CA, USA.

In animals, high levels of vitamin A stimulate bone resorption and inhibit bone formation. In humans, observational studies suggest a detrimental effect of Vitamin A on bone, but these studies have largely been cross-sectional and have not focused on midlife women.

To study the association between vitamin A intake and longitudinal change in bone mineral density (BMD), we analyzed data from the Study of Women's Health Across the Nation (SWAN), a multi-ethnic, community based, cohort study of women aged 42 to 52 years at entry. Dietary and supplement vitamin A intakes were estimated at baseline from an interviewer-administered food frequency questionnaire. This analysis includes African-American (N =287), Caucasian (N = 645), Chinese (N =162) and Japanese (N =183) participants. The mean total daily vitamin A (diet + supplement) and dietary vitamin A (from food only) intakes were 2731 and 993 RE/day, respectively. BMD were measured at lumbar spine, hip and femoral neck (FN) sites, both at baseline and follow up visits. Energy-adjusted Vitamin A intakes were calculated using the residual method. Linear regression models were run separately for each site (spine, FN, and total hip); change in BMD between baseline and the 4th annual follow up visit were the outcome variables. Separate regression models considered 2 primary vitamin A exposure variables: quartiles of energy-adjusted total vitamin A intake (diet + supplements) and quartiles of energy-adjusted dietary vitamin A intake (food sources only). All models controlled for age, ethnicity, study site, smoking history, physical activity, dietary calcium, body mass index, duration of hormone use during the study, duration in different menopause transition status, and site-specific BMD at baseline.

Dietary vitamin A and total vitamin A were not associated with change in spine or FN BMD. Higher dietary vitamin A was associated with a longitudinal decline in hip BMD. Compared to the lowest quartile of dietary vitamin A intake, the beta coefficients for 2nd to 4th quartiles were -0.0036, -0.0017 and -0.0071 (p = 0.03). In contrast, total vitamin A (diet + supplement) was not associated with longitudinal change in hip BMD.

Our data provide some support for the detrimental effect of high vitamin A from dietary sources on hip BMD. The effect of total vitamin A intake (diet + supplement) on BMD may be confounded by other constituents in the supplements (e.g. vitamin D).

Beer Intake in Men, and Wine Intake In Post-Menopausal Women, Is Associated With Higher Bone Mineral Density. K. L. Tucker*[1], J. Powell*[2], N. Qiao*[1], L. A. Cupples*[3], D. P. Kiel[4]. [1]USDAHuman Nutrition Research Center, Tufts University, Boston, MA, USA, [2]Human Nutrition Res Lab, Med Research Council, Cambridge, United Kingdom, [3]Epidemiology, Boston University, Boston, MA, USA, [4]Hebrew Rehab Ctr for Aged, Harvard Med Sch, Boston, MA, USA.

Although alcoholism is associated with osteoporosis, positive associations between moderate alcohol intake and BMD have been noted. However, it is not known if this is due to alcohol per se, or to components in alcoholic beverages, such as silicon (si) in beer or phytochemicals in wine. We examined intake of total alcohol and of wine, beer and liquor with BMD in the Framingham Offspring cohort. BMD was measured at the spine and hip using a Lunar® DPX-L. Dietary intake was assessed by food frequency questionnaire. We regressed each BMD measure onto alcohol intake, as g/d, for men, post-menopausal and pre-menopausal women, adjusting BMI, height, age, physical activity, smoking, osteoporosis medication, calcium or vitamin D supplements, dietary intake of energy, protein, magnesium, calcium and vitamin D, season of measurement and for women, menopause status and estrogen. We repeated analyses replacing total alcohol with beer, wine and liquor. Finally, we categorized intakes as none, moderate (up to 1 drink/d women; 2/d men), and heavy, and compared adjusted LS means for BMD. Linear results follow with coefficients for the trochanter, as example, and # (of 5) BMD sites where p <.05:

	Men		Post-menopausal Women		Pre-menopausal Women	
	b	#	b	#	b	#
Alcohol	.00064**	1	.00100***	5	.00028 (0)	0
Beer	.00102**	2	.00023	0	-.00080 ()	0
Wine	.00105+	0	.00177***	0	.00059 ()	0
Liquor	.00004	0	.00128	2	.00308 (ns)	0

+p<.1, *<.05, ** <.01, *** <.001

In men, beer was significantly associated with BMD at the femoral neck and trochanter, and approached significance for total BMD and spine. Adjustment for si intake attenuated results with beer, but not wine, suggesting that si in beer could partially explain this association. For post-menopausal women, wine was significant at all 5 sites, and liquor at the trochanter and spine. No form of alcohol was associated with BMD in pre-menopausal women, but power was low in this group. Comparison of LS means by intake category confirmed a tendency to linear trend, except for liquor in men, where heavy drinkers had lowest BMD at all sites. These results reinforce the idea that moderate alcohol use is protective for bone, but suggest that wine and beer may contain additional protective components.

The Relationship Between Historical Height Loss and Multiple Vertebral Fractures. K. Siminoski[1], K. Lee*[2], H. Jen*[2], R. Warshawski*[2]. [1]Radiology and Medicine, University of Alberta, Edmonton, AB, Canada, [2]Radiology, University of Alberta, Edmonton, AB, Canada.

We have analyzed the relationship between historical height loss (HHL) and the presence of multiple prevalent vertebral fractures Subjects were women referred for specialist assessment of osteoporosis (n=490; average age 56 yrs; range: 18-92 years). HHL was determined as the difference between the tallest recalled height and height measured using a stadiometer. Vertebral morphometry was performed on all subjects from T4 to L4. Prevalent vertebral fracture was defined as a vertebral height ratio < 0.80. One or more fractures were present in 34.3%; the average number of fractures among those with fractures was 2.3±0.3.

The areas under the receiver operating characteristics curves (AUC) increased for the ability of HHL to detect greater numbers of fractures. For detection of 1 or more fractures, the AUC was 0.69; for 2+ fractures AUC = 0.74; for 3+ fractures AUC = 0.79; for 4+ fractures AUC = 0.81; and for 5+ fractures AUC = 0.90.

The odds ratios (OR) for detecting 1 or more fractures increased with the amount of height loss, as shown in the figure. The rate of increase was modest until HHL = 6-8 cm, where OR = 9, and only increased sharply when HHL >8 cm, where OR = 20. The same relationship was seen for detecting higher numbers of fractures, with the OR rising sharply after HHL >6 cm. For detecting 5 or more fractures, HHL = 6-8 cm produced an OR of 9, while HHL >8 cm produced OR = 64.

Two relationships were revealed by these analyses. First, the greater the number of prevalent vertebral fractures to be detected, the better HHL performed as a clinical test. Second, for a specific number of predicted vertebral fractures, the OR remained relatively flat until HHL >6 cm, and only rose substantially when HHL >8 cm. We conclude that there is a moderate relationship between historical height loss and prevalent vertebral fractures, and that the relationship is even stronger with multiple vertebral fractures. This is further evidence of the utility of using historical height loss in the assessment of osteoporotic patients or those at risk for osteoporosis.

Knee Pain, Knee Osteoarthritis and the Risk of Fracture. N. K. Arden*[1], S. Crozier*[1], H. Smith*[1], F. Anderson*[1], P. Maslin*[2], H. Raphael*[1], C. Cooper[1]. [1]Southampton University Hospitals, MRC Epidemiology Resource Centre, Southampton, United Kingdom, [2]Department of Academic Primary Care, Southampton, United Kingdom.

Patients with knee osteoarthritis have increased BMD but whether this is translated into a reduced risk of fracture is uncertain. The relevance of knee pain (KP) versus a clinician diagnosis of knee OA (COA) is also uncertain. We studied 6,641 elderly men and women who participated in a three year RCT of intramuscular vitamin D. Patients were randomised to 300,000 units of ergocalciferol or placebo annually for three years and completed fracture and fall diaries every 6 months.All subjects were asked if they suffered from knee pain or had COA.

The median age was 78.8 (IQR 76.7, 81.7) and 54% were female. There was no effect of vitamin D on non-vertebral fractures and so the two groups were combined and treatment group added into the statistical model.

2,186 subjects reported knee pain at study entry (PKP)and 581 during follow up (IKP). 277 reported COA at entry (PCOA) and 82 during follow up (ICOA). Both KP ((HR 95% CI)1.27 (1.19, 1.36)) and COA (1.14 (1.01, 1.29)) were associated with an increased risk of falls. There was no significnt difference between the incident and prevalent groups. The risk of fracture (table) were increased for both KP and COA, but with greater HR's for COA. When falls were added into the statisitical model, the hazard ratios were substantially reduced for knee pain, remaining significant only for hip fracture and PKP (1.86 (1.10, 3.16)). The addition of falls had less of an effect on the association with COA, the association with PCOA still 1.53 (1.04, 2.24). The computed 5 year risk of a non-vertebral fracture for a 75 year old man without KP, with KP and with COA are 4.7%, 6.0% and 7.0% respectively.

Despite an increase in BMD, patients with KP and COA have an increased risk of non-vertebral and hip fracture, which is partially explained by an increased risk of falls. When assessing a patients risk of fracture, KP and COA should be included as important risk factors .

Hazard ratio of fracture in knee pain and knee osteoarthritis

	PKP	IKP	PCOA	ICOA
Non-vertebral	1.17 (0.93, 1.48)	1.37 (1.01, 1.87)	1.60 (1.10, 2.36)	1.72 (0.89, 3.33)
Hip	2.00 (1.18, 3.37)	1.01 (0.39, 2.58)	2.21 (0.95, 5.13)	2.46 (0.60,10.1)
Wrist	0.92 (0.55, 1.55)	1.42 (0.76, 2.64)	0.76 (0.24, 2.42)	2.57 (0.81, 8.13)

Changes in Hip Geometry from Medieval to Modern Times. A. Chumley*[1], G. Petley*[1], C. J. Edwards*[2], P. Taylor*[1], S. Mays*[3], J. Sofaer Derevenski*[4], P. Mahon*[5], C. Cooper[5], N. K. Arden*[5]. [1]Medical Physics, Southampton, United Kingdom, [2]Department of Rheumatology, Southampton, United Kingdom, [3]English Heritage, Brighton, United Kingdom, [4]Department of archaeology, University of Southampton, United Kingdom, [5]MRC Epidemiology Resource Centre, Southampton, United Kingdom.

The age and sex adjusted rates of hip fracture are increasing in many countries. Femoral neck geometry, especially femoral neck axis length (FNAL) has increased over the last 40 years and may partially explain this association. Here we extend these observations to femurs dating from the 10th-16th Centuries.

Sixty two adult female femora from the medieval archaeological site of Wharram Percy, England were scanned using pencil beam DXA. FNAL and the femoral neck width (FNW) were evaluated.. These measurements were compared with age and sex matched femoral scans from randomly selected volunteers in Southampton, England collected in the 1990's using the same densitometer.The use of pencil beam, as opposed to fan beam DXA, ensured that there were no magnification errors in comparing the two sets of results. Identical scan modes and settings were used to acquire both sets of femoral scans. Rigorous theoretical modelling, showed that there may be errors in the results, if femurs from the different eras were not positioned identically. To account for this, a positioning rig for the medieval femora was constructed. This allowed each femur to be positioned with the correct amount of rotation and abduction, ensuring that the femoral neck was parallel to the surface of the scanner. The scans were analysed by one operator (A-C). Measurement of the FNAL and the FNW were assessed using the DXA software, and the ratio FNAL/FNW was calculated. These results were then adjusted for the difference in height between the two groups.

FNAL and the FNAL/FNW ratio were found to be significantly greater in modern femurs ($p<0.001$) compared with medieval femurs after adjustment for height. No significant change in FNW was found.

These findings indicate that the proximal femur has undergone a change in shape, as opposed to an overall increase in size. An increase in the FNAL/FNW ratio of modern women, suggests that the femoral neck is now narrower for a given length and this may offer a partial explanation for the increase in fracture incidence in this group.

Mean (SD) femoral neck dimensions (values adjusted for height)

	Medieval	Modern	p value
Femoral neck length (mm)	85.8 (5.0)	92.4 (5.3)	<0.001
Femoral neck width (mm)	28.8 (2.1)	28.6 (1.9)	0.38
Femoral neck length / Femoral neck width	3.0 (0.2)	3.2 (0.2)	<0.001
Height (cm)	154.6 (20.5)	162.6 (6.6)	0.006

Effect of Age and Bone Mineral Density (BMD) on Short-term Fracture Risk in Postmenopausal Women Age 50 - 99. E. S. Siris[1], S. K. Brenneman[2], Y. Chen[2], P. D. Miller[3], S. Sajjan*[2], E. Barrett-Connor[4]. [1]Columbia University, New York, NY, USA, [2]Merck & Co., Inc., West Point, PA, USA, [3]Colorado Center for Bone Research, Lakewood, CO, USA, [4]University of California, San Diego, La Jolla, CA, USA.

The relationship between bone mineral density (BMD) and fracture risk has been reported mostly in women age 65 years and older. Less is known about the risk of fracture for younger women. Using the National Osteoporosis Risk Assessment (N.O.R.A.) data, we report fracture events during 3 years of follow-up and their associations with baseline peripheral BMD measures by age in decades for women age 50 - 99 years. Women were eligible for N.O.R.A. if they were ≥ 50 years old, postmenopausal, had no diagnosis of osteoporosis and were not currently taking bone-specific medication (HT use was allowed); 170,090 women who had a baseline BMD measurement at one peripheral site (forearm, heel, finger) and who responded to either the first or second follow-up survey (median: 37 months; 99% range: 11- 46 months) after testing were included in the analysis. New fractures at the hip, spine, rib, wrist and forearm were identified by self-report. T-scores were categorized into three groups: T > -1.0; -2.0 < T ≤ -1.0; and T ≤ -2.0. Ages were categorized into 4 groups: 50-59, 60-69, 70-79 and 80-99. Fracture rates per person were calculated for the first fracture occurring since baseline weighted for time of follow-up. Relative risk (RR) and 95 % confidence interval (CI) of fracture was calculated for each age group and T-score group by Cox proportional hazards model adjusting forage, prior fracture, HT usage, ethnicity, health status maternal history of fracture, education level, and smoking status. A total of 5312 women reported 5676 fractures (868 hip, 2420 wrist/forearm, 1531 rib and 857 spine). Fracture rate per 1000 person-years and relative risk (RR) for any fracture are shown; absolute fracture rates increased with age, but relative risks by BMD did not (p = 0.07)

	50 - 59		60 - 69		70 - 79		80 - 99	
	Fx Rate (95% CI)	RR (95% CI)	Fx Rate (95% CI)	RR (95% CI)	Fx Rate (95% CI)	RR (95% CI)	Fx Rate (95% CI)	RR (95% CI)
>-1.0	6.7 (6, 7)	Ref	7.3(7,8)	Ref	11.7(11,13)	ref	19.0(15,23)	Ref
-1.0 to -2.0	13.0(12,14)	1.8(1.6,2.1)	13.2(12,14)	1.7(1.5,1.9)	19.1(18,20)	1.5(1.3,1.7)	27.1(23,31)	1.4(1.0,1.8)
≤ -2.0	21.1(18,25)	2.6(2.2,3.2)	23.7(21,26)	2.8(2.4,3.2)	32.0(30,34)	2.4(2.1,2.7)	42.8(39,47)	2.0(1.5,2.5)

Although fracture rates increase with increasing age, rates are similar in women aged 50-59 and 60-69 within each T-score category. Greater relative risk for fracture associated

with lower BMD T-score is observed regardless of age and the risk levels are not substantially different across age groups. BMD is an important risk factor in all ages for identifying women who have increased risk for fracture.

F340

Prevalence of Vertebral Fractures in Brazil, Puerto Rico and Mexico. Preliminary Report of the Latin American Vertebral Osteoporosis Study (LAVOS). P. Clark[1], S. Ragi[2], L. Haddock[3], E. Suarez*[3], C. Pérez*[3], F. Cons Molina[4], M. Deleze[5], J. Salmeron*[6], L. Palermo*[7], S. R. Cummings and the LAVOS Group[7]. [1]Faculty of Medicine UNAM, IMSS, Mexico City, Mexico, [2]CEDOES, Vitoria, Brazil, [3]Universidad de Puerto Rico, San Juan, Puerto Rico, [4]Unidad de Diagnostico de Osteoporosis, Mexicali, Mexico, [5]Clinica de Osteoporosis, Puebla, Mexico, [6]Unidad de Epidemiologia y Sistemas, IMSS, Morelos, Mexico, [7]Coordinating Center, UCSF, San Francisco, CA, USA.

The risk of fractures in women in Latin America is assumed to be much lower than the United States and Northen Europe. However, there has been no population-based study of the rates of vertebral fracture in Latin America.

To determine the rates of vertebral fracture in varios regions of Latin-America, we undertook the Latin American Vertebral Osteoporosis Study (LAVOS), the first multi-country population based study of vertebral fractures in Latin America.

Using an identical design, we selected age-stratified (50-59, 60-69, 70-79 and 80+) and truly random samples of 400 women in Vitoria Brasil, 400 in San Juan, Puerto Rico and 400 in Puebla, Mexico. Over 80% of the women contacted participated in a face to face interview and questionnaire. We measured BMD of the hip and and spine and took lateral spine X-rays on all women. Vertebral fractures were assessed centrally in Mexicali, Mexico using morphometry and compared with independent reading at the San Francisco Coordinating Center with very good agreement (kappa=0.75). Fractures were defined according to a modified Eastell method as used in the comparative US study.

The overall prevalence of vertebral fractures was 14.8 in Brazil, 12.1 in Puerto Rico and 19.5 in Mexico and increases with age. The oveall rates of fracture in these 3 LA countries Brazil, Puerto Rico and Mexico were lower than SOF rates although Mexico presented the highest rate of these countries, similar to SOF rates in women over 70 years (table)

We conclude that the rate of vertebral fractures in Latin American women is high. Vertebral fractures are a substantial problem in Latin America and should be the focus of research, clinical and public health measures to prevent them.

Age-Stratified Prevalence

Age	Brazil PV 95% IC	Puerto Rico PV 95% IC	Mexico PV 95% IC	White USA* SOF Study 95% IC
50-59	6.7 2.7-13.2	5.4 1.9-11.3	8.3 2.7-13.8	-
60-69	8.0 3.5-15.1	8.3 3.8-15.1	12.6 6.1-19.1	14.5 13.4-15.5
70-79	19.4 12.3-28.4	17.0 10.5-25.2	18.6 10.7-26.4	22.0 20.8-23.3

Does 'ORACLE' Provide Good Risk Assessment for Osteoporotic Fracture? A. Stewart*[1], M. Garton*[2], S. Ogston*[3], G. Leese*[4], D. Reid[1]. [1]Osteoporosis Research Unit, University of Aberdeen, Aberdeen, United Kingdom, [2]Perth Royal Infirmary, Perth, United Kingdom, [3]Department of Epidemiology and Public Health, University of Dundee, Dundee, United Kingdom, [4]Department of Medicine, Ninewells Hospital, Dundee, United Kingdom.

A new osteoporosis risk assessment tool (ORACLE) has been developed based on age, bone mineral density (BMD) Z-scores and historical incidence figures for fracture. A 10-year absolute risk for hip, vertebral, wrist and other type of fracture is then computed. We have applied these risk estimates to a population-based sample of women who have been followed up for over 10 years with incident fracture data collected. At baseline women aged 45 to 54 years attended for BMD of spine and hip as part of the Aberdeen Prospective Osteoporosis Screening Study (APOSS). Over a period of approx. 10 years the women were followed up on 2 occasions and incident factures noted and validated by examining x-ray reports. We have compared the ORACLE calculated risk for these women, according to BMD decile, with the actual fracture rate noted over the follow-up period (mean = 9.7 years, SD 1.1 years, range 7.49 to 12.2 years). As these women have now only reached the mean age of 58.4 years the most common type of fracture to have occurred is wrist fracture. We have therefore used the ORACLE calculated risk for wrist fracture only. ORACLE risks were calculated using both spine and hip Z-scores. The baseline BMD at both spine and hip were divided into deciles and the average ORACLE risk was calculated per decile. We then calculated the actual percentage of women in each decile who had an incident fracture of the wrist. In Table 1 we show the results.

Decile of BMD measurement	Deciles of Spine BMD		Deciles of neck of femur BMD	
	ORACLE risk (%) based on spine BMD	Actual % with incident wrist fractures	ORACLE risk (%) based on hip BMD	Actual % with incident wrist fractures
1	4.96	6.3	5.95	6.0
2	3.12	2.7	3.83	4.0
3	2.59	4.7	2.98	3.2
4	2.20	1.3	2.48	3.5
5	1.95	2.5	2.12	2.9
6	1.74	4.0	1.78	2.2
7	1.53	3.1	1.48	1.3
8	1.33	0.9	1.16	0.9
9	1.13	0.9	0.86	1.3
10	0.82	0.7	0.50	1.6

Using a Chi-square test comparing the predicted and actual risk there were no significant difference in the actual % of incident wrist fracture and the ORACLE risk based on spine BMD (p = 0.599) or for hip BMD (p = 0.939). This simple risk assessment tool performs very well when applied to our population based random sample for which we have incident fracture data. The 10-year risk assessment tools such as this are likely to become essential tools in clinical practice in the near future.

Children With Bone Fragility Fractures Have Reduced Volumetric Bone Mineral Density of the Radius. J. D. Landoll*[1], S. L. Mobley*[1], E. Ha*[1], N. E. Badenhop-Stevens*[1], T. N. Hangartner*[2], V. Matkovic[1]. [1]Bone and Mineral Metabolism Laboratory, The Ohio State Univ., Columbus, OH, USA, [2]BioMedical Imaging Laboratory, Wright State Univ., Dayton, OH, USA.

Bone fragility fractures in children are very common during the pubertal growth spurt. Two underlying causes may be a reduced bone mineral density at this time, or physically smaller bones. Peripheral quantitative computed tomography (pQCT) is able to evaluate separately bone geometry and true (volumetric) bone mineral density (BMD).

This study measured volumetric BMD of 613 male and female children aged 7-17 y (mean 10.9 +/- 2.2 y) as part of a case-controlled study evaluating the risk factors for bone fragility fractures. Case subjects (n=307; age = 10.8 +/- 2.2 y) had a forearm fracture caused by low to moderate trauma. Control subjects (n=306; age = 10.9 +/- 2.2 y) were free from previous fracture and were matched for age, gender and socio-economic status (from either the same class/school or a similar school). BMD of the proximal (33%) and distal (4%) radius was measured by pQCT using a Norland-Stratec XCT 2000. For case subjects, measurements were made on the non-fractured arm. For control subjects, measurements were made on the matching (dominant vs. non-dominant) arm.

There were significant differences in bone mineral density between the fracture group as a whole and the paired control group. Fracture cases had significant reduction in volumetric bone density at both the distal ($p<0.0001$) and proximal ($p< 0.0001$) radial sites. In addition, volumetric bone mineral density of the trabecular bone at the distal radius was significantly ($p< 0.0001$) reduced in the fracture cases. The cross-sectional bone areas at the two radial sites in both groups were the same. This indicates that bone geometry was not an important contributing factor for the pathogenesis of fractures in the cohort. The deficiency of bone tissue within the volume of an anatomical bone seems to be a single reason for the fracture, besides trauma itself.

Results of this study show that low BMD (not small bones) is one of the most powerful determinant of bone fragility fracture in children. This emphasizes the importance of adequate calcium intake during this critical time of growth. The results also underscore the importance of volumetric bone mass measurements in growing individuals.

Inhaled Steroid Induced Risk of Osteoporotic Fractures Confounded by Disease Severity in Obstructive Airway Disease. F. de Vries*[1], T. van Staa[1], H. Leufkens*[1], M. Bracke*[1], J. Lammers*[2], C. Cooper[3]. [1]Dept. of Pharmacoepidemiology and Pharmacotherapy, Utrecht Institute for Pharmaceutical Sciences - Utrecht University, Utrecht, Netherlands, [2]Dept. of pulmonary diseases, Utrecht Medical Center, Utrecht, Netherlands, [3]MRC Environmental Epidemiology Unit, Southampton General Hospital, Southampton, United Kingdom.

Background: an earlier study conducted in the UK General Practice Research Database (GPRD) found a dose response with use of inhaled corticosteroids and hip fracture risk, and concluded that this was related to corticosteroid intake. However, severe obstructive airway disease (OAD) has been associated with a decreased bone mineral density of the hip and spine, and it has yet to be established whether this effect is related to the disease itself or to extensive use of respiratory medication. ***Objective*:** to evaluate the relation between OAD severity and osteoporotic fracture risk. ***Methods*:** a large case-control study (n=108.754) was conducted among adults using data from the GPRD. Cases were defined as patients with a first record for a fracture of the radius/ulna, hip, distal femur, unspecified femur, ribs, humerus, vertebrae and clavicle. For each case, one patient without a history of a fracture was randomly selected as control patient. They were matched to cases by age, gender, and practice. Control patients were assigned the index date of their matched case. Indicators of severe OAD included exacerbations, use of oxygen, and oral steroids prior to index date. Current exposure was defined as at least one prescription 6 months prior. ***Results:*** we found a dose response relationship between the use of inhaled steroids and he risk of osteoporotic fractures. Current users of high dose inhaled steroids (>1600 mcg beclomethasone equivalent per day) with a history of OAD had increased risk of osteoporotic fractures (crude OR 1.95, 95% CI: 1.68-2.27), hip fractures (crude OR 1.78, 95% CI: 1.21-2.62) and vertebral fractures (crude OR 6.11, 95% CI: 3.73-10.01). After adjustment for general risk factors, specific OAD disease severity markers and daily dose of bronchodilators, the dose response relationship disappeared. Current users of high dose inhaled steroids (>1600 mcg per day) with a history of OAD had the following risks of osteoporotic fractures (adj. OR 1.19, 95% CI: 1.01-1.41), hip fractures (adj. OR 1.18, 95% CI: 0.75-1.85), and vertebral fractures (adj. OR 1.85, 95% CI: 1.01-3.38). ***Conclusions:*** patients with severe OAD and using high dose inhaled steroids are at increased risk of osteoporotic fractures. Adjustment for disease severity is essential when the association between use of inhaled corticosteroids and risk of osteoporotic fractures is studied in observational research.

The Effect of Recent Fracture on Quality of Life in Postmenopausal Women. S. K. Brenneman[1], E. Barrett-Connor[2], P. D. Miller[3], Y. Chen[1], S. Sajjan*[1], L. E. Markson*[1], E. S. Siris[4]. [1]Merck & Co., Inc., West Point, PA, USA, [2]University of California, San Diego, La Jolla, CA, USA, [3]Colorado Center for Bone Research, Lakewood, CO, USA, [4]Columbia University, New York, NY, USA.

Health-related quality of life (HRQoL) has been well-studied after vertebral and hip fractures. Less is known about HRQoL following clinical fractures at peripheral sites. We studied the impact of clinical fractures on HRQoL in participants in the National Osteoporosis Risk Assessment (NORA). 86,010 postmenopausal women who completed both the first and the second follow-up surveys (median 11 and 37 months after baseline) were included in the analyses. At both follow-up surveys, information on HRQoL was assessed by Short Form-12 (SF-12: an instrument standardized to have a mean of 50, SD 10) and new fractures (hip, vertebral, wrist/forearm and rib) were collected by self-report. Means for the SF-12 physical component scores (PCS) and mental component scores (MCS) were calculated for each survey. The effect of recent fracture on HRQoL was assessed by comparing PCS and MCS for women with and without new fractures at the 2nd survey by fracture type and by age and adjusted for PCS and MCS at the 1st survey. Age-specific means and standard deviations of PCS and MCS in NORA overall and among those who did not fracture were similar to the reported norms for the US population. New fractures (364 hip, 478 vertebral, 694 rib, 1078 wrist/forearm) occurring during the 2nd survey interval were reported by 2,477 women. Regardless of age, women with new fractures had poorer PCS compared to those who had not fractured for hip, vertebral and rib fractures ($p \leq 0.001$). The greatest observed differences in PCS between women with and without fractures across age cohorts were for hip (range -4.7 to -3.7) and spine (range -7.1 to -4.8) fractures. These differences are similar to those found for patients with comorbidities such as asthma, COPD, osteoarthritis, and hip impairment compared to patients without the comorbidity. Wrist/forearm fractures had an impact on PCS only in women ≤ 65 of age ($p<0.0001$), but not > 65 of age ($p > 0.10$). MCS was less affected by fracture status, but women with vertebral fracture at all ages ($p< 0.05$) and women with rib or hip fractures age > 75 years ($p<0.001$) had poorer MCS compared to those who did not fracture within their age cohort. Recent fractures of the hip, vertebrae, rib and wrist/forearm have significant impact on HRQoL physical domain as measured by SF-12. The impact of all fracture types should be considered in estimations of the burden osteoporosis.

Bone Resorption and Osteoporotic Fractures in Elderly Men: The Dubbo Osteoporosis Epidemiology Study. C. Meier[1], T. V. Nguyen[2], J. R. Center[2], M. J. Seibel[1], J. A. Eisman[2]. [1]Bone Research Program, ANZAC Research Institute, University of Sydney, Concord NSW, Australia, [2]Bone and Mineral Research Program, Garvan Institute of Medical Research, St. Vincent's Hospital and University of NSW, Sydney NSW, Australia.

Approximately one third of osteoporotic fractures occur in men. Among the potential risk factors for fragility fractures, bone turnover is considered an important determinant. The association between fracture risk and rates of bone turnover has not been well established in men. We examined this relationship in elderly community-dwelling men.

This case-cohort control study included 50 men with incident low-trauma fractures (cases) and 101 men without fracture (controls), aged 71±5.2 yrs (mean±SD) who have been prospectively followed in the Dubbo Osteoporosis Epidemiology Study for a median of 6.3 yrs (range, 2-13 yrs). Bone mineral density at the lumbar spine (LSBMD) and at the femoral neck (FNBMD), and markers of bone turnover were measured at baseline. Bone resorption was assessed by serum carboxyterminal cross-linked telopeptides of type I collagen (S-ICTP, S-CTX). Bone formation was assessed by serum aminoterminal propeptide of type I procollagen (S-PINP).

At baseline and compared to controls, cases had lower BMD, both at the femoral neck and the spine, lower dietary calcium intake, and higher S-ICTP levels. Age, BMI, ΔFNBMD/yr, smoking habits, S-CTX and S-PINP did not differ between groups. Based upon univariate regression analysis, S-ICTP (RR 2.2, 95% CI, 1.5-3.2), FNBMD (RR 1.5, 95% CI, 1.0-2.1), LSBMD (RR 1.5, 95% CI, 1.1-2.2), and age (RR 1.4, 95% CI, 1.0-1.9) were all associated with increased risk of fracture. In multivariate logistic regression analyses, only S-ICTP (RR 2.3, 95% CI, 1.4-3.5) and FNBMD (RR 1.8, 95% CI, 1.2-2.9) remained independent predictors of fracture risk in men. Men within the highest quartile of S-ICTP had a 2.8-fold (95%CI 1.4-5.4) increased risk of fracture compared with men with levels in the lowest quartile. The incidence of osteoporotic fractures was 10 times higher in men with high S-ICTP and low FNBMD as compared to men with low S-ICTP and high FNBMD. Of the fracture risk in the population, 31% was attributable to high S-ICTP and/or low FNBMD, and S-ICTP contributed 24% to the estimated risk.

In conclusion, high bone resorption is associated with an increased risk of osteoporotic fracture in elderly men, independent of BMD. Combining measurements of BMD and bone turnover improved fracture prediction in this cohort. In populations and studies were biological variability (i.e. fasting state, diurnal variation) can not be controlled, S-ICTP appears to be a more robust marker of future fracture risk than S-CTX.

Relationship of Volumetric Density, Size, Geometry and Bone Structure at Different Skeletal Sites to Sex Steroid Levels in Men. S. Khosla, L. J. Melton, E. J. Atkinson*, A. E. Oberg*, R. Robb*, J. Camp*, B. L. Riggs. Mayo Clinic, Rochester, MN, USA.

Serum sex steroids, particularly estrogen (E) levels, are known to be associated with bone mass in men. However, previous studies addressing this issue have exclusively used DXA, which cannot separate cancellous from cortical bone or provide information on bone geometry or structure. We assessed bone geometry and volumetric bone mineral density (vBMD) by QCT at the lumbar spine (LS), femoral neck (FN), and distal radius (DR) and related these to circulating estrone (E_1), bioavailable estradiol (bio E_2) and testosterone (bio T) levels in an age-stratified population sample of 314 men (ages 22 to 91 yrs). Using stepwise regression models that included age and the sex steroid levels (transformed where appropriate), none of the sex steroid variables were related to the vBMD/structural parameters in young men (age 20-39 yrs). However, there were significant associations between many of these variables and sex steroid levels in middle-aged men (age 40-59 yrs) and even more so in elderly men (age 60+ yrs) (Table below, asterisks indicate level of significance: *P < 0.05; **P < 0.01; ***P < 0.001; sign indicates positive or negative correlation.)

Variable	Age	E_1	Bio E_2	Bio T	Model R^2 (%)
LS Total bone area (middle-aged)	--	--	--	--	--
LS Total bone area (elderly)	--	(-)***	--	--	7.4
LS Trabecular vBMD (middle-aged)	--	--	--	(+)***	14.0
LS Trabecular vBMD (elderly)	(-)***	(+)**	--	--	18.4
FN Cortical area (middle-aged)	--	(+)*	--	--	4.2
FN Cortical area (elderly)	(-)**	--	(+)*	--	10.8
FN Total vBMD (middle-aged)	--	--	--	--	--
FN Total vBMD (elderly)	(-)*	--	(+)**	--	11.4
FN Trabecular vBMD (middle-aged)	--	(+)**	--	--	6.0
FN Trabecular vBMD (elderly)	(-)**	--	(+)**	--	14.7
FN Cortical vBMD (middle-aged)	--	--	--	--	--
FN Cortical vBMD (elderly)	--	--	(+)*	--	3.7
DR Total bone area (middle-aged)	--	--	--	--	--
DR Total bone area (elderly)	--	--	--	(-)*	2.7
DR Trabecular vBMD (middle-aged)	--	(+)*	--	(+)*	10.3
DR Trabecular vBMD (elderly)	--	--	(+)*	--	2.8
DR Cortical vBMD (middle-aged)	--	--	--	--	--
DR Cortical vBMD (elderly)	(-)***	--	--	--	20.9

In summary, (1) the lack of association between vBMD/structural parameters and sex steroid levels in young men suggests that these men are largely sex steroid sufficient, and variations in their relatively high sex steroid levels do not impact bone mass/structure; (2) the association between these parameters in middle-aged, and particularly elderly, men suggests that the declining bio E and T levels with age become increasingly important in

determining vBMD/structural variables in these men; and (3) other than a negative association between DR bone area and bio T levels, all of the other vBMD/structural variables were independently associated solely with serum E (E_1 or bio E_2) levels in the elderly men, consistent with a more important role for declining bio E levels (as compared to bio T levels) in determining these vBMD/structural parameters in aging men.

Endogenous Sex Steroids, Weight Change and Rates of Hip Bone Loss in Older Men: The MrOS Study. K. Ensrud[1], L. Lambert[2], B. Taylor[1], H. Fink[1], E. Barret-Connor[3], C. Lewis[4], J. Cauley[5], E. Orwoll[2]. [1]VAMC & U of MN, Mpls, MN, USA, [2]OHSU, Portland, OR, USA, [3]UCSD, SD, CA, USA, [4]U of AL, Birmingham, AL, USA, [5]U of Pittsburgh, Pittsburgh, PA, USA.

Weight loss in older men may be associated with higher rates of bone loss for several reasons, including lower levels of endogenous sex steroids (ESS) produced in adipose tissue & muscle. To test whether ESS levels modify the association between weight loss & hip bone loss in older men, we measured body weight, ESS (total, bioavailable and free estradiol and testosterone in paired serum samples using sensitive immunoassay) & total hip bone mineral density (THBMD) at a baseline and subsequent exam (mean 1.8 yrs between exams) in a cohort of 1263 men aged ≥65 yrs at baseline. During this period, 10% of participants lost ≥5% of their baseline weight (weight loss), 81% had a <5% change from their baseline weight (stable weight) & 8% gained ≥5% or more of their baseline weight (weight gain). The effect of baseline ESS & change in ESS was much smaller in magnitude than the effect of weight change on % change in THBMD/yr; men with weight loss had higher rates of hip bone loss compared to those with stable weight and those with weight gain, irrespective of baseline ESS or change in ESS. However, among men with weight loss, the rate of decline in THBMD steadily increased with decreasing level of baseline bioavailable estradiol (test for trend p <0.02) and greater decreases in bioavailable testosterone from baseline (test for trend p <0.001). The test for interaction between weight change and ESS for prediction of change in THBMD almost reached significance for change in bioavailable testosterone (p=0.052), but not for baseline bioavailable estradiol (p=0.242).

Category of Weight Change	Mean Annual % Change in THBMD (95% CI)† Quartile of Baseline Bioavailable Estradiol*			
	Q1 (Lowest)	Q2	Q3	Q4 (Highest)
Weight Loss (N = 131)	-1.8 (-2.2, -1.4)	-1.4 (-1.8, -0.9)	-1.1 (-1.6, -0.6)	-1.0 (-1.6, -0.5)
Stable Weight (N = 1027)	-0.5 (-0.6, -0.3)	-0.5 (-0.6, -0.3)	-0.3 (-0.5, -0.2)	-0.2 (-0.4, -0.1)
Weight Gain (N = 105)	0.4 (-0.1, 1.0)	-0.1 (-0.6, 0.4)	0.0 (-0.5, 0.4)	0.2 (-0.4, 0.8)

†Adj. for baseline age and weight; *Quartile cutpoints: 9.6 pg/ml, 11.9 pg/ml, 14.6 pg/ml

Among older men, weight change is a stronger predictor of change in THBMD than ESS. However, our finding that the effect of weight loss on hip bone loss is most pronounced in men with the lowest estradiol or greatest decline in testosterone supports the hypothesis that the relationship between weight loss and hip bone loss is in part mediated by sex steroid insufficiency.

Vertebral Deformities in Older Black and White Men: Data from the Baltimore Men's Osteoporosis Study. J. K. Tracy*[1], R. H. Flores*[2], M. Grigoryan*[3], B. Fan[3], H. Genant[3], M. C. Hochberg[2]. [1]Epidemiology, University of Maryland, Baltimore, MD, USA, [2]Medicine, University of Maryland, Baltimore, MD, USA, [3]Radiology, University of California, San Francisco, CA, USA.

Data from participants in the Baltimore Men's Osteoporosis Study (MOST) were examined 1) to estimate the prevalence of vertebral deformities (VFx) in older men, 2) to determine whether there were differences in prevalence of VFx by race, and 3) to examine factors associated with the presence of VFx in older men. Baseline data on the 694 men age 65 and above enrolled in MOST have been published (J Bone Miner Res 2003;18:2238-44). 542 men (415 white and 127 black) completed a second clinic visit after a mean (SD) follow-up of 1.5 (0.5) years. At this visit, lateral radiographs of the thoracic and lumbar spine were taken using standard protocols. Films were digitized using standardized methods and morphometry was performed. In addition, all films were read by an expert radiologist and each vertebra was scored for presence and severity of deformity using the technique of semiquantitative grading. VFx were defined using the Eastell method (a height ratio [h(a)/h(p), h(m)/h(p), or h(p)/h(p+1)] that was >3 SDs below the normative mean ratio for a particular vertebra). 514 men (398 white and 116 black) with a mean (SD) age of 75.8 (5.6) years had complete data for analysis. 30 men had 1 or more VFx (25 had 1 and 5 had 2 or more); the overall prevalence of VFx in this sample was 5.8% (95% CI: 4.0%, 8.3%). VFx were significantly more common in white (29 [7.3%]) than black (1 [0.9%]) men (Fishers' exact P = 0.01): age-adjusted odds ratio (95% CI) = 8.33 (1.10, 62.5). Further analyses were limited to the white men. Men with VFx were shorter than men without VFx (P < .05); there were no significant differences in age, weight, body mass index, knee height, proportion of current smokers or drinkers, grip strength or femoral neck, total hip or lumbar spine bone mineral density between groups (Table). These data demonstrate that, in this cohort of older healthy volunteers, white men have a higher prevalence of VFx than black men. The results extend our prior observations that older black men have higher BMD and a lower rate of decline in total hip BMD than older white men.

Factors associated with vertebral deformities in older white men

Variable (mean [SD])	VFx present	VFx absent
Age, years	77.0 (6.0)	76.4 (5.5)
Height, cm	170.0 (6.1)	172.6 (6.6)
Weight, kg	80.9 (15.3)	82.5 (13.0)
Femoral neck BMD, g/cm2	0.78 (0.17)	0.78 (0.13)
Total hip BMD, g/cm2	0.91 (0.15)	0.94 (0.14)
Lumbar spine BMD, g/cm2	1.16 (0.22)	1.13 (0.21)
Grip strength	26.8 (6.8)	29.3 (7.3)

'Viva le Difference!' Bone Mass and Fractures in Men versus Women from SOF (Study of Osteoporotic Fractures) and MrOS (Osteoporotic Fractures in Men). S. R. Cummings[1], P. M. Cawthon[1], J. A. Cauley[2], K. E. Ensrud[3], D. C. Bauer[4], H. A. Fink[3], D. M. Black[4], E. S. Orwoll[5]. [1]Research Institute, California Pacific Medical Center, San Francisco, CA, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]University of Minnesota, Minneapolis, MN, USA, [4]University of California, San Francisco, CA, USA, [5]Oregon Health Sciences University, Portland, OR, USA.

We measured femoral neck (FN) and total hip (Hip) BMD in 5,119 men and 6,583 women aged ≥65. During 2.7 years, 850 non-spine (101 hip) fractures occurred in women, 200 (29 hip) in men.

Non-spine fractures: Compared with men, women had a 3.4 (2.8, 4.2) age-adjusted RR of fracture, unchanged (3.2; 2.7, 3.9) by adjustment for estimated volumetric bone density (FN BMAD) but largely attenuated by adjustment for FN BMC (1.7; 1.3, 2.1).

The age-adjusted relationship of Hip BMD to fracture risk (1.9 RR/SD; 1.7, 2.1) was not significantly different (P=0.3) in women and men. However, women had a 1.6-fold (1.3, 2.1) greater risk at all Hip BMD levels (Figure) and appaer to have a greater risk at equivalent gender-specific T-scores (Table)

Hip fracture: The association between Hip BMD and hip fracture risk was significantly (P=0.008) stronger in men (4.3 RR/SD) than women (2.6 RR/SD).

Conclusions: The male-female difference in risk of non-spine fracture is mostly attributable to the difference in bone mass not density. Women and men share a similarly strong relationship between BMD and non-spine fracture, but at any BMD or T-score, women have a higher risk than men. The relationship between Hip BMD and hip fracture is stronger for men than for women.

Total Hip T-score	Non-spine fx (%/yr)	
	Men	Women
Above -1	0.9%	2.7%
-1 to -2.5	1.7%	4.2%
< -2.5	9.5%	7.9%

Circadian Activity Rhythms and Bone Density in Men. D. R. Miller*, L. Silva*, S. Rich*, E. Krall. Chqoer, Boston University, Bedford, MA, USA.

Regular daily activity patterns may be considered a measure of health and well-being, and irregular patterns have been associated with a number of medical and psychiatric conditions. Circadian activity rhythms have not been well studied in relation to bone even though physical activity and circadian patterns in other measures (e.g. cortisol) are related to bone density. We studied circadian activity rhythms in the VALOR study, a longitudinal, observational study of bone in older men (mean age of 70 years). Femur and radius BMD were measured by dual energy x-ray absorptiometry and bone strength of the calcaneus by quantitative ultrasound up to 3 times over a mean follow-up of 2 years. Activity patterns were measured in 426 men who wore wrist actigraphs for at least one 7 day period, recording activity counts at one minute intervals. We calculated four summary statistics of circadian rhythms: goodness-of-fit to the 24 hour cosinor model, a measure of circadian rhythmicity; acrophase (time of day of the cosinor model peak); amplitude (height of the peak); and autocorrelation coefficient, a measure of the consistency of activity levels at each time of day across the seven days measured. Goodness-of-fit was related directly to BMD at the forearm and femoral neck and to bone strength ($p<0.01$), even with adjustment by linear modeling for age, body mass index, disability, physical activity (by self-report or actigraphy), sleep time, depression, and other factors. Adjusted BMD was lower and rates of osteopenia (<1 SD below norm in femoral neck BMD) were higher in the lowest quartile (mean BMD= 0.916 g/cm2, 66.5%) relative to the highest quartile (0.964, 56.1%) ($P<0.05$) of goodness-of-fit (mean r=0.502+/-0.096). Comparable results were found for autocorrelation coefficient (mean r=0.319+/-0.107) and the other circadian activity measures. A significant interaction was observed with physical activity in that the associations were absent in those who exercised regularly and were strongest in those with little or no exercise. These findings suggest that circadian rhythms of physical activity are a marker for bone density and strength independent of total activity, sleep time, and mental conditions and they may be an important new marker of modifiable risk of fracture.

The Association Between Bone Mineral Density and Neurologically Active Medications: Results from NHANES III. M. Kinjo*[1], S. Setoguchi*[2], S. Schneeweiss*[2], D. H. Solomon[2]. [1]Internal Medicine, Teine Keijinkai Hospital, Teine-ku Sapporo, Japan, [2]Division of Pharmacoepidemiology, Brigham and Women's Hospital, Boston, MA, USA.

Background: Decreased bone mineral density (BMD) defines osteoporosis and is an important predictor of future fractures. The use of several types of CNS active drugs, including benzodiazepines, anti-depressants, narcotics and anticonvulsants, have all been associated with an increased risk of fracture. It is unclear whether this is related to an effect on BMD or other mechanisms, such as an increased risk of falls.

Objective: To examine the relationship between BMD and the use of benzodiazepines, anti-depressants, narcotics and anticonvulsants in a representative US population-based sample.

Method: We analyzed data on adults aged 17 and older from The Third National Health and Nutrition Examination Survey (NHANES III: 1988-1994). Total femoral BMD of 7,114 male and 7,532 female participants was measured by dual-energy x-ray absorptiometry. Multivariable linear regression models were examined that considered total femoral BMD as the dependent variable and the CNS medications as the exposures of interest. All models controlled for age, gender, race, tobacco use, alcohol, history of hip and wrist fracture, cognitive impairment, menopausal status, chronic disease, BMI, exercise, fall, self-reported health, hormone replacement therapy, calcium intake, steroid and thiazide use, and serum vitamin D level.

Results: We included 14646 persons in these analyses. 4.8% of the study sample had femoral neck BMD measurements with t-scores < -2.5. The percentage of subjects with osteoporosis taking benzodiazepines was 6.1%, anti-depressants was 5.2%, narcotics was 3.2%, and anticonvulsants was 14.1%. In linear regression models, subjects taking anticonvulsants had significantly lower femoral neck BMD,0.915 g/cm2, compared to nonusers,0.952 g/cm2 (difference = 3.9%, p = 0.017). None of the other CNS active drugs -- benzodiazepines, antidepressants, or narcotics - were associated with significantly lower BMDs. Among anticonvulsants, the mean BMDs of users of carbamazepine, phenytoin and phenobarbital were consistently lower than nonusers.

Conclusions: The use of anticonvulsants is associated with significantly lower BMD. None of the other CNS active agents studied were associated with lower BMD. These findings have implications for fracture prevention strategies.

Use of Selective Serotonin Receptor Inhibitors Increases the Rate of Hip Bone Loss. S. Diem*[1], T. Blackwell[2], K. Yaffe[3], D. Bauer[4], K. Ensrud[5]. [1]Medicine, University of Minnesota, Minneapolis, MN, USA, [2]California Pacific Medical Center Research Center, San Francisco, CA, USA, [3]Psychiatry, Neurology, & Epidemiology, University of California, San Francisco, CA, USA, [4]Medicine, University of California, San Francisco, CA, USA, [5]Medicine & Epidemiology, VA Medical Center &University of Minnesota, Minneapolis, MN, USA.

Depression is associated with low bone mineral density (BMD) in some studies but the biologic mechanisms underlying this association are unknown. Serotonin transporters have been documented in bone and the use of antidepressant medications, which often block the serotonin transporter, are associated with an increased risk of fractures in older women. To test the hypothesis that elderly women who use selective serotonin receptor inhibitors (SSRIs) have increased rates of hip bone loss, we assessed current use of SSRIs using an interviewer-administered questionnaire and serial BMD measurements in a cohort of 2556 elderly women (mean age 78.5 yrs) participating in the Study of Osteoporotic Fractures. Hip BMD was measured at the 6th exam and an average of 4.9 years later at the 8th exam. We verified current antidepressant use (defined as daily or almost daily use in the preceeding 30 days) by inspection of medication containers and classified type of medication from product brand or generic names using a computerized medication dictionary. We categorized women according to their reported SSRI use as users (use at either exam or both) or non-users (use at neither exam). Individual drug use within the user category included fluoxetine, paroxetine, sertraline, citalopram, escitalopram, and fluvoxamine. Users of other classes of antidepressants at either visit were excluded. The mean annual % change in total hip BMD (THBMD) and 3 subregions were calculated by category of SSRI use. Depressive symptoms were identified using a cutoff score of >= 6 on the Geriatric Depression Scale as measured at the 6th exam. All results were adjusted for the following characteristics measured at the 6th exam: age, race, health status, functional status, walking speed, cognitive function, calcium supplement use, vitamin D supplement use, estrogen use, thiazide use, weight change, THBMD at the 6th visit, and depressive symptoms.

THBMD at the 6th visit did not differ among users and non-users (p= .33), but mean TH bone loss was -.47%/yr among non-users vs. -.81%/yr among the SSRI users (p=.0008). Findings were similar at the subregions of the hip and when women with depressive symptoms were excluded from the analysis.

Use of SSRIs in elderly women in this cohort is associated with increased rates of hip bone loss. Further work is needed to determine if this widely-used class of drugs has a direct effect on bone metabolism.

Evaluation of Easily Measured Risk Factors in the Prediction of Osteoporotic Fractures. R. Bensen*[1], A. Papaioannou[2], J. D. Adachi[2], G Ioannidis[2], W. Olszynski*[3], R. Sebaldt*[2], T. Murray*[4], R. Josse*[4], J. Brown*[5], D. Hanley*[6], A. Petrie*[2], C. Goldsmith*[2]. [1]Medical Sciences, McMaster University, Hamilton, ON, Canada, [2]McMaster University, Hamilton, ON, Canada, [3]University of Saskatchewan, Saskatoon, SK, Canada, [4]University of Toronto, Toronto, ON, Canada, [5]Laval University, Ste-Foy, PQ, Canada, [6]University of Calgary, Calgary, ON, Canada.

The purpose of this study was to examine the effectiveness of easily measurable risk factors for new hip, vertebral, wrist and rib fractures in postmenopausal women registered in CANDOO.

The CANDOO registry is a multi-site clinical dataset related to osteoporosis. A total of 3653 postmenopausal women with a baseline and follow-up visit were considered. Of these, a total of 40, 158, 99, and 64 women respectively developed a new hip, vertebral, wrist or rib fractures. The mean (SD) weight for those with a fracture was 63.6 (12.9) kg while age was 68.0 (7.5) years. We examined seven risk factors predictive of fracture in research trials including: age (<65, 65-69, 70-74, 75-79, 80+ years), rising from a chair with arms (yes, no), weight (< 57, ≥ 57 kg), maternal history of a hip facture (yes, no), a prior fracture after the age of 50 years (yes, no), total hip t-score (>-1, -1 to >-2.5, ≤-2.5), and current smoking status (yes, no). Multivariable logistic regression analysis was used to examine each risk factors ability to independently predict new fracture.

The inability to rise from a chair without the use of arms (3.58; 95% CI: 1.173, 10.927) was the most significant risk factor for new hip fracture. New wrist fractures were significantly identified by low body weight (1.71, 95% CI: 1.007, 2.897) and prior fracture after 50 years (1.96; 95% CI: 1.191, 3.223). Predictors of new rib fractures include a maternal history of a hip facture (2.89; 95% CI: 1.035, 8.081) and a prior fracture after 50 years (2.16; 95% CI: 1.201, 3.874). Notable risk factors for predicting new vertebral fractures were: low body weight (1.57; 95% CI: 1.035, 2.373), current smoking (1.95; 95% CI: 1.199, 3.184) ages 75-79 years (1.96; 95% CI: 1.096, 3.508). Fracture represents the most important clinical event in patients with osteoporosis, yet few if any premonitory symptoms are present. It is critical that physicians at all levels of care be able to effectively and efficiently identify those individuals at increased risk of fracture. This study has shown that there exists many predictors of future fracture, besides BMD, that can be easily assessed by a physician. Of greatest interest is the fact that decreased mobility/strength, as represented by an inability to rise from a chair, is perhaps the most identifiable significant risk factor for hip fracture and can be easily incorporated into clinical practice.

F373

Use of Clinical Risk Factors to Select Elderly Women for Treatment or Bone Densitometry. P. Dargent-Molina, S. Piault*, G. Breart*. Unite 149, INSERM, Villejuif, France.

It has been suggested that a strategy of triage, based on the calculation of a clinical fracture risk score, could be used to stratify individuals in three groups : a group at high risk for whom a treatment is indicated, an intermediate group for whom further assessment by DXA is indicated, and a group at low risk.

We used prospective data from the EPIDOS study (7512 women 75+ followed for an average of 3.9 yrs) to assess the potential value of such a strategy to identify elderly women who have a risk of hip fracture two times higher than the average risk in the cohort (ie greater than 20 per 1000 women-years). To construct the score, we selected factors that were associated both with the risk of hip fracture and with low BMD. We used the final risk function (Cox model) to calculate an individual fracture risk score based on each woman's characteristics. We compared this strategy to systematic BMD measurement and to current recommendations in Europe (ie, selection of women for bone densitometry based on specific risk factors, followed by treatment of women with T-score below -2.5). The main criteria used for comparison were the number of high risk women identified, their average level of risk, the sensitivity for hip fracture, and the number needed to screen to prevent one hip fracture (hypotheses: all identified women are treated; treatment reduces fracture risk by 35%).

The set of osteoporosis-related risk factors that are most predictive of the risk of hip fracture includes age, history of fracture since the age of 40, BMI, number of IADL for which assistance is needed, grip strength, and visual acuity. A strategy of triage based on these factors allows the identification of a large number of women at high risk of hip fracture (20% of the cohort). About 75% of the identified women have been selected based on clinical factors only. The rest have been identified after BMD measurement (with a threshold at -2.5 T-score). The results are summarized below:

	Triage based on clinical score	Systematic BMD measurement	Current recommendations
Sensitivity (%)	51.0 (45.3 - 56.8)	34.9 (29.5 - 40.3)	46.9 (41.2 - 52.5)
High risk group:	20	15	27
% women	29.8 (25.0 - 34.6)	26.8 (21.7 - 31.9)	19.6 (16.4 - 22.9)
average risk of hip fx (p. 1000 women-yrs)			
No. needed to screen to prevent one hip fx	29	30	41
BMD examinations (%)	10	100	52

A major issue with the triage strategy concerns the efficacy of treatments in women identified solely on the basis of clinical factors since 37% of them are not osteoporotic. However, most of these non-osteoporotic women have osteopenia and a risk of hip fracture close to our high risk threshold. We conclude that the proposed strategy of triage could be a useful clinical tool to select elderly women for treatment or bone densitometry.

A Family History of Fracture and Fracture Risk: A Meta-Analysis. O. Johnell, J. A. Kanis, H. Johansson*, A. Oden*, C. De Laet*, J. A. Eisman, E. V. McCloskey, E. V. McCloskey, D. Mellstrom*, L. J. Melton, H. A. P. Pols*, J. Reeve, A. J. Silman, A. Tenenhouse. Centre for Metabolic Bone Diseases, University of Sheffield, Sheffield, United Kingdom.

The aims of the present study were to determine whether a parental history of any fracture, or hip fracture specifically, are significant risk factors for future fracture in an international setting, and to explore the effects of age, sex and bone mineral density (BMD) on this risk. We studied 34,928 men and women from 7 prospectively studied cohorts followed for 134,374 person-years. The cohorts comprised the EPOS/EVOS study, CaMos, the Rotterdam Study, DOES and cohorts at Sheffield, Rochester and Gothenburg. The effect of family history of osteoporotic fracture (or hip fracture) in first degree relatives, BMD and age on all fracture, osteoporotic fracture and hip fracture risk alone was examined using Poisson regression in each cohort and for each sex. The results of the different studies were merged from the weighted β coefficients.

A parental history of fracture was associated with a modest but significantly increased risk of any fracture, osteoporotic fracture and hip fracture in men and women combined. The risk ratio (RR) for any fracture was 1.17 (95% CI = 1.07-1.28), for any osteoporotic fracture was 1.18 (95% CI = 1.06-1.31), and for hip fracture alone was 1.49 (95% CI = 1.17-1.89). The risk ratio was higher at younger ages but not significantly so. No significant difference in risk was seen between men and women with a parental history for any fracture (RR = 1.17 and 1.17, respectively) or for an osteoporotic fracture (RR = 1.17 and 1.18, respectively). For hip fracture, the risk ratios were somewhat higher, but not significantly higher, in men than in women (RR = 2.02 and 1.38, respectively). A family history of hip fracture in parents was associated with a significant risk both of all osteoporotic fracture (RR 1.54; 95% CI = 1.25-1.88) and of hip fracture (RR = 2.27; 95% CI = 1.47-3.49). The risk was not significantly changed when BMD was added to the model.

We conclude that a parental history of fracture confers an increased risk of fracture that is independent of BMD. Its identification on an international basis supports the use of this risk factor in case-finding strategies.

Osteoporosis and Cardiovascular Disease are Highly Associated Comorbidities in Elderly Women. L. B. Tankó, Y. Z. Bagger, P. Alexandersen, C. Christiansen. Center for Clinical and Basic Research, Ballerup, Denmark.

The purpose of the study was to investigate associations between bone and cardiovascular status in a large population-based sample of 5409 elderly women participating in the Prospective Epidemiological Risk Factors (PERF) study. Age of participants was between 60 and 85 years (mean 71 years). Main study parameters on the bone side were bone mineral density (BMD) at the hip, lumbar spine, and forearm measured by DEXA, radiographic vertebral fracture(s), and self-reported non-vertebral fractures. Cardiovascular status was characterized by a surrogate of atherosclerosis, aorta calcification (AC) visualized and graded on lateral X-rays using validated scoring system, and self-reported cardiovascular diseases (angina pectoris, myocardial infarct, stroke, intermittent claudicatio) verified by hospital discharge summaries. There was 2118 (39.1%) fractures registered, of which 1064 (19.7%) was vertebral fracture verified by X-ray. The number of women with manifest cardiovascular disease was 558 (10.3%). Table 1 summarizes the main findings of the analysis. After adjustment for age, the risk of CVD was 2.30-fold higher in women in the highest compared with the lowest quartile of AC. Age-adjusted BMD showed a significant inverse association with the severity score of AC at the hip and the forearm, but not at the lumbar spine. However, the frequency of osteoporotic vertebral fractures was significantly higher in the largest compared with the lowest quartile of AC (35.1% vs. 15.7%, $p<0.001$) and the age-adjusted relative risk of having an osteoporotic vertebral fracture was 29% higher in the highest compared with the lowest quartile of AC. Associations with the frequency of non-vertebral fractures was weaker and statistically non-significant. Finally, those with manifest CVD had a 22% increased risk for having at least one vertebral fracture compared with controls without CVD. These observations provide strong support for the coexistence of osteoporosis with cardiovascular disease in elderly women suggesting potential causal links. The results also emphasize that elderly women with severe osteoporosis at the hip and forearms should be referred to proper cardiovascular diagnostics to reveal or exclude the presence of subclinical CVD.

	Quartiles of Aortic Calcification			
Age-adjusted	1	2	3	4
Odds ratio for CVD (95% CI)	1.0	1.11 (0.8-1.6)	1.54 (1.2-2.0)*	2.30 (1.8-2.9)*
Forearm BMD (g/cm2)	0.367	0.364	0.361	0.355*
Hip BMD (g/cm2)	0.793	0.795	0.783*	0.764*
Spine BMD (g/cm2)	0.910	0.908	0.900	0.904
Odd ratio for vertebral fracture (95% CI)	1.0	1.24 (0.9-1.6)	1.19 (1.0-1.4)	1.29 (1.1-1.6)*

The Rate of Bone Loss Is associated with an Increased Risk of Fracture in Postmenopausal Women. The OFELY Study. E. Sornay-Rendu*, F. Munoz*, F. Duboeuf*, P. D. Delmas. Unit 403, INSERM, Lyon, France.

A low bone mineral density (BMD) is a major determinant of fragility fractures but the role of the rate of postmenopausal bone loss is still unclear. In the OFELY study, we analyzed the risk of fracture in postmenopausal women according to the rate of bone loss. BMD was measured annually by dual-energy X-ray absorptiometry (DXA) at the forearm in 671 postmenopausal women (mean age 62.2 ± 9 years), for up to 11 years. Peripheral fractures, all confirmed by radiographs, were prospectively registered and vertebral fractures were evaluated with spine radiographs every four years. During a median 9.1 yr (IQ :2.3) of follow-up, 158 incident fragility fractures including 50 vertebral and 108 non-vertebral fractures were recorded in 116 women. The annual mean rate of bone loss, calculated from the slope (mean ± SD), was -0.30 ± 0.3 at the mid radius, -0.28 ± 0.3 at the distal radius and -0.15 ± 0.3 at the ultradistal radius. Bone loss was associated with a significant increased risk of fracture. A 1 SD increase of bone loss at the mid, distal and ultradistal forearm was associated with an odds ratio (95% CI) of 2.62 (1.02-6.8), 1.98 (1.02-3.5) and 2.70 (1.03-7.1) respectively, after adjusting for age, prior fractures and baseline BMD. In that multivariate model, baseline BMD (T score <-2.5) and prevalent fractures were also predictor (1.74 [1.35-2.24] and 2.93 [1.37-6.25] respectively) and age >65 yrs was borderline significant (1.82 [0.99-3.36]). In summary, the rate of bone loss in postmenopausal women is significantly associated with fracture risk independently of other well known predictors such as BMD and history of fractures. Our data suggest that BMD and the rate of bone loss contribute to a similar extent to the risk of fractures.

Disclosures: ***E. Sornay-Rendu****, None.*

Baseline Buckling Ratio Derived from Hip Structure Analysis Predicts the Risk of Nonvertebral Fracture. G. G. Crans*[1], T. J. Beck*[2], L. M. Semanick*[2], K. D. Harper[1], K. V. Pinette[1], E. F. Eriksen[1]. [1]Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN, USA, [2]The John's Hopkins University School of Medicine, Baltimore, MD, USA.

The purpose of this study was to determine if buckling ratio (BR), an index of cortical bone stability derived from Hip Structural Analysis (HSA) (Beck et al. 1990 and 2000), is able to predict nonvertebral fracture (NVFx) risk. The HSA program analyzes 5mm cross-sectional regions traversing the proximal femur across the intertrochanter (IT), femoral neck and femoral shaft. HSA has the ability to measure BMD, cross-sectional area, cross-sectional moment of inertia, section modulus, subperiosteal width and estimated mean cortical thickness. BR is derived as the ratio of the maximum distance from the region center of mass to the outer cortex divided by the estimated mean cortical thickness. A decrease in BR suggests an improvement of local cortical stability (Beck et al. 2001). We investigated the relationship between three-year NVFx risk and baseline BR in the placebo group of the MORE study (Ettinger et al.1999). Two analyses were conducted on the three HSA regions of the proximal femur. First, we used an Armitage trend test to determine if NVFx risk was associated with baseline BR tertiles. Second, logistic regression was used to help understand the quantitative nature of the relationship; we modeled three-year NVFx risk as a function of BR (up to cubic terms). The same analysis strategy was repeated using three-year hip fracture data. There was a strong relationship between NVFx risk and baseline BR, Table 1. The test for trend was significant ($p < 0.05$) for the IT and shaft BR, and near significant for the neck ($p = 0.07$). The results from the logistic regression analyses confirmed these results, as the main effect of BR was significant for each location. The relationship was linear (on the logit scale), as neither quadratic nor cubic effects were statistically significant. The trend for hip fracture risk was only significant for the IT BR, Table 2. Although the numeric trend of the hip data suggests an increased fracture risk with increasing baseline BR, there were, unfortunately, too few hip fractures in MORE to adequately address this very interesting question. In conclusion, despite the limitations of the estimate, BR derived from HSA may be able to predict the risk of NVFx in postmenopausal women with osteoporosis.

Table 1. Any Nonvertebral Fracture	**First Tertile**	**Second Tertile**	**Third Tertile**	**p-value**
Intertrochanter	23/442 (5.20)	47/444 (10.59)	49/443 (11.06)	0.0023
Femoral Neck	35/456 (7.68)	41/461 (8.89)	51/455 (11.21)	0.0658
Femoral Shaft	31/443 (7.00)	37/444 (8.33)	51/443 (11.51)	0.0186
Table 2. Hip Fracture	**First Tertile**	**Second Tertile**	**Third Tertile**	**p-value**
Intertrochanter	0/442 (0.00)	2/444 (0.45)	6/443 (1.35)	0.0092
Femoral Neck	2/456 (0.44)	1/461 (0.22)	5/455 (1.10)	0.1909
Femoral Shaft	2/443 (0.45)	1/444 (0.23)	5/443 (1.13)	0.1924

How Carolic Restriction Affects Bone Mass and Trabecular Structure. S. Tatsumi*[1], M. Ito[2], K. Tsutsumi*[3], H. Takasu[3], K. Ikeda[3]. [1]Pharmaceuticals and Medical Device Agency (Pmda), Tokyo, Japan, [2]Nagasaki University Hospital, Nagasaki, Japan, [3]Department of Bone and Joint Disease, National Center for Geriatrics and Gerontology (NCGG), Obu, Japan.

Caloric restriction (CR) is the only and evolutionally conserved remedy that has been demonstrated to extend life-span of various organisms, as diverse as yeast, worms, flies and mammals, although the underlying mechanism is not fully understood. CR is also known to slow or block the onset of age-related disorders, including neurodegenerative disease, cancer, atherosclerosis and renal disease. With respect to CR and bone metabolism, conflicting results have been reported, from acceleration of bone loss to preventive effect through counteraction of age-related development of secondary hyperparathyroidism, and underlying mechanisms are not clear. In the present study, we have examined the effect of long-term CR (by alternate day feeding) vs. AD (ad libitum feeding) on bone remodeling in male C57B6 mice and F344 rats, focusing on its relation to energy balance. CR was started at the age of 3 months to minimize its effect on bone growth and was continued for up to 13 months. CR by 40% for 6 months (i.e. at the age of 9 months) caused decreased adipose tissue and body weight, in association with decreased serum leptin and insulin concentrations but comparable albumin levels, assuring that animals are not in malnutirition state. Micro CT scanning revealed that CR causes a substantial decrease in 3D BV/TV, both in mice and rats, with significant decreases in connectivity density and trabecular (Tb) number and increases in SMI (structure model index) and Tb separation, compared with AD group, while Tb thickness did not differ. Bone histomorphometry showed that reduction in BV was due to suppressed bone formation with elevated bone resorption. Ex vivo cultures revealed increases in both osteoclastogenesis and osteoblastogenesis in CR mice-derived marrow cultures, suggesting a feedback mechanism for osteoblast recruitment. In control AD mice, BV decreased between 9 and 16 months of age, whereas this age-related decline of bone mass did not occur in CR group, suggesting that CR may have biphasic effect on bone. In db/db mice with defective leptin receptor, CR failed to decrease bone mass. Also, reduced bone mass by CR was restored to AD level by administration of a beta adrenergic blocker, propranorol. Thus, CR may regulate bone formation through leptin signaling in the hypothalamus and elevated tone of sympathetic nervous system.

The Postprandial Bone Resorption Process Is Regulated by Gastrointestinal Signal. D. B. Henriksen[1], B. Hartmann*[2], P. B. Jeppesen*[3], J. Miholic*[4], C. Christiansen[5], J. J. Holst*[2]. [1]Sanos Bioscience A/S, Herlev, Denmark, [2]Department of Medical Physiology, University of Copenhagen, Copenhagen, Denmark, [3]Department of Medicine CA, National University Hospital, Copenhagen, Denmark, [4]Department of Surgery, University of Vienna, Vienna, Austria, [5]Center for Clinical & Basic Research, Ballerup, Denmark.

The circadian pattern of bone resorption as assessed by s-CTX is tightly regulated to respond to food intake and the process is significantly dampened by meal ingestion. In contrast, the bone formation process is seemingly unaffected by ingestion of nutrients.

We conducted two studies, one in patients with short bowl (SB) syndrome and one in patients with total gastrectomy. The objective was to elucidate whether the signal for the acute reduction of bone resorption after a meal was initiated from the stomach or the intestine.

SB patients with a preserved colon (n=5) and patients with SB and colectomy (n=7) and healthy controls (n=8) were admitted for a breakfast test meal (936 kcal) after an overnight fast. Blood samples were collected 15 minutes before and at 30, 60, 120, and 180 minutes after the meal. Patients who had total gastrectomy (n=8) were studied after an oral glucose (75g in 150ml). Blood samples were collected at 0, 30, 60, 90, 120, 150, and 180 minutes after ingestion.

We found that the normal reduction in bone resorption (s-CTX) after a meal was completely abolished in SB patients without colon. SB patients with a preserved colon had an intermediate response with a 27% ($p<0.05$) reduction of s-CTX after 120 minutes as compared to 66% ($p<0.001$) for normal controls. A significant reduction of 53% ($p<0.001$) was seen in individuals with total gastrectomy after oral glucose, which is comparable to published data for OGTT in healthy subjects (50% reduction over 120 min). Bone formation was unchanged for both SB and gastrectomy patients after ingestion of nutrients.

These data imply that the signal regulating the acute postprandial reduction in bone resorption arises from the intestine. Several hormones are released in response to the ingestion of nutrients. In particular the gastrointestinal hormone glucagon like peptide-2 (GLP-2) is thought to serve, together with the other proglucagon-derived peptides, in the regulation of absorption and disposal of ingested nutrients. The acute postprandial reduction of bone resorption coincides with the release of GLP-2 from the intestine. Furthermore, a subcutaneous injection of GLP-2 have been shown to result in a significant and acute reduction of the bone resorption in a dose dependent manner and with an apparent positive effect on bone formation as assessed by osteocalcin.

Mice Failing to Undergo Puberty Due to Targeted Inactivation of the GPR54 Gene Exhibit Alterations in Body Composition and Reduced Bone Mass. R. Brommage[1], N. Qian*[2], P. Vogel*[3], G. Liu*[1], M. Kelly*[4], D. R. Powell*[1]. [1]Endocrinology, Lexicon Genetics, The Woodlands, TX, USA, [2]Target Validation, Lexicon Genetics, The Woodlands, TX, USA, [3]Pathology, Lexicon Genetics, The Woodlands, TX, USA, [4]Molecular Genetics, Lexicon Genetics, The Woodlands, TX, USA.

GPR54 has recently been identified as a critical receptor involved in the initiation of puberty, as humans and mice with loss of GPR54 function have hypogonadotropic hypogonadism (de Roux et al., PNAS USA 100:10972-10976; 2003, Seminara et al., New Engl J Med 349:1614-1627; 2003, and Funes et al., Biochem Biophys Res Commun 312:1357-1363; 2003). The natural ligand for GPR54 is metastin (also known as KiSS-1), a 54 amino acid peptide containing an amidated carboxy-terminal phenylalanine. As part of Lexicon Genetics' efforts to examine phenotypes of knockout (KO) mice with targeted inactivations of novel genes that are potential pharmaceutical targets, KO mice with deletion of all 5 exons of the GPR54 gene were generated using homologous recombination. Both male (N = 3) and female (N = 4) KO mice are infertile. KO males (N = 3) have hypoplastic testes, epididymidies, seminal vesicles and prostates whereas KO females (N = 3) have hypoplastic uteri and ovaries. PIXImus DEXA measurements were performed at ~14 weeks of age in 7 KO males, 11 KO females, 5 male and 8 female wild-type littermates. Male KO mice have reduced body weight (↓22%) and lean body mass (LBM, ↓26%) but normal fat content, and therefore have an increased body fat percentage (↑18%). Female KO mice have normal body weight and LBM, but elevated body fat content (↑65%), and therefore have an increased body fat percentage (↑50%). Total body volumetric bone mineral density (vBMD) is reduced in both male (↓12%) and female (↓7%) KOs, with the BMC/LBM ratio being normal in males but low in females (↓26%). Femur and spine BMD are reduced in KOs of both genders (↓14% to ↓29%). Bone architecture was determined at ~16 weeks of age by microCT (Scanco μCT40) in 7 KO males, 6 KO females, 5 male and 6 female wild-type littermates. KO mice exhibit reduced LV5 trabecular bone volume (↓58% in males and ↓47% in females) and reduced femur midshaft cortical thickness (↓22% in males and ↓12% in females) and total cross-sectional area (↓29% in males and ↓23% in females) in both genders. All reported differences are statistically significant at $P < 0.05$. In summary, male and female mice with developmental hypogonadotropic hypogonadism have low bone mass. Male mice have low LBM whereas female mice have excess body fat. These alterations in body composition and bone mass are consistent with sex hormone deficiency throughout life.

A Two-year Study of Bone Mineral Density in Adolescent Girls using either Depot Medroxyprogesterone Acetate or Oral Contraceptives. B. Cromer*[1], A. Bonny*[1], J. Ziegler*[2], R. Lazebnik*[3], E. Rome*[4], S. M. Debanne*[2]. [1]Pediatrics, MetroHealth Medical Center/Case Western Reserve University, Cleveland, OH, USA, [2]Case Western Reserve University, Cleveland, OH, USA, [3]Pediatrics, University Hospitals of Cleveland/Case Western Reserve University, Cleveland, OH, USA, [4]Pediatrics, The Cleveland Clinic/Case Western Reserve University, Cleveland, OH, USA.

There are mixed results on the effects of hormonal contraception on adolescent bone mineral density (BMD). In question are the effects of depot medroyxprogesterone acetate (DMPA) and oral contraceptives (OC) containing 20mcg ethinyl estradiol on BMD. The purpose of this study was to compare BMD over 24 months in adolescents who selected either DMPA (n=58) or OC (n=181), and girls who received no treatment with hormonal contraception [control group (N=161)]. The study population comprised 400 healthy, post-menarcheal girls aged 12 - 18 years recruited from four primary care clinics in a large, urban area. At baseline, 6, 12, 18, and 24 months, BMD of the lumbar spine (L1-L4) and femoral neck were obtained with dual x-ray absorptiometry (DXA). Data were also obtained on tobacco use, calcium intake, physical exercise, and menstrual history.

Mean chronologic age in years at baseline was as follows: DMPA (15.8±1.6 SD), OC (16.0±1.4 SD), and control (14.9±1.6 SD). The control group was significantly younger than the other two groups (p<.001). Approximately 60% of each group self-reported race as black. Mean weight in kilograms was as follows: DMPA 60.4(±12.8 SD), OC 69.1(±17.2 SD), and control 63.3(±16.8 SD). The OC group weighed significantly more than the other two groups (p<.001). To date, a total of 130 girls have completed the study: DMPA (n=17), OC (n=44), and control (n=69). Using analysis of covariance, after adjusting for age, race, and body weight, the results were as follows: percent change in BMD at femoral neck over 24 months was as follows: DMPA -5.2%, OC 3.0%, and control 3.8% (p< .001). Post hoc testing showed significance for DMPA vs. OC (p<.001) and DMPA vs. control (p<.005). Percent change in BMD at L1 - L4 spine over 24 months was as follows: DMPA -1.4%, OC 4.2%, and control 6.2% (p<.001). Post hoc testing showed significance for DMPA vs.OC (p<.001) and DMPA vs. control (p<.001).

Conclusion: Over a 24 month period, adolescent girls receiving DMPA had significant bone loss in both the femoral neck and lumbar spine compared to bone gain in these areas in the other two groups. The clinical implication of these results is whether use of DMPA reduces peak bone mass during a crucial period of bone development in adolescent girls.

Increases in Femoral Neck Strength Indices with Alendronate versus Placebo. A. Karlamangla[1], D. Black[2], E. Barrett-Connor[3], J. Liu*[1], D. Kado[1], G. Greendale[1]. [1]Division of Geriatrics, UCLA, Los Angeles, CA, USA, [2]UCSF, San Francisco, CA, USA, [3]UCSD, La Jolla, CA, USA.

The fracture risk reduction achieved with alendronate therapy in clinical trials is greater than would be expected from the increases seen in bone mineral density. This discordance may be a consequence of the effects of the therapy on bone size. We therefore set out to study the effects of alendronate therapy on composite indices of femoral neck strength, which integrate bone mineral density, bone size, and body size:

Compression Strength Index = BMD * FNW / Weight,

Bending Strength Index = BMD * $(FNW)^2$ / (HAL * Weight),

Impact Strength Index = BMD * FNW * HAL / (Height * Weight).

Here, BMD refers to projected (areal) bone mineral density of the femoral neck, FNW is femoral neck width, and HAL is hip axis length. These indices have previously been shown to predict hip fracture risk in older women.

In all participants from 2 sites of the Fracture Intervention Trial (post- menopausal women, N=573), we measured BMD, HAL, and FNW from archived DXA hip scans and calculated the 3 strength indices at baseline and final follow up (3-4 years later).

At baseline, mean values of FNW and strength indices were similar in the 2 arms of the trial (p>0.3). By final follow up, FNW had increased in both groups (p=.0008 for placebo, p<.0001 for alendronate), but since BMD decreased in the placebo group (p=.0003) and increased in the alendronate group (p<.0001), the composite strength indices remained essentially unchanged in the placebo arm (p=.08 for compression index, p=.14 for bending index, and p=.79 for impact index), while they increased significantly in the alendronate arm (p<.0001 for all 3 indices).

Femoral Neck Variables	**Mean Change (%)**		*p value for comparison of 2 groups*
	Alendronate (N=288)	*Placebo* (N=285)	
Femoral Neck Width	+ 0.9	+ 0.6	0.25
Femoral Neck BMD	+ 3.1	- 0.9	< .0001
Compression Strength Index	+ 4.1	- 0.2	< .0001
Bending Strength Index	+ 4.4	+ 0.0	< .0001
Impact Strength Index	+ 5.1	+ 0.5	< .0001

As BMD declined with aging in the placebo group, there was a compensatory increase in FNW, which minimized the effect on bone strength. However, in the alendronate group, the increase in BMD was still accompanied by an increase in FNW similar to that seen in the placebo group. Thus increases in femoral neck strength in the alendronate group were substantially larger than the increases in the placebo group. In future studies, we will investigate how much of the fracture risk reduction in the alendronate group is explained by these increases in strength indices.

Drug Therapy For Early Post-menopausal Osteopenic Women in the Absence of Prior Fracture Is NOT Cost-Effective. J. T. Schousboe[1], K. E. Ensrud[2], J. A. Nyman*[3], R. L. Kane*[3], L. J. Melton[4]. [1]Park Nicollet Health Services, Minneapolis, MN, USA, [2]Univ of Minnesota & MVAMC, Minneapolis, MN, USA, [3]Univ of Minnesota, Minneapolis, MN, USA, [4]Mayo Clinic, Rochester, MN, USA.

Some drugs are FDA approved to prevent bone loss in osteopenic (spine or hip T-score between -1.0 and -2.5) post-menopausal women, and are currently being marketed for that indication by industry. In the absence of prior fracture, osteopenic women are not at high risk of fracture. Targeting healthy women at the menopause may be especially problematic. To evaluate this issue, we used a Markov model with seven health states (No Fracture, Wrist, Clinical Vertebral, Hip, Vertebral and Hip, Other Fractures, & Death) to estimate the incremental lifetime costs & health benefits of a strategy of alendronate therapy for five years compared to no drug therapy in osteopenic early post-menopausal women. "Other" fractures included distal femur, humerus, proximal radius, pelvis, rib, and fibula/tibial fractures. Fracture rates, direct medical costs of fracture, & long-term care costs after hip fracture were derived from comprehensive population-based data of Rochester, MN. We assumed 1) the worst estimates for loss of quality of life from fracture published in the medical literature, 2) a 50% reduction in vertebral and 34% reduction in non-vertebral fractures with alendronate therapy in the no fracture state, 3) a 50% reduction in all fractures with alendronate therapy after any incident fracture, 4) discount rates of 3% for costs & health benefits, 5) alendronate cost equal to U.S. average wholesale price for 2001, and 6) gradual offset of fracture reduction benefit over 5 years after alendronate discontinuation. The table below shows the incremental cost (in 2001 US $) per quality adjusted life-year saved with this strategy compared to no drug therapy, from Monte Carlo simulations (20,000 trials each) of the model.

Age	**Femoral Neck T-Score**		
	-1.0	-1.5	-2.0
50	$258,609	$196,138	$135,161
55	$211,178	$150,896	$100,379
60	$183,161	$129,756	$85,676

These results are insensitive to varying fracture rates or costs by 30%. Even assuming a very high societal willingness to pay of $100,000 per QALY saved & best case scenario regarding drug efficacy, alendronate therapy for healthy osteopenic early post-menopausal women who have not had a fracture is not cost-effective. These results are highly likely to be applicable to other anti-resorptive drugs, since they are similar in cost to & no more efficacious in preventing fracture than alendronate.

Disclosures: ***J.T. Schousboe****, Hologic, Inc 2.*

Reduction of Osteoporotic Fractures with Risedronate in Osteopenic Postmenopausal Women. E. S. Siris[1], I. P. Barton*[2], M. R. McClung[3], A. Grauer[4]. [1]Columbia University, New York, NY, USA, [2]Procter & Gamble Pharmaceuticals, Egham, United Kingdom, [3]Oregon Osteoporosis Center, Portland, OR, USA, [4]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

There is increasing evidence that a significant number of vertebral and non-vertebral osteoporotic fractures occur in patients with BMD values in the osteopenic range. Using data obtained from the VERT and BMD studies, we investigated the efficacy of risedronate in reducing osteoporotic fractures in postmenopausal women who had a baseline femoral neck BMD T-Score above -2.5 SD (NHANES-III) and no prevalent vertebral fracture (VFx). We studied the effect of 3 years of risedronate 5mg vs. placebo daily on reducing the combined risk of vertebral and non-vertebral fractures. Patients were stratified per trial and data were analysed using a time-to-first fracture analysis. All patients received 1000mg calcium and, if needed, 500IU vitamin D/day. There were 707 patients with a femoral neck T-score higher than -2.5 SD without prevalent VFx at baseline (355 on placebo, 352 on risedronate). They were well matched for mean age (64 vs 64 years) and mean femoral neck T-score (-1.68 vs. -1.71). The fracture incidence in the placebo group over three years was 8.3%, compared to 2.1% in the risedronate treated patients (RR 0.25, CI 0.09-0.67, p<0.006). The results were similar when only the 371 patients who had a BMD T-score above -2.5 at both femoral neck and lumbar spine were included (placebo 7.0%, risedronate 1.1%, RR 0.24 (CI 0.05-1.11, p=0.068). Risedronate significantly reduced the risk for vertebral and non-vertebral osteoporotic fractures over 3 years in patients with a femoral neck T-score higher than -2.5 and no prevalent VFx by 75%. In addition to its established fracture risk reduction in osteoporotic patients, these data demonstrate that risedronate also significantly reduces the risk of both spine and non-spine fractures in patients without prevalent VFx and femoral neck-BMD values in the osteopenic range.

Monthly Oral Ibandronate Significantly Reduces Bone Resorption in Postmenopausal Osteoporosis: 1-Year Results from MOBILE. R. R. Recker[1], D. L. Kendler[2], S. Adami[3], C. Hughes*[4], E. Dumont*[5], R. C. Schimmer[4], C. Cooper[6]. [1]Creighton University, Omaha, NE, USA, [2]University of British Columbia, Vancouver, BC, Canada, [3]University of Verona, Verona, Italy, [4]F. Hoffmann-La Roche Ltd, Basel, Switzerland, [5]GlaxoSmithKline, Collegeville, PA, USA, [6]University of Southampton, Southampton, United Kingdom.

Bisphosphonate therapies are effective in normalizing the elevated rate of bone turnover associated with postmenopausal osteoporosis (PMO). Ibandronate (Boniva®) is a potent, nitrogen-containing bisphosphonate with proven antifracture efficacy when administered daily or intermittently in postmenopausal women with osteoporosis (3-year vertebral fracture risk reduction: 52% and 50%, respectively).[1] An ongoing, randomized, double-blind, phase III, non-inferiority study (MOBILE) is comparing the efficacy and safety of monthly oral 50/50mg (single doses on consecutive days), 100mg (single day) and 150mg (single day) ibandronate regimens with the proven oral daily (2.5mg) regimen in 1,609 women with PMO. In MOBILE, relative change (%) in the biochemical marker of bone resorption, sCTX, is a secondary efficacy endpoint, measured immediately prior to the scheduled ibandronate doses at 3, 6, 12 and 24 months. After 1 year, the magnitude of median sCTX suppression in the oral daily arm was 67.3% (**Table**). A comparable magnitude of sCTX suppression was reported in each of the monthly oral arms after 1 year (one month after dosing): 62.8%, 66.7% and 75.8% in the 50/50mg, 100mg and 150mg arms, respectively (**Table**). Substantial decreases in sCTX were also observed after 3 and 6 months (**Table**). At all assessment points, the 150mg regimen provided the greatest magnitude of sCTX suppression. In summary, monthly oral ibandronate rapidly suppresses bone resorption to normal levels within 3 months of initiation, and maintains this magnitude of suppression with continued therapy. Monthly oral ibandronate also provides a comparable magnitude of sCTX suppression to that observed with an oral daily ibandronate regimen of proven antifracture efficacy (3-year vertebral fracture risk reduction: 52%). These findings indicate that monthly oral ibandronate is a highly effective alternative to more frequently administered bisphosphonates in PMO.

1. Chesnut CH, et al. J Bone Miner Res (In press).

Table. Median relative change (%) from baseline in sCTX

	Daily ibandronate	Monthly ibandronate		
Month	2.5mg (n=318)	50/50mg (n=330)	100mg (n=315)	150mg (n=327)
3	-53.6	-50.0	-53.2	-66.1
6	-63.5	-60.7	-63.2	-73.4
12	-67.3	-62.8	-66.7	-75.8

F408

Monthly Oral Ibandronate Is at Least as Effective as Oral Daily Ibandronate in Postmenopausal Osteoporosis: 1-Year Results from MOBILE. P. D. Miller[1], M. K. Drezner[2], P. D. Delmas[3], J. A. Stakkestad*[4], C. Hughes*[5], B. Bonvoisin[5], J. Y. Reginster[6]. [1]Colorado Center for Bone Research, Lakewood, CO, USA, [2]University of Wisconsin, Madison, WI, USA, [3]Claude Bernard University and INSERM Research Unit 403, Lyon, France, [4]CECOR AS, Haugesund, Norway, [5]F. Hoffmann-La Roche Ltd, Basel, Switzerland, [6]University of Liège, Liège, Belgium.

Adherence to oral daily and weekly bisphosphonates in postmenopausal osteoporosis (PMO) is suboptimal. Less frequent dosing regimens, such as once monthly, are expected to enhance long-term compliance and persistence with therapy, optimizing therapeutic outcomes. Ibandronate (Boniva®) is a potent, nitrogen-containing bisphosphonate with proven antifracture efficacy in PMO when administered daily or intermittently with a between-dose interval >2 months (3-year vertebral fracture risk reduction: 52% and 50%, respectively). A 2-year, randomized, double-blind, phase III, non-inferiority study (MOBILE) is comparing the efficacy and safety of 2 years' treatment with 50/50mg (single doses on consecutive days), 100mg (single day) and 150mg (single day) monthly oral ibandronate regimens versus the proven oral daily (2.5mg) regimen. A total of 1,609 postmenopausal women (aged 55-80 years; YSM: ≥5 years) with osteoporosis (lumbar spine BMD T-score <-2.5 and ≥-5) were enrolled into the study. Calcium (500-1,500mg) and vitamin D (400 IU) supplements are provided. The primary endpoint is mean relative change (%) from baseline in lumbar spine (L2-L4) BMD after 1 year. Relative changes (%) in total hip, femoral neck and trochanter BMD after 1 year are secondary efficacy endpoints. After 1 year, lumbar spine BMD increased by 3.9%, 4.3%, 4.1% and 4.9% in the daily (n=318), 50/50mg (n=330), 100mg (n=315) and 150mg (n=327) treatment arms, respectively (per-protocol population). Non-inferiority to the oral daily regimen was proven for all monthly oral regimens (margin of non-inferiority: 1%). In addition, superiority of the 150mg regimen to the oral daily regimen was prospectively demonstrated as part of the primary analysis. Significant and substantial increases in hip (all sites) BMD were also reported with all regimens. In post-hoc analyses, non-inferiority to the daily regimen was demonstrated for all monthly oral regimens in terms of total hip and trochanter BMD and the 100mg and 150mg regimens with respect to femoral neck BMD. Superiority of the 100mg and 150mg regimens to the oral daily regimen for total hip and trochanter BMD was also demonstrated. These findings confirm that the unique monthly oral ibandronate regimens evaluated in MOBILE provide efficacy that is at least equivalent to an oral daily ibandronate regimen of proven antifracture efficacy in PMO.

Effects of Bisphosphonates on Hip Fracture Risk Reduction: A Bayesian Analysis of Clinical Trials. N. D. Nguyen, J. A. Eisman, T. V. Nguyen. Bone and Mineral Program, Garvan Institute of Medical Research, Sydney, Australia.

Following 7 randomized clinical trials (RCTs) with 16557 patients since 1995, the evidence of anti-hip fracture efficacy of alendronate and risedronate is conflicting. Two trials (one each with alendronate and risedronate) suggested a beneficial effect, but the rest found no significant effect on hip fracture risk. Meta-analysis for each drug also yielded no statistically significant effect.

The discrepancy in results is partly related to "conventional" statistical analyses of RCTs, including meta-analysis, and p-values derived from those analyses that do not take into account pre-existing data about therapeutic effect. To address this issue and to assess the effects of bisphosphonates on hip fracture risk, the Bayesian concept of probability was utilized to systematically review past RCT data. In this analysis, three basic elements were considered: prior distribution, likelihood of present RCT data, and posterior distribution. The prior distribution describes a clinical belief *a priori,* or in this case, previously observed effect of bisphosphonates; the likelihood function captures how the present data modify the prior knowledge of the therapeutic effect; and the posterior distribution synthesizes both prior knowledge and likelihood function to provide the ultimate answer, e.g., the probability that bisphosphonates reduce hip fracture risk by a minimal magnitude of effect and its *credible interval*.

Data from a previous RCT involved alendronate treatment showed that the RR of hip fracture was 0.22 (95% confidence interval: 0.02, 2.13, p = 0.90). By incorporating these prior data to the sequential data from 3 subsequent RCTs, the average posterior RR of hip fracture was estimated at 0.60 (95% credible interval: 0.39, 0.92). Moreover, the probability that alendronate reduces hip fracture risk by at least 30% was 76%. A similar analysis of 3 risedronate trials yielded an RR of 0.61 (95% credible interval: 0.45, 0.85), with the probability that risedronate reduces hip fracture risk by at least 30% (ie, RR<0.3) was 80%. Furthermore, the probability that alendronate and risedronate reduce hip fracture by at least 50% (ie, RR<0.5) was 23% and 12%, respectively. These Bayesian analyses indicated that relative to placebo, alendronate or risedronate treatment reduces hip fracture risk at a clinically significant and public health relevant magnitude.

Alendronate Produces Greater Gains in BMD and Greater Reduction in Markers of Bone Turnover than Risedronate with Similar Tolerability. C. Rosen*[1], M. Hochberg*[2], S. Bonnick*[3], M. McClung*[4], P. Miller*[5], S. Broy*[6], R. Kagan*[7], E. Chen*[8], R. A. Petruschke*[8], A. E. de Papp[8]. [1]Maine Center of Osteoporosis Research and Education and Saint Joseph Hospital, Bangor, ME, USA, [2]University of Maryland Division of Rheumatology, Baltimore, MD, USA, [3]Institute for Women's Health-Texas Woman's University, Denton, TX, USA, [4]Oregon Osteoporosis Research Center, Portland, OR, USA, [5]Colorado Center for Bone Research, Lakewood, CO, USA, [6]Illinois Bone and Joint Institute, Morton Grove, IL, USA, [7]Foundation for Osteoporosis Reseach and Education, Oakland, CA, USA, [8]Merck & Co., Inc., West Point, PA, USA.

We performed a 12 month, double-blind trial of once weekly (OW) alendronate (ALN) 70 mg and OW risedronate (RIS) 35 mg at 78 US sites. 1053 postmenopausal women with low bone mineral density (BMD) (T-score ≤-2.0 at hip trochanter, total hip, femoral neck or spine) were randomly assigned to OW ALN 70 mg and OW RIS placebo, or OW RIS 35 mg and OW ALN placebo. Treatment was administered fasting, in the morning, and patients were instructed to remain fasting for 30 minutes post dosing. The primary endpoint was the hip trochanter BMD at 12 months. Secondary endpoints included total hip, femoral neck and spine BMD, markers of bone turnover (uNTx/Cr, serum CTxI, serum BSAP, and serum P1NP), and tolerability as assessed by adverse experience (AE) reporting.

The mean age of subjects was 64 years, with a mean time since menopause of 18.4 years. ALN produced significantly greater increases in BMD at all sites measured, than did RIS (P<0.001 for hip trochanter, total hip, lumbar spine, and P=0.005 for femoral neck). Significant differences were seen at all BMD sites as early as 6 months.

Significantly greater reduction in all markers of bone turnover was seen with ALN compared to RIS at 12 months; treatment differences were significant as early as 3 months.

76.5% of ALN patients and 76.1% of RIS patients reported any clinical AE during the study. There was no significant difference in the percent of patients reporting any upper GI AE (22.5% ALN, 20.1% RIS, p=0.364) or discontinuation due to an upper GI AE (2.5% ALN, 3% RIS, p=0.708).

In this one year head-to-head study, ALN produced significantly greater gains in BMD and greater reductions in markers of bone turnover than RIS, with no differences in overall and upper GI tolerability. The greater antiresorptive efficacy of ALN was seen as early as 3 months.

The Low Creatinine Clearance Associated High Risk of Falls Can Significantly Be Treated With Alfacalcidol. L. C. Dukas*[1], E. Schacht[2], Z. Mazor[3], H. B. Stähelin*[4]. [1]Acute Geriatric University Clinic, Kantonsspital, Basel, Switzerland, [2]Metabolic Bone Disease Unit, Universitätsklinik Balgrist, Zürich, Switzerland, [3]Bone Metabolism Unit, TEVA Pharmaceutical Industries, Jerusalem, Israel, [4]Acute Geriatric University Clinic, Kantonsspital Basel, Basel, Switzerland.

In elderly a treatment with D-hormone analogues can significantly reduce the number of fallers and falls. The synthesis of D-hormone is dependent on renal function. We determined the cutoff level of creatinine clearance (CrCl) at which D-hormone serum levels decline and using the cutoff, we further investigated in a post hoc analysis of a double-blind randomized study, if CrCl is associated with the risk of falls and whether treatment with Alfacalcidol can reduce this risk.

For 36 weeks 378 community-dwelling elderly men and women received randomly 1µg Alfacalcidol (Alpha-D_3® TEVA) or placebo daily. Using radioimmunoassay we measured regularly serum calcitropic hormones and assessed falls by a questionnaire. In multivariate-controlled logistic regression models we assessed, according to treatment groups and according to a CrCl cutoff at 65ml/min, the risk of becoming a faller and the risk of falling. Results are from ITT analyses.

In multivariate-controlled analyses D-hormone serum levels were significantly associated with CrCl ($p<0.0001$) and steadily declined below a CrCl of 65ml/min. A CrCl of <65ml/min was in multivariate controlled analyses associated with significantly lower D-hormone serum levels ($p=0.0008$). In the Placebo group participants with a CrCl of <65ml/min. were found to be, compared to participants with a CrCl of ≥65ml/min, 4 times significantly more prone to become fallers (OR 4.01, 95%CI 1.48-10.98, $p=0.006$). 36 weeks of treatment with Alfacalcidol were, compared to placebo, in participants with a CrCl of <65ml/min associated with a significant 74% reduction in the number of fallers (95% CI 20-92%, $p=0.019$), and a significant 71% reduction in the number of falls (95% CI 12-91%, $p=0.028$). The difference in number of fallers and falls between treatment groups was already significant after a 24 week treatment with Alfacalcidol ($p=0.022$ for number of fallers, $p=0.039$ for number of falls). No clinically relevant hypercalcemia was observed.

A reduced CrCl of <65ml/min is associated with a significant 4 times increased risk of falls. Treatment with Alfacalcidol is safe and is, compared to placebo, in a community-dwelling elderly population with a CrCl of <65ml/min, associated with a significant 74% decrease in number of fallers and a significant 71% decrease in number of falls.

Results of a 5 year Double Blind, Placebo Controlled Trial of Calcium Supplementation (CAIFOS); Vertebral Deformity and Clinical Vertebral Fracture Outcomes. I. M. Dick[1], A. Devine[1], S. S. Dhaliwal*[2], R. L. Prince[1]. [1]School of Medicine and Pharmacology, University of Western Australia, Western Australia, Australia, [2]School of Public Health, Curtin University of Technology, Western Australia, Australia.

Vertebral fracture is a major public health problem in elderly women. We chose to test the hypothesis that calcium supplementation (calcium carbonate 600mg twice per day) offered to unselected individuals would reduce vertebral deformities and clinical spine fracture events compared to identical placebo tablets over 4 years.

1460 women mean age 75 were recruited from the whole population using a recruitment letter strategy. Responders were excluded if they were on bone active treatment, calcium supplementation or had diseases that may have prevented them completing the study. Of the responders 18% were eligible and agreed to participate. Vertebral deformities were assessed using morphometric X-ray absorptiometry (MXA) software version MXA 9.1 on a Hologic 4500A densitometer at years 1 and 5. The cv error varied from 5.8% at T6 to 3.1% at L4. A local reference range for vertebral deformities was developed using the McCloskey Kanis algorithm in 120 elderly women. Incident vertebral deformities were defined as vertebral deformities not present at baseline, with a reduction in posterior, mid or anterior heights of 20%. Clinical vertebral fractures were recorded from diaries reviewed 4 monthly and verified from spinal x-ray reports. The study outcomes were examined using logistic regression for MXA and Hazards Ratios (HR) were calculated using Cox Proportional Hazards Model for clinical vertebral fracture.

The prevalence of vertebral deformities was the same in the calcium compared to the placebo group (calcium 33%; placebo 36%, $p=0.42$). The incident vertebral deformity rate in those subjects who had a second MXA scan (n=883) was similar in the calcium and placebo group (calcium 10.2%; placebo 11.1%, RR 0.90: 0.59-1.39). Inclusion of BMI or prevalent vertebral deformity did not modify these results. In the per protocol subjects (n=706), the incident deformity rate was similar in the calcium compared to the placebo group (calcium 7.8%; placebo 11.1%, RR 0.67: 0.40-1.12).

Clinical spine fracture occurred in 76 subjects overall and in 17 subjects who finished the study per protocol. No difference in vertebral fracture between calcium and placebo groups in the whole study (HR 0.90: 0.57-1.41) or those who finished per protocol (HR 0.82: 0.32-2.14) was observed.

These data show that there were no detectable effects of calcium supplementation on incident vertebral fracture or deformity over the four years of this study.

Bone Loss and Lower Extremity Loading During Long-Duration Space Flight. A. J. Rice*[1], C. C. Maender*[2], K. O. Genc*[1], R. S. Ochia*[3], J. G. Snedeker*[4], P. R. Cavanagh[1]. [1]The Cleveland Clinic Foundation, Cleveland, OH, USA, [2]NASA - Johnson Space Center, Houston, TX, USA, [3]Rush Presbyterian-St. Luke's Medical Center, Chicago, IL, USA, [4]ETH, Zurich, Switzerland.

Bone loss in the lower extremities is an established consequence of long-duration human space flight, whereas bone mass in the upper extremities appears to be maintained. These changes may be the result of selective disuse atrophy of bone in the lower extremities. Reduction in load bearing on the feet may play a key role in these changes, but no quantitative data showing loads on-orbit currently exist. The purpose of the present experiment was to measure loads on the feet over an entire day in the same subject during daily life on the ground and on the International Space Station (ISS). In-shoe forces were monitored with modified Pedar insoles (Novel Gmbh, Munich, Germany) placed inside the shoes of a single astronaut on a 161-day ISS mission. DXA scans were also performed pre- and post-flight. All instrumentation was built into a Lower Extremity Monitoring Suit custom made for the subject, who gave informed consent to participate in the IRB-approved experiment. The force data were analyzed by a custom routine written in MATLAB (Mathworks Inc., Natick, MA). Daily load stimulus (DLS), a mathematical model used to relate changes in bone mineral density to daily loading histories, was calculated from the in-shoe force data. Average monthly BMD losses in the proximal femur, total hip, and lumbar spine regions were 0.64%, 0.72% and 2.31%, respectively. There was a net BMD gain of 0.32% per month in the arms. Peak force histograms from sample days in 0g and 1g (Fig. 1) show a marked shift in the two main modes of loading (walking and running from 260% and 120% BW in 1g to 160% and 90% BW in 0g). The total number of peaks above 5% BW was greatly reduced (10,112 peaks in 1g vs. 2,569 peaks in 0g) and force peaks greater than 200% BW were absent in 0g. The ratio of mean DLS in 0g to that in 1g varied from 0.44 to 0.55. Thus, exercise in space over an entire work day provided only approximately half the stimulus to bone experienced during a typical work day on Earth. These data suggest that in-flight exercise countermeasures for loss in bone mass should be augmented to restore key regions of the 1g daily loading profile in space.

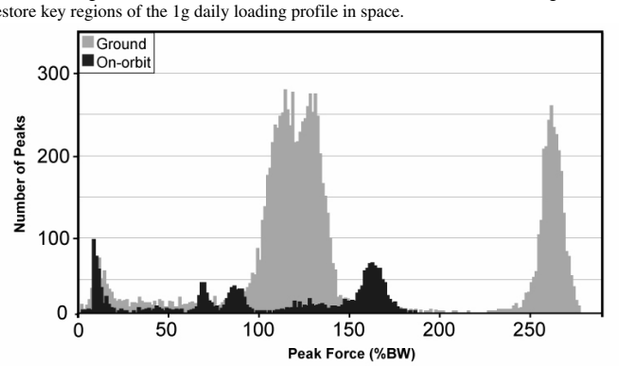

Figure 1: Peak force histograms in percent body weight (%BW) units for typical days on earth (light) and on the ISS (dark).

Comparison of Lasofoxifene and Raloxifene for the Prevention of Bone Loss in Postmenopausal Women. M. McClung[1], M. Omizo*[1], S. Weiss*[2], A. Moffett[3], M. Bolognese*[4], R. Civitelli*[5], V. Somayaji*[6], A. Lee[6]. [1]Oregon Osteoporosis Center, Portland, OR, USA, [2]Center on Drugs and Public Policy, University of Maryland School of Pharmacy, Baltimore, MD, USA, [3]OB-Gyn Associates of Mid-Florida, Leesburg, FL, USA, [4]The Bethesda Health Research Center, Bethesda, MD, USA, [5]Washington University School of Medicine and Barnes-Jewish Hospital, St Louis, MO, USA, [6]Global Research and Development, Pfizer, New London, CT, USA.

Bone loss in early menopause is an important determinant of fracture risk in older women. Estrogen therapy (ET) is effective in preventing bone loss but has recently been shown to have adverse extraskeletal effects. Selective estrogen receptor modulators (SERMs) may be attractive alternatives to ET. In this 2-yr, phase 2 study, the effects on skeletal health of lasofoxifene, a next generation SERM, were compared to placebo and raloxifene.

410 postmenopausal women were randomized: 82 each to receive lasofoxifene 0.25 mg/d and 1.0 mg/d, 163 to raloxifene 60 mg/d, and 83 to placebo. All women also received daily calcium 1000 mg and vitamin D 250 IU. Bone mineral density (BMD) at the lumbar spine (LS) and hip by DXA and biochemical markers of bone turnover (urinary N-telopeptide and deoxypyridinoline crosslinks; serum bone-specific alkaline phosphatase and osteocalcin) were measured at different time points over the treatment period.

At baseline, treatment groups were comparable for age (mean age 58-59 yrs), weight (mean weight 68-69 kg), years post menopause (8-10 yrs) and lumbar spine BMD (mean T-score -1.0). Statistically significant improvement in BMD in lumbar spine and total hip and reduction of biochemical markers of bone turnover occurred after 2 years of lasofoxifene treatment compared to placebo. Overall lasofoxifene was well tolerated, with an adverse event profile similar to raloxifene.

In conclusion, lasofoxifene significantly reduced indices of bone turnover and increased BMD in younger postmenopausal women. The responses were similar to or greater than those observed with raloxifene. These results support the use of lasofoxifene in postmenopausal women at risk for osteoporosis.

Mean Percent Changes from Baseline to Month 24

	Lasofoxifene 0.25 mg/d	Lasofoxifene 1.0 mg/d	Raloxifene 60 mg/d	Placebo

Lasofoxifene, a Next Generation SERM, Is Effective in Preventing Loss of BMD and Reducing LDL-C in Postmenopausal Women. A. H. Moffett, Jr.[1], M. Ettinger[2], M. Bolognese*[3], S. Weiss*[4], V. Somayaji*[5], R. Brunell*[5], A. Lee[5]. [1]OB-GYN Associates of Mid-Florida, P.A., Leesburg, FL, USA, [2]Radiant Research, Stuart, FL, USA, [3]The Bethesda Health Research Center, Bethesda, MD, USA, [4]School of Pharmacy, Uni. of Maryland, Baltimore, MD, USA, [5]Global Research and Development, Pfizer, New London, CT, USA.

This study investigated the efficacy and safety of lasofoxifene, a next generation SERM, on BMD and LDL-C in early postmenopausal non-osteoporotic women.

Healthy postmenopausal women (n=394) with a mean age of 58 yrs (50-74 yrs) and mean duration since menopause of 9 yrs with a mean lumbar spine BMD T-score of -1.0 and mean LDL-C of 135 mg/dL were randomized to lasofoxifene 0.017 mg/d, 0.05 mg/d, 0.15 mg/d, 0.5 mg/d, or control groups for 1 yr; all patients received daily calcium and vitamin D. The primary endpoint was % change in BMD of lumbar spine and hip at 1 yr. Secondary analyses included changes in markers of bone turnover and lipid metabolism. BMD response was analyzed using a least significant change approach with 3% as the criterion for a significant change.

For lumbar spine at 6 months, the proportion of women who gained or did not significantly lose BMD was 92%, 95%, 93%, 97% and 91% for 0.017 mg/d, 0.05 mg/d, 0.15 mg/d, 0.5 mg/d and calcium + Vit D treated control groups, respectively with response on lasofoxifene 0.15 and 0.5 mg/d superior to control (p≤0.008). At 1 yr, response was 97%, 97%, 94%, 98% and 85% for 0.017 mg/d, 0.05 mg/d, 0.15 mg/d, 0.5 mg/d and control groups, respectively with response on all lasofoxifene groups superior to control (p≤0.001). For total hip at 6 months, proportion of subjects who gained or did not significantly lose BMD was 90%, 97%, 95%, 98% and 96% for 0.017 mg/d, 0.05 mg/d, 0.15 mg/d, 0.5 mg/d and control groups, respectively with response on lasofoxifene 0.15 mg/d superior to control (p=0.008). At 1 yr, response was 95%, 92%, 98%, 98% and 90% for 0.017 mg/d, 0.05 mg/d, 0.15 mg/d, 0.5 mg/d and control groups, respectively with response on lasofoxifene 0.05 and 0.15 mg/d superior to control (p<0.05). For LDL-C at 6 months, lasofoxifene therapy resulted in dose dependent decreases of 12.8%, 16.3%*, 20.6%*, 21.1%* and 6.1% for 0.017 mg/d, 0.05 mg/d, 0.15 mg/d, 0.5 mg/d doses and control group, respectively (*p<0.001 vs control). Lasofoxifene was well tolerated and no dose response was seen for AEs. Vasodilatation, leg cramps, and increased vaginal moisture were most frequently reported AEs attributed to lasofoxifene. No clinically meaningful effect on endometrium was observed with lasofoxifene and no breast cancer cases were reported.

Lasofoxifene effectively prevented loss of BMD, with a very high percent of responders, and reduced LDL-C in healthy non-osteoporotic postmenopausal women.

Effects of Raloxifene on the Risk of Nonvertebral Fractures After 8 Years: Results from the Continuing Outcomes Relevant to Evista (CORE) Study. E. S. Siris[1], S. T. Harris[2], R. Eastell[3], J. Zanchetta[4], S. Goemaere[5], A. Diez-Perez[6], J. Song*[6], G. Crans*[6], S. R. Cummings[2]. [1]Columbia University, New York, NY, USA, [2]University of California San Francisco, San Francisco, CA, USA, [3]University of Sheffield, Sheffield, United Kingdom, [4]Universidad del Salvador, Buenos Aires, Argentina, [5]University of Ghent, Ghent, Belgium, [6]Lilly Research Laboratories, Indianapolis, IN, USA.

The multicenter, double-blind, placebo (PL)-controlled CORE study assessed the effects of raloxifene on invasive breast cancer for an additional 4 years from the 4-year MORE trial, with new nonvertebral fractures (NVF) studied as a secondary endpoint. In the 4011 postmenopausal women from MORE, those receiving PL in MORE (n=1286) continued with PL in CORE, whereas those treated with raloxifene (60 or 120 mg/d) in MORE received raloxifene 60 mg/d (RLX, n=2725) in CORE. Analyses were based on the time-to-first-event. The incidence of any new NVF was similar in the PL (22.9%) and RLX (22.8%) groups [hazard ratio (HR)(Bonferroni-adjusted confidence interval (CI)); 1.00 (0.82, 1.21)]. The incidence of NVF6 (clavicle, humerus, wrist, pelvis, hip, leg) was 17.5% in both groups [HR 1.01 (Bonferroni-adjusted CI 0.81, 1.26)]. No significant effect was found at individual fracture sites. Pre-specified subgroup analyses of age and BMD tertiles, prevalent NVF and vertebral fractures (VF), VF severity (SQ grade) at baseline of MORE, and study drug compliance did not reach statistical significance in the CORE population (n=4011). Post hoc Poisson analyses, to account for event rate (number of fractures/ time on therapy), showed neutral NVF and NVF6 effects in the overall populations. However, NVF6 risk was reduced in women with prevalent VF [HR 0.78 (95% CI 0.63, 0.96)], but did not reach statistical significance in those with severe (SQ grade 3) baseline VF [HR 0.66 (95% CI 0.43, 1.02)]. In the combined MORE and CORE cohort (N=7705), NVF6 risks were also decreased in women with SQ grade 3 baseline VF [HR 0.64 (95% CI 0.44, 0.92)], with an unchanged risk in the corresponding low-risk subgroups. Interaction effects were significant (P<0.10) for the subgroup analyses. Limitations in assessing NVF efficacy in CORE were due to selection bias, as women who enrolled in CORE had less severe osteoporosis than those who did not enroll. Also, 20% of those enrolled never took study drug and more women in the PL group (P=0.026) used other bone-active agents, as permitted in this breast cancer prevention study protocol. In conclusion, raloxifene had overall neutral effects on NVF after 8 years, with NVF6 efficacy in some high-risk subgroups shown by exploratory analyses, consistent with results of MORE.

Hetereogeneity in Skeletal Response to Full-length Parathyroid Hormone (PTH). D. E. Sellmeyer[1], L. Palermo[2], M. L. Bouxsein*[3], J. Bilezikian[4], S. Greenspan[5], K. Ensrud[6], D. M. Black[2], C. J. Rosen[7]. [1]Medicine/Endocrine, Univ. CA San Francisco, San Francisco, CA, USA, [2]Epidemiology & Biostatistics, Univ. CA San Francisco, San Francisco, CA, USA, [3]Beth Israel Deaconess Medical Center, Boston, MA, USA, [4]Columbia Univ., New York, NY, USA, [5]Univ. of Pittsburgh, Pittsburgh, PA, USA, [6]Univ. of Minnesota, Minneapolis, MN, USA, [7]Maine Center for Osteo Research & Education, St. Joseph's Hospital, Bangor, ME, USA.

To examine variation in response to PTH (1-84) therapy, we examined the first year changes in BMD and bone markers from two arms of the PTH and Alendronate (PaTH) trial in which 119 women were randomized to PTH 1-84 (100mcg rhPTH/day, NPS) and 60 to alendronate (ALN, 10 mg/day, Merck). We also examined the data for subgroups with larger responses to PTH.

We found much greater variation in response to PTH compared to ALN for both BMD and bone markers. For example, the standard deviation (SD) of 12 month % change in cancellous spine BMD (by QCT) was 32% among those on PTH compared to 15% on ALN (p<0.0001, test for equality of standard deviations). We also found that substantial numbers of women on PTH had large increases in BMD. For example, as shown in the table below, 39% of the women on PTH had an increase of more than 30% in cancellous spine BMD compared to 6% on alendronate. In addition, despite the large mean increase in cancellous BMD (29%) among those on PTH, 17% of the women on PTH had no increase in cancellous BMD, a value similar to the 21% on alendronate. Results were similar, although less extreme, for DXA spine BMD.

For biochemical markers we found similarly high variation in response to PTH. The SD of 3 month change in bone alkaline phosphatase (BAP) was 72% in PTH compared to 15% in ALN (p<0.0001). The SD of 3 month change in serum type I collagen C-telopeptides (CTX) was 170% in PTH compared to 25% in ALN (p<0.0001).

Distribution of participants (ppts) by categories of change in bone density and bone turnover markers during therapy with PTH or alendronate.

	PTH (n=109)	Alendronate (n=57)	p-value (2x3 chi squared)
	% of ppts in category	% of ppts in category	
% change in cancellous spine BMD by QCT (baseline to 12 month)			
<=0	17%	21%	<0.001
0-30	44%	72%	
>30	39%	6%	
Total	100%	100%	
% change in spine BMD by DXA (baseline to 12 month)			
<=0	15%	11%	0.17
0-10	65%	79%	
>10	20%	11%	
Total	100%	100%	
% change in BAP (baseline to 3 month)			
<=0	13%	95%	<0.001
0-100	67%	5%	
>100	20%	0%	
Total	100%	100%	
% change in CTX (baseline to 3 month)			
<=0	25%	95%	<0.001
0-100	38%	5%	
>100	37%	0%	
Total	100%	100%	

None of the baseline factors we examined including age, BMI, BMD or bone markers explained this heterogeneity among PTH users. Analyses restricted to PTH adherers (per protocol analysis) did not substantially change these results.

In conclusion, there is significant individual variability in the skeletal response to PTH which exceeds that observed with alendronate. It is not known whether this heterogeneity is a characteristic feature of PTH therapy or anabolic therapy in general. Further investigation is needed to clarify which patients maximally respond to PTH.

Treatment of Osteoporotic Women with Parathyroid Hormone 1-84 for 18 Months Improves Cancellous Bone Formation and Structure: A Bone Biopsy Study. R. R. Recker[1], S. P. Bare*[1], M. A. Miller[2], M. K. Newman[2], J. Fox[2]. [1]Creighton University, Omaha, NE, USA, [2]NPS Pharmaceuticals, Salt Lake City, UT, USA.

Histomorphometry studies in rhesus monkeys have shown that daily treatment with full-length parathyroid hormone 1-84 (PTH) increases new bone formation and bone volume. However, there is no information on the effects of PTH treatment on bone microarchitecture in humans. We obtained iliac crest biopsies from postmenopausal osteoporotic women given daily injections of placebo or 100 μg PTH for 18 months to assess the effects of treatment on cancellous and cortical bone formation and structure. All subjects received background treatment with Ca (700 mg) and vitamin D (400 IU). At baseline there were no significant differences between groups in age, weight, bone turnover markers, and spine and hip bone mineral density. The histomorphometry results are summarized in the table.

Parameter	Placebo	PTH	P-value*
BV/TV (%)	15.5 ± 1.6	22.8 ± 2.5	0.036
Tb.N (/mm)	1.19 ± 0.09	1.47 ± 0.09	0.046
Tb.Th (μm)	130 ± 10	152 ± 9	0.172
Tb.Sp (μm)	858 ± 59	678 ± 39	0.046
MS/BS (%)	5.9 ± 1.3	12.1 ± 3.4	0.046
MAR (μm/day)	0.48 ± 0.04	0.53 ± 0.02	0.208
BFR/TV (mm3/mm3/yr)	0.027 ± 0.007	0.079 ± 0.031	0.021
OS/BS (%)	11.9 ± 2.5	16.1 ± 3.6	0.294
Ac.F (/yr)	0.39 ± 0.10	0.69 ± 0.18	0.074
ES/BS (%)	1.67 ± 0.48	1.75 ± 0.35	0.674
Ct.Po (%)	4.2 ± 0.8	5.6 ± 0.8	0.294

Values are mean ± SE, n=8/group. *Mann-Whitney U-test

Trabecular bone volume was 48% higher in subjects treated with PTH; this increase was the combined effect of 24 and 17% higher trabecular number and thickness, respectively, and resulted in a 21% lower trabecular separation. Treatment with PTH significantly increased bone formation rate (BFR) primarily by increasing mineralizing surface; mineral appositional rate was not increased significantly. Osteoblast and osteoid surfaces were 58 and 35%, respectively, higher in the PTH-treated group, but the increases were not significant. No index of bone resorption was significantly affected by PTH treatment, although a trend towards increased activation frequency was noted. No significant effects of PTH treatment were observed on periosteal or endocortical BFR, or on cortical thickness or porosity. The new bone produced by PTH treatment had normal lamellar structure and mineralization; there were no abnormal histological findings, including marrow fibrosis or osteomalacia. In conclusion, treatment of osteoporotic women for 18 months with PTH was generally safe and resulted in marked increases in cancellous bone formation and bone volume in the iliac crest without significantly affecting bone resorption.

Pthrp **Haploinsufficiency Impairs Bone Formation but Potentiates the Bone Anabolic Effects of PTH (1-34).** M. A. Sorocéanu*[1], D. S. Miao[1], Y. Jiang[2], J. J. Zhao[2], X. Y. Bai[1], H. Su*[1], H. K. Genant[2], N. Amizuka[3], D. Goltzman[1], A. C. Karaplis[1]. [1]Medicine, McGill University, Montreal, PQ, Canada, [2]Osteoporosis and Arthritis Research Group, University of California, San Francisco, CA, USA, [3]Department of Oral Biological Sciences, Niigata University, Niigata, Japan.

Despite normal serum PTH levels, *Pthrp*$^{+/-}$ mice exhibit decreased *Pthrp* expression in bone and an inappropriate, early (3-month-old) low trabecular bone content with increased marrow adipocity. This inverse relationship suggests that these animals are afflicted by a genetic form of osteoporosis.

To determine the etiology of these skeletal changes, histomorphometric analysis of long bones was undertaken. In *Pthrp*$^{+/-}$ specimens, osteoclast number and surface area were diminished but there was an even more marked decrease in osteoblast number and in mineral apposition rate (MAR) (36%) following calcein/tetracycline labeling. The number of apoptotic osteoblasts and osteocytes was also increased. Moreover, *ex vivo* bone marrow cell cultures from these mice exhibited a profound reduction in their capacity to give rise to ALP positive staining colonies.

Next, we sought to examine how the anabolic action of daily administered PTH 1-34 is influenced in the setting of PTHrP haploinsufficiency. Three-month-old *Pthrp*$^{+/-}$ male mice and wild type (WT) male litter mates were injected with either vehicle or PTH 1-34 (40 μg/kg/d) for three months and μCT and dynamic histomorphometric analysis of the skeleton was undertaken. In WT bones, PTH 1-34 had modest positive effects whereas profound anabolic changes were observed in bone specimens from treated *Pth*$^{+/-}$ mice. BV/TV increased 178% from baseline compared to 19% in WT mice. Similarly, Tb.N (25% vs. -4%), Tb.Th (55% vs. 14%), connectivity (306% vs. 38%) and DA (9% vs. -6%) increased while Tb.Sp (-22% vs. 3%) and SMI (-32% vs. -1%) decreased in specimens from *Pthrp*$^{+/-}$ mice. MAR also increased compared to treated control litter mates (260% vs. 44%). Cortical thickness increased by 25% in bone specimens from treated *Pth*$^{+/-}$ mice compared to 18% in WT mice, while cortical porosity decreased (72% vs. 1%).

These findings demonstrate that: (i) impaired bone formation is the basis of the osteoporotic phenotype in *Pthrp*$^{+/-}$ mice; these animals would therefore serve as useful model for testing new anabolic agents, (ii) that normal levels of PTHrP within the skeletal microenvironment are critical for healthy postnatal bone development and maintenance by promoting recruitment and survival of osteogenic cells, and (iii) the anabolic action of exogenous PTH is potentiated in the *Pthrp*$^{+/-}$ background, alluding to a pivotal interaction of these related proteins on the mechanism that promotes bone formation.

F435

A No Observable Carcinogenic Effect Dose Level Identified in Fischer 344 Rats Following Daily Treatment with PTH(1-84) for 2 Years: Role of the C-Terminal PTH Receptor? C. E. Wilker*[1], J. Jolette*[2], S. Y. Smith[2], N. Doyle*[2], J. F. Hardisty*[3], A. J. Metcalfe*[1], T. B. Marriott[1], J. Fox[1], D. S. Wells*[1]. [1]NPS Pharmaceuticals, Salt Lake City, UT, USA, [2]CTBR, Senneville, PQ, Canada, [3]EPL, Research Triangle Park, NC, USA.

Administration of teriparatide, the N-terminal 1-34 fragment of parathyroid hormone, induces osteosarcoma in Fischer 344 rats. The carcinogenic potential of full-length parathyroid hormone 1-84 (PTH) was assessed by daily sc injection (0, 10, 50, 150 µg/kg/day) for 2 years in the same rat strain. Histopathological analyses were conducted on the standard set of soft tissues, selected bones (femur, tibia, lumbar spine, sternum), and all tissues with macroscopic abnormalities. In addition, whole body radiographs were also taken at term on all surviving rats to better ensure that all bone abnormalities were examined. All PTH doses caused widespread osteosclerosis and increased femoral and vertebral BMD in both sexes. The incidence of bone proliferative changes was comparable in control and low dose groups providing a no-carcinogenic effect dose of 10 µg/kg/day for PTH. In the mid and high dose groups, proliferative changes were dose dependent; osteosarcoma was most common, followed by focal osteoblast hyperplasia, osteoblastoma, osteoma and skeletal fibrosarcoma. Increased mortality, attributed to skeletal tumors, occurred only in high-dose males.

Number of animals with skeletal neoplasia (treated for up to 2 years)

Gender (N=60/sex/group)	Findings	PTH (µg/kg/day)				
		0	0	10	50	150
Males	Osteosarcoma	0	0	1	13	27
	All bone neoplasms	0	0	1	17	30
Females	Osteosarcoma	2	0	0	5	13
	All bone neoplasms	2	0	0	10	21

In contrast to PTH, teriparatide induced osteosarcoma at all doses tested. The rat-to-human exposure ratio (3- to 4-fold) was comparable for the lowest doses of the two peptides. Moreover, the incidence of osteosarcoma was lower with PTH than teriparatide at all doses. We propose that structural differences between PTH and teriparatide provide a mechanism for these observations. Both peptides contain the N-terminal region that activates the PTH-1 receptor, leading to their anabolic effects, e.g., bone cell anti-apoptosis. PTH, however, contains the C-terminal region that activates a different receptor with distinct biological activities, e.g., pro-apoptosis. Balancing the effects of the N- and C-terminal regions may lead to the lesser proliferative response of PTH vs. teriparatide. In conclusion, a safety margin between the pharmacological and carcinogenic effects of PTH was demonstrated in this study.

Parathyroid Hormone Added to Raloxifene and Subsequent Maintenance of BMD Gain with Raloxifene Alone. F. Cosman, J. Nieves, N. Barbuto*, M. Zion*, R. Lindsay. Clinical Research Center, Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, USA.

Many women treated with anti-resorptive medications remain at high risk for fracture as a result of their prior fracture history, very low starting BMD or suboptimal response to anti-resorptive treatment. The influence of prior anti-resorptive agents on PTH treatment effect may differ by medication used, and the ability of antiresorptive agents to maintain BMD after stopping treatment with PTH might also vary. We performed a study of 40 postmenopausal women (mean age 67, range 47-82) already treated with raloxifene (60 mg/day) for at least 1 year (mean 2.7 years) who had recent fractures or persistent osteoporosis by BMD criteria at the spine or hip. Women were randomly assigned to stay on raloxifene alone or to receive (1-34)hPTH 25 mcg/day subcutaneously for 12 months while continuing raloxifene, and were then followed for 1 subsequent year on raloxifene alone. Bone turnover markers [Serum aminoterminal propeptide of Type 1 Procollagen (P1NP), osteocalcin (OC), and urinary N-telopeptide (NTX)] and bone density by DXA were measured at baseline and every 3 months. Data are presented for the first 28 completers of the 12-month treatment study and for 15 women who completed the subsequent 12-month follow-up. Biochemical indices of formation increased rapidly, reaching a peak within 6 months of initiating PTH treatment, whereas NTX continued to drift upward between 6 and 12 months. At 6 months, P1NP levels increased to 567% above baseline and OC to 111% above baseline. At 12 months, urinary NTX increased to 222% above baseline. There were no significant biochemical marker changes in the raloxifene alone group. Mean BMD after 1 year of PTH treatment increased 10.9% at the spine and 3% at the total hip in the PTH plus raloxifene group (both p<0.008), with no significant BMD change in the raloxifene alone group. In the subgroup of patients followed for 1 year after completing PTH, spine BMD declined 2.6% (from a peak of 13.6% above baseline) and total hip BMD declined 1.1% (from a peak of 3.6% above baseline) after one year of follow-up off PTH, while continuing raloxifene (both NS). We conclude that substantial BMD gain occurs with PTH treatment in people on prior and ongoing raloxifene. Although a slight drift downward in BMD after PTH withdrawal was seen, there was no significant BMD loss in patients maintained on raloxifene after PTH withdrawal. PTH-induced BMD benefits remain 1 year after stopping PTH when raloxifene is continued.

Effects of Parathyroid Hormone, Alendronate, or Both on Bone Density in Osteoporotic Postmenopausal Women. R. Neer, A. Hayes*, J. Wyland*, J. Finkelstein. Endocrine Unit, Mass General Hospital, Boston, MA, USA.

We recently reported that alendronate blunts parathyroid hormone (PTH)-induced increases in serum alkaline phosphatase and spine and hip bone mineral density (BMD) in osteoporotic men. We now report final results of a companion study, testing how alendronate affects skeletal responses to PTH in osteoporotic postmenopausal women. We randomly assigned 93 such women with a spine and/or femoral neck BMD T-score ≤ minus 2.0 to 30 months treatment with oral alendronate 10 mg/day (ALN, n=31), sc PTH 37 ug/day (PTH, n=31), or BOTH (n=31). PTH treatment started at month 6. All women had normal serum PTH, 25-OH D, and TSH levels at entry. None had other disorders that (or took medications that) affect bone metabolism or BMD. We maintained calcium intake at 500-1500 mg/day and serum 25-OH vitamin D >15 ng/mL. We measured BMD by DXA in the lumbar spine, proximal femur, radius diaphysis, and total body (without head) every 6 months, vertebral trabecular BMD at month 0 and 30 by QCT, and serum alkaline phosphatase at months 0,1,2,3,6,7,8,9,12,18,24, and 30.

ALN blunted PTH-induced increases in serum alkaline phosphatase and vertebral trabecular BMD, total vertebral BMD, femoral neck BMD, and total hip BMD, reduced PTH-induced decreases in radius shaft BMD (each $p < 0.01$-0.05), and did not alter PTH effects on total body BMD. BOTH increased serum alkaline phosphatase, vertebral trabecular BMD, and total vertebral BMD more than ALN, and decreased radius shaft BMD (each $p < 0.01$-0.05), but increased femoral neck, total hip, and total body BMD no more than ALN. Tabulated below are mean (±SEM) percent changes in BMD at month 30 and serum alkaline phosphatase at month 18, calculated on an intention-to-treat basis:

Rx/ months	QCT Spine	DXA Spine	Femoral Neck	Total Hip	Radius Shaft	Total Body	Alkaline P'tase
PTH/24	57 ± 7	18.5 ± 2.3	10 ± 1.3	6.4 ± 1.0	- 6.9 ± 1.0	4.2 ± 0.7	79 ± 14
BOTH	23 ± 5	14.8 ± 1.4	4.8 ± 1.2	5.3 ± 1.1	- 2.2 ± 0.9	5.4 ± 0.6	4 ± 5
ALN/30	0 ± 1	6.8 ± 0.8	3.8 ± 0.8	3.1 ± 0.8	0.3 ± 0.6	4.7 ± 0.4	- 15 ± 4

Our data suggest that PTH effects on bone formation depend partly on its ability to increase bone resorption, or that ALN directly inhibits bone formation or PTH effects thereon. Studies of other anti-resorptive drug-PTH interactions can discriminate among these possibilities and clarify bone formation-resorption coupling.

Early BMD Response to Teriparatide (rhPTH 1-34) in Patients with and without Prior Antiresorptive Treatment: Interim Results from the EUROFORS Study. J. Farrerons[1], R. Eastell[2], H. Minne[3], M. Audran[4], G. Lyritis[5], E. Simoes*[6], F. Marin*[7], T. Nicholson*[7], P. Ochs*[7], R. Alonso*[7], T. N. Nickelsen[7]. [1]Hospital Santa Creu i Sant Pau, Barcelona, Spain, [2]University of Sheffield, Sheffield, United Kingdom, [3]Klinik Der Fuerstenhof, Bad Pyrmont, Germany, [4]Centre Hospitalier Universitaire, Angers, France, [5]University of Athens, Athens, Greece, [6]Instituto Portugues de Reumatologia, Lisbon, Portugal, [7]Eli Lilly & Company, Indianapolis, IN, USA.

EUROFORS is a prospective randomized trial of 24 months duration, designed to investigate various sequential treatments of teriparatide over two years in postmenopausal women with established osteoporosis. We divided participants into three subgroups: osteoporosis treatment-naïve patients (group 1), and patients with adequate (group 2) or inadequate (group 3) clinical outcome to prior antiresorptive (AR) therapy. For the purpose of this study, inadequate clinical outcome to prior AR therapy was predefined as: (a) sustaining ≥1 new clinical fragility fracture(s) despite prescription of AR therapy during the 12 months prior to fracture; (b) a T-score of at least -3,0 SD or (c) a BMD decrease of ≥3.5% at the lumbar spine (LS), total hip or femoral neck ≥ 2 years after initiating AR therapy. In the first year, all patients (n=863) receive an open-label treatment with teriparatide 20 µg/d and supplements of 500 mg/d of calcium and 400-800 IU/d of vitamin D. Here we report the 6-month interim BMD results for the first 201 patients (mean age, 69.8±7.2 years) who obtained a follow-up BMD measurement.

At baseline, mean lumbar spine and total hip BMD were comparable among the groups. The BMD changes from baseline to month 6 (mean±SD) were as follows:

Group (n)	Lumbar spine (%)	*p-value*	Total hip (%)	*p-value*
1 (31)	+6.9 ± 4.8	<.001	+0.7 ± 3.2	.219
2 (40)	+4.5 ± 4.7	<.001	-0.1 ± 3.1	.826
3 (130)	+4.0 ± 5.5	<.001	-0.9 ± 4.0	.010

While the changes in total hip BMD are in agreement with previous results from the teriparatide after antiresorptive drugs (AAA) study (Ettinger et al., JBMR 2003; 18 Suppl 2:S15), the increases in LS BMD seen in our patients who used prior ARs (mostly bisphosphonates; groups 2 and 3) are more pronounced than those in prior alendronate users from that trial. As the requirements for treatment duration and compliance with prior AR use were less strict in our study than in the AAA trial, this difference in results may be interpreted as a more robust BMD response to teriparatide in AR-pretreated patients when ARs were given in the less controlled, naturalistic conditions of routine care.

Small Molecule GSK3 Inhibitor Stimulates Bone Formation and Restores Bone Mass in Osteopenic, Ovariectomized Rats. Q. Zeng*[1], M. Sato[1], A. Schmidt*[1], J. Hoover*[1], S. Malhotra*[1], T. A. Engler*[1], Q. Zhang*[2], W. S. Jee*[2], C. E. Ruegg*[1], B. R. Berridge*[1], C. A. Frolik*[1], H. U. Bryant[1], Y. L. Ma[1]. [1]Bone and Inflammation, Eli Lilly and Company, Indianapolis, IN, USA, [2]Radiobiology, University of Utah, Salt Lake City, UT, USA.

In the canonical Wnt pathway, glycogen synthase kinase-3β (GSK3β) activity is critical for phosphorylation and degradation of cytosolic β-catenin. Inactivation of GSK3β allows β-catenin to accumulate and migrate to the nucleus where it can interact with DNA-binding protein to activate the expression of target genes. We examined the skeletal effects of 603281-31-8, a GSK3 α and β dual-inhibitor in osteopenic, ovariectomized (Ovx) rats. 603281-31-8, 0.5 or 3 mg/kg/d po or PTH (1-38) 10 ug/kg/d sc were given for 2 months to 7-month old ovx rats which had been permitted to lose bone for 1 month. Most of the bone effects for 603281-31-8 at 0.5 mg/kg/d were not significant, but 603281-31-8 at 3 mg/kg/d completely restored Ovx-induced loss of bone mineral content (BMC) and density (BMD) in the 4th lumbar vertebra and significantly increased mid-femur BMC over both Sham (8%) and Ovx controls (13%). When compared to Ovx controls, trabecular area in the proximal tibial metaphyses was 70% higher, and it was accompanied by a thickening of the trabeculae and improved trabecular connectivity. In the tibial shaft, 603281-31-8 significantly increased cross sectional area (3%), cortical area (12%) and decreased the marrow cavity area (-26%) compared to Ovx controls. The cortical effects were comparable to PTH treatment. Furthermore, bone formation rate tended to increase on trabecular and endocortical surfaces and significantly increased on the periosteal surface (506%). Endocortical eroded surface was decreased (-35%) when compared to Ovx controls. These data show that the orally active, small molecular weight, GSK3 inhibitor 603281-31-8 increases bone mass by stimulating bone formation activity in osteopenic, ovariectomized rats.

Effect of MRL123, an Orally Administered alphaVbeta3 Integrin Antagonist, on Markers of Bone Turnover and Bone Mineral Density in Postmenopausal Osteoporotic Women. M. Murphy*[1], K. Cerchio*[1], S. Stoch[1], K. Gottesdiener*[1], M. Wu*[1], R. Recker[2]. [1]Department of Clinical Pharmacology, Merck Research Laboratories, Rahway, NJ, USA, [2]Osteoporosis Research Center, Creighton University, Omaha, NE, USA.

The $\alpha_v\beta_3$ integrin (vitronectin receptor) has been shown to play a pivotal role in mediating bone resorption. We hypothesized that administration of MRL123, an orally administered $\alpha_v\beta_3$ integrin antagonist, would be a potent inhibitor of bone resorption, thereby increasing bone mass as assessed by bone mineral density (BMD) in women with postmenopausal osteoporosis. We determined the effects of MRL123 administration on BMD and biochemical markers of bone turnover including urinary N-telopeptide crosslinks [NTx] for 12 months. In a multicenter, randomized, double-blind, placebo-controlled, 12-month study, 227 women (mean ± SD 63.4 ± 8.1 years) with low lumbar spine or femoral neck BMD and no history of osteoporosis or fractures were randomly assigned (1:1:1:1 ratio) to one of four treatment groups for 12 months: MRL123 100 mg once daily (q.d.), MRL123 400 mg q.d.; MRL123 200 mg twice daily (b.i.d.); or placebo. All patients received 500 mg calcium plus 250 IU Vitamin D daily. Administration of MRL123 for 12 months significantly increased lumbar spine BMD (2.1, 3.1 and 3.5% for the 100 mg q.d., 400 mg q.d. and 200 mg b.i.d. treatment groups, respectively, vs -0.1% for placebo; $P < 0.01$ for all treatments vs placebo). Administration of MRL123 200 mg b.i.d significantly increased BMD at the hip (1.7% vs 0.3% for placebo; $P < 0.03$) and femoral neck (2.4% vs 0.7% for placebo; $P < 0.05$) as well and maintained an upward trend over the 12 months of the study. Effects on total body BMD, however, were similar among the MRL123 groups and not significantly different from placebo. Administration of MRL123 for 12 months significantly decreased NTx from baseline. The net treatment effects were similar, approximately -42%, for all active treatment groups vs placebo ($P < 0.001$). MRL123 was generally well tolerated and adverse events resulting in discontinuation from the study were relatively infrequent. In conclusion, the antiresorptive effect of the $\alpha_v\beta_3$ integrin antagonist MRL123 translated into significant increases in bone mineral density of the lumbar spine. Furthermore, administration of 200 mg MRL123 twice daily consistently provided efficacy at the hip sites. These data suggest that the $\alpha_v\beta_3$ integrin antagonist MRL123 could be developed as an effective therapeutic agent for osteoporosis.

Should all Older People in Residential Care Receive Vitamin D to Prevent Falls? Results of a Randomised Trial. L. Flicker[1], R. J. MacInnis*[2], M. S. Stein*[3], S. C. Scherer*[4], K. E. Mead*[5], C. A. Nowson*[6], J. Thomas*[1], C. Lowndes*[5], J. L. Hopper*[5], J. D. Wark[5]. [1]University of Western Australia, Perth, Australia, [2]The Cancer Council Victoria, Melbourne, Australia, [3]Royal Melbourne Hospital, Melbourne, Australia, [4]Royal Freemasons' Homes, Melbourne, Australia, [5]University of Melbourne, Melbourne, Australia, [6]Deakin University, Melbourne, Australia.

We found previously that a 25-hydroxyvitamin D (25D) level of less than 25nmol/l was present in 22% of residents in 60 assisted living facilities (ALF) and 45% of residents in 89 nursing homes (NH) located in urban and rural centers across three states of Australia. Serum 25D level was independently associated with time to first fall. The aim of this study was to test whether vitamin D supplementation could reduce the risk of falls and fractures in this setting.

2454 NH and 1797 ALF residents were approached, and 952 NH and 667 ALF residents consented to participate in screening. Subjects with 25D levels less than 25 nmol/l or greater than 90 nmol/l were excluded. Subjects were randomised to ergocalciferol (initially 10, 000 IU per week, then 1000 IU per day) or matching placebo. All subjects received 600 mg of elemental calcium as calcium carbonate. Residents, institutional staff and study staff were blinded to treatment allocation. Institutional staff recorded falls and fractures prospectively in diaries for a 2 year intervention period. Compliance with ergocalciferol was monitored by pill counts and categorised as $< 50\%$ and $\geq 50\%$. Logistic regression, Cox proportional hazard and negative binomial models were used to estimate the effect of vitamin D supplementation on the outcomes of falls and fractures, both before and after excluding non-compliant subjects.

601 subjects entered the intervention phase. The two randomised groups had similar baseline characteristics. The Odds Ratio (OR) [95% CI] for the effect of vitamin D supplementation on the risk of ever falling was 0.85 [0.61-1.17] and was 0.72 [0.42-1.25] on the risk of ever fracturing. The incident rate ratio between groups for falls was 0.78 [0.60-1.00] and the hazard ratio for time to first fall was 0.86 [0.70-1.06]. Restricting the analyses to the 534 subjects whose compliance was $\geq 50\%$ produced an OR of 0.71 [0.50-1.00] for ever falling and of 0.68 [0.42-1.25] for ever fracturing. The incident rate ratio between groups for falls was 0.67 [0.52-0.88] and the hazard ratio for time to first fall was 0.80 [0.64-1.00]. We conclude that vitamin D supplementation reduces the risk of falls and possibly of fractures in older people in residential care, whose vitamin D level is greater than 25 nmol/l. This effect was apparently additional to any effect of calcium supplementation but may depend on calcium.

Pamidronate Therapy in Children with Osteogenesis Imperfecta: Effect on the Bone Material Level. M. Weber*[1], P. Roschger[1], F. Rauch[2], T. Schoeberl*[3], N. Fratzl-Zelman*[1], F. H. Glorieux[2], P. Fratzl*[4], K. Klaushofer[1]. [1]Ludwig Boltzmann Institute of Osteology, 4th Med. Dept., Hanusch Hospital and UKH-Meidling, Vienna, Austria, [2]Genetics Unit, Shriners Hospital for Children, and McGill University, Montreal, PQ, Canada, [3]Erich Schmid Institute of Material Science, Austrian Academy of Sciences and Institute of Metal Physics, University Leoben,, Leoben, Austria, [4]Max Planck Institute of Colloids and Interfaces, Dept. Biomaterials, Potsdam, Germany.

Treatment with cyclical intravenous pamidronate has been reported to increase bone mass and to decrease fracture incidence in children with osteogenesis imperfecta (OI). This beneficial effect may be partly explained by increasing cortical width and trabecular bone volume, but possibly pamidronate treatment also influences material bone properties. This is an important issue, because disturbed material properties conceivably might negate the beneficial effects of increasing bone mass during therapy. We therefore studied paired iliac bone biopsies from patients (age 10-15 y) with OI types III and IV (n=6) before and after pamidronate treatment, in comparison to an age-matched control group (n=6). Quantitative backscattered electron imaging was applied to determine the typical bone calcium content (Ca_{Peak}) and its variation (Ca_{Width}). Nanoindentation was employed to determine hardness and stiffness (E-modulus). One-way ANOVA revealed a significant increase in baseline Ca_{Peak}, hardness and E-modulus for OI patients as compared to controls (+10 % at $P<0.0001$, +18 % at $P<0.05$ and +9 %, $P<0.05$, respectively). However, paired t-test between OI before and after treatment showed no treatment specific change on the bone matrix for any of the parameters measured. This is in contrast to the effect of bisphosphonate treatments in osteoporosis, where the calcium content is known to increase. In conclusion, our data show that stiffness, hardness and calcium content are elevated in OI patients with respect to controls, but that these matrix characteristics are not influenced any further by pamidronate treatment. Thus, the beneficial effect of the antiresorptive treatment on trabecular bone volume and cortical width does not seem to be accompanied by any alterations at material level.

***Col1a2^{oim}* Mice Express Dentinogenesis Imperfecta.** G. E. Lopez Franco[1], A. Huang*[2], N. P. Camacho[2], R. D. Blank[3]. [1]Medicine, University of Wisconsin-Madison, Madison, WI, USA, [2]Research Division, Hospital for Special Surgery, New York, NY, USA, [3]Geriatrics Research, Education, and Clinical Center, William S. Middleton Veterans' Hospital, Madison, WI, USA.

Dentinogenesis imperfecta (DI) is an inconstant feature of osteogenesis imperfecta (OI), an inherited disorder resulting from mutations of the genes encoding type I collagen, the major structural protein in bone and dentin. Whether the apparent absence of dental abnormalities in some OI cases reflects biology or insensitivity of the diagnostic methods applied to teeth remains an open question. We therefore studied the dental phenotype of mice harboring the *Col1a2^{oim}* mutation (*oim*), a well-studied mouse model of α2(I) chain deficiency. There is no gross dental phenotype in *oim*/+ mice, while *oim*/*oim* teeth are fragile. To further define the phenotype, we examined teeth by light and scanning electron microscopy (SEM). Both *oim*/*oim* and *oim*/+ mice demonstrate reduced pulp chamber size, with nearly complete obliteration in *oim*/*oim* and reduction to about ½ normal size in *oim*/+. SEM of teeth fractured at the level of the junctional epithelium reveals several notable features. First, there is a clear difference of surface roughness among the +/+, *oim*/+ and *oim*/*oim* teeth. Second, there is a reduction in the number and regularity of spacing of the dentin tubules in *oim*/+ and *oim*/*oim* teeth. Third, the images suggest an impairment of matrix mineralization and ultrastructural ordering of the tissue in *oim*/+ and *oim*/*oim* teeth. These abnormalities are more severe in *oim*/*oim* than *oim*/+ animals, indicating dose-dependence of the mutant phenotype. In *oim*/+ heterozygotes, abnormalities are more pronounced in incisors than in molars. These findings demonstrate that both *oim*/*oim* and *oim*/+ mice suffer from DI. DI features are, as expected, more severe in the *oim*/*oim* than *oim*/+ animals. The more severe *oim*/+ incisor phenotype may be a reflection of incisors' continuous growth throughout the life of the animal. The presence of microscopic abnormalities in clinically normal *oim*/+ teeth suggests that reliance on insensitive diagnostic criteria may have resulted in underestimation of the prevalence of human DI in OI patients.

A Randomized, Controlled Study of Oral Alendronate vs. IV Pamidronate Therapy for Children with Osteogenesis Imperfecta. L. A. DiMeglio[1], L. Ford*[2], C. McClintock*[2], R. McClintock*[2], M. Peacock[2]. [1]Pediatrics, Indiana University, Indianapolis, IN, USA, [2]Endocrinology, Indiana University, Indianapolis, IN, USA.

Bone mineral density (BMD) increases in children with osteogenesis imperfecta (OI) treated with intravenous (iv) bisphosphonate. The efficacy and safety of oral alendronate have not been established. We have conducted an open-label, prospective, 2 year, randomized clinical trial of oral alendronate compared to iv pamidronate in 15 children with OI. Children were stratified according to bone age, pubertal stage, and type of OI and randomized to receive iv pamidronate, 3 mg/kg over 3 days every 4 months or oral alendronate 1 mg/kg daily. Primary efficacy outcome was change in BMD. Secondary outcomes included change in growth rate, biomarkers of bone turnover, and fracture incidence.

14 children were randomized, 7 to oral and 7 to iv. One was assigned to iv treatment because of chronic abdominal pain. In the iv group, 3 patients had type III/IV OI, while 5 had type I. In the oral group, 3 had type III/IV, while 4 had type I. The mean age of the oral group was 9.1 years (range 3.8-12.7); the iv group was also 9.1 years (range 3.5-13.7).

On treatment, both groups had a sustained and significant increase in total body and L2-L4 BMD (see table), above that expected from normal accrual for age. Although the response at L2-4 was greater at all times measured with oral treatment the differences in BMD between oral and intravenous treatment were not significant.

Growth showed moderate improvement with treatment, with length/height SDS for age going from -3.1 to -2.8 ($p<0.01$). All children had a decrease in biochemical markers of bone turnover, with significant changes over time ($p<0.05$ by RM ANOVA) in the serum bone formation markers, total alkaline phosphatase and osteocalcin and in the urine bone resorption markers, NTX/Cr, and DPD/Cr. Urine Ca/Cr decreased significantly but serum Calcium, TRAP, and PTH did not change significantly. There was a trend toward decreased fracture incidence in the two groups combined (from a mean of 2.0 ± 1.5 to 1.3 ± 1.5 fractures/year, $p=0.05$). Other than transient fevers following the first dose of iv pamidronate, no adverse effects of treatment were noted. These data suggest that oral and iv bisphosphonate therapy are equally safe and effective for children with OI. Supported by NIH K23 RR15538-01

BMD Responses	Oral	Sig	iv	Sig
24 month change in total body BMD (g/cm^2)	0.132 +/- 0.080	0.005	0.126 +/- 0.075	0.002
24 month change in total body BMD z-score	+0.9 +/- 0.7	0.019	0.9 +/- 0.9	0.031
24 month change in L2-L4 BMD (g/cm^2)	0.312+/- 0.163	0.002	0.284 +/- 0.127	<0.001
24 month change in L2-L4 z-score	+2.1+/- 1.1	0.002	+2.0 +/- 1.3	0.003

LRP5 and High Bone Mass Disease. S. Mumm[1], X. Zhang*[1], M. Rickels*[2], A. Burshell[3], W. R. Reinus*[4], F. E. McKiernan[5], M. P. Whyte[6]. [1]Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA, [2]Division of Endocrinology, Diabetes, and Metabolism, University of Pennsylvania School of Medicine, Philadelphia, PA, USA, [3]Bone Mineral Density Facility, Ochsner Clinic Foundation, New Orleans, LA, USA, [4]Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, MO, USA, [5]Center for Bone Diseases, Marshfield Clinic, Marshfield, WI, USA, [6]Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children, St. Louis, MO, USA.

Gain-of-function mutation (*Gly171Val*) of the gene encoding LDL receptor-related protein 5 (LRP5) was first discovered in 2002 in two American kindreds (AJHG 70:11, 2002; NEJM 346:1513, 2002). Both had uncomplicated high bone density and one also featured asymptomatic torus palatinus and a wide jaw. In 2003, however, 6 novel *LRP5* missense mutations affecting the same LRP5 protein domain were reported in individuals from the Americas and Europe, some with clinically significant dense bone disease (AJHG 72:763, 2003).

We have studied, clinically and molecularly, 3 patients with a high bone mass phenotype consistent with LRP5 activation. PCR amplification and sequencing of *LRP5* exons 2-4 and adjacent splice sites revealed heterozygosity for 3 *LRP5* missense mutations, *Arg154Met*, *Gly171Val*, and *Ala214Thr* (molecular study of a fourth patient is underway). These LRP5 changes affect the same first "-propeller" module as the 7 previously reported gain-of-function missense mutations. Notably, one patient with high bone mass and the same mutation (*Gly171Val*) as the original 2 families with benign high bone mass has significant skeletal disease including cranial nerve palsies, Chiari malfunction, and extensive maxillary and mandibular exostoses surrounding her teeth. She also has diffuse bone pain. Another patient has a previously reported LRP5 mutation (*Ala214Thr*) and lost vision in childhood and later had craniectomy for a small skull. The third patient has a novel mutation (*Arg154Met*) and has undergone surgical removal of mandibular exostoses for recurrent infections.

Because our patients' LRP5 mutations alter the region responsible for the receptor's antagonism by dickkopf (Dkk), their clinical features and high bone mass likely reflect increased Wnt signaling through LRP5. As yet uncertain nutritional, environmental, or more likely genetic factors condition *Gly171Val* effects so that LRP5 gain-of-function and increased Wnt signaling in bone may not always be benign.

PTHrP Appears Selectively Less Effective than PTH in Stimulating 1,25(OH)$_2$D Production in Humans. M. J. Horwitz[1], M. Tedesco*[1], S. Sereika*[1], A. Bisello[1], A. Garcia-Ocana*[1], P. Dann*[2], J. J. Wysolmerski[2], G. Marshall*[1], B. Hollis[3], A. F. Stewart[1]. [1]U of Pittsburgh, Pittsburgh, PA, USA, [2]Yale U, New Haven, CT, USA, [3]U. South Carolina, Charleston, SC, USA.

Humans with humoral hypercalcemia of malignancy display reductions in plasma 1,25(OH)$_2$D, whereas those with primary hyperparathyroidism show increases. Long-term (46 hour) continuous steady-state infusions of both hPTH(1-34) and hPTHrP(1-36) using a single dose (8 pmol/kg/hr) in humans suggest that PTHrP may be slightly less calcemic than PTH, and may have an attenuated effect on circulating 1,25(OH)$_2$D. To confirm and quantitate the magnitude of the differences between the two peptides, we employed continuous, 46 hour steady-state infusions of hPTH(1-34) or hPTHrP(1-36) in multiple doses ranging from 8 to 28 pmol/kg/hr to 50 healthy normals. The composition and potency of the peptides was confirmed by mass spectroscopy, amino acid analysis, and adenylyl cyclase assay in SaOS-2 cells.

Serum total and ionized calcium increased significantly for both peptides at all doses ($p < 0.0001$). The PTHrP group displayed slightly milder hypercalcemia (mean = 10.7 mg/dl), than those receiving PTH (11.5 mg/dl) ($p = 0.0016$), but, surprisingly, the degree of hypercalcemia did not depend on PTH or PTHrP dose ($p = 0.96$). The percentage of individuals reaching the safety limit (serum calcium ≥ 12.0 mg/dl) was greater, and occurred at a lower dose, in those receiving PTH vs. PTHrP (12 vs. 28 pmol/kg/hr). Both peptides had predicable effects on serum phosphorus ($SP0_4$), TmP/GFR, fractional excretion of calcium (FECa) and suppression of endogenous PTH(1-84), and no differences between the two peptide groups were observed.

In striking contrast, subjects receiving PTH displayed markedly higher plasma 1,25(OH)$_2$D responses at every dose studied. For example, at the PTH 12 pmol/kg/hr dose, plasma

$1,25(OH)_2D$ rose from 33 pg/ml to 100 pg/ml. For the same PTHrP dose, the mean plasma 1,25 rose to only 48 pg/ml. For even the highest PTHrP dose, 28 pmol/kg/hr, $1,25(OH)_2D$ rose to only 85 pg/ml.

Thus, PTH may be marginally more calcemic than PTHrP in humans, but the two peptides have comparable effects on $SP0_4$, TmP, FECa and suppression of endogenous PTH(1-84). In contrast, PTH produces markedly greater increments than PTHrP in $1,25(OH)_2D$ in humans. The differential calcemic effect could reflect: 1) relative instability of PTHrP as compared to PTH in the human circulation; 2) the higher $1,25(OH)_2D$ levels that result from PTH infusion, and/or 3) differences in intrinsic ability to stimulate bone resorption. The differences in $1,25(OH)_2D$ may reflect differential effects on renal tubular signal transduction pathways associated with 1-alpha hydroxylase activation in humans.

Tissue-nonspecific Alkaline Phosphatase: A Novel Therapeutic Target for Arterial Calcification. D. Harmey, J. L. Millan. The Burnham Institute, La Jolla, CA, USA.

Abnormalities in the production or degradation of inorganic pyrophosphate (PP_i), a potent inhibitor of mineralization, leads to defects in mineral deposition. Tissue-nonspecific alkaline phosphatase (TNAP) hydrolyzes PP_i, and deletion of the TNAP gene (*Akp2*) in mice results in hypophosphatasia, characterized by elevated levels of PP_i and poorly mineralized bones. In contrast, genetic ablation of the molecules that produce and transport PP_i, *i.e.* nucleosidetriphosphate pyrophosphohydrolase (NPP1) and ANK, causes soft tissue ossification and hyperostosis. Abnormalities in NPP1- (*Enpp1*$^{-/-}$) and ANK- (*ank/ank*) deficient mice are ameliorated by deletion of *Akp2*, thus mice lacking both TNAP and either NPP1 or ANK displayed normalized skeletal mineralization in comparison to mice lacking either gene alone. In addition to bone abnormalities, *Enpp1*$^{-/-}$ mice develop arterial calcification and are a model of the human disease, idiopathic infantile arterial calcification (IIAC), characterized by hydroxyapatite deposition and smooth muscle proliferation in the internal elastic lamina. We hypothesized that arterial calcification would also be observed in ANK-deficient mice, and moreover, that the arterial calcification in *Enpp1*$^{-/-}$ and *ank/ank* mice would be normalized by the genetic or pharmacological ablation of TNAP function.

To establish if *ank/ank* mice display arterial calcification, hydroxyapatite deposition was examined using von Kossa and Alizarin Red staining. These analyses confirmed that *ank/ank* arteries have phosphate and calcium deposits. Also, H&E and van Giesson's staining of the arterial wall and elastic fibers revealed abnormalities in arterial wall morphology in comparison to wild-type (WT) mice, including thickening of the wall and disrupted elastic fiber organization. In order to assess the mineralizing capacity of aorta-derived cells from the mutant mice, *in vitro* studies were performed using primary vascular smooth muscle cells (VSMCs) which form mineralized nodules when cultured in the presence of β-glycerophosphate. We found that the number of mineralized nodules formed in cultures of *Enpp1*$^{-/-}$ and *ank/ank* VSMCs was increased compared to WT controls. Importantly, TNAP activity in mutant cells was significantly higher than in WT cells. Interestingly, treatment of these VSMC cultures with tetramisole, a specific uncompetitive inhibitor of TNAP, normalized TNAP activity in the mutant cells.

Our data support the hypothesis that TNAP is a potential therapeutic target for treatment of arterial calcification, and suggest that increased TNAP activity may contribute to the ossification abnormalities in both the skeleton and aortas of *Enpp1*$^{-/-}$ and *ank/ank* mice.

Early Lethality in FGF23(R176Q) Transgenic Mice with Targeted Deletion of the *Pth* Gene. X. Bai, D. S. Miao, H. Fu*, J. R. Li*, Q. W. Xia*, D. Goltzman, A. C. Karaplis. Medicine, McGill University, Montreal, PQ, Canada.

Mutations in *FGF23* cause ADHR. Transgenic mice that express human FGF-23 (R176Q) (m*FGF23*^{Tr}) recapitulate the biochemical and skeletal alterations associated with ADHR. Unexpectedly, the transgenic mice also exhibit low-normal serum calcium levels with increased urinary calcium excretion and circulating PTH levels, consistent with secondary hyperparathyroidism. While its cause is not entirely clear, high PTH may contribute to the observed renal phosphate wasting and associated hypophosphatemia.

To examine the role of PTH in the pathophysiology of the observed phenotype, mice homozygous for the *Pth*-null allele carrying the FGF-23 (R176Q) transgene were generated. The *Pth*$^{-/-}$/m*FGF23*^{Tr} genotype was observed at the expected frequency but these mice were much smaller and very few of them were alive longer than 10 weeks after birth when maintained on regular rodent chow (0.61% Pi, 1.0% calcium and 4.5 IU/kg vitamin D_3). Analysis of serum biochemistry was performed in the four genotypes (wild-type (WT), *Pth*$^{-/-}$, m*FGF23*^{Tr}, *Pth*$^{-/-}$/m*FGF23*^{Tr}) at 50 days after birth. In the *Pth*$^{-/-}$/m*FGF23*^{Tr} mice, serum Pi levels were comparable to those in the WT mice, while in m*FGF23*^{Tr} mice the serum concentration was significantly decreased. Serum calcium levels were reduced in the *Pth*$^{-/-}$/m*FGF23*^{Tr} mice, more profoundly so than those in *Pth*$^{-/-}$ animals, while in m*FGF23*^{Tr} mice they were slightly decreased. Circulating levels of $1,25(OH)_2D_3$ were progressively lower in the *Pth*$^{-/-}$ and m*FGF23*^{Tr} mice and undetectable in the *Pth*$^{-/-}$/m*FGF23*^{Tr} mutants, reflecting the combined effect of increased FGF23 and lack of PTH activity on renal 1-alpha (Cyp27b1) and 24-hydroxylase (Cyp24) activity. Serum PTH levels in m*FGF23*^{Tr} mice were elevated compared to WT, but were undetectable in the *Pth*$^{-/-}$ groups. Interestingly, the renal threshold for phosphate, and urine calcium concentration were increased in *Pth*$^{-/-}$/m*FGF23*^{Tr} mutants but were significantly suppressed in the m*FGF23*^{Tr} mice. Introduction of rescue diet (0.5% Pi, 2.0% calcium, lactose 20%) improved survival as well as the biochemical and skeletal abnormalities associated with transgene overexpression.

The present findings indicate that the likely cause of death in the *Pth*$^{-/-}$/m*FGF23*^{Tr} mice is hypocalcemia. A potential role for FGF-23 in promoting secondary hyperparathyroidism by suppressing renal Cyp27b1 activity while activating Cyp24 is proposed. Hence, the combined effect of very low $1,25(OH)_2D_3$ levels and absence of circulating PTH leads to hypocalcemia and early lethality. Hyperparathyroidism, therefore, is an integral component of the pathophysiology of ADHR that also contributes to the renal phosphate transport defect in this disorder.

Disclosures: ***X. Bai****, None.*

Matrix Extracellular Phosphoglycoprotein (MEPE) Fragments Circulate in Excess in Patients with Tumor-Induced Osteomalacia (TIO) and X Linked Hypophosphatemic Rickets (XLH). S. M. Jan de Beur[1], A. Jain*[2], M. Khan*[1], N. S. Fedarko[2]. [1]Endocrinology, Johns Hopkins Medical Institute, Baltimore, MD, USA, [2]Geriatrics, Johns Hopkins Medical Institute, Baltimore, MD, USA.

MEPE, an extracellular matrix protein first discovered in and highly expressed in mesenchymal tumors associated with tumor-induced osteomalacia (TIO), is a regulator of bone mineralization and formation. MEPE was initially considered a candidate for phosphatonin, the circulating inhibitor of renal phosphate reabsorption elaborated in TIO, but evidence of its phosphaturic effect has been inconsistent. Recent studies suggests that proteolytic fragments of MEPE have disparate actions on bone mineralization and formation. MEPE (507-525) inhibits mineralization in a mouse osteoblastic cell line; whereas, MEPE (242-264) stimulates new bone formation in neonatal mouse calvariae. MEPE excess has been implicated in the pathophysiology of XLH as *mepe* expression is markedly upregulated in osteoblast from *hyp* mice. Furthermore, MEPE may serve as a substrate for PHEX, the metalloprotease that is defective in XLH. Since MEPE has been implicated in the aberrant renal phosphate handling and bone mineralization in TIO and XLH, we hypothesized that MEPE and/or MEPE fragments would be elevated in the serum of patients with XLH and TIO. We developed competitive ELISAs that measure intact MEPE (~60 kD) and a C terminal fragment of MEPE (~ 30 kD) and measured fasting serum samples from patients with XLH (N =13), TIO (N=13) and age-matched controls (N=11 for C terminal and N=28 for intact). Serum C terminal MEPE was elevated in TIO (579.0+/-280.0 ng/ml) and XLH (768.5+/-641.0 ng/ml) and was significantly different than age-matched controls (212.2 +/- 80.0 ng/ml). In contrast, intact MEPE was not significantly different in TIO (561.0+/-135.0 ng/ml) or XLH (589.0+/-116.5 ng/ml) than in age-matched controls (674.7 +/-284.5 ng/ml). In two TIO patients with pre and post surgical serum samples available, serum C terminal MEPE levels dropped but intact MEPE levels remained unchanged. In TIO and XLH, the correlation between intact MEPE and MEPE fragment ($r=0.2$, $p<0.5$) was much weaker than in age-matched controls ($r=0.45$, $p<.005$). These data suggest that although intact MEPE is not elevated, MEPE fragments circulate in excess and may mediate the profound mineralization defects observed in TIO and XLH. Defining the precise bioactive MEPE peptides that circulate in XLH and TIO will elucidate the role of MEPE in the pathogenesis of the renal phosphate wasting and bone demineralization observed in these disorders and yield important information about the normal physiological function of MEPE in mineral ion homeostasis, bone formation and mineralization.

Zoledronic Acid Produces Greater Clinically Relevant Reductions in Biochemical Markers in Patients with Paget's Disease Versus Risedronate. D. J. Hosking[1], P. Miller*[2], J. Brown[3], W. Fraser[4], K. Lyles[5], I. Reid[6], P. Mesenbrink*[7]. [1]General Medicine and Metabolic Bone Disease, Nottingham City Hospital, Nottingham, United Kingdom, [2]Colorado Center for Bone Research, Lakewood, CO, USA, [3]Le Centre Hospitalier Universitaire de Quebec, Quebec, PQ, Canada, [4]Liverpool University Hospital, Liverpool, United Kingdom, [5]Duke University Medical Center, Durham, NC, USA, [6]University of Auckland, Auckland, New Zealand, [7]Novartis Pharmaceuticals Corporation, East Hanover, NJ, USA.

Bisphosphonates have revolutionised the treatment of Paget's disease. However, the need remains for therapies that achieve clinically meaningful reductions in serum alkaline phosphatase (SAP) and other biochemical markers to increase the likelihood of long-term remission. Zoledronic acid (ZA), a nitrogen-containing bisphosphonate, offers a single intravenous infusion with the possibility of achieving prolonged remissions. This randomised controlled trial assessed the efficacy and safety of a single 15-minute infusion of ZA 5 mg (n=88) in patients with confirmed Paget's disease over 6 months compared with oral risedronate (RIS) 30 mg/day for 60 days (n=90). The primary efficacy end point was defined as a ≥75% reduction in SAP excess or its normalisation at 6 months. Secondary efficacy end points included changes in serum CTx, urine α-CTx, and serum P1NP. These have previously been reported. More stringent and clinically relevant responses (percentage of patients who achieve a turnover below the midpoint of the normal range and above the lower limit of the normal range for each marker) have also been evaluated and are reported here. For each biochemical marker, ZA demonstrated a consistent, statistically greater response at 6 months relative to RIS (all $P<.001$). At 6 months, the percentage of ZA patients below the midpoint of normal ranged from 54.6% for SAP and urine α-CTx to 67.0% for P1NP. In comparison, RIS patients ranged from 23.6% for SAP to 32.6% for urine α-CTx . These differences were equal to or greater than those observed for the original definition of response. Within 3 days of drug administration, influenza-like symptoms occurred in 14% of ZA and 6% of RIS patients. Other symptoms, mostly transient, such as fever, myalgia, arthralgia, and bone pain occurred less commonly. Adverse events, including gastrointestinal and renal, were similar between groups. We conclude that, compared with RIS, ZA achieves more profound reduction in biochemical markers that are reflective of a true clinically relevant response.

Wildtype SQSTM1 Protein Co-Localizes and Aggregates In Vivo with SQSTM1 Proteins Carrying Mutations in the UBA Domain. T. L. Johnson-Pais[1], Y. M. Ench*[2], J. H. Wisdom*[2], F. R. Singer[3], R. J. Leach[2]. [1]Pediatrics, Univ. of TX Health Science Center-San Antonio, San Antonio, TX, USA, [2]Cellular and Structural Biology, Univ. of TX Health Science Center-San Antonio, San Antonio, TX, USA, [3]John Wayne Cancer Institute, Santa Monica, CA, USA.

Six unique sequestosome 1 (SQSTM1) mutations clustered within the ubiquitin-associated (UBA) domain have been reported to predispose an individual to Paget's disease of bone (PDB). The P387L and P392L mutant proteins contain single amino acid substitutions within the UBA domain, while the other 4 mutant proteins are prematurely truncated near the start of the UBA domain. Since some of these mutant proteins bind ubiquitin and some do not, alterations in ubiquitin-binding may not be the cause of the abnormal osteoclast activity found in PDB. To understand the mechanism by which these different mutant proteins predispose an individual to PDB, we wanted to determine if mutant SQSTM1 proteins, differing in the UBA domain, can interact with wildtype SQSTM1 protein *in vivo.*

Wildtype and mutant SQSTM1 cDNAs were synthesized by RT-PCR using mRNA isolated from lymphocytes of control and PDB patients. The cDNAs were cloned into expression vectors to create N-terminus fluorescently-labeled proteins corresponding to wildtype SQSTM1, and the P392L, P387L and D391fsX394 mutant proteins. These constructs were transiently transfected into HEK293, HepG2 and RAW264.7 cells and analyzed by confocal microscopy.

In all three cell lines, wildtype SQSTM1 was localized in a punctate cytoplasmic pattern. The P392L and P387L proteins both formed much larger aggregates within the cytoplasm, while the truncated protein was localized in a very diffuse cytoplasmic pattern, as compared to the wildtype protein. Interestingly, co-transfection of wildtype and either P392L or P387L proteins resulted in co-localization of the wildtype and mutant protein in a large aggregate, very similar to the aggregate formed by either P387L or P392L alone. Co-transfection of the D391fsX394 truncated protein with the wildtype protein resulted in co-localization of the mutant and wildtype proteins in a punctate cytoplasmic pattern that was identical to the pattern of the wild-type protein alone.

The SQSTM1 protein contains an N-terminal dimerization domain that mediates the formation of homotypic arrays. Since the wildtype protein co-localizes in the cytoplasm with each of the mutant proteins, we assume the proteins are interacting through the N-terminal domain. Our results suggest that in PDB the function of wild-type SQSTM1 may be disrupted in a dominant-negative mechanism by interaction with the mutant protein, irregardless of the ubiquitin-binding capability of the mutant protein.

Interaction of LIMD1 with p62/Sequestosome1 Is Required for Maximal Osteoclastogenesis in vivo. H. Zhao[1], Y. Feng*[2], S. L. Teitelbaum[1], F. P. Ross[1], G. Longmore*[2]. [1]Department of Pathology and Immunology, Washington University School of Medicine, St. Louis, MO, USA, [2]Departments of Medicine and Cell Biology, Washington University School of Medicine, St. Louis, MO, USA.

Paget's disease of bone (PDB) is a common bone disorder of aging characterized by foci of increased osteoclastic bone resorption followed by increased and chaotic new bone formation. Several potential susceptibility loci for familial PDB have been identified by genome-wide screen, including one on chromosome 5q35, coding for p62/sequestosome1. Importantly, genetic inactivation of p62 in mice leads to impaired osteoclastogenesis. We have performed studies to establish how p62 regulates osteoclast differentiation and function. In a yeast two-hybrid screen we find that p62 specifically interacts with LIMD1, a novel LIM domain-containing protein. By co-expression of Myc-tagged LIMD1 and a series of FLAG tagged p62 deletion mutants in 293 cells we establish that 50 amino acids between the RIP and TRAF6 binding domains of p62 are required for LIMD1 binding. To characterize further the role of LIMD1 in vivo, we generated knockout (KO) mice by homologous recombination. The KO mice are viable and appear healthy. Histological analysis of sections from tibia demonstrated similar bone volume and the number of osteoclasts as compared to wildtype (WT). Initially, we examined the role of LIMD1 in osteoclast differentiation by culturing bone marrow macrophages from WT and KO mice with MCSF and RANKL for 5 days. Osteoclast differentiation is dramatically decreased in LIMD1-deficient cells, a phenotype rescued completely by retroviral transduction of full-length of LIMD1 into KO macrophages. Consistent with the essential role of NFκB and AP-1 in osteoclasttogenesis, the activation of these two transcription factors in KO pre-osteoclasts is aberrant compared with that in WT cells. Finally, when LIMD1 null mice are injected subcutaneously with 100μg of recombinant RANKL for 7 days, the number of $TRAP^+$ osteoclasts in the calvaria of KO mice is reduced significantly compared to WT controls. These data indicate that, like the NIK and p62 knockouts, basal osteoclast differentiation is not affected by the loss of LIMD1, whereas the molecule is required for maximal stimulated osteoclastogenesis. Thus, LIMD1 is a new mediator of p62 signaling in response to RANKL/RANK activation.

Mild Primary Hyperparathyroidism Is Associated with Low BMD but not Fracture Risk, Quality of Life or Mortality in Community Dwelling Elderly Women. E. McCloskey[1], D. deTakats*[1], M. Beneton*[1], J. Cliffe*[1], L. Reaney*[1], C. McGurk*[1], D. Charlesworth*[1], T. Jalava*[2], J. Kanis[1]. [1]University of Sheffield, Sheffield, United Kingdom, [2]Schering Oy, Helsinki, Finland.

Conservative management of mild primary hyperparathyroidism is recommended in patients without a history of complications. We wished to examine the impact of mild hyperparathyroidism (serum calcium <0.4mmol above the upper reference range) on fracture risk, mortality and quality of life in elderly community-dweeeling women.

Albumin-adjusted serum calcium and serum phosphate were measured in 5212 women aged at least 75 years at entry to the MRC Hip Fracture Study. Serum PTH was measured if adjusted serum calcium was greater than 2.60mmol/l to confirm the diagnosis as women with non-parathyroid hypercalcaemia were excluded from the study. Other assessments included measurements of total hip BMD (Hologic QDR4500), quality of life (Euroqol), incident fractures and mortality.

The mean age in the population was 79.5±3.8 years at entry to the study. A total of 126 (2.4%) women fulfilled the above criteria for primary hyperparathyroidism (cases). There were no significant differences in mean age, height or weight compared to the rest of the population (controls). Quality of life as measured by Euroqol was similar in cases and controls (P=0.75). Serum phosphate and serum creatinine were significantly lower (mean difference -0.12±0.01mmol/l) or higher (+3.7±1.7μmol/l) respectively in the cases. Bone mineral densities at the total hip (0.70±0.14 vs. 0.76±0.14g/cm2, P<0.001) and all hip subregions (P<0.003) were significantly lower in mild primary hyperparathyroidism. There was no significant interaction between the presence of mild primary hyperparathyroidism and the ability of clodronate to prevent fractures (20% reduction). Over a median follow-up of 4 years, the incidence of all clinical fractures was similar in the cases compared to controls (17.5 vs. 14.3%, OR 1.27, 95%CI 0.80-2.02, P=0.31) though the trend was stronger for peripheral fractures (OR 1.53, 0.83-2.80). The incidence of hip fracture was similar in both groups (3.2 vs. 3.6% in controls, OR 0.88, 0.32-2.42, P=0.81). The mortality rate in the cases was slightly but not significantly lower than in the controls (12.7 vs. 14.5%, OR 0.86, 0.50-1.45, P=0.7).

Mild primary hyperparathyroidism appears to have no major consequences for elderly women living in the community. Conservative management appears to be an appropriate management strategy.

Parafibromin, Product of the Hyperparathyroidism-Jaw Tumor Gene *HRPT2,* Is a Nucleocytoplasmic Protein that Regulates Cyclin D1 Expression. G. E. Woodard*, L. Lin*, S. K. Agarwal*, S. J. Marx, W. F. Simonds. Metabolic Diseases Branch, National Institutes of Health, Bethesda, MD, USA.

Parafibromin is the 531-amino acid protein product encoded by the recently identified *HRPT2* gene, a putative tumor suppressor gene implicated in the hyperparathyroidism-jaw tumor syndrome (HPT-JT) and sporadic parathyroid cancer. HPT-JT is an autosomal dominant familial cancer syndrome with high but incomplete penetrance. The major features are primary hyperparathyroidism (90%) including 15% of all affected by HPT-JT with parathyroid cancer, fibro-osseous jaw tumors (30%), bilateral renal cysts (10%), and less commonly solid renal tumors. Parafibromin contains no identified functional domains though it has weak homology to a protein in *S. cerevisiae*, Cdc73p, which participates as a cofactor in an alternative complex with RNA polymerase II. This study was undertaken to understand the expression, subcellular distribution, and functional properties of endogenous and recombinant human parafibromin.

Polyclonal antibodies were raised in rabbits to a purified recombinant protein consisting of glutathione S-transferase fused to amino acids 2 -135 of human parafibromin and the IgG fraction of this antiserum (NC190) was isolated by Protein A affinity chromatography. For transient transfection studies human parafibromin cDNA was modified with two copies of an in-frame N-terminal AU5 epitope and the construct placed downstream of the CMV promoter in the mammalian expression vector pcDNA3 (AU5-parafibromin). COS-7 cells transfected with AU5-parafibromin, but not empty vector, expressed a single band of 61 kD reactive with both AU5 monoclonal antibody and NC190. A survey of human tissues analyzed by immunoblotting showed NC190-reactivity with a 61 kD band in adrenal and parathyroid glands, kidney and heart, and a ~42 kDa NC190-reactive band also present in heart and skeletal muscle. The reactivity of all NC190-positive bands was blocked by preabsorption with purified His6-parafibromin (2-135) fusion protein. Subcellular fractionation of normal human parathyroid gland homogenate demonstrated expression of a 61 kD NC190-immunorective band in the cytoplasmic and nuclear fractions. Transient transfection of AU5-parafibromin, but not empty vector, strongly inhibited expression of cyclin D1/ PRAD1, a key cell cycle regulator previously implicated in parathyroid neoplasia. These results demonstrate that endogenous human parafibromin is a nucleocytoplasmic protein and demonstrate a potent biologic effect of parafibromin on a key cell cycle regulator consistent with its postulated role as a tumor suppressor protein.

Cinacalcet HCl Effectively Treats Hypercalcemia in Patients with Parathyroid Carcinoma. S. J. Silverberg[1], C. Faiman*[2], J. P. Bilezikian[1], D. M. Shoback[3], M. R. Rubin*[1], R. Smallridge[4], L. E. Schwanauer*[5], K. A. Olson*[5], S. A. Turner*[5], M. Peacock[6]. [1]Columbia Univ Med Ctr, New York, NY, USA, [2]Cleveland Clin Found, Cleveland, OH, USA, [3]Dept of Veterans Affairs Med Ctr, Univ California, San Francisco, San Francisco, CA, USA, [4]Mayo Clin Jacksonville, Jacksonville, FL, USA, [5]Amgen Inc., Thousand Oaks, CA, USA, [6]Indiana Univ Sch Med, Indianapolis, IN, USA.

Cinacalcet HCl reduces serum calcium by effects mediated through the calcium-sensing receptor. In parathyroid carcinoma, a rare but important cause of severe hypercalcemia, the cancer retains PTH-secreting function. Most patients suffer with significant sequelae, including renal and skeletal complications. Although surgical removal can be curative, local seeding of functional parathyroid carcinoma cells in the neck and recurrence with metastases do occur. The cancer is commonly resistant to chemotherapy and radiotherapy, making medical management a challenge. We evaluated cinacalcet in a single-arm, dose-titration trial in 21 patients with parathyroid carcinoma. The cinacalcet dose was adjusted sequentially (30 mg twice daily to 90 mg four times daily) in a titration phase to achieve a ≥1 mg/dL reduction in serum calcium. The end of the titration phase occurred when serum calcium was ≤10.0 mg/dL or after 16 weeks, whichever came first.

All 21 patients had prior parathyroid surgery and one or more symptoms of hypercalcemia (somnolence, nausea and vomiting, decreased appetite, fatigue, and depression). Evaluation also revealed kidney stones (48%), acute renal failure/renal insufficiency (19%), and pathological bone fractures (14%). In 8 patients, parathyroid surgery had been performed multiple times, including 1 patient who had 6 operations. 81% of patients had been treated previously with bisphosphonates. The baseline mean (range) serum calcium was 14.5 (9.4 to 20.2) mg/dL and the baseline iPTH (nl range: 10-65 pg/mL) was markedly elevated, 856 (232 to 2106) pg/mL. At the end of the titration phase, cinacalcet reduced serum calcium to 12.4 (9.0 to 17.0) mg/dL; 71% (15/21) of patients achieved a target reduction in serum calcium of ≥1 mg/dL. In one patient, the calcium fell from 17.9 to 11.4 mg/dL. Pre-dose iPTH levels were reduced modestly (719; range 191 to 1130 pg/mL); even lower levels of iPTH were observed at 2 and 4 hours post-dose (mean of 630 and 610 pg/mL, respectively). Serum calcium reductions have been maintained for up to 3 years. Cinacalcet was generally well-tolerated in this study; the most common adverse events were nausea and vomiting.

Cinacalcet effectively reduced the extent of severe hypercalcemia in these patients with parathyroid carcinoma and can fulfill an unmet medical need in this critically ill patient population.

Clinical Course of 10 Patients with Inoperable Parathyroid Carcinoma Treated with the Calcimimetic Cinacalcet HCl. M. R. Rubin, J. Sliney*, S. J. Silverberg, J. P. Bilezikian. Columbia University College of Physicians & Surgeons, New York, NY, USA.

Management of inoperable parathyroid carcinoma (PTHCa) presents a challenge because effective medical therapy has not been available. Morbidity and eventual mortality are consequences of severe hypercalcemia. The calcimimetic, cinacalcet HCl, reduces PTH secretion by binding to the calcium receptor and increasing its affinity for calcium. The resulting increase in intracellular calcium inhibits PTH with consequent reductions in the serum calcium. In primary hyperparathyroidism, cinacalcet normalized serum calcium levels for up to 3 years. We examined the clinical course of 10 patients with inoperable PTHCa treated with cinacalcet.

4 women and 6 men (52 ± 5 yr) underwent parathyroidectomy 6.8 ± 2 yrs prior to study. Metastatic disease had been resected in 9 patients: lung (n=6), neck (n=2) or esophagus (n=1). Hypercalcemia had not resolved with bisphosphonate use in 8; 7 had kidney stones and 4 had fractures. All had symptoms of hypercalcemia. Baseline biochemistries included marked elevations in the serum calcium (15.4 ± 1 mg/dl), PTH (mean: 914 pg/ml; range: 232-2106), urinary calcium excretion (503 ± 134 mg per 24 hrs; n=4), total alkaline phosphatase(AP, 203 ± 41 U/L; nl: <100), Bone-specificAP (BSAP, 60 ± 19 ng/ml; nl: 3.0-20.9), and serum NTX (178 ± 56 nM BCE; nl: 5.4-24.2). Cinacalcet was started at 30 mg twice daily and titrated over 16 weeks to a maximum of 90 mg four times daily. 8 patients required the maximal dose. The serum calcium fell to 11.8 ± 0.5 mg/dl and PTH to 700 pg/ml (range 191-984). The reduction in serum calcium was maintained for up to 1.5 yr, although PTH levels actually rose 42% from baseline values. Urinary calcium excretion decreased by 46% to 295 ± 107 mg 24 hrs (n=3) while bone turnover markers increased (serum NTX by 29%, BSAP by 110%).

Marked improvement in symptoms of hypercalcemia occurred in all, including increases in appetite, energy and strength. Nausea and vomiting occurred in 6 patients, necessitating discontinuation of cincacalcet in 1, but resolving fully in the others over time. Effects on tumor burden by sequential sestamibi scanning did not reveal a change in metastatic lesions (n=4). 4 patients sustained hip fractures and 1 patient died from acute congestive heart failure.

Cinacalcet was effective in reducing serum calcium in patients with inoperable PTHCa and is associated with symptomatic improvement. It represents an important treatment option in this patient population in which morbidity and mortality are high. Effects on the natural history of PTHCa, including tumor burden, fracture rate and mortality are unknown.

Recombinant Osteoprotegerin Treatment Potently Inhibits Bone Resorption in Subjects with Osteoprotegerin Deficiency. T. Cundy[1], J. Davidson*[1], C. Stewart*[2], A. De Paoli[3]. [1]Department of Medicine, University of Auckland, Auckland, New Zealand, [2]Amgen Inc., Thousand oaks, CA, USA, [3]Amgen Inc., Thousand Oaks, CA, USA.

The autosomal recessive syndrome of Juvenile Paget's Disease/Familial Hyperphosphatasia (MIM239000) arises most commonly from inactivating mutations in the *TNFRSF11B* gene that encodes osteoprotegerin. Osteoprotegerin (OPG) is a critical regulator of bone resorption, and in its absence a high turnover deforming bone disease develops in infancy or childhood, that is relatively resistant to calcitonin and bisphosphonate treatment. In two siblings, aged 31 and 26, with OPG deficiency resulting from a 3bp deletion in the ligand-binding domain of OPG (delAsp182) we have studied the effect of synthetic OPG replacement treatment. OPG was produced as a recombinant Fc-OPG fusion molecule (AMGN 0007; 30mg/ml solution), and administered by subcutaneous injection. Sequential measurements were made of plasma total calcium, phosphate, and alkaline phosphatase (ALP) activity, and the bone resorption markers of deoxypyridinoline (DPD) and N-telopeptide (NTX) excretion. Bone resorption was rapidly inhibited at doses of 0.1 and 0.3 mg/kg body weight, with an obvious dose effect on intensity and duration of action. 0.3 mg/kg recombinant OPG suppressed uDPD to ~65% of basal values; in normal subjects uDPD is suppressed by ~40%, suggesting increased sensitivity in OPG-deficient subjects.

With continued treatment it was possible to suppress completely uNTX excretion with once weekly injections of 0.4 mg/kg. Over 6 months elevated plasma ALP also suppressed to within the normal range in both subjects. Apart from moderate hypocalcemia and hypophosphatemia there were no adverse events. Hematologic, renal, hepatic and thyroid function were unaffected. Replacement treatment with subcutaneous injections of recombinant OPG, or another means of inhibiting RANK-ligand, could be an effective long term treatment for OPG deficiency.

The Results of a Study to Assess the Effects of Lanthanum Carbonate versus Calcium Carbonate on Bone Histomorphormetry in Patients with End-Stage Renal Disease. A. J. Freemont[1], J. Denton[1], C. Jones*[2], M. Gill*[2]. [1]Osteoarticular Pathology, University of Manchester, Manchester, United Kingdom, [2]Shire Pharmaceuticals Development Ltd, Basingstoke, United Kingdom.

In this study (LAM-IV-303), the effect of treatment with lanthanum carbonate, a new non-aluminium-, non-calcium-based phosphate binder, on bone in patients with end-stage renal disease (ESRD) was compared with the effect of treatment with calcium carbonate.
The trial was an open-label, multicentre, parallel-group study involving patients with ESRD initiated onto dialysis within 12 weeks of recruitment. Phosphate binder treatment was stopped, tetracycline labelling administered, and a transiliac bone biopsy taken. After randomization to treatment with lanthanum carbonate or calcium carbonate, patients were titrated to an optimum dose of elemental lanthanum (maximum: 3750 mg/day) or elemental calcium (maximum: 9000 mg/day) for 8 weeks, and maintained at this dose or titrated further as required for 44 weeks. Phosphate binders were then stopped, the bone was again labelled with tetracycline, and a second biopsy taken. Biopsies were analysed histomorphometrically and the data compared with normal values. Primary parameters included mineralization lag time (Mlt), % osteoid surface (%OS), % osteoid volume (%OV), % osteoblast surface (%ObS), bone formation rate (BFR), % osteoclast surface (%OcS) and mean erosion depth. Secondary parameters included activation frequency (AcF) and %OcS *vs.* BFR.
Paired biopsies from 63 patients were suitable for analysis; 33 from lanthanum carbonate-treated patients, and 30 from calcium carbonate-treated patients. The treatment groups were well balanced in terms of age, sex and race. Medical and surgical histories were typical of patients with ESRD. An analysis of the incidence of adynamic bone and hyperparathyroidism (%OcS *vs.* BFR) showed that 55% of lanthanum carbonate-treated patients moved towards normal bone, whereas 33% of patients receiving calcium carbonate treatment improved. A change towards normal %ObS in the lanthanum carbonate-treated group supported this finding. Lanthanum carbonate was also found to improve global bone cell activity (AcF) in 52% of patients, compared with improvement in 23% of calcium carbonate-treated patients. Osteoclast and osteoblast activity and bone matrix parameters indicated that lanthanum carbonate had no toxic effect on bone. In particular, it had none of the toxic effects associated with the use of aluminium-based phosphate binding agents.In conclusion, this study indicates that, compared with calcium carbonate, lanthanum carbonate treatment for 1 year may improve bone and bone cell activity in patients with ESRD.

Dysfunction of Membrane-Bound Prostaglandin E Synthase-1 (mPGES-1) Reduces Inflammatory Bone Resorption. K. Yamakawa*[1], M. Saegusa[1], D. Kamei*[2], Y. Takegoshi*[2], S. Uematsu*[3], S. Akira*[3], M. Murakami*[2], I. Kudo*[2], K. Nakamura[1], H. Kawaguchi[1]. [1]Univ. of Tokyo, Tokyo, Japan, [2]Showa Univ., Tokyo, Japan, [3]Osaka Univ., Osaka, Japan.

Prostaglandin E_2 synthase (PGES) is the terminal and specific enzyme following phospholipase A_2 and cyclooxygenase in the biosynthetic pathway of PGE_2 that induces various catabolic disorders including bone resorption. Among three isozymes of PGES: membrane-bound PGES-1 (mPGES-1), mPGES-2, and cytosolic PGES (cPGES), only the mPGES-1 mRNA level was upregulated in cultured mouse calvariae by proinflammatory cytokines TNF-α and IL-1. When an antisense oligonucleotide against mPGES-1 was added to the coculture of mouse bone marrow cells and osteoblasts on a dentine slice, it not only suppressed mPGES-1 expression and PGE_2 production, but also reduced by 80-90% the osteoclastogenesis and resorbed pit formation stimulated by the cytokines, which was restored by addition of exogenous PGE_2. To further examine the role of endogenous mPGES-1 *in vivo*, we created mice lacking the *mPGES-1* gene (*mPGES-1* KO) by homologous recombination in mouse ES cells. The KO mice developed and grew normally without abnormalities of major organs. Radiological and histomorphometric analyses also showed no difference in long bones and vertebrae between KO and wild-type (WT) littermates under physiological conditions during observation periods up to 26 weeks of age. However, pain nociception determined by the acetic acid writhing response was about 80% reduced, and inflammatory granulation tissue formation in the dorsum induced by subcutaneous implantation of a cotton thread was about 50% reduced in KO relative to WT. When arthritis was induced by the intraperitoneal injection of anti-type II collagen antibody, PGE_2 production and mPGES-1 mRNA level were markedly increased in paws of WT, which was rarely seen in KO. mPGES-2 and cPGES mRNA levels were not affected by the arthritis induction in either WT or KO. Histological analysis revealed that synovial hypertrophy, pannus formation and cartilage destruction were much milder in KO joints, and the arthritis score of the KO paws was about 40% of WT. The decrease of bone density and the histomorphometric parameters for bone resorption (N.Oc/B.Pm & ES/BS) around the KO knee joint were about half those of WT (all $p<0.01$). In contrast to the arthritis induction, bone decreases after ovariectomy or unloading by tail-suspension were similarly seen in KO and WT littermates. We conclude that mPGES-1 contributes to pain sensitivity, inflammation, and inflammatory bone resorption without affecting physiological conditions, implying that an inhibitor of mPGES-1 could be a highly selective treatment for these disorders such as rheumatoid arthritis.

Increased Expression of ADAM8 in Rheumatoid Pannus. J. Mandelin[1], T. F. Li*[2], M. Hukkanen*[1], M. Ainola*[1], S. J. Choi[3], Y. T. Konttinen*[4]. [1]Institute of Biomedicine/anatomy, University of Helsinki, Finland, [2]Department of Orthopedics, University of Rochester Medical Center, Rochester, NY, USA, [3]Medicine-Hematology/Oncology, University of Pittsburg, Pittsburg, PA, USA, [4]Medicine/Invärtes medicin, Helsinki University Hospital, Helsinki, Finland.

A disintegrin and a metalloproteinase (ADAM)8, a recently identified osteoclast-activating factor, may promote tissue destruction in rheumatoid arthritis (RA). The presence of ADAM8 in RA characterized by bone erosions was compared to that of osteoarthritis (OA) characterized by subchondral bony sclerosis.
RA pannus (n=10), RA synovitis (n=10) and OA synovial membrane (n=10) samples were studied using tissue extraction and Western blotting, immunostaining and morphometry, tartrate-resistant acid phosphatase staining, in situ hybridization and quantitative reverse transcriptase-polymerase chain reaction (RT-PCR).
Western blots of tissue extracts showed the typical 65 kDa ADAM8 band in all samples prepared from RA pannus, RA synovitis tissue and OA synovial membrane. Immunostaining, confirmed with *in situ* hybridization, disclosed high ADAM8 expression in RA compared to OA (60.0 ± 2.2 % in RA pannus and 47.1 ± 2.1 % in RA synovial membrane compared to 9.8 ± 1.1 % in OA, $p < 0.001$), in particular in the pannus-cartilage junction, often close to tartrate-resistant acid phosphatase positive multinucleate cells. Pannus contained 23 ± 7 ADAM8 mRNA copies per 10,000 β-actin copies compared to 1.7 ± 0.3 in OA ($p<0.001$).
ADAM8, upregulated in RA pannus overlying developing erosions, may be actively involved in joint destruction through its role in monocyte-macrophage adhesion, direct cartilage degradation by its protease-like property and bone destruction by its osteoclast-activating effect.

The Mechanism Used by Parathyroid Hormone to Arrest the Cell Cycle Progression of Osteoblastic Cells from G1 to S Phase. L. Qin, X. Li*, J. Ko*, N. C. Partridge. Physiology and Biophysics, University of Medicine and Dentistry of NJ, Piscataway, NJ, USA.

Parathyroid hormone (PTH) plays a major role in bone remodeling. Current interest has focused on its ability to increase bone mass after intermittent administration. High concentrations of PTH inhibit the growth of UMR 106-01 cells, a rat osteosarcoma cell line, arresting them in G1 phase. Here we demonstrate that PTH employs at least three mechanisms to do this: inducing expression of MAP kinase phosphatase 1 (MKP-1) and $p21^{Cip1}$, and decreasing expression of cyclin D1. The induction of MKP-1 by PTH is a rapid primary response, with mRNA increasing 14-fold induction after 1 h. This was confirmed by Western blot analysis. Phosphorylated extracellular signal-regulated kinase 1/2 (ERKs1/2) are substrates for MKP-1 activity. We observed a coincident ERK dephosphorylation and MKP-1 induction after PTH (10^{-8} M) treatment of UMR cells. Inhibition of *de novo* protein synthesis by cycloheximide abolished both effects of PTH on dephosphorylation of ERK and increase in MKP-1 protein suggesting the new synthesis of MKP-1 may be required for ERK1/2 dephosphorylation. Orthovanadate, a tyrosine phosphatase inhibitor, also eliminates PTH's effect on ERK dephosphorylation. Moreover, overexpression of MKP-1 arrested UMR cells in G1. Since phosphorylated ERKs are important for cell growth, these data strongly suggest that the induction of MKP-1 by PTH affects cell cycle progression possibly by dephosphorylation of active ERKs. Phosphorylated ERKs stimulate cell growth by increasing the expression of cyclin D1, which is critical for G1 to S phase transition. We found PTH indeed decreases cyclin D1 protein level by 3-fold in UMR cells after 8 h of treatment and this is a secondary response. Orthovanadate abolished this decrease, suggesting MKP-1 may play a role in inhibiting the expression of cyclin D1. Furthermore, we identified $p21^{Cip1}$, a potent cyclin-dependent kinase inhibitor preventing G1 to S phase progression, but not $p27^{kip1}$, is an immediate response gene for PTH in UMR cells. More importantly, PTH injection (80 μg/kg) produces similar effects on expression of MKP-1, cyclin D1 and $p21^{Cip1}$ in rat femoral metaphyseal primary spongiosa. While 1 injection of PTH in rats only increases $p21^{Cip1}$ mRNA 2-fold 1 h later, intermittent daily injections of PTH for 14 days significantly increase $p21^{Cip1}$ mRNA 8-fold 1 h after the last injection. We propose that repeated PTH injections make the osteoblast more sensitive to successive PTH treatments and this feature is important for PTH's anabolic functions. Our data also suggest that one important mechanism for PTH's anabolic effect is to arrest the cell cycle progression of osteoblast and hence increase its differentiation.

Parathyroid Hormone (PTH) Regulates Placental Calcium Transfer Independently of PTH-related Protein (PTHrP). C. S. Noseworthy[1], N. J. Fudge*[1], G. Karsenty[2], A. C. Karaplis[3], C. S. Kovacs[1]. [1]Memorial University of Newfoundland, St. John's, NF, Canada, [2]Baylor College of Medicine, Houston, TX, USA, [3]McGill University, Montreal, PQ, Canada.

PTH and PTHrP regulate fetal blood calcium (Ca) and skeletal mineralization, while only PTHrP has been shown to regulate placental Ca transfer. Evidence against a role for PTH includes the fact that *Pthrp* null fetuses increased placental Ca transfer in response to PTHrP treatment while PTH was without effect. However, exogenous PTH treatment may have been ineffective because *Pthrp* null fetuses have a 3 to 4-fold increase in endogenous PTH.

To determine if PTH regulates placental Ca transfer, we examined fetal mice that are either partly deficient in PTH (*Gcm2* null) or which lack PTH altogether (*Pth* null).

Fetal serum PTH was 41.9 pg/ml in wt, but was reduced to 5.03 pg/ml in *Gcm2* null fetuses, and was reduced to the limit of detection (1.6 pg/ml) in *Pth* null fetuses ($p<0.001$). Both *Gcm2* and *Pth* null fetuses exhibited evidence of hypoparathyroidism. In *Pth* null fetuses, mean ionized Ca was reduced to 1.31 mmol/l (wt: 1.75 mmol/l), serum P was increased to 3.5 mmol/l (wt: 3.00 mmol/l), and serum Mg was reduced to 1.11 mmol/l (wt: 1.17 mmol/l) ($p<0.001$ for all vs. wt). *Gcm2* null fetuses similarly had low Ca, high P and low Mg. *Gcm2* null and *Pth* null fetuses differed with respect to the net skeletal mineralization and rate of placental 45Ca transfer. *Gcm2* null fetuses had normal ash weight and normal von Kossa staining of tibial sections, indicating normal mineral content of the fetal skeleton. *Pth* null fetuses had an ash weight reduced to 90% of wt value ($p<0.001$) and reduced staining of mineral by von Kossa. Placental 45Ca transfer was significantly increased to 119% of normal in *Gcm2* null fetuses ($p<0.02$) but was not increased in *Pth* null fetuses (104% versus 105% in wt and 100% in het). Finally, in preliminary experiments, fetuses were injected *in utero* with 1 nmol PTH 1-84 or vehicle 70 minutes prior to measuring placental 45Ca transfer. Compared to 3 saline injected *Pth* nulls, placental 45Ca transfer increased to 120% in 3 *Pth* null fetuses treated with PTH 1-84.

In summary, hypocalcemic *Gcm2* null mice upregulated placental Ca transfer and maintained skeletal mineralization. Despite equivalent hypocalcemia, *Pth* null mice did not upregulate placental Ca transfer and had a deficit in skeletal mineral content. Preliminary experiments indicate that *Pth* null fetuses upregulated placental Ca transfer in response to PTH 1-84.

In conclusion, PTH can regulate placental Ca transfer, because *Gcm2* null mice (which produce PTH) were able to upregulate placental Ca transfer in response to modest hypocalcemia, while *Pth* null mice (which do not produce PTH) did not until treated with PTH injections.

Bone Anabolic Effects of PTH in LRP5 (G171V) Transgenic High Bone Mass Mice. Y. Kharode[1], P. Bodine[1], P. Green*[1], C. Milligan*[1], J. Li[2], E. Smith-Adaline[2], P. Yaworsky*[3], F. Bex[1]. [1]Women's Health Research Institute, Wyeth Reserach, Collegeville, PA, USA, [2]Women's Health Research Institute, Wyeth Reserach, Cambridge, MA, USA, [3]Genomics Division, Wyeth Reserach, Cambridge, MA, USA.

Transgenic mice expressing a G171V mutation in the low density lipoprotein receptor related protein 5 (LRP5) have a high bone mass phenotype (HBM), an increased response to skeletal loading and a resistance to bone loss due to skeletal unloading. LRP5 is a co-receptor in the Wnt β-catenin pathway and the mutation results in a gain in function in this pathway. PTH, in addition to its osteogenic activity, also has been reported to affect skeletal loading responses as well as act on components of the Wnt β-catenin pathway. To evaluate the interrelation of the skeletal effects of HBM and PTH, groups of 9, 26, 36 and 52 week-old HBM transgenic and age-matched non-transgenic (NTG) male mice were treated with 100 μg/kg/day, sc hPTH 1-34 or vehicle for 30 days. Total vBMD of the distal femur measured by pQCT was significantly increased ($p< 0.01$) by PTH treatment in both HBM and NTG mice at all of the ages tested. However the magnitude of the increase in the HBM groups (16-29%) was consistently greater than NTG (6-14%) despite the fact that total vBMD in HBM vehicle controls was already 46-63% greater than in the NTG controls. The PTH-induced increase in vBMD in HBM mice was almost entirely due to trabecular changes, with little or no effect on cortical vBMD. In contrast, increases in cortical vBMD appeared to be primarily responsible for the PTH anabolic effect in NTG. Analysis of the trabecular bone by μCT indicates that the increased bone volume in HBM is associated with increased trabecular thickness although increases in trabecular number are evident in the older age groups. Like the femur, the L_5 vertebrae of HBM showed a greater PTH-induced increase in BV/TV than NTG, primarily due to effects on trabecular thickness.

Recent studies suggest that the magnitude of the anabolic response to PTH is dependent on the amount of trabecular bone template available. The markedly greater response of axial and appendicular trabecular bone in HBM would support this concept. This is in contrast with results in the sFRP-1 KO animal where there appeared to be an inverse relationship between the existing skeletal phenotype and the magnitude of the PTH response. Since sFRP-1 KO exerts skeletal effects, at least in part, through the Wnt β-catenin pathway, the results suggest shared components with the anabolic action of PTH. However, the ability of PTH to increase BMD in HBM suggests a complementary rather than common pathway for Wnt β-catenin and PTH skeletal activity.

Ablation of Osteoblasts, but not Lining Cells, in 3.6Col1a1-tk Transgenic Mice Prevents the Anabolic Effect of Intermittent PTH: Evidence Against the Lining Cell Activation Hypothesis. R. L. Jilka, I. Gubrij, A. A. Ali, R. A. Wynne*, R. S. Weinstein, C. A. O'Brien, S. C. Manolagas. Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

The anabolic effect of intermittent PTH is due at least in part to attenuation of osteoblast apoptosis. However, the possibility that PTH activates lining cells to become matrix synthesizing osteoblasts has not been ruled out. To address this issue, we made mice expressing herpes thymidine kinase (tk) under the control of a 3.6-kb fragment of the rat collagen1a1 promoter (3.6Col1a1-tk mice). Previous studies had established that this promoter is active in the early stages of osteoblast differentiation. Because the nucleoside analog ganciclovir is toxic in the presence of tk, daily administration of ganciclovir to these mice will deplete bone of osteoblasts because osteoblast production ceases and the existing mature osteoblasts either die, become incorporated into bone as osteocytes, or become lining cells. At this point only the lining cells should remain, permitting unambiguous ascertainment of lining cell activation upon administration of PTH. After establishing that PTH did not interfere with ganciclovir-induced cytotoxicity of cultured osteoblastic cells expressing tk, transgenic mice were made in the FVB strain. TaqMan PCR demonstrated tk expression in calvaria, femurs and vertebrae of transgenic mice but not in soft tissues. Daily administration of 8 mg/kg ganciclovir caused a time dependent decrease in serum osteocalcin that was <10% of vehicle-injected mice after 17 days, whereas wild-type littermates were unaffected by ganciclovir. Examination of vertebral bone from ganciclovir-treated 3.6Col1a1-tk mice revealed the absence of osteoblasts and osteoid perimeter, as well as depletion of marrow elements. Nevertheless, osteocyte and lining cell morphology was normal, and neither cell type was labeled by ISEL staining to detect apoptotic cells. Daily injection of both ganciclovir and PTH for 8 days to 3.6Col1a1-tk mice pretreated with ganciclovir for 17 days failed to increase osteoblast number or osteoid perimeter, whereas 8 days of PTH administration to 3.6Col1a1tk mice not pretreated with ganciclovir increased osteoblast number and osteoid perimeter by 3-fold. We conclude that intermittent PTH administration does not directly activate lining cells to become matrix synthesizing osteoblasts. However, it remains possible that osteoblasts, their progenitors, or hematopoietic cells are required for PTH-induced lining cell activation.

Synergistic Actions of Parathyroid Hormone and Beta-Catenin in the Canonical Wnt Signaling Pathway in Osteoblastic Cells. E. S. Leman*[1], M. Bencsik*[1], P. Nguyen*[2], U. Marvi*[1], R. A. Nissenson[3]. [1]Endocrine Research Unit - VA Medical Center, Univ California San Francisco, San Francisco, CA, USA, [2]Endocrine Research Unit - VA Medical Center, Univ California San Francisco, San Francisco, CA, USA, [3]Endocrine Research Unit - VA Medical Center, Departments of Medicine and Physiology, Univ California San Francisco, San Francisco, CA, USA.

Parathyroid hormone (PTH) produces an anabolic effect on the skeleton, but the mechanism of this action is poorly understood. Low-density lipoprotein receptor-related protein (LRP) 5 and 6 serve as co-receptors for canonical wnt signaling in many tissues. A critical role for this pathway in bone is evidenced by the low bone mass phenotype in individuals with loss of function mutation in LRP5, and the high bone mass present in patients with gain of function mutation in LRP5. In this study, we assessed whether signaling by the G protein-coupled PTH receptor converges with the wnt/LRP pathway. UMR 106 osteoblastic cells were transfected with an expression vector for the transcription factor LEF/TCF together with a LEF/TCF-responsive luciferase reporter (pTOP). Addition of PTH for 5 hours produced a dose-dependent increase in reporter activity in UMR 106 cells. Treatment with LiCl (to inhibit degradation of beta-catenin) or expression of a stable form of beta-catenin produced an increased in pTOP luciferase reporter activity that was synergistic with that produced by PTH administration. Treatment of UMR 106 cells with recombinant wnt-3A slightly increased the reporter activity, whereas treatment with both PTH and wnt-3A further increased LEF/TCF activity. Both LiCl and recombinant wnt-3A increased endogenous levels of beta-catenin, whereas PTH treatment produced little if any increase in beta-catenin levels. Treatment with either forskolin or 8-Br-cAMP resulted in a small increase in pTOP luciferase reporter activity, but failed to fully reproduce the effect of PTH, indicating that signaling via pathway(s) other than cAMP/PKA was responsible for activation of LEF/TCF signaling by PTH. An inhibitor of phospholipase C (U 73122) blunted the ability of PTH to promote LEF/TCF signaling by more than 50 %, indicating that this signaling pathway contributes to the effect of PTH. Thus, PTH treatment activates a LEF/TCF-responsive reporter and does so by a mechanism distinct from that utilized by wnt-3A. Synergism between PTH action and the canonical wnt signaling pathway in osteoblasts may contribute to the anabolic effect of PTH in bone.

The IGF-I Receptor Is Required for the Anabolic Actions of Parathyroid Hormone on Bone. Y. Wang[1], S. Nishida[1], A. Burghardt*[2], H. Z. ElAlieh*[1], S. Majumdar[2], B. P. Halloran[1], T. L. Clemens[3], D. D. Bikle[1]. [1]Endocrine Unit, University of California, San Francisco/VAMCSF, San Francisco, CA, USA, [2]Radiology, University of California, San Francisco, San Francisco, CA, USA, [3]Medicine, University of Cincinnati, Cincinnati, OH, USA.

Although the ability of parathyroid hormone (PTH) to stimulate bone formation is well known, the mechanism is not clear. To examine the role of insulin-like growth factor I (IGF-I) signaling in mediating the actions of PTH on bone, we investigated the bone response to PTH in 3 month old male and female and mice with a bone specific IGF-I receptor null mutation (bIGF-IR$^{-/-}$) (floxed IGF-IR x osteocalcin promoter driven Cre recombination) and their normal littermates treated with vehicle or PTH (80 µg/kg bw/day for 2 weeks).Structural measurements of the proximal and mid-shaft of the tibia were made by micro-CT. Cortical bone formation at the tibiofibular junction (TFJ) was made by bone histomorphometry. Bone marrow stromal cells (BMSCs) were obtained to assess the effects of PTH on osteoprogenitor number and differentiation. The fat free weight of bone normalized to body weight (FFB/BW), bone volume (BV), and cortical thickness (C.Th) in both proximal tibia and shaft were all less in the bIGF-IR$^{-/-}$ mice compared to controls. PTH decreased FFB/BW, total volume (TV), and BV of the proximal tibia more substantially in controls than in bIGF-IR$^{-/-}$ mice, although the increase in C.Th after PTH in the proximal tibia was comparable in both control and bIGF-IR$^{-/-}$ mice. Periosteal bone formation at the TFJ was markedly lower in the bIGF-IR$^{-/-}$ mice than in the control mice, as was the response to PTH. Endosteal bone formation was comparable in control and bIGF-IR$^{-/-}$ mice, but PTH stimulated endosteal bone formation only in the control animals. Compared with BMSCs from control mice, BMSCs from bIGF-IR$^{-/-}$ mice showed far fewer alkaline phosphatase (ALP) positive colonies on day 14 and essentially no mineralization on day 28. Administration of PTH increased the number of ALP positive colonies and mineralization on day 14 and 28 in BMSCs from control mice, but not in BMSCs from bIGF-IR$^{-/-}$ mice. Our results indicate that the IGF-IR null mutation in mature osteoblasts leads to less bone and decreased periostеal bone formation in part due to the requirement for the IGF-IR in mature osteoblasts to enable PTH to stimulate osteoprogenitor cell proliferation and differentiation.

Calcium-Mediated PTH mRNA Destabilization In Parathyroid Cells Requires Gene Transcription. C. S. Ritter*, S. Pande*, I. Krits*, E. Slatopolsky, A. J. Brown. Renal Division, Washington University, Saint Louis, MO, USA.

Extracellular calcium suppresses PTH release by inhibiting secretion, promoting peptide degradation and destabilizing PTH mRNA. Calcium-regulated PTH mRNA stability has not been investigated directly in parathyroid cells due to the unavailability of a suitable cell model. We have recently reported a culture system for bovine parathyroid cells that promotes the formation of small organoids (termed pseudoglands) that retain a stable response to calcium over several weeks (J Bone Min Res 19:491, 2004). Using this model, we confirmed that calcium directly regulates PTH mRNA levels. Time course studies showed that switching the medium from 0.4 mM calcium to 3.0 mM calcium reduced PTH linearly over 16 hours to a nadir of 20 to 30% basal. Switching from 3.0 mM to 0.4 mM calcium medium gradually increased PTH to a maximum by 48 h. Addition of the transcription inhibitor 5,6-dichloro-1-beta-D-ribofuranosylbenzimidazole (DRB) to pseudoglands pre-incubated for 24 hours in 0.4 mM Ca did not alter PTH mRNA over the ensuing 24 hours, indicating that PTH mRNA is completely stable when parathyroid cells are exposed to low calcium. In contrast, addition of DRB to pseudoglands 2 hours after addition of 3.0 mM calcium medium produced a 62% decrease in PTH mRNA over a 24-hour period (estimated half-life = 20 hours). The decrease with DRB treatment was slower than when DRB was absent, suggesting a requirement for transcription in calcium-mediated decay of PTH mRNA. This was confirmed by pre-incubating the pseudoglands with DRB 30 minutes prior addition of the 3.0 mM calcium medium, a maneuver that almost completely blocked the destabilization of PTH mRNA by calcium. Our results demonstrate for the first time that calcium directly accelerates the turnover of PTH in parathyroid cells, confirming earlier studies by Naveh-Many and co-workers using an in vitro degradation assay. Furthermore, using this novel parathyroid cell culture model, we have documented the requirement for calcium-dependent gene transcription in the destabilization of PTH mRNA.

Exogenous PTHrP Administration Rescues Double Knockout Mice Which Are Homozygous for Both the 1α-Hydroxylase and PTH Null Alleles. Y. B. Xue, Z. L. Zhang*, A. C. Karaplis, G. N. Hendy, D. Goltzman, D. S. Miao. Medicine, McGill University, Montreal, PQ, Canada.

Double mutant mice which are homozygous for both the 1α-hydroxylase and PTH null alleles (1α-(OH)ase$^{-/-}$PTH$^{-/-}$) die with tetany 1-3 weeks after birth. We examined the effect of PTHrP on calcium homeostasis and bone remodelling in these animals by administering PTHrP (1-86), 0.2 µg per mouse per day subcutaneously from day 4 to 2 weeks of age. Serum calcium rose from 1.25±0.2 mmol/L (48% of wild-type) in vehicle-treated 1α-(OH)ase$^{-/-}$PTH$^{-/-}$ mice to 1.8±0.1 mmol/L (70% of wild-type) in PTHrP-treated 1α-(OH)ase$^{-/-}$PTH$^{-/-}$mice. Renal levels of mRNA encoding calbindin-D_{28K} and calbindin-D_{9K} rose by 2.6 fold and by 2.1 fold, respectively, after PTHrP treatment and protein levels of calbindin-D_{28K} and calbindin-D_{9K} rose by 1.4 fold and by 1.5 fold, respectively. The treatment of PTHrP also up-regulated both mRNA and protein expression levels of calbindin-D_{28K} in a dose dependent manner in primary renal cell cultures from wild-type and 1α-(OH)ase$^{-/-}$ mice. Osteoclast numbers in bone did not increase significantly in the PTHrP-treated double mutants compared to either vehicle-treated wild-type or vehicle-treated double mutants. In contrast, alkaline phosphatase-positive osteoblasts were increased in PTHrP-treated double mutants compared to vehicle-treated double mutants, although they did not reach the levels observed in wild-type mice. In association with increased osteoblast number, Cbfa1 expression and matrix deposition of type I collagen and osteocalcin were significantly increased and mineralized trabecular and cortical bone were increased compared to vehicle-treated double mutants. The width of the cartilaginous growth plate was also augmented by PTHrP treatment, and long bone length was increased. With continued treatment, in contrast to vehicle-treated mutants which died at 1-3 weeks of age, PTHrP-treated mice remained viable for at least 1 month and continued to increase their bone mineral density and cortical and trabecular bone volume. These parameters even exceeded levels in vehicle-treated wild-type animals at 1 month of age. These results indicate that increases in systemic PTHrP in the post-natal state can increase serum calcium by renal mechanisms, which can maintain viability, and promote bone growth. In the early post-natal period, the major effect of NH_2-terminal PTHrP is to increase bone anabolism and not bone resorption.

Importin 4, not Importin Beta, Is Responsible for the Ligand-Independent Nuclear Translocation of Vitamin D Receptor. Y. Miyauchi*[1], T. Michigami[1], T. Sekimoto*[2], Y. Yoneda*[2], M. Yamagata*[1], K. Ozono[3]. [1]Department of Environmental Medicine, Osaka Medical Center and Research Institute for Maternal and Child Health, Izumi, Osaka, Japan, [2]Department of Frontier Biosciences, Osaka University Graduate School of Frontier Biosciences, Suita, Osaka, Japan, [3]Department of Pediatrics, Osaka University Graduate School of Medicine, Suita, Osaka, Japan.

Vitamin D receptor (VDR) is localized in nuclei and acts as a ligand-dependent transcription factor. Although several nuclear localization signals (NLSs) have been identified, the molecular mechanisms underlying the nuclear translocation of VDR remain unclear. To address this issue, we utilized an in vitro nuclear transport assay where nuclear translocation of molecules of interest can be reconstructed using semi-intact cells consisting of permeabilized plasma membrane and intact nuclear envelope. This assay can dissect the nuclear import event from nuclear accumulation and nuclear export which also determine nuclear localization. When subjected to this assay, recombinant full-length VDR was imported to nuclei even in the absence of ligand. A truncated mutant, VDR[DBD-Hinge] lacking the ligand-binding domain, was also imported to nuclei regardless of the presence or absence of ligand. In contrast, VDR[LBD] possessing only the ligand-binding domain failed to be imported both in the presence and absence of ligand. Interestingly, another mutant VDR[Hinge-LBD], which carries the hinge region and the ligand-binding domain but lacks DNA-binding domain, was not imported to nuclei in the absence ligand, but was efficiently imported in the liganded form. The data suggest that there are two distinct mechanisms underlying the nuclear translocation of VDR; the ligand-dependent and -independent pathways in which the responsible NLSs are likely to be localized in the hinge and DNA-binding domain, respectively. Next, we attempted to identify the molecules which confer the nuclear translocation of VDR. In the yeast two-hybrid screening using DBD-Hinge as the bait, importin 4, a member of importin beta-like family, was identified as an interacting protein. To examine whether importin 4 confers the nuclear translocation of VDR, recombinant importin 4 was subjected to the nuclear transport assay where all the required molecules were supplied as recombinant proteins. As the result, importin 4 transported VDR even in the absence of ligand. In contrast, importin beta, which is the classical member of importin family, failed to transport VDR. In conclusion, 1) VDR has two distinct mechanisms of nuclear translocation; ligand-dependent and -independent pathways, and 2) importin 4 is responsible for the ligand-independent nuclear translocation of VDR.

Characterization of the Hairless Protein as a Vitamin D Receptor Corepressor: Mapping the Physical and Functional Interaction between Two Proteins Required for the Mammalian Hair Cycle. S. A. Slater*[1], J. C. Hsieh[1], J. L. Dawson*[1], J. M. Sisk*[2], T. K. Barthel[1], M. L. Thatcher*[1], C. A. Haussler[1], P. W. Jurutka[1], G. K. Whitfield[1], C. C. Thompson*[2], M. R. Haussler[1]. [1]Biochemistry & Molecular Biophysics, University of Arizona, Tucson, AZ, USA, [2]Neuroscience, Johns Hopkins University School of Medicine & Kennedy Krieger Institute, Baltimore, MD, USA.

The hairless gene product (Hr), vitamin D receptor (VDR) and retinoid X receptor (RXR) are all essential for mammalian hair cycling. VDR and RXR signal as a heterodimeric complex bound to vitamin D responsive elements (VDREs) in target gene promoters. Transcriptional activation is achieved by 1,25-dihydroxyvitamin D_3 (1,25D) liganding of VDR-RXR and recruitment of coactivators, whereas the mechanism of gene repression by VDR is uncharacterized. We demonstrate that rat Hr (rHr), a protein expressed primarily in skin and brain that functions as a corepressor of the thyroid hormone receptor (TR) and orphan nuclear receptor ROR, is a potent repressor of VDR-mediated transcription driven by both natural and synthetic VDREs. Utilizing both in vitro pulldown and coimmunoprecipitation, rHr was found to interact significantly with VDR irrespective of 1,25D, but only minimally with nuclear receptors not functionally repressed by Hr. The rHr contact site(s) in human VDR is independent of the C-terminal activation function-2 domain that recruits coactivators, and is located instead in the ligand binding domain in a region (helices 3-6) that attracts corepressors in other nuclear receptors. Con-

versely, VDR binding to rHr, assessed by deletion and point mutant analyses, is absent in an N-terminal fragment (residues 31-568) and occurs strongly with the C-terminal half of rHr (residues 568-1207). The C-terminal half of rHr acts as a potent VDR corepressor and contains two TR repressive domains that partially overlap two LXXLL and two ΦXXΦΦ (Φ = hydrophobic) motifs required for respective ROR and TR binding by rHr. Generation of smaller rHr deletants and point mutation of the hydrophobic interaction motifs revealed that rHr utilizes all four nuclear receptor interaction domains (residues 586-590, 778-782, 817-821 and 1028-1032) in contacting and maximally repressing VDR. Therefore, rHr represses VDR signaling by employing a combination of ROR and TR interaction sites that contact the helix 3-6 region of VDR, with repressive domains in the C-terminal half of rHr presumably attracting histone deacetylases (HDACs) that modify chromatin architecture to silence target gene transcription. We propose that RXR-VDR-Hr-HDAC repression of an unknown target gene(s) triggers the telogen to anagen phase transition of the hair cycle.

Cell-Specific Crosstalk between the Vitamin D Receptor and beta-Catenin Signal Transduction Pathways in $1,25(OH)_2D_3$ Target Tissues. P. W. Jurutka[1], N. Hall*[2], G. K. Whitfield[2], M. Gurevich*[2], T. K. Barthel[2], J. C. Hsieh[2], C. A. Haussler[2], M. R. Haussler[2]. [1]Life Sciences, Arizona State University West, Phoenix, AZ, USA, [2]Biochemistry & Molecular Biophysics, University of Arizona, Tucson, AZ, USA.

β-catenin, a mediator of canonical Wnt signaling, is dysregulated in many cancers and has been implicated in hair growth as well as bone development, maintenance and repair. Previous work suggests that the vitamin D receptor (VDR) inhibits β-catenin activity in colonic cells. We evaluated the physical and functional association between VDR and β-catenin in colon cancer cells as well as in keratinocytes and osteoblasts. Human colon cancer cells (Caco-2) were transfected with a luciferase reporter vector containing TCF/LEF binding sites (TOPFLASH) to monitor β-catenin-mediated transactivation. Cotransfection of VDR resulted in a 50% decrease in reporter activity. GST pulldown assays demonstrated an association between GST-VDR and labeled β-catenin or GST-β-catenin and labeled VDR, an interaction independent of 1,25-dihydroxyvitamin D_3 (1,25D) or the VDR AF-2, but partially disrupted by the carcinogenic VDR ligand, lithocholate (LCA). Mammalian two hybrid assays confirmed the β-catenin-VDR association in Caco-2, and revealed that this interaction also occurs in human keratinocytes (KERTr-1106) and osteoblasts (TE85). Therefore, we tested the effect of VDR overexpression on β-catenin transactivity in these cells and, unlike the results in Caco-2, β-catenin-driven TOPFLASH transcription was stimulated up to 2-fold with increasing amounts of transfected VDR expression vector, but not empty vector. Thus, when VDR interacts with β-catenin, distinct functional effects are observed depending on the cellular milieu. In colon cells, downregulation of Wnt/β-catenin signaling provides a molecular basis for the known anticancer action of VDR, and could also explain why exposure of colonic cells to LCA, which disrupts the association between VDR and β-catenin, may lead to tumorigenesis. In contrast, VDR-β-catenin interaction in keratinocytes or osteoblasts results in stimulation of β-catenin transactivity. Hair cycling is initiated by a surge of β-catenin in keratinocytes, and we propose that VDR collaborates with β-catenin to regulate the expression of genes required for hair growth. Finally, Wnt/β-catenin signaling is crucial for bone formation, as loss of function mutations in the Wnt coreceptor, LRP5, reduce bone mass, whereas gain of function mutations elevate bone mineral density (BMD). Thus, promotion of β-catenin activity by VDR in osteoblasts represents a potential crosstalk mechanism whereby VDR could impact the Wnt signaling pathway to enhance osteoblastogenesis and BMD.

Glucocorticoid Enhances the Expression of Dickkopf-1 in Cultured Human Osteoblasts: Novel Mechanism of Glucocorticoid-Induced Osteoporosis. K. Ohnaka*[1], H. Taniguchi*[1], H. Kawate*[1], H. Nawata*[2], R. Takayanagi*[1]. [1]Department of Geriatric Medicine, Kyushu University, Fukuoka, Japan, [2]Department of Medicine and Bioregulatory Science, Kyushu University, Fukuoka, Japan.

Glucocorticoid-induced osteoporosis (GIO) is a serious problem during glucocorticoid therapy. Although the major cause of GIO is considered to be impairment of bone formation, detailed mechanism underlying GIO remains to be fully elucidated. Recently, the Wnt signal emerged as a novel regulator of bone formation. The aim of this study is to determine whether glucocorticoid would affect the Wnt signal of bone formation in human osteoblasts. We examined the effect of glucocorticoid on the expression of the Wnt signal-related molecules in primary cultured human osteoblasts. Dexamethasone markedly induced the expression of mRNA for dickkopf-1(Dkk-1), an antagonist of Wnt, in a dose- and time-dependent manner. The expression of Kremen1, a receptor for Dkk, did not change by the treatment with dexamethasone, while that of low-density lipoprotein receptor-related protein 5 (LRP5), a Wnt coreceptor, slightly decreased by the treatment with dexamethasone. Dexamethasone increased the transcriptional activity of the human Dkk-1 gene promoter in cultured human osteoblasts. Serial deletion and mutation analyses of the Dkk-1 promoter showed that one putative glucocorticoid responsive element-like sequence located from -788 to -774 bp is essential for the enhancement of Dkk-1 promoter activity by dexamethasone in human osteoblasts. Since the Wnt signal is now recognized as a crucial regulator for bone formation, the Dkk-1 enhanced by glucocorticoid may inhibit the Wnt signal in osteoblasts, which may be involved in the pathogenesis of GIO.

MNAR Regulates the Non-genotropic Action of the Vitamin D_3 Receptor. F. Barletta*, G. O'Donnell*, B. S. Komm, B. J. Cheskis*. Women's Health Research, Wyeth Research, Collegeville, PA, USA.

The vitamin D receptor (VDR) is a member of the nuclear hormone receptor superfamily of ligand-activated transcription factors that regulate target gene expression. The actions of 1,25 dihydroxyvitamin D_3 (1,25D3), the active form of vitamin D, are mediated through the VDR, and have been shown to be essential for maintaining calcium homeostasis and proper bone health. Recently, there has been a dramatic increase in evidence supporting rapid signaling actions of 1,25D3. This rapid action of 1,25D3 has been linked to activation of c-Src, phospholipase C, PKCI, and the MAPK signaling cascade. Previously, we have identified a novel scaffolding protein, MNAR, which integrates the interaction of the estrogen receptor (ER) with Src tyrosine kinase, and has been shown to be required for the rapid activation of the Src/MAPK pathway by estrogens. To gain insight into the rapid actions of 1,25D3, we investigated the role of MNAR in VDR mediated signaling and osteoblast function. We have shown that endogenous MNAR, c-Src, and VDR interact in a ligand-dependent manner. Further analysis using GST pulldown experiments reveal that the ligand-dependent interactions between VDR/MNAR and VDR/c-Src are direct, and require the receptor's ligand binding domain (LBD). The SH2 domain of Src is sufficient for the VDR/Src interaction, while the VDR/MNAR interaction requires one of MNAR's LXXLL motifs. We have previously reported that MNAR interacts with the SH3 domain of Src through an N-terminal PXXP motif (Barletta *et. al*., Molecular Endocrinology, 18:1096-1108,2004). We propose that VDR, MNAR, and c-Src form a ligand-inducible ternary complex through these interactions, similar to the formation of the ER/MNAR/Src complex. We show that MNAR can modulate the ability of 1,25D3 to activate the MAPK pathway, resulting in the phosphorylation of Erk 1/2. Overexpression of MNAR in UMR-106 cells results in a 4-fold increase of the 1,25D3 induced levels of phosphorylated Erk 1/2 at 5 min with a 20 min treatment resulting in a 9-fold enhancement. Additionally, the 1,25D3 induced expression of two markers of osteoblast differentiation, osteocalcin (OC) and alkaline phosphatase (AP), are also enhanced by MNAR overexpression. The 1,25D3 induction of alkaline phosphatase activity is blocked by co-treatment with both Src kinase and PI3K inhibitors, PP2 and LY294002, respectively. However, co-treatment with the PKC inhibitor, Go6983, was unable to block the induction of AP. These results suggest the involvement of both Src and PI3K activation in osteoblast differentiation and indicate that MNAR may play an important role in VDR-mediated signaling and osteoblast development.

Alternative Splicing of Human Vitamin D 24-Hydroxylase (CYP24) Gene. S. Ren[1], L. Nguyen*[1], M. Hewison[2], J. S. Adams[1]. [1]Endocrinology, Cedars-Sinai Medical Center, Los Angeles, CA, USA, [2]Endocrinology, The University of Birmingham, Birmingham, United Kingdom.

Alternative splicing of genes is more the rule than the exception. 40-60% of the human genes are alternatively spliced. Alternative splicing in cytochrome P450 genes has been reported to cause changes in functional activity, substrate preference, tissue-specific expression and subcellular localization of the P450 proteins. However, the functional consequences of alternative splicing have not been reported with vitamin D metabolizing P450s. We have previously reported that alternative splicing of avian CYP24 gene produced a cytoplasmically-localized (i.e. exo-mitochodrial), truncated protein in chick macrophage HD-11 cells. This splice variant, which retains its promoter-driven 1,25-dihydroxyvitamin D (1,25-D) responsiveness but lacks a mitochondria targeting domain, functions to down-regulate 1,25-D production by acting as a catabolically-inactive decoy acceptor of substrate 25-hydroxyvitamin D (25-D). We hypothesized that this mode of altering 1,25-D catabolism by creation of a non-metabolically-active CYP24 gene product was not unique to avian species. We now report that similar alternative splicing events exist in human cells. Using total RNA from the human monocytic cell line THP-1 post-exposure to 1,25-D as template and a series of nested, bridging primers derived from adjacent exons and introns of the human CYP24 gene to perform RT-PCR, four splice variants (SVs) of the human CYP24 gene have been identified and cloned. One of the SVs, the CYP24-SV1, recapitulated the splicing pattern of the chick CYP24 gene and encoded an N-terminally-truncated protein. The human CYP24-SV1 1] lacked the mitochondria targeting domain, missing the N-terminal 139 amino acids of the holo protein, but 2] retained an intact sterol-binding domain. This structure permitted the CYP24-SV1 product to be capable of capturing substrate 25-D but unable to be inserted in the mitochondria membrane and function to catabolize 1,25-D. As a consequence, transient transfection of antisense CYP24-SV1 cDNA in THP-1 cells increased the 1,25-D production by 40% ($p = 0.03$) compared to the control, vector-alone-transfected cells. A screen of human tissue-specific expression of the CYP24-SV1 revealed its presence in decidual cells of the placenta, epidermal keratinoncytes, as well as in other macrophage-like cells, all recognized extra-renal sites for 1,25-D hormone synthesis. In summary, alternative splicing of the human CYP24 gene appears to be a means of regulating 1,25-D production at extra-renal sites by securing substrate 25-D in the cell cytoplasm and away from the mitochondrial hydroxylation machinery.

Change in Maternal Calcaneal QUS during Pregnancy and Intrauterine Bone Mineral Accrual in the Offspring. M. K. Javaid[1], S. Crozier*[1], P. Taylor*[2], N. Harvey*[1], E. Dennison*[1], H. M. Inskip*[1], K. Godfrey*[1], N. Arden*[1], C. Cooper*[1]. [1]Medical Research Council Environmental Epidemiology Unit, Southampton, United Kingdom, [2]Southampton University Hospitals NHS Trust, Southampton, United Kingdom.

During pregnancy, the fetus acquires 30g of calcium for skeletal growth and to meet this demand the mother undergoes several adaptations including increased bone resorption. We have previously demonstrated that lower maternal milk intake and nulliparity are associated with accelerated loss in maternal calcaneal QUS measurements during pregnancy; however, it is not known whether measured changes in maternal skeletal status influence fetal bone mineral accrual. We have therefore investigated the relationship between change in maternal calcaneal QUS during pregnancy, as measured by an Hologic Sahara instrument, and neonatal whole body BMC, measured using a Lunar DPX-L, in a sample of 106 pregnancies from the Southampton Women's Survey, a longitudinal study of healthy mothers whose lifestyle and anthropometry was assessed during early and late pregnancy. The QUS measurements were performed at 11 and 34 weeks and the neonatal DXA scans performed within 2 weeks of birth.

During pregnancy, there were significant reductions in maternal calcaneal SOS (-0.34 SD, p<0.001) and BUA (-0.22 SD, p<0.001). Mothers with larger reductions in calcaneal SOS during pregnancy had babies with greater whole body bone mineral content and bone area (r=-0.22, p=0.04 and r=-0.23,p=0.02, respectively, adjsuting for maternal size) This relationship was not weakened by adjustment for changes in maternal heel width, parity, milk intake or season during early pregnancy. Change in maternal QUS was weakly negatively associated with neonatal lean mass but there was little association with neonatal fat mass.

These findings suggest the maternal skeletal response to pregnancy is an important determinant of linear foetal growth. The mechanism is likely to involve the capacity of maternal skeleton to deliver mineral balanced with the fetal demand. Further investigation of the mechanisms involved may lead to strategies to optimize peak bone mass accrual.

Impact of Parathyroid Status and Ca and Vitamin-D Supplementation on bone Mass and Muscle-Bone Relationships in 208 Belarussian Children after Thyroidectomy because of Thyroid Carcinoma. P. Schneider[1], J. Biko*[1], C. Reiners*[1], Y. Demidchik*[2], V. Drozd*[2], R. Capozza*[3], G. Cointry*[3], J. Ferretti[3]. [1]Clinic for Nuclear Medicine, University of Wuerzburg, Wuerzburg, Germany, [2]Endocrinology, University of Minsk, Wuerzburg, Belarus, [3]Cemfoc, University of Rosario, Rosario, Argentina.

This observational study analyses Ca-P metabolism and its impact on bone mass accrual and density and the muscle-bone mass/mass relationship in male and female children and adolescents who were parathyroidectomized because of thyroid carcinoma.

208 children and adolescents (119 girls and 89 boys) from Gomel city (Belarus) and its rural surroundings were referred to our institution after having undergone total thyroidectomy for the treatment of advanced papillary thyroid cancer. A subgroup of children with demonstrated primary hypoparathyroidism received dihydrotachysterol (AT-10) and / or Ca supplementation. Among routine procedures over a maximum follow-up period of 5 years (average 3.7 years, maximum 8 visits), whole- body scans were taken using dual energy X-ray absorptiometry (DXA) at each visit in order to determine whole-body bone mineral content (TBMC), projected "areal" bone mineral density (TBMD), total lean mass (TLM) and total fat mass (TFM).

The average serum Ca, P and AP concentrations over the whole observation period were significantly different between the groups; however, TBMC z-scores for all studied children were statistically similar in all visits. In girls, no between-group differences in height- and weight-controlled TBMC and TBMD or the TBMC/TLM ratio were observed and supplementation exerted no effect on these data, suggesting that the total bone mass accrual was not impaired by PTH deficiency in the studied conditions. However, non-supplemented boys showed lower values of the TBMC/TLM ratio than girls, and supplementation normalized these values in direct correlation with the induced improvement in serum P availability to bone.

Results indicate that the primary impairment in parathyroid function and bone metabolism indicators in the thyroidectomized children was unrelated to any measurable change in crude bone mass values. However, in boys this condition impaired the TBMC/TLM ratio in such a way that the administered supplementation could normalize it as a function of improved P availability. Girls´ skeleton seemed to have been naturally protected against the negative metabolic effect of the studied condition. An estrogen-induced enhancement of the biomechanical impact of muscle contractions on bone mass and structure could not be excluded in this group.

Body Composition of Newborn Twins Versus Singletons. S. DeMarini*[1], W. W. K. Koo[2], E. M. Hockman*[3]. [1]Neonatology, Istituto per l'Infanzia, Trieste, Italy, [2]Pediatrics, Wayne State University, Detroit, MI, USA, [3]Computing and Information Technology, University of Tennessee, Memphis, TN, USA.

At birth, infants from multiple gestations frequently weighed less than gestation matched singletons. However, there are no data to indicate whether normally grown twins have same bone mass and body composition as normal singletons. Anthropometric and dual energy X ray absorptiometry (DXA) measurements were performed in 76 infants from twin gestations with appropriate birth weights (between the 10th and 90th percentile) for gestational age (AGA), and same number of AGA singleton neonates matched as closely as possible for birth weight. Studies were performed at a mean of 3.8 ± 3.2 days after birth. Clinical details of study subjects are shown in Table 1. The absolute and percentage of each component of bone mass and body composition are shown in Table 2.

We conclude that for normally grown neonates, the body composition, with respect to bone, fat and lean mass components, is similar regardless of whether they are products of singleton or twin pregnancies.

Table 1. Clinical details of twins with appropriate birth weight for gestation (AGA) matched for birth weight of AGA singletons*

	AGA Twin	Matched Singleton
n	76	76
Birth weight (g)	2191 ± 50	2200 ± 51
Gestational age (weeks)	34.5 ± 0.3	34.4 ± 0.3
White/Black/Asian	14/61/1	26/50/0
Male/Female	44/32	44/32
Naked weight (g) at study	2128 ± 49	2119 ± 52
Study length (cm)	43.9 ± 0.2	44.1 ± 0.3
Study head circumference (cm)	31.5 ± 0.2	31.1 ± 0.2

* Measure of agreement for race and sex, kappa coefficient = 0.642 and 1.000 respectively, p <0.001 for both. Independent samples t-test for other comparisons, no significant difference between groups. Values are expressed as mean ± SE.

Table 2. Dual energy X ray absorptiometry (DXA) measurements of appropriate birthweight for gestation twins versus matched singletons (n = 76 per group)

	Bone mineral content	Fat mass	Lean mass
Absolute Values			
Twin	38.2 ± 1.1	243 ± 11	1926 ± 41
Singleton	39.5 ± 1.2	235 ± 10	1939 ± 44
As percentage of total weights			
Twin	1.71 ± 0.02	10.7 ± 0.3	87.5 ± 0.3
Singleton	1.76 ± 0.02	10.4 ± 0.2	87.9 ± 0.2

AGA = appropriate for gestation. Profile analysis using repeated measure analysis of variance showed that there were no significant differences in bone, fat and lean mass either as absolute values or as percentage of total weight. Values are expressed as mean ± SE.

Site-specificity in Differential Rates of Bone Mineral Accrual from Adolescence into Adulthood. D. A. Bailey, A. D. G. Baxter-Jones*, R. L. Mirwald*, R. A. Faulkner. College of Kinesiology, University of Saskatchewan, Saskatoon, SK, Canada.

The tempo of bone mineral accrual during the growing years may have implications in terms of adolescent fracture risk and fracture prediction as an adult. In this study 51 boys and 56 girls were measured annually for six consecutive years across the adolescent growth spurt and again five years later when all the subjects had reached skeletal maturity with a mean age of 22.2 ± 1.9 y and 21.0 ± 1.9 y for the boys and girls respectively. Bone mineral content of the lumbar spine (L1 to L4), femoral neck and total body was measured by DXA (Hologic 2000 QDR in the array mode). The purpose of the study was to determine the percentage of adult status attained at similar developmental ages during adolescence for the total body, lumbar spine and the femoral neck compared to linear growth. The developmental age points chosen for comparison were the age of peak height velocity

(PHV), mean age for girls 11.8 ± .85 y and for boys 13.4 ± 1.0, and two years beyond the age of peak height velocity (PHV +2). As shown in the following table, at the ages of PHV and PHV +2, BMC of the femoral neck is much more advanced (closer to adult status) than BMC for the lumbar spine or total body. In terms of percentage of adult status, BMC for all sites in both sexes lags behind linear growth in height, indicating a possible transient period of relative skeletal weakness during adolescence. No gender-specific differences in percent adult values were observed.

Percent Adult Bone Mineral Content

	Males		Females	
	At Age of PHV	At Age PHV+2	At Age of PHV	At Age PHV+2
Height	91%	99%	92%	99%
BMC Fem. Nk.	74%	95%	75%	94%
BMC Tot Body	57%	81%	60%	80%
BMC PA Spine	52%	82%	52%	81%

Sexual Dimorphism in Cortical Bone Characteristics across Puberty: 20-month pQCT Study of the Tibial Shaft. S. Kontulainen[1], S. Manske*[2], K. Khan*[3], H. McKay[4], H. Macdonald*[5]. [1]Department of Orthopaedics, University of British Columbia, Faculty of Medicine, Vancouver, BC, Canada, [2]University of British Columbia, School of Human Kinetics, Vancouver, BC, Canada, [3]University of British Columbia, Faculty of Medicine, Vancouver, BC, Canada, [4]Department of Orthopaedic Engineering Research, University of British Columbia, Faculty of Medicine, Vancouver, BC, Canada, [5]School of Human Kinetics, University of British Columbia, Vancouver, BC, Canada.

Greater fracture risk in women compared with men can be attributed to a smaller female skeleton that experiences greater cortical thinning after menopause. Sex differences in bone size and density are evident at puberty. However, there are no longitudinal data that describe sex-differences in cortical bone cross-sectional geometry, density and its distribution across puberty. We assessed 20-month bone structural and material changes by peripheral quantitative computed tomography (pQCT) at the 30 and 50% sites of the tibial shaft across EARLY-, PERI- and POST -puberty in boys (N=60) and girls (N=68). pQCT scans were analysed using Bonalyse 2.1 software (BonAlyse Oy, Jyväskylä). Outcome variables were total, and cortical bone cross-sectional areas (*ToA, CoA,* mm^2 respectively), *CoA/ToA,* area of marrow cavity (*CavA,* mm^2), average cortical bone mineral density (*CoD,* mg/cm^3) and radial distribution of cortical density.

ToA and CoA did not differ between sexes within maturity groups at baseline. ToA and CoA increased more for boys (p<0.05) than girls in all maturity group. We observed no endosteal contraction for girls across maturity although marrow cavity increased less for girls compared with boys. Changes in the *CoA/ToA*-ratio did not differ between sexes. *Cortical density* was greater for girls in each maturity group at baseline, and EARLY- and PERI-pubertal girls also increased CoD significantly more (p<0.001) than boys (Fig 1). An examination of radial distribution showed that increased CoD was explained by increased CoD throughout the midcortex. Increase in bone size is greater for boys than girls at puberty. In contrast, girls increase cortical density more than boys. This sexual dimorphism of CoD is consistent with the hypothesis that rising estrogen levels in girls induce consolidation of bone mineral as maturity progresses.

Figure 1. Change in the average cortical density between sexes and maturity categories.

What Factors Contribute Toward Maximizing Peak Bone Mass in Japanese Young Women? Y. Onoe[1], Y. Miyabara*[1], R. Yoshikata*[1], A. Harada*[2], H. Okano[1], S. Sasaki*[3], T. Kuroda*[4], M. Shiraki[5], H. Ohta[1]. [1]Obstetrics and Gynecology, Tokyo Wemen's University, Tokyo, Japan, [2]Biostatistics, University of Tokyo, Tokyo, Japan, [3]National Institute of Health and Nutrition, Tokyo, Japan, [4]Public Health Research Foundation, Tokyo, Japan, [5]Research Institute and Practice for Involutional Diseases, Nagano, Japan.

Lifestyle management, including moderate physical activity and nutritional intake required for bone health, is assumed to play a key role in maximizing peak bone mass. However, these factors remain to be prioritized, as well as weighed for their relative impact on bone mass accumulation. This cross-sectional study was designed to establish a methodology for maximizing peak bone mass in young Japanese women by investigating the impact of intake of various nutrients, as well as physical activity, on BMD values in these women.

The study subjects (n = 139) comprised healthy women aged between 19 to 25 years of age. Subject background data surveyed included age, weight at birth, age at menarche, and current menstrual status. Measurements included height, body weight, lumbar vertebrae 2-4 BMD (L 2-4 BMD), and total BMD of the proximal femur (QDR 4500). To evaluate physical activity in these subjects, we used the number of steps taken per week as measured by using Suzuken Lifecorder EX. Nutritional intake by these subjects was evaluated by means of a self-administered Diet History Questionnaire (DHQ), and physical activity by the Physical Activity Questionnaire (PAQ) developed by the JALS Physical Activity Working Group.

Mean weight at birth was 3,101 g; mean age at menarche was 12.0 years of age; and L 2-4 BMD and total BMD of the proximal femur were 0.90 g/cm^2 and 0.99 g/cm^2, respectively. Based on the interquartile analysis of their L 2-4 values, study subjects were divided into a low-BMD group (L 2-4 BMD < 0.92 g/cm^2), or a high-BMD group (L 2-4 BMD > 0.92 g/cm^2). The variables for which statistically significant differences were noted between these groups were height, body weight, body mass index (BMI), weight at birth, total energy on the PAQ, energy expenditure as measured by using Lifecorder EX, cholesterol and P on the DHQ. Thus, height was shown to be significantly (p < 0.01) shorter, body weight significantly (p <0.01) lighter, and weight at birth significantly (p < 0.05) lighter in the low-BMD group, compared to the high-BMD group.

Bone Mass Status of the School-Aged Children in Taiwan Assessed by Quantitative Ultrasound - Preliminary Results of the Nutrition and Health Survey in Taiwan, 2001-2002. Y. Lin[1], S. Tu*[2], W. Pan*[1]. [1]Institute fo Biomedical Sciences, Academia Sinica, Taipei, Taiwan Republic of China, [2]Center for Survey Research, Academia Sinica, Taipei, Taiwan Republic of China.

Bone health status in childhood and adolescence may be important factors influencing the attainment of peak bone mass. The Children Nutrition and Health Survey in Taiwan, 2001-2002 was carried out to evaluate the overall nutrition and health status of school children aged between 6 and 13 years. The survey was conducted using a multi-stage complex sampling scheme. Townships and city districts in Taiwan were classified into 13 strata. Bone mass measured as broadband ultrasound attenuation (BUA, in dB/MHz) was taken at heel by quantitative ultrasound (QUS) bone densitometry (CUBA Clinical, McCue), and the corresponding Z-score was calculated. 1164 boys and 1016 girls who had complete physical examination data with ultrasound bone scan were included in the current analysis. Statistical analyses were performed using SAS v8.1 and SUDAAN v8.0. All variables were weighted to represent the children population in Taiwan.

Subjects were grouped by gender and/or age. The overall mean BUA Z-score was -0.55±0.02 for boys and -0.25±0.03 for girls, respectively, and girls had significantly higher mean BUA Z-score than boys. Most boys and girls had BUA Z-score in between 0 and -1 (45.8% of the boys and 49.3% of the girls, respectively), and 36.3% of the boys and 22.2% of the girls had BUA Z-score below -1. There were no apparent differences in BUA across all strata for both genders. Results of univariate regression analyses showed that in both genders, age (r^2=0.29 for boys and r^2=0.26 for girls), height (r^2=0.36 for boys and r^2=0.35 for girls), body weight (r^2=0.36 for boys and r^2=0.37 for girls) and BMI (r^2=0.18 for boys and r^2=0.19 for girls) were significant predictors of BUA (p<0.0001 for all the variables above in boys and girls, respectively). In boys, there was a significant inverse relationship between age and BUA Z-score (β=-0.11, p<0.0001). Similar inverse association was also observed in girls with less significance (β=-0.04, p=0.0236).

This is the first island-wide survey with the attempt of using QUS bone densitometry as the screening tool to investigate the bone health status of the children in Taiwan. The inverse association between age and BUA Z-score as shown in the results suggested that the strategies enhancing the accrual of bone mass may be considered to prevent suboptimal development of bone mass in children in Taiwan

Seasonal Variation of BMC in Lumbar Spine and Hip in Early-puberty Girls. H. T. Viljakainen*[1], A. Palssa*[1], A. Natri*[1], J. Jakobsen*[2], K. D. Cashman*[3], C. Mølgaard*[4], C. Lamberg-Allardt[1]. [1]Department of Applied Chemistry and Microbiology, division Nutrition, University of Helsinki, Helsinki, Finland, [2]Danish Institute for Food and Veterinary Research, Söborg, Denmark, [3]Department of Food and Nutritional Sciences, University College Cork, Ireland, [4]Research Department of Human Nutrition, The Royal Veterinary and Agricultural University, Frederiksberg C, Denmark.

The seasonal variation of serum 25-hydroxy-vitamin D (25-OHD) and calciotrophic hormones is thought to determine the seasonal variation of bone mass. In healthy adults it is shown to compromise a 2%-variation, but in adolescent girls it has not been reported. Furthermore, the impact the seasonal variation has on growing bones has not been fully investigated.

The aim of this study was to define the existence of a seasonal variation in serum 25-OHD, parathyroid hormone (PTH), bone markers and site-specific bone mineral content (BMC) in early-puberty Finnish girls.

Subjects (N=196) were healthy Finnish early-puberty Caucasian girls, mean (sd) age 11.4 (0.4) y, recruited from the Helsinki area from September 2001 to March 2002. Of the subjects 77.4% scored in Tanner 2 (T2) and 32.6% in Tanner 3 (T3). Their median daily dietary intakes of calcium and vitamin D were 1240 (700) mg and 4.7 (4.1) µg, respectively.

Serum 25-OHD was measured from fasting samples by a HPLC method, intact PTH by OSTEIA assay and osteocalcin by ELISA. Bone mineral densities were measured by DXA Hologic 4500 at the lumbar spine (L1-L4) and the left femoral neck. In the analysis BMC was adjusted for bone area and age.

We found a seasonal variation in serum 25-OHD, which was higher in autumn (September-October) than in winter (November-March) ($p<0.0001$), but PTH did not differ between season. A seasonal variation in BMC in lumbar spine and at the femoral neck was observed in the T2-girls: in autumn the BMC was 5.35% higher in the lumbar spine ($p=0.007$) and 4.81% higher BMC in hip ($p=0.03$) than girls measured in the winter, after adjustment for bone area and age. Moreover, the osteocalcin concentration was higher in autumn than in winter ($p=0.04$) in T2. No variation was observed in the BMC or osteocalcin in girls in T3. In conclusion, a seasonal variation in both 25-OHD and in site-specific BMC was observed, even though no correlation was found. However, the results differed between puberty development stages 2 and 3. Whether this variation is of clinical importance remains to be evaluated.

A Transgenic Dwarf Rat Strain as an Experimental Model for the Study of Senile Osteoporosis. M. Tomita[1], I. Shimokawa*[2], S. Motokawa*[3]. [1]Medicine, Orthopaedic Surgery, Kitakyushu City Yahata Hospital, Kitakyushu, Fukuoka, Japan, [2]Medicine, Pathology & Gerontology, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan, [3]Medicine, Orthopaedic Surgery, National Nagasaki Medical Center, Omura, Nagasaki, Japan.

Introduction: Bone mineral density (BMD) is known to decrease with advancing age, a condition of senile osteoporosis. Secretion of growth hormone (GH) and insulin like growth factor-1 (IGF-1) are also known to decrease with age. In order to elucidate the effect of GH-IGF-1 axis on age-dependent changes in BMD, we analyzed the femoral bone in the transgenic dwarf rat strain in which GH-IGF-1 axis is selectively suppressed by over-expression of antisense GH-gene. Materials and Methods: Transgenic male rats (mini), control Wistar (WT) rats, and their F1 hybrid rats (F1) were used. At 6, 15, and 24 months of age, rats were sacrificed and femoral bones were removed to measure the length and BMD with peripheral quantitative CT (pQCT). On sacrifice at 6 months of age, we also collected trunk blood to measure the plasma IGF-1 concentration by radioimmunoassay (RIA). Results: Mean plasma concentrations of IGF-1 were 1058.3 ng/ml in WT, 626.5 ng/ml in F1, and 265.8 ng/ml in mini. The length of femoral bones was significantly shorter in mini and F1 than WT, but there were no significant differences between mini and F1. BMD of the cortical and cancellous bones of femoral bone significantly decreased in mini, and F1 rats, as compared with WT rats; BMD in F1 was greater than mini. BMD of the cancellous bone, but not of the cortical bone, was decreased with age. The age-dependent decrease of cancerous bone BMD was suppressed in mini. Discussion: In human, BMD decreases with age, and this change is obviously seen in the cancellous bone but not in the cortical bone. WT rats showed a similar age-dependent decrease of BMD. In mini and F1 rats, BMD in the cancellous bone was decreased even at the young age. The present results suggest that selective suppression of GH-IGF-1 axis alone produces a condition similar to that of senile osteoporosis in the young age; thus the transgenic rat strain is a useful animal model to study human osteoporosis.

Increased Osteonal Degree of Mineralization Was Associated with Deteriorated Cortical Structure in the Fibular Shaft of Aged Women. T. Mashiba, S. Mori, N. Gomi*, Y. Kaji*, T. Manabe*, H. Norimatsu. Dept. of Orthopedic Surgery, Faculty of Medicine, Kagawa University, Kagawa, Japan.

Age related changes in bone quality have not been clarified yet. This study was designed to evaluate the effects of aging on the cross-sectional structure and degree of mineralization in the cortical bone of human fibular diaphyses.

Specimens for this study came from fibular mid-shafts of nineteen women (50-78 y.o.) who underwent high tibial osteotomy for medial type osteoarthritis or osteonecrosis of the knee. The protocol of this study has been checked and approved by the clinical research institute of Kagawa University. The collected bones were stored frozen at -80°C until specimens were made. After thawing at room temperature, they were stained en-bloc with 1% basic fuchsin dissolved in ascending concentration of ethanol, defatted with xylene, and embedded in methyl methacrylate. A 125 µm-thick transverse ground section was made for the static histomorphometry and measurement of degree of mineralization of bone (DMB). For DMB measurement, quantitative contact microradiograph was taken and DMB at each osteon was calculated using a computerized microdensitometric method. Measured DMB parameters include mean osteonal DMB and the distribution of osteon based on DMB. Age related changes in static cortical histomorphometric parameters and DMB parameters were evaluated.

Percent cortical area and cortical thickness decreased with age whereas total cross sectional area was not significantly changed. Medullary area and cortical porosity increased with age. Mean osteonal DMB significantly increased with age. Especially in the patients over 70 years old, the range of distribution of osteonal DMB was higher and narrowed in association with the decrease in the number of osteons with lower DMB when compared with younger patients.

As previously reported, cross sectional geometrical evaluation in this study demonstrated the age related structural deterioration of cortical bone, characterized by the bone marrow expansion, cortical thinning and increased cortical porosity. Because older osteon should have higher DMB, narrow and higher distribution of DMB in aged patients also suggests that replacement of old into new osteon was suppressed by lower osteonal remodeling activity. However, increased mean osteonal DMB shown in aged patients changes bone quality and this may be a compensative mechanism for the structural deterioration to maintain the mechanical strength of cortical bone.

Kudzu Isoflavones Reduce Bone Loss in Ovariectomized Rats. J. Yong*. Foods & Nutrition, Purdue University, West Lafayette, IN, USA.

Isoflavones have been proposed as an alternative to steroid hormone replacement therapy to prevent postmenopausal bone loss. Soy isoflavones have been the most studied. Kudzu is another rich source of isoflavones. Puerarin, the main isoflavone from Kudzu root, is more effective at binding to ER-β than any other legume isoflavones. The objective of the present study was to determine whether Kudzu isoflavones reduce postmenopausal bone loss in an older ovariectomized rat model. Kudzu powder was given as a dietary supplement to 6-month-old ovariectimized Sprague Dawley rats for 8 weeks with an isoflavone concentration of 5g/kg diet in the high dose group, 0.05 g/kg diet in the low dose group and 0g/kg diet in the control group (n = 15/group). BMD and BMC of cortical and trabecular bone were analyzed by pQCT. By the end of the treatment, uterine weight in the high dose group was significantly ($P < 0.05$) higher than in the low dose and control groups. At the intertrochanteric site, total BMC, trabecular area, BMD, cortical area, BMC were significantly ($P < 0.05$) higher in the high dose group than in control and low dose groups. At the midshaft site, cortical area and cortical BMC were significantly ($P < 0.05$) higher in the high dose group than in low dose and control groups; At the distal site, total BMD and trabecular BMD were significantly ($P < 0.05$) higher in the high dose group than in low dose and control groups. This study indicates that Kudzu isoflavones have an estrogenic effect on the uterus. Kudzu isoflavones can reduce bone loss caused by estrogen deficiency in both trabecular and cortical bone, but the effect is site specific.

Young-Elderly Differences In Medullary Compartment Size, Bone Mass, And Density At The Femoral Neck And Trochanteric Region In Caucasian Women. M. Meta[1], Y. Lu[1], K. Joyce[2], T. Lang[1]. [1]Radiology, University of California San Francisco, San Francisco, CA, USA, [2]Orthopedic Surgery, University of California Irvine, Irvine, CA, USA.

At the proximal femur, aging is characterized by cortical thinning, periosteal apposition, and decreased bone mass. However, differences in size and bone distribution in the tissue adjacent to the cortical compartment (subcortical) and in the center of the medullary compartment (central trabecular) have not been examined. To address this issue 28 young (41±3 years) and 129 elderly (74 ±3 years) healthy Caucasian-American women underwent volumetric quantitative computed tomography (vQCT) at the hip. We estimated medullary (m), subcortical (sc) and central trabecular (ct) volume (VOL), bone mineral content (BMC) and bone mineral density (BMD) at the femoral neck (FN) and trochanteric (TR) regions. The F-test was used to compare mean differences between young and elderly after adjusting for height and body mass

index in an ANOCOVA model. Mean values (SD) are tabulated below. The F-test for interaction compared logarithmic young/elderly differences between FN and TR after adjusting for height and body mass index in an ANOCOVA model. P-values are tabulated below.

	mVOL cm^3	scVOL cm^3	ctVOL cm^3	mBMC g	scBMC g	ctBMC g	mBMD g/cm^3	scBMD g/cm^3	ctBMD g/cm^3
Femoral Neck									
Young	6.30 [a] (2.07)	3.65 [a] (1.21)	2.65 [a] (1.08)	0.81 [ns] (0.26)	0.47 [c] (0.14)	0.35 [a] (0.15)	0.132 [a] (0.03)	0.133 [a] (0.02)	0.130 [a] (0.04)
Elderly	8.76 (2.86)	5.75 (1.66)	3.06 (1.35)	0.75 (0.39)	0.58 (0.23)	0.17 (0.20)	0.085 (0.03)	0.102 (0.02)	0.049 (0.04)
Trochanteric									
Young	35.30 [a] (7.86)	13.77 [a] (2.91)	21.53 [a] (5.33)	4.80 [ns] (0.87)	2.08 [a] (0.33)	2.72 [a] (0.69)	0.140 [a] (0.04)	0.155 [a] (0.03)	0.130 [a] (0.03)
Elderly	43.40 (10.05)	19.01 (4.22)	24.78 (5.54)	4.50 (1.44)	2.45 (0.66)	2.08 0.84	0.105 (0.03)	0.130 (0.03)	0.086 (0.03)
p-value FN/TR	0.044	0.029	0.719	0.967	0.420	0.001	0.069	0.132	0.0001

p value (young vs elderly) [a] $p<0.001$, [b] $p<0.01$, [c] $p<0.05$, [ns] $p>0.05$.

In the elderly medullary size is larger, ct bone mass is lower and interestingly, subcortical bone mass is larger with no inter-site difference. The FN showed a larger cross-sectional age-related decrease in trabecular BMD and increase in sc and medullary spaces than the TR. The larger young-old differences in BMD and volume at the FN may be due to differences in modes of mechanical loading between these two anatomic sites.

Aging Is Associated with Up-Regulation of Insulin-like Growth Factor Receptor Type I (IGF-I) and Down-Regulation of IGF-I Signaling Pathways. J. J. Cao, P. S. Kurimoto*, B. P. Halloran. Medicine, UCSF, San Francisco, CA, USA.

Osteoblast activity and bone formation decrease with aging, as does the serum concentration of IGF-I. That IGF-I is abundant in bone, and can stimulate osteoblast formation and activity suggests that decrease in serum IGF-I, alterations in IGF-I signaling or both may contribute to age-related bone loss. To determine whether aging affects IGF-I intra-cellular signaling in osteoblasts, we examined the effect of IGF-I on bone *in vivo* and bone marrow stromal cells (BMSCs) cultured *in vitro* from 6 week (young), 6 month (adult), and 24 month (old) old mice. We evaluated the response of BMSCs to IGF-I administration with respect to activation of two IGF-I signaling pathways *in vitro* i.e. the Ras/MAPK pathway and the phosphatidy inositol 3 kinase (PI3K)/Akt pathway. With aging, IGF-I receptor expression increased at both the message and protein levels. Treatment with IGF-I for two hours had no effect on its receptor expression. Total ERK and the basal level of phosphorylated MEK and ERK did not change with age. IGF-I stimulated the activation of MEK and ERK 1/2 (p44/42 MAPK) in cultured BMSCs from young mice, but these effects were blunted in cells from mice of increasing age. These data suggest that the responsiveness of BMSCs to IGF-I treatment decreases with age and is in part due to down-regulation of IGF-I signaling.

Subcellular Trafficking and Potential Functions of Klotho Proteins. J. Barsony[1], Y. Nabeshima*[2], J. G. Verbalis*[1]. [1]Division of Endocrinology and Metabolism, Georgetown University, Washington, DC, USA, [2]Department of Pathology and Tumor Biology, Kyoto University, Kyoto, Japan.

The recently discovered klotho gene products are thought to be negative regulators of the ageing process by protecting mammals against of ageing-related diseases including osteoporosis. Disruption of the klotho gene in mice decreased the number of osteoblast progenitors in the bone marrow and decreased the activities of osteoblastic cells. The klotho gene is predominantly expressed in the kidney and encodes a type I membrane protein with a large N-terminal extracellular domain. The effects of Klotho in bone and other tissues were presumed to be due to a humoral factor. Interestingly, the 130 kD Klotho protein has also been recently detected in human and mouse sera and cerebrospinal fluid, and appeared to be generated by proteolytic cleavage from the membrane-bound Klotho. To gain initial insight into the mechanisms of klotho functions, we generated fluorescent protein fusions of Klotho: a C-terminal fusion for the detection of the membrane-bound protein (Kl-GFP) and an N-terminal fusion (GFP-Kl) for the detection of the circulating form. Fusion proteins were stably expressed in kidney-derived cells (COS, LNCaP). Confocal laser scanning microscopy in living cells demonstrated for the first time distinct subcellular distribution and functions of klotho proteins in the kidney and in a target cell population (SaOS-2 human osteoblastic cells). Under steady-state conditions, Kl-GFP was predominantly at the plasma membrane (PM) of kidney-derived cells and underwent rapid endocytosis following treatment with insulin. The Kl-GFP containing endocytic vesicles fused with the Golgi after 15 minutes and returned to the PM by 30-60 min. This finding, in conjunction with reported effect of klotho decreasing insulin sensitivity, strongly suggests that klotho plays a role in insulin signaling in the kidney. The second fusion protein, GFP-Kl, was detected intracellularly and in the culture media. GFP-Kl colocalized with markers of endoplasmic reticulum (rhodamine B) and mitochondria (red MitoTracker CMX) in kidney-derived cells. GFP-Kl was also secreted into the culture media. Culture media was collected from COS-7 cells expressing GFP-Kl for 6 hours and was added to SaOS-2 cells. The GFP-Kl taken up from the media was readily detectable in vesicles and in the mitochondria of SaOS-2 cells. GFP-Kl protected mitochondrial morphology and membrane potential from hydrogen peroxide or tobacco extract induced oxidative stress in SaOS-2 cells. These findings suggest that protection of mitochondrial integrity and modulation of energy production in osteoblasts may contribute to the bone-protective effect of klotho.

β-Adrenergic Receptor Antagonist Enhances Ectopic Bone Formation Induced by Bone Morphogenetic Protein 2 and Fibroblast Growth Factor 2 in Rodent. T. Suzuki*[1], H. Takita*[2], A. Yokoyama*[1], M. Tamura[2]. [1]Oral Functional Science, Graduate School of Dental Medicine, Hokkaido University, Sapporo, Japan, [2]Department of Biochemistry and Molecular Biology, Graduate School of Dental Medicine, Hokkaido University, Sapporo, Japan.

The existence of systemic control of osteoblast activity and bone formation has been the subject of speculation for some time. Leptin has been identified as a powerful inhibitor of bone formation. Subsequent studies have led to the identification of hypothalamic neurons involved in this anti-osteogenic function of leptin and the sympathetic nervous system has been identified as its peripheral mediator. Takeda et al. (2002) also showed that catecholamine-deficient mice have a high bone mass and beta-blockers increase bone formation and bone mass. However, it is not clear how local bone formation is controlled by the sympathetic nervous system or what molecular mechanisms are involved. Here, we examined whether local application of the β-adrenergic receptor antagonist, propranolol, modulated ectopic bone formation induced by bone morphogenetic protein (BMP) 2 and fibroblast growth factor (FGF) 2 in the rat. Propranolol or vehicle together with 0.8 μg of BMP2 and 0.1 μg of FGF2 were mixed with fibrous glass membrane as a carrier and implanted subcutaneously into the back of male rats weighting 60-70g. After 2 weeks, soft X-ray radiographs showed a trabecular pattern indicating that formation of calcified trabeculae was increased by application of propranolol compared with vehicle. Calcium content, ALP activity and mRNA expression of α1(I) collagen, osteocalcin and Runx2 of implants also increased with application of propranolol, indicating that local application of propranolol enhanced ectopic bone inductive activity in our experimental system. However, when intraperitoneal injections of propranolol were administered daily for 21 consecutive days, we could not detect enhancement of ectopic bone formation by BMP2 and FGF2. These results suggest that osteoblasts in ectopic bone formation might express β-adrenergic receptors and regulate bone formation via synaptic interaction with the central nervous system.

Lentivirus-Mediated BMP-2 Transduction Induced Long-Term Protein Expression In Vitro and New Bone Formation In Vivo. O. Sugiyama*[1], D. An*[2], S. Gamradt*[1], B. T. Feeley*[1], N. Q. Liu*[1], I. S. Y. Chen*[2], J. R. Lieberman*[1]. [1]Orthopaedic Surgery, UCLA David Geffen School of Medicine, Los Angeles, CA, USA, [2]AIDS Institute, UCLA David Geffen School of Medicine, Los Angeles, CA, USA.

Ex vivo gene therapy has the potential to be used to treat difficult bone repair problems. Selection of an appropriate vector is critical to determine the duration of protein expression. Lentiviral vectors are attractive vectors for gene therapy because of the potential for long-term expression and because both dividing and non-dividing cells can be transduced. The objective of this study was to examine the potential for ex vivo gene therapy using a lentiviral vector to enhance bone repair. W-20-17 cells (murine bone marrow stromal cell line) or primary rat bone marrow stromal cells (BMSCs) were transduced with the lentiviral vector encoding enhanced green fluorescent protein (EGFP) under the control of the RhMLV or the CMV promoter (Lenti-RhMLV-EGFP or Lenti-CMV-EGFP). The mean fluorescent intensity (MFI) of EGFP expression was determined in cells by flow cytometry. Lenti-RhMLV-EGFP-transduced cells showed significantly higher MFI than Lenti-CMV-EGFP-transduced cells at 1, 2, 4, 6 and 8 weeks after transduction. Next, we constructed the lentiviral vector encoding human bone morphogenetic protein-2 (BMP-2) cDNA instead of EGFP (Lenti-RhMLV-BMP-2 or Lenti-CMV-BMP-2). W-20-17 cells or rat BMSCs were transduced with these vectors and BMP-2 protein production was detected in media by ELISA. Lenti-RhMLV-BMP-2-transduced cells secreted significantly greater BMP-2 than Lenti-CMV-BMP-2-transduced cells at 2, 4, 6 and 8 weeks. Finally, 2.5 million of rat BMSCs transduced with Lenti-RhMLV-BMP-2 or Lenti-CMV-BMP-2 were implanted into a muscle pouch in hindlimbs of severe combined immune deficient (SCID) mice with a collagen sponge. Three weeks after implantation, ectopic new bone formation was noted on plain radiographs in the hindlimbs of mice implanted with BMP-2 transduced cells. Increased bone formation was noted with implantation of Lenti-RhMLV-BMP-2-transduced cells in comparison to Lenti-CMV-BMP-2-transduced cells. Histological examination revealed woven bone with reconstitution of the bone marrow cavity with implantation of the Lenti-RhMLV-BMP-2-transduced cells. These results demonstrate that lentiviral vectors expressing BMP-2 can induce long-term gene expression in vitro and new bone formation in vivo under the control of the RhMLV promoter. This may be advantageous for developing tissue-engineering strategies to repair large bone defects.

Alendronate Promotes Increased Ossicle Mineralization in a Rat Vascularized Bone Formation Model. M. E. Cunningham*[1], E. A. Tomin[1], S. B. Doty*[2], E. R. Myers*[2], J. M. Lane[1]. [1]Orthopaedics, The Hospital for Special Surgery, New York, NY, USA, [2]Research, The Hospital for Special Surgery, New York, NY, USA.

Vascularized bone grafts are optimal in orthopaedics, providing immediate structural support and accelerated healing, but have unacceptable morbidity. Using a rat model for production of rhBMP-2 induced vascularized neo-ossicles, we previously found rapid early bone production, followed by aggressive late bone resorption. The purpose of the current experiment using osteogenic protein-1 (OP-1/BMP-7) for osteoinduction and alendronate (Fosamax) to limit late bone resorption, was to test the hypotheses: (1) OP-1/bone marrow would form neo-ossicles, (2) OP-1 would have more bone present at late time points than historical controls, and (3) bisphosphonate would prevent late neo-ossicle mineral resorption. Silastic chambers containing isogenic bone marrow and 20 mcg OP-1 were implanted around the inferior epigastric pedicle of male Lewis rats, and neo-ossicles produced were assessed at 1, 2 4 and 8 week time points. Using micro-CT analysis, a significant increase in total mineral content was found between 4 and 8 week samples ($p<0.001$, n=6,9), with alendronate significantly increasing total mineral content in the 8 week samples ($p=0.009$, n=9,8), but not at 4 weeks ($p=0.226$, n=6,8). Histological and histomorphometrical analysis of decalcified sections revealed sparse bone production (1 to 5%) at one week, and a plateau of bone production at 2, 4 and 8 week time points (7 to 12%) that did not trend with time, and did not demonstrate alendronate effects. Maturation of tissues through time was also observed (early red marrow production vs. late fatty marrow, and transition from woven to lamellar bone). We conclude that OP-1 induced neo-ossicle production in this model is comparable to historical controls, that OP-1 does not predispose ossicles to late osteolysis, and that alendronate can be utilized to augment mineralization of neo-ossicles.

Enhanced Osteoblastic Cell Differentiation by Co-transfection with the OP-1 Gene and the IGF-I Gene. L. C. Yeh*, J. C. Lee. Biochemistry (MC7760), Univ. Texas Health Sci. Ctr. at San Antonio, San Antonio, TX, USA.

Osteogenic Protein-1 (OP-1, BMP-7), a member of the bone morphogenetic protein (BMP) family that belongs to the transforming growth factor-β superfamily, induces formation of new bone and cartilage *in vivo*. OP-1 stimulates IGF-I expression in a variety of osteoblastic cells. Previous studies from this laboratory showed that the action of OP-1 on osteoblastic cell differentiation could be enhanced by protein factors, such as IGF-I. In the present study, we examined the effects of gene transfer of osteoblastic cells with an OP-1 expressing plasmid in combination with an IGF-I-expressing plasmid. Fetal rat calvaria (FRC) cells were transfected with pW24, a plasmid that contains the OP-1 gene under the control of the CMV promoter. Transfected cells showed substantial production of OP-1 proteins by Western blot analysis and a maximum 4-fold increase in alkaline phosphatase (AP) activity in a DNA concentration-dependent manner. Mineralized bone nodules were observed in the transfected cells after 26 days in culture, whereas control cells did not exhibit bone nodules under similar experimental conditions. These transfected cells also showed a dose-dependent enhancement in AP activity when treated with exogenous IGF-I. Moreover, the effects of co-transfection of FRC cells with pW24 and pI, a plasmid containing the IGF-I gene under the control of the CMV promoter were examined. FRC cells transfected with a constant amount of pW24 and varying concentrations of pI showed increased AP activity. The increase in AP activity was pI DNA concentration dependent. Control FRC cells transfected with pI alone or co-transfected with both empty plasmids did not exhibit an enhanced AP activity. The observations suggested that the stimulation of AP activity in these co-transfected FRC cells was the result of the synergistic action of OP-1 and IGF-I produced intracellularly under the direction of the plasmid-borne genes. In conclusion, the current data show that transfection of OP-1 gene to osteoblastic cells increases cell differentiation *in vitro*. The present results also extend the previous observation that a synergy between OP-1 and IGF-I exists in stimulating biochemical and morphological markers characteristic of bone cell differentiation when FRC cells were treated with OP-1 and IGF-I proteins. This study demonstrates the feasibility of employing gene transfer of a second gene in combination with an OP-1 vector to produce enhanced OP-1 activity.

Expression of Two Morphogenic Families During Distraction Osteogenesis in Mouse Tibia. K. Jacobsen*, E. Tsiridis*, T. A. Einhorn, L. C. Gerstenfeld, R. S. Carvalho. Orthopaedic Surgery Research Laboratory, Boston University Medical Center, Boston, MA, USA.

Clinical correction of limb length discrepancies has been made possible with the advent of distraction osteogenesis (DO) techniques. Many therapeutic applications have been established to accomplish elongation of long bones which were abnormally short as a result of injury, disease or malformation. A simple and reproducible model of murine tibia DO was developed using a monolateral external fixator. The aim was this study was to assess the expression of two classes of morhphogens; Wnts and bone morphogenetic proteins (BMPs) following DO in the mouse tibia. DO was carried out on the tibia of Balb-c mice using the monolateral fixator with three distinct phases; a latency phase of 7 days following surgery; an active distraction phase of 10 days (0.15 mm distraction/day) and a consolidation phase of 14 days after the end of active DO. Time course used for analysis was: a) 0 days (no surgery), b) 7 days (no DO), c) 10 days (3 d after DO), d) 17 days (end of DO), e) 20 days (3 days into consolidation) and f) 31 days (end of consolidation). RNA expression of Wnts and BMPs was assessed using ribonuclease protection assays. VEGF activity was blocked on some animals by selectively inhibiting its receptors VEGFR-1 (Flt1) and VEGFR2 (Flk-1). Standard histology was also performed for all time periods. DO promoted new bone formation through an intramembranous process with maximum osteogenesis during the active distraction phase. The analysis of the steady state mRNA expression levels suggests that the major BMPs are upregulated by DO, particularly at day 17. When VEGF blocking antibodies were used, all BMPs appeared to be equally upregulated across the time course, except for BMP7 which peaked at 17 days and returned to control levels by day 31. BMPs 4 and 5 peaked earlier during DO with VEGF blocking. DO also enhanced the expression of Wnts 1, 3, 3a, 4, 5b and 6. These were upregulated at day 7, peaking at day 17 and returned to lower levels at day 31. Wnt 4 showed the highest expression. These results suggest that these two families of morphogens contribute to the process of bone formation induced by DO. Additional study is required to test the precise role of individual genes from these families as mediators of this unique type of bone formation.

Overexpression of Human Bone Morphogenetic Protein-4 (BMP4) Driven by the 1.1kb Murine Bmp4 Promoter Results in Smaller Size and Reduced Bone Mineral Density in Transgenic Mice. J. Zhang*, S. Harris, V. Dousevich*, X. Tan*, D. Guo*, D. Eick, L. Bonewald, J. Feng. Oral Biology, University of Missouri-Kansas City, Kansas City, MO, USA.

Clearly, Bmp4 will induce ectopic bone formation. The Bmp4 null is an early embryonic lethal clearly showing that Bmp4 is essential for development. Our original hypothesis was that overexpression of Bmp4 would lead to new dentin and new bone formation. We generated mice using a 1.1kb Bmp4 promoter that had shown expression specificity in the ameloblast in order to increase enamel. We have shown endogenous Bmp4 gene expression in osteoblasts, osteocytes, and osteoclasts using a Bmp4 Lac Z reporter model. We also performed *in situ* hybridization of normal mice which also showed high expression in osteoblasts, osteocytes and osteoclasts. Unlike the endogenous promoter, Lac Z expression driven by the 1.1kb Bmp4 promoter was highly observed in osteoclast lineage, but was reduced in osteoblasts, and not detectable in osteocytes as revealed by both LacZ staining and LacZ mRNA *in situ* hybridization.Overexpression of human Bmp4 driven by the 1.1 kb Bmp4 promoter resulted in smaller mice with lower bone mineral density at 5 weeks, 4 months and up to 20 months as compared with wild type control. The bones appeared morphologically normal but there was a decrease trabecular bone. The numbers of osteoclasts per bone surface in these mice were similar to normal mice, but the sizes were larger and had more nuclei and more intensely stained for TRAP, suggesting elevated enzyme activity. Homozygote mice showed severe hypomineralized enamel. These findings suggest the 1.1kb region of the Bmp4 promoter may be more highly expressed in ameloblasts and osteoclasts and that continuous expression of Bmp4 in the osteoclast may induce or maintain osteoclast activation resulting in greater bone resorption that is unaccompanied by or not balanced with increased bone formation. This work is supported by NIH/NIDCR F32 DE015465-01(ZJ).

Three Dimensional Characterization of Cortical Bone Porosity on Microcomputed Tomography Images: A New Method of Evaluation. A. Basillais*[1], C. Chappard[1], S. Bensamoun*[2], B. Brunet-Imbault*[1], M. Ho Ba Tho*[2], C. Benhamou[1]. [1]Ipros, Université d'Orléans, Orleans, France, [2]Laboratoire de Biomécanique et Génie Biomédical, Université de Technologie de Compiègne, Compiègne, France.

Evaluation of cortical images mainly involves geometry measurements such as cortical thickness and pores diameter, or two dimensions (2D) porosity quantification. On microcomputerized tomography (μCT) images, cortical bone appears as a compact structure which is difficult to characterize (Fig. A). An inversion of the image leads, after reconstruction, to volumes prone to be analyzed by the same algorithms as trabecular bone (Fig. B).

Nineteen parallelepipedic cortical samples were prepared from 3 cadaveric human male femurs. The femur diaphysis was divided into three segments : top (16 to 40 %), middle (40 to 55%) and bottom (55 to 70%). Four samples of femur I were extracted from the top of the diaphysis (I/T), 6 samples of femur II from the middle diaphysis (II/M), 4 samples of femur II from the bottom diaphysis (II/B) and 5 samples of femur III from bottom diaphysis (III/B). They have been scanned with a μCT (Skyscan ®1072) with an isotropic resolution of 7.81

µm. After reconstruction and thresholding (a unique threshold for the whole dataset), images similar to figure B were analysed. The pore volume represented the equivalent of BV/TV in the trabecular bone, it was labelled PoV/TV for pore volume / total volume expressed in %. The porosity was also evaluated from 2D femoral sections at the same levels observed by Scanning Electron Microscopy. Mean PoV/TV ± SD were measured : 3.8 ± 3.11 % (femur I/T), 9.3 ± 5.7 % (Femur II/M), 51.3 ± 7.7 % (Femur II/B) and 53.7 ± 19 % (femur III/B). Correlation coefficient with porosity measured on sections was : r = 0.98 ($p<10^{-4}$). These data suggest that 3D cortical porosity can be efficiently evaluated on µCT images, with a good degree of validation using a direct evaluation by scanning electron microscopy of 2D sections.

Rat CIA Model: Evaluation of Markers of Bone and Cartilage Turnover and Juxta-Articular Changes. J. Mayer*, N. Doyle*, I. Moreau*, A. Varela, L. Chouinard, M. Boyer*, S. Y. Smith. CTBR Bio-Research Inc., Montreal, PQ, Canada.

The rat collagen-induced arthritis (CIA) model is used to evaluate the efficacy of potential disease modifiers for the treatment of rheumatoid arthritis (RA). The purpose of this study was to evaluate several biochemical markers of bone and cartilage turnover as well as juxta-articular morphological changes. Osteoclast-derived tartrate-resistant acid phosphatase form 5b (TRAP 5b, SBA Sciences), C-terminal peptide of collagen type I (CTx), osteocalcin (OC), collagen type II cleavage (C2C), procollagen II C-propeptide (CPII), and aggrecan chondroitin sulfate 846 epitope (CS846) (Ibex Diagnostics) were measured. Disease progression was monitored using limb circumference measurements, radiographic scoring and micro-CT images using a Scanco VivaCT40. *Ex vivo* bone densitometry was performed by pQCT and joints were scored histologically.

Female Lewis rats were randomly assigned into the following groups at the onset of arthritis: CIA Vehicle controls (saline), CIA treated with Dexamethosone (Dex) at 0.025 mg/kg/day for 6 days, CIA treated with Methotrexate (MTX) 0.1 mg/kg/day for 12 days. Additional rats were assigned as Non-disease (ND) controls.

With the exception of OC, all markers evaluated were increased 6 days post-onset of arthritis compared to ND controls, significant for TRAP 5b and CTx. Increases were also noted 12 days post-onset, significant for CPII. Increases in CTx were positively and significantly correlated with radiographic scoring and limb circumference. Micro-CT imaging showed clear evidence of disease progression *in vivo*. Bone density (BMD) at the proximal tibia metaphysis was significantly decreased. At the dose level selected, Dex partially inhibited the increases in markers, reduced limb circumference, radiographic and histologic scores. MTX at the dose level selected failed to consistently modify the CIA-induced response, although C2C, CPII and CS846 were notably lower than CIA vehicle controls.

These data support the use of bone and cartilage biochemical markers, radiographic scoring, micro-CT scanning, densitometry and histology to provide a comprehensive assessment of disease progression in bone and cartilage, and to assess potential disease modifiers in this rat model of RA.

Relationship Between Structure Analysis Based on the 3D Scaling Index Method and DXA in Postmenopausal Women with Osteoporotic Spine Fractures. D. Mueller*[1], R. Monetti*[2], S. Majumdar[3], D. C. Newitt[3], H. Boehm*[1], C. Raeth*[2], E. J. Rummeny*[1], T. M. Link[3]. [1]Department of Radiology, Technische Universitaet Muenchen, Muenchen, Germany, [2]Max Planck Institute for Extraterrestrial Physics, Garching, Germany, [3]Department of Radiology, UCSF, San Francisco, CA, USA.

The scaling index method (SIM) is a recently proposed non-linear technique to extract texture measures for the quantitative characterisation of the trabecular bone structure in high resolution magnetic resonance imaging (HR-MRI). This new non-linear method, which demonstrated to improve the diagnostic performance in differentiating postmenopausal women with and without osteoporotic spine fractures, was applied to high resolution magnetic resonance images of the distal radius in patients with osteoporotic spine fractures. The purpose of this study was to investigate the relationship between the SIM and dual energy x-ray absorptiometry (DXA) at different sides of the body of postmenopausal women with osteoporotic spine fractures.

Axial HR-MR images of the distal radius were obtained at 1.5 T in 66 women with osteoporotic spine fractures. A three-dimensional gradient-echo sequence was used with a voxel size of 500x195x195 µm³. After normalization and segmentation of each MR-image trabecular structure analysis was performed using algorithms based on our new local 3D scaling index method. In addition BMD measurements of the distal radius, the spine and the proximal femur using dual energy X-ray absorptiometry (DXA) were obtained in all patients. Linear regression was applied to the data to describe the relationship between the SIM and BMD using DXA at different sides of the body. However, there was no significant ($p>0.05$) correlation found for any of the BMD values versus the 3D structure measure based on the local scaling index method (radius BMD vs. SIM: r=.09, spine BMD vs. SIM: r=.17, femur BMD vs. SIM: r=.14)

The results of this study suggest that our recently developed algorithm based on a local 3D scaling index method, which showed a high diagnostic performance in differentiating postmenopausal patients with and without osteoporotic fractures, determines different entities of trabecular bone that are important for the prediction of individual fracture risk and are not reflected by BMD.

A Scanning Small Angle X-Ray Scattering (SAXS) Study of the Nanometer Length Scale Bone Structure in Connection with Implants. M. H. Bünger*[1], K. Erlacher[1], M. Foss*[1], H. Li*[2], Z. Xuenong*[2], B. Langdahl[3], F. Besenbacher*[1], J. Pedersen*[1]. [1]Interdisciplinary Nanoscience Center (iNANO), University of Aarhus, Aarhus, Denmark, [2]Department of Ortopedics, Aarhus University Hospital, Aarhus, Denmark, [3]Dept of Endocrinology and Metabolism C, Aarhus University Hospital, Aarhus, Denmark.

The understanding of the interaction between bone and orthopedic implants is important for the development of biomaterials with improved biocompatibility. The SAXS technique has previously been applied to offer structural information on mean crystal thickness, predominant orientation and degree of orientation of mineral particles in bone. Therefore, one possible application of SAXS is to investigate the nanostructure of bone in connection with ingrowth on implants, which is not possible with conventional optical techniques.

Three 190µm thick sections of vertebrae bone from three 6 month old Danish Landrace pigs were examined. One sample included the neurocentral growth zone, while the other two were sections with bone and either titanium or tantalum implants from pigs that 3 month previously had undergone spinal surgery.

At predefined regions, Scanning SAXS were done with a step width of 50µm and a diameter of the X-ray beam slightly larger than 100µm. The number of recorded SAXS-2d frames was approximately 1000 frames for each of the implant samples and 299 frames in the region of the growth zone.

The mean crystal thickness in the titanium implant sample was 2.40nm (σ =0.251nm) and 2.47nm (σ =0.288nm) in the titanium sample ($P<0.01$). Bone provided a strong SAXS signal and relatively low transmission intensity, whereas regions within the neurocentral growth zones showed a high transmission as well as a high SAXS signal. Combining the transmission and the SAXS data, it was clearly possible to differentiate between areas of fibrous tissue and bone. This was supported by elemental analysis performed by SEM-EDAX. The mineral particles in the cancellous bone were aligned along the trabeculae, with less orientation close to the growth zone. Also, the mineral particles tended to be aligned along the implant surfaces. Within the individual bone samples, a large variation in all SAXS parameters was observed depending on the bone position relative to the implant. Furthermore, larger particle thicknesses were found in areas of bone formation, which matches our growth zone data.

In conclusions, scanning SAXS offers unique information of the bone structure on a nanometer length scale. The data suggests that the parameters obtained by SAXS can be used to assay the local mineral particle growth. This indicates that SAXS is a powerful tool for the characterization of the detailed mineral structure of bone in the vicinity of implants.

Identification of the Elemental Composition of Metal Particles from a Failed Joint Prosthesis by Laser Ablation Inductively Coupled Plasma Mass Spectrometry. A. G. Cox*[1], M. Holt*[2], J. Denton*[3]. [1]Centre for Analytical Sciences, University of Sheffield, Sheffield, United Kingdom, [2]Orthopaedic Surgery, Wythenshawe Hospital, Manchester, United Kingdom, [3]Osteoarticular Pathology, University of Manchester, Manchester, United Kingdom.

The purpose of this study was to investigate the potential of Laser Ablation Inductively Coupled Plasma Mass Spectrometry (LA-ICP-MS) to identify metal particles in connective tissues from a failed surgical implant. Samples of connective tissues obtained at open operation from the area surrounding a painful, failing, shoulder prosthesis were obtained. The shoulder prosthesis was composed of a HDPE glenoid component with a cobalt-chromium alloy stem and head. In order to enhance osteo-intigration, the metal stem component had been coated with titanium by plasma deposition. At operation the tissues surrounding the prosthesis were clearly abnormal, of a grey colour and contained necrotic tissue debris. The samples were LR White (Hard Grade) embedded and sections taken for histological examination. On section and staining a macrophage response with giant cell formation was evident. The macrophages contained numerous intracellular black particles. On the surface of the block it was apparent that there were also larger (>50 micron) pieces, of what appeared from their shiny surface, to be metal. The surface of this block was used for the investigation without further treatment. The technique of LA-ICP-MS is an analytical beam technique whereby a 4 micron diameter laser beam (213nm) is used to vaporise the surface of any material in a controlled, precise manner. The vaporisation takes place inside a sample chamber which has a controlled argon gas flow passing through it. The entrained vaporised sample is then carried to the argon plasma (8000K) where it is ionised. The ions are resolved and analysed using a quadrapole mass spectrometer. Single line scans through the intracellular black particles show their composition to be chromium-cobalt alloy, identical to the metal composition of the implant. The elemental composition of the larger particles seen in the block surface was shown to be titanium, different to the intracellular debris composition. These findings demonstrate the ability of LA-ICP-MS to spatially resolve the elemental composition of connective tissues and to give a precise indication of metal composition.

Direct Measurement of Bone Turnover Using ^{41}Ca. R. L. Fitzgerald*[1], T. L. Griffin*[1], D. J. Hillegonds*[2], D. W. Burton[3], L. J. Deftos[3], S. Mullaney*[3], J. Vogel*[2], D. A. Herold*[1]. [1]Pathology, University of California and SDVAMC, San Diego, CA, USA, [2]Center for Accelerator Mass Spectometry, Lawrence Livermore National Laboratory, Livermore, CA, USA, [3]Medicine, University of California and SDVAMC, San Diego, CA, USA.

Currently most of the laboratory methods for determining the status of bone health are indirect. The ideal measure of bone health would be a direct measurement of the amount of calcium that is being resorbed from the bone matrix. This can be accomplished using accelerator mass spectrometry (AMS) to measure attomole concentrations of calcium isotopes. Small quantities of the radioactive ^{41}Ca isotope (10 nCi) are administered to volunteers and the ratio of ^{41}Ca to naturally occurring calcium (^{41}Ca/Ca) in urine or serum is monitored as the tracer reaches equilibration with deep bone compartments. In healthy patients the terminal elimination half-life of ^{41}Ca is expected to be significantly longer than that of patients with resorptive bone disease. The ^{41}Ca solutions were prepared for IV administration under sterile conditions. Each 9 mL ^{41}Ca dosing solution contains: 10 nCi ^{41}Ca (the isotope that will be monitored); 1 mg Ca (to prevent loss of ^{41}Ca due to nonspecific binding); 0.6 mg of $NaHCO_3$ (buffering agent); and 9 mL of 0.9 % NaCl (diluent). Individual 9 mL prepared doses passed sterility and endotoxin tests according to the USP protocol. To ensure that the solution does not trigger an immunologic response a Limulus Amebocyte Lysate assay gave a result of < 0.27 EU/9 mL (acceptable limit is 175 EU/9 mL dose). USP Bacteriostasis and Fungistasis assay showed no growth at 14 days. We use ICP-MS to demonstrate that only Ca was present above 1 ppm in the $NaHCO_3$ / NaCl solution. Five normal controls and seven end-stage renal disease patients on hemodialysis have been dosed. Urine and serum samples have been collected for AMS measurements and subsequent characterization of absorption and elimination kinetics. The samples are acid digested, precipitated as calcium oxalate, re-dissolved in nitric acid for purification over cation exchange resin and then re-precipitated as CaF_2. This sample is mixed with silver powder and analyzed by AMS. The method is linear over 5 orders of magnitude, from background concentrations (approximately 5.6 x 10^{-14}) to 1 x 10^{-9} ratios of ^{41}Ca/Ca. The precision at concentrations expected in serum samples ranged from 1 to 8% with errors ranging from 1 to 14%. These results demonstrate that ^{41}Ca has potential to be used to directly monitor bone turnover in health and disease allowing for better clinical management of bone disorders caused by end-stage renal disease.

Loading Direction Affects Mechanical Property Results in Bending of Rat Tibia Specimens. H. A. Hogan[1], D. Older*[1], M. Rose*[1], S. Vaculik*[1], M. R. Allen[2]. [1]Mechanical Engineering, Texas A&M University, College Station, TX, USA, [2]Anatomy & Cell Biology, Indiana University School of Medicine, Indianapolis, IN, USA.

Mechanical properties from biomechanical tests are important outcome measures in skeletal research. A common and effective way to assess cortical bone in rodents animal models is to conduct bending tests on one of the long bones of the appendicular skeleton. The objective of the current study was to determine whether loading direction affects mechanical properties measured from 3-point bending tests of the tibia. Both left and right tibiae were harvested from 21 animals acquired through a tissue sharing program. Animals were not involved in skeletal studies and were all male Sprague-Dawley rats varying in age and size (body mass 230g to 885g). Left and right bones were randomly assigned to two groups and tested by loading in the medial-lateral plane with opposite loading directions. One group was placed with the medial side down and the loader contacting the lateral surface to load in a "lateral-to-medial" direction (designated LM). The other group was loaded "medial-to-lateral" (designated ML). Cross-sectional moment of inertia at mid-diaphysis was assessed by pQCT. Despite the wide range in size of the animals, statistical differences (one-way ANOVA) were found between the two groups for many variables. Values in the table are mean(SE). Stiffness and strength properties (both extrinsic and intrinsic) were generally higher for the LM group. Post-yield displacement was dramatically lower for the LM group. Two-way ANOVA was also conducted to test for effects due to the size (body mass) of the animals. Differences for load direction were the same as for the one-way ANOVA for all variables except yield load, which did not show a load direction effect in the two-way ANOVA (P=0.098). These findings suggest that care should be taken in choosing a loading direction for bending tests of rat tibae. Caution should also be exercised in comparing numerical values of properties from different studies since both loading directions are commonly used. Post-yield displacement is a measure of ductility, which is the opposite of brittleness, and the ML test direction produces a much more progressive failure response (as evidenced by higher values). This direction is thus better for investigating differences in brittleness.

One-Way ANOVA

	LM	ML	different?	P-value
Stiffness (N/mm)	250(20)	235(17)	N	0.154
Ultimate Load (N)	125(10)	103(7)	Y	0.001
Yield Load (N)	113(10)	93(6)	Y	0.020
Post-Yield Disp. (mm)	0.11(0.03)	0.45(0.10)	Y	0.015
Elastic Modulus (GPa)	8.1(0.5)	7.6(0.5)	N	0.311
Ultimate Stress (MPa)	208(8)	177(6)	Y	0.002
Yield Stress (MPa)	187(10)	161(6)	N	0.058

Vasopressin Enhanced Na-dependent Pi Transport Activity and the Mineralization in Vascular Smooth Muscle Cells. A. Suzuki[1], K. Nishiwaki-Yasuda*[1], Y. Ono*[1], A. Kakita*[2], Y. Ishiwata*[1], T. Matsumoto*[1], S. Imamura*[1], T. Kato*[1], N. Hayakawa*[1], N. Oda*[1], Y. Oiso*[3], M. Itoh*[1]. [1]Department of Internal Medicine, Fujita Health University, Aichi, Japan, [2]Hekinan Municipal Hospital, Aichi, Japan, [3]Division of Metabolic Diseases, Nagoya University Graduate School of Medicine, Aichi, Japan.

We have previously reported that A-10 rat aortic vascular smooth muscle cells (VSMCs)expressed type III sodium-dependent inorganic phosphate (Pi) transporter, Pit-1 (Glvr-1), and that platelet-derived growth factor enhanced its expression and Pi transport activity in these cells. In the present study, we investigated the effect of arginine vasopressin (AVP) on Pi transport activity, which has been reported to be involved in the mechanism of atherosclerosis, in VSMCs. AVP dose-dependently (1 pM to 100 nM)stimulated Pi transport in A-10 cells. The effect was time-dependent and sustained for up to 24 h. Protein kinase C (PKC) inhibitor calphostin C suppressed the stimulatory effect of AVP on Pi transport. On the other hand, inhibition of mitogen-activated protein (MAP) kinases by selective inhibitors did not affect Pi transport. Furthermore, the long-term treatment with AVP (100 nM) stimulated the calcification of VSMCs. In summary, these results indicated that AVP selectively enhanced the Pi transport activity in VSMCs, resulting in the calcification of these cells. The mechanism responsible for this effect is not mediated by MAP kinase, but involves activation of PKC.

Inter-individual Heterogeneity Index of Mineralization Is an Important Determinant of the Quality of Bone. G. Boivin, P. J. Meunier. Faculté de Médecine R. Laennec, INSERM Unité 403, Lyon, France.

Bone quality determinants include the degree of mineralization of bone (DMB) mainly measured by quantitative microradiography (Boivin & Meunier Calcif Tissue Int 2002, 70:503-11). Mean DMB and intra-individual Heterogeneity Index of the distribution of DMB (mean full width at half-maximum of the individual DMB curve) reflect the DMB known to vary over basic structure units with their secondary mineralization. The intra-individual Heterogeneity Index depends on the rate of remodeling, a high turnover leading to a large heterogeneity of DMB and conversely a low one leading to a decreased heterogeneity. From the individual data, a mean Inter-individual Heterogeneity Index (Inter HI) is calculated. In control women who were divided into pre- and post-menopausal groups, on the basis of age, mean DMB is not different between the two groups while Inter HI is significantly higher (p=0.038) in pre- than in post-menopausal group, and reflects a significant homogeneization of DMB with age (p<=0.01). In post-menopausal group only, DMB and Inter HI were correlated (p=0.05).

Changes in bone remodeling rate influence not only the DMB but also the Inter HI. When antiresorptive agents cause a decrease of the remodeling rate - this is well documented in osteoporotic women treated for 2-3 yrs with alendronate (10mg/day) - mean DMB is significantly increased after alendronate (Boivin et al. Bone 2000, 27:687-94) with a shift of DMB values towards highest values. In parallel, and specially after 3 yrs, the Inter HI is decreased concomitantly to the shift of DMB. If such a high DMB combined with a low Inter HI was maintained after long-term treatments, the mechanical properties of bone tissue could be changed. Zoledronic acid given for only 1 yr (Boivin et al. J Bone Miner Res 2003, 18 Suppl. 2:S261) provoked a small increase of DMB (+4-5%) associated with a normal Inter HI. When less potent antiresorptive agents as raloxifene (Boivin et al. J Clin Endocrinol Metab 2003, 88:4199-205) and estrogen (Boivin et al. Osteoporos Int 2004, 15 Suppl. 1:abstract P338SU) are used, mean DMB increased but the shift of DMB is not accompanied by significant changes in Inter HI except after high doses of estrogen. Conversely, in case of accelerated remodeling activity, for example in 11 patients with primary hyperparathyroidism, mean DMB is decreased with a shift of the distribution of DMB towards the lowest values but Inter HI does not change. In 9 patients with skeletal fluorosis mean DMB is decreased but Inter HI remains normal.

Beside DMB, this new approach leads to consider also Inter HI as a determinant of bone quality. It remains to evaluate the properties of bone at the tissue (micro-indentation) and crystal (infrared spectroscopy) levels.

Association Between Hand and Lumbar Exostoses and Abdominal Aortic Calcification: The Framingham Study. D. Karasik[1], D. K. Kiely*[1], L. A. Cupples*[2], P. W. F. Wilson*[3], C. J. O'Donnell*[4], D. P. Kiel[1], D. T. Felson[5]. [1]Research, Hebrew Rehab Center for Aged, Boston, MA, USA, [2]Biostat, BU Sch Pub Health, Boston, MA, USA, [3]Endocrin, Med Uni S. Carolina, Charleston, SC, USA, [4]NHLBI Framingham Heart Study, Framingham, MA, USA, [5]Clin Epid, BU Sch Med, Boston, MA, USA.

Bone proliferation (exostoses) and vascular calcification are common in elderly men and women. It is unclear whether the increased prevalence of both exostoses and aortic calcification with aging is due to a common etiology.

In this cross-sectional study, lateral lumbar and hand radiographs were obtained in 715 men and 1004 mostly postmenopausal women (mean age 61, range 47-80 yrs), from the Framingham Heart Study Original Cohort (1967-1970). Each group of hand exostoses, specifically apiostoses (tufting), enthesophytes, and nodes (osteophytes), were graded on a scale 0-3 (absent to severe) and summed across phalanges of digits II-V. Anterior lumbar osteophytes (OPH) were graded on a scale 0-3 for each vertebra and summed across L1-L5. Abdominal aortic calcification (AAC) was graded 0-3 for the anterior and posterior aortic walls in each lumbar segment (L1 to L4) and then summed. Information on known risk factors (age, sex, BMI, smoking, alcohol consumption, physical activity, systolic blood pressure, total cholesterol levels, diabetes, and estrogen replacement therapy in women) was obtained at the time of radiography. We excluded participants with diffuse idiopathic skeletal hyperostosis (7.6% of the sample) who have bony proliferation and a high prevalence of diabetes.

After initial correlation analysis, we used logistic regression models to assess multivariate-adjusted relations between dichotomized AAC score (0 or 1+) and exostoses, in each gender.

Prevalence and severity of hand exostoses, anterior lumbar OPH, and AAC positively correlated with age in both genders. Spearman age-adjusted partial correlations between exostoses ranged from -0.06 (hand apiostoses and anterior lumbar OPH) to 0.33 (enthesophytes and apiostoses).

Multivariate adjusted logistic regression analysis revealed a significant association between AAC and anterior lumbar OPH (per increase in summary score) in men (OR 1.2, 95%CI 1.1-1.3) and women (OR 1.3, 1.2-1.4, both P<0.0001). Additionally, a significant association was found between apiostoses and AAC in men (OR 1.1, 1.0-1.2, P=0.02), and enthesophytes and AAC in women (OR 0.8, 0.7-0.9, P<0.001). Nodes were not significantly associated with AAC.

In conclusion, AAC was associated with anterior lumbar osteophytes in both men and women. Sex-specific factors are involved in association between abdominal aortic calcification and hand exostoses.

Galectin-3 in Osteoarthritis: from the Protection to the Destruction Role. C. Boileau*[1], J. Martel-Pelletier*[1], M. Guévremont*[1], J. Pelletier*[1], F. Poirier*[2], P. Reboul[1]. [1]Arthritis Unit, University of Montreal, Montreal, PQ, Canada, [2]Laboratoire de Génétique et de Développement des Mammifères, Institut Jacques Monod, Paris, France.

Osteoarthritic (OA) chondrocytes are able to re-express numerous genes normally activated in the growth plate. Among these genes, we are interested in studying galectin-3 (gal-3) since we have recently demonstrated that its expression was increased in OA cartilage. Gal-3 is a mammalian lectin and is involved in numerous functions such as adhesion, splicing activity, cell cycle regulation and apoptosis. These functions are related to the galectin-3 cellular localization. In the present study, we investigated the role(s) of gal-3 by using both mono-iodoacetate-induced OA model and in vitro experiments.

OA was induced with an injection of iodoacetate into each knee joint of four month-old mice (WT) or galectin-3 null mice (KO). Mice were sacrified 7, 14 and 21 days after the injection. Histologic evaluation was performed on sagittal sections knee joint. OA lesions were graded using a modified histologic/histochemical scale of Mankin. Intracellular and extracellular roles of gal-3 were investigated in both human chondrocytes and chondrogenic ATDC5 cells.

Intra-articular injection of MIA up-regulated the expression of gal-3 in WT mice 7 days post injection, reaching a statistical significance 14 days post injection (p<0.05). Histologic grading score indicated that KO mice (control group) had a poorer quality of cartilage compared to WT mice (control group). Moreover, the induction of OA in KO mice showed a marked decreased of bone surface (p<0.05).

Therefore, it seemed that gal-3 was important for the cartilage homeostasis. As it was suggested that gal-3 could be implicated in chondrocyte survival, we treated human OA chondrocytes with SNP, which is known to generate chondrocyte cell death. Our results showed that gal-3 was much further decreased than was Bcl2 in the same conditions. Moreover, SNP decreased the gal-3 phosphorylation, which is a key process in the capacity of gal-3 to prevent cell death. Finally, ATDC5 cells transfected with a gal-3-expressing vector, were more resistant to SNP-induced cell death compared to those transfected with the empty vector. On the other hand, gal-3 was found in synovial fluid, particularly during inflammation. Therefore, we investigated the potential role of exogenous gal-3 in chondrocyte cultures. Surprisingly, we found that exogenous gal-3 induced chondrocyte death.

In that study, we demonstrated the role of gal-3 in cartilage homeostasis in gal-3 KO model and the importance of gal-3 for bone by inducing OA in KO mice. Moreover, we showed different effects of gal-3 on chondrocytes depending its localization.

Expression of Mouse Receptor Activator of NF-κB Ligand (RANKL) in Growth Plate and Articular Cartilage. K. Kishimoto*[1], R. Kitazawa[1], A. Darwanto*[1], T. Kondo[1], S. Maeda*[1], M. Kurosaka*[2], S. Kitazawa[1]. [1]Division of Molecular Pathology, Kobe University Graduate School of Medicine, Kobe, Japan, [2]Division of Orthopaedic Surgery, Kobe, Japan.

Based on developmental fate and function, cartilage tissue is broadly classifiable into transient cartilage (embryonic or growth plate: GP) and permanent cartilage (articular cartilage: AC). The former eventually disappears and is replaced by bone (endochondral ossification). RANKL is expressed in not only osteoblasts but also prehypertrophic chondrocytes to recruit chondroclasts at endochondral ossification sites, indicating that RANKL is an essential factor defining the fate of transient and permanent cartilage. We investigated the expression pattern of factors regulating differentiation and function of osteo(chondro)clasts as well as of Runx2 and its putative upstream genes in GP and AC. Knee joints of male BALB/c mice aged 8 weeks were dissected, fixed with 4% paraformaldehyde in 0.1 M phosphate buffer (PB) at 4 C for 3 days, decalcified with 20% EDTA in 0.1M PB for 4 days, and then subjected to tartrate-resistant acid phosphatase (TRAP) staining to detect osteo(chondro)clasts. BMP-2, -4, -6 and type X collagen mRNA were detected by in situ hybridization (ISH). Immunostaining was conducted using anti-RANKL, Runx2, Dlx5 and Msx2 antibodies. The methylation status of the mouse RANKL gene promoter in both GP and AC was analyzed by sodium bisulfite mapping using microdissected mouse bone tissue. Besides showing osteoblasts positive for Runx2 and RANKL lining the trabecular bone surface, RANKL expression was observed in hypertrophic chondrocytes in GP, where numerous TRAP-positive osteo(chondro)clasts were observed, but barely in chondrocytes in the deep zone of AC. At the boundary between the calcifying and the hypertrophic chondrocytes of GP, RANKL-expressing chondrocytes overlapped those expressing Runx2, Dlx5 and Msx2. Although similar BMP-2 and -4 expression was observed in chondrocytes in both GP and AC as well as in maturing osteoblasts, a rather restricted BMP-6 expression pattern was observed in chondrocytes in GP. On the other hand, sodium bisulfite mapping showed that mainly non-CpG methylation was similarly scattered in a non-specific manner in chondrocytes in GP and AC. Taken together with the fact that putative Runx2 binding elements are located in the RANKL promoter, our data suggested that Runx2, an essential transcription factor for skeletal development, may also be a key regulator of RANKL expression in chondrocytes that promotes endochondral ossification. Furthermore, a selective expression of a subset of BMP, as an upstream factor of Runx2, may play an important role in defining the fate of chondrocytes.

Extracellular Calcium and Parathyroid Hormone-related Protein (PTHrP) Signaling Determines the Pace of Cell Differentiation of Mouse Growth Plate Chondrocytes (mGPCs). L. Rodriguez*, T. H. Chen*, C. Tu*, D. Shoback, W. Chang. Endocrine Unit, VAMC, UC San Francisco, San Francisco, CA, USA.

Raising the extracellular $[Ca^{2+}]$ ($[Ca^{2+}]_e$) promotes the differentiation of chondrogenic RCJ3.1C5.18 cells and mGPCs by inhibiting the expression of early chondrogenic markers and increasing the expression of markers of terminal differentiation. These effects are opposite to those of the PTHrP/Indian hedgehog (Ihh) feedback mechanism that delays chondrocyte maturation. To assess the interactions between extracellular Ca^{2+} and PTHrP/Ihh-mediated signaling, we tested the ability of PTHrP to alter the effects of Ca^{2+} and vice versa on proteoglycan (PG) synthesis by alcian green staining, matrix mineralization by alizarin red staining, and gene expression by quantitative real-time PCR in mGPCs. In the absence of PTHrP, raising $[Ca^{2+}]_e$ from 0.5 to 3.0 mM dose-dependently suppressed PG accumulation and the expression of early markers of chondrocyte differentiation (type II collagen and aggrecan) and increased signs of terminal differentiation -- matrix mineral deposition and the expression of osteopontin and osteocalcin -- with ED_{50}'s ≈ 1-2 mM Ca^{2+}. Incubation of cells with PTHrP (10^{-7} M), in contrast, blunted the effects of high $[Ca^{2+}]_e$ on PG synthesis, matrix mineralization, and gene expression as indicated by right-shifted Ca^{2+} dose-response curves. Although with reduced potency, high $[Ca^{2+}]_e$ (3 mM) continued to influence the above biochemical pathways in the presence of maximal doses of PTHrP (10^{-7} M). High $[Ca^{2+}]_e$ did not change PTHrP-induced cyclic AMP formation but did decrease RNA levels for both PTH/PTHrP receptors and Ihh by ≈75% and 95%, respectively. High $[Ca^{2+}]_e$ also affected the expression of several components of the insulin-like growth factor-1 (IGF-1) signaling pathway that is known to promote GPC differentiation. Raising $[Ca^{2+}]_e$ from 0.5 to 3.0 mM increased RNA levels for IGF-1 and the IGF-1 receptors by 4- and 2-fold, respectively, and decreased RNA levels for IGF-1 binding proteins (IGF1BP 2, 3, and 4) by 50-85%. The effects on these binding proteins should raise free IGF-1 levels. These effects of high $[Ca^{2+}]_e$ were blocked (80-90%) by co-incubating the cells with PTHrP (10^{-7} M). Taken together, these studies support the idea that signaling by extracellular Ca^{2+} and PTHrP/Ihh determines the pace of differentiation in cultured chondrocytes either by direct interactions between the two pathways or indirect interactions with other regulators of chondrocyte differentiation such as IGF-1, its receptor, and associated proteins.

Disease Modifying Effects of a Selective COX-2 Inhibitor in the Rat Anterior-cruciate Ligament Transection (ACLT) Model of Osteoarthritis. T. Hayami*[1], Y. Zhuo*[1], G. Wesolowski*[1], M. Pickarski*[1], S. Lerger*[2], G. A. Rodan[1], L. T. Duong[1]. [1]Merck Res. Labs., West Point, PA, USA, [2]Merck Frosst Centre for Therapeutic Res., Montreal, PQ, Canada.

Osteoarthritis (OA) is a degenerative joint disease characterized by articular cartilage degradation, subchondral bone sclerosis, and osteophyte formation. To investigate the potential contribution of inflammation and bone turnover to OA progression, we examined the effects of MF tricyclic, a potent and selective inhibitor of cyclooxygenase (COX)-2, in combination with Alendronate (ALN), on the disease progression in the rat surgically induced OA model. Male rats received sham- or ACLT-surgery in the right knee; the study duration was 10 wk post-surgery. By comparison to sham using real time quantitative PCR, we found that COX-2 expression was up-regulated 2-fold in the articular cartilage of ACLT-joints. Using immunohistochemistry, we also detected the increase in COX-2 protein in articular cartilage derived from both rat and human OA joint tissues. Next, sham- and ACLT-rats were dosed with vehicle, MF tricyclic (3 mg/kg, daily p.o.), or ALN (120 μg/kg/wk, s.c.), or with a combination of both drugs. Similar to ALN, the COX-2 inhibitor had significant chondroprotective effects on the ACLT-joints. MF tricyclic and ALN partially reduced the histological Mankin score ($p<0.05$ and <0.001, respectively) of cartilage damage during OA progression, and suppressed the elevated levels of urinary Col2CTx, a cartilage degradation marker, 2-wk post-surgery. While MF tricyclic did not inhibit generalized bone resorption, as determined by urinary Col1CTx, this compound ($p<0.0001$) significantly inhibited local subchondral bone sclerosis in the ACLT-joints as evaluated by histomorphometry, by comparison to ALN ($p<0.001$). Osteophyte formation was also suppressed by both COX-2 inhibitor and ALN. Interestingly, there was no additive effects observed in chondroprotection and osteophyte formation in the ACLT-joints treated with the combination of both drugs. Immunohistochemical analysis revealed that protein levels of COX-2 and mPGES in articular chondrocytes were inhibited in the ALN-treated ACLT-joints. Moreover, we observed that ALN (30 μM) reduced COX-2 mRNA levels and PGE2 production in IL-1-treated primary culture of human articular chondrocytes. Taken together, this study suggests that COX-2-mediated pathway is up-regulated in both human and rat OA tissues, and inhibition of this enzyme results in structure-modifying effects in the rat OA model. In addition, the lack of additivity of the two compounds *in vivo*, together with the inhibition of COX-2 activity by ALN *in vitro,* suggest that ALN may directly modulate the COX-2/PGE2 pathway.

Overexpression of CDK6 and CCND1 in Chondrocytes Induces Chondrocyte Proliferation and Apoptosis and Causes Dwarfism. Z. Maruyama[1], N. Kanatani*[2], C. Yoshida*[2], K. Nakamura[1], H. Kawaguchi[1], T. Komori[2]. [1]Orthopaedic Surgery, Surgical Science, Sensory and Motor System Science, Graduate School of Medicine and Faculty of Medicine,the University of Tokyo, Tokyo, Japan, [2]Division of Oral Cytology and Cell Biology, Department of Developmental and Reconstructive Medicine, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan.

In endochondral bone formation, chondrocytes develop through sequential processes, including initiation, proliferation, and maturation, and finally undergo apoptosis. G1 cyclins play a fundamental role in cell cycle entry, and growth arrest is required for cell differentiation and maturation. To assess the function of G1 cyclins during skeletogenesis, we generated transgenic (Tg) mice that overexpress cyclin dependent kinase 6 (CDK6) or cyclin D1 (CCND1) under the control of Col2a1 promoter/enhancer. Several lines of Tg mice with different levels of transgene expression were established in each gene. Both CDK6 Tg lines and CCND1 Tg lines showed grossly normal skeletal development. We further generated CDK6/CCND1 double Tg mice. The double Tg mice displayed dwarfism and died at birth from respiratory failure. In the growth plate of double Tg mice, chondrocyte maturation was mildly delayed at embryonic day (E) 15.5, as shown by the delayed vascular invasion and the absence of osteopontin-positive terminal hypertrophic chondrocytes. The frequency of BrdU labeling was increased in double Tg mice (27.7 ± 2.6 %) as compared with wild-type mice (14.3 ± 2.8 %) ($P < 0.005$, $n = 3$) at E 15.5. In wild-type mice, TUNEL-positive cells were restricted to the terminal hypertrophic chondrocytes. In double Tg mice, however, many TUNEL-positive cells, which have apoptotic bodies and fragmented nuclei, were observed in immature chondrocytes that expressed Col2a1. The TUNEL-positive cells were most frequently observed in the epiphises at E15.5. These apoptotic cells were accumulated in the cartilage, because they escaped phagocytosis. It is considered that the dwarfism of double Tg mice was caused by apoptosis, because chondrocyte proliferation was increased and the delay in chondrocyte maturation was not severe in double Tg mice. These findings demonstrate that overexpression of both CDK6 and CCND1 in chondrocytes promotes cell cycle progression but also induces chondrocyte apoptosis in vivo.

Osteopontin-Deficiency Suppresses TNF-alpha Induced Cytotoxicity in Chondrocytes. K. Yumoto[1], M. Ishijima[1], S. R. Rittling[2], K. Tsuji[1], Y. Tsuchiya[3], S. Kon[4], A. Nifuji[1], T. Uede[4], D. T. Denhardt[2], M. Noda[1]. [1]Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Rutgers University, Piscataway, NJ, USA, [3]IBL, Gumma, Japan, [4]Hokkaido University, Sapporo, Japan.

Apoptosis of chondrocytes in articular cartilage has been observed in rheumatoid arthritis patients. However, the mechanisms underlying chondrocyte apoptosis in arthritic joints have not been fully understood. We previously reported that apoptosis of chondrocytes was enhanced in anti-type II collagen antibodies and lipopolysaccharide (mAbs/LPS)-induced arthritis in mice and osteopontin (OPN)-deficiency suppressed chondrocyte apoptosis in this arthritis model (*PNAS* **99**:4556, 2002). To understand the mechanisms of OPN-deficiency-induced resistance against chondrocyte apoptosis, we examined the cellular basis for such protection. Chondrocytes were prepared from mouse ribs and the release of lactate dehydrogenase (LDH), a cytotoxic marker, from wild-type chondrocytes in culture, was induced by LPS or TNF-alpha. In contrast to wild-type, LDH release by LPS or TNF-alpha was significantly suppressed in chondrocytes derived from OPN-deficient mice. Furthermore, OPN-overexpression using adenovirus vector in OPN-deficient chondrocytes enhanced the levels of LDH release induced by TNF-alpha. These data indicated that the presence of OPN in chondrocytes is involved in the apoptosis susceptibility of these cells to TNF-alpha. It was reported that p38 MAPK was activated by recombinant OPN fragments in osteoblastic cells (*Biomaterials* **24**:1059, 2003). To understand the pathway involved in the TNF-alpha induced intra-cellular signals leading to cytotoxicity in chondrocytes, we examined the effects of the MAPK inhibitors on TNF-alpha induced cytotoxicity. MEK inhibitor U0126 did not alter the TNF-alpha induced LDH release. On the other hand, p38 inhibitor SB203580 significantly suppressed TNF-alpha induced LDH release. These observations suggest that TNF-alpha induced cell death in chondrocytes is mediated by OPN and p38 MAPK.

The RhoA/ROCK Signaling Pathway Coordinates Cell Shape, Cytoskeletal Organization and Tissue-Specific Gene Expression During Chondrogenesis. A. Woods*, G. Wang*, F. Beier. Physiology and Pharmacology, University of Western Ontario, London, ON, Canada.

Rho GTPases have been identified as regulators of cytoskeletal organization and control of gene expression in several cell types. Because of the well-documented direct correlation between chondrocyte shape, gene expression and stage of differentiation, we hypothesized that RhoA and its effector kinases ROCK1/2 regulate expression of chondrocyte-specific genes through modulation of the actin cytoskeleton. RhoA and ROCK1/2 are expressed throughout chondrogenic differentiation of primary mouse limb bud cells. Inhibition of ROCK activity with the pharmacological compound Y27632 results in rounding of cells and cortical actin organization, characteristic features of chondroyctes. In contrast, overexpression of RhoA in the chondrogenic cell line ATDC5 causes the opposite phentoype of increased stress fibre formation. Real-time PCR and western blotting demonstrated that ROCK inhibition induces expression of the chondrogenic transcription factor Sox9. Sox9 induction is accompanied by increased alcian blue staining, a marker of chondrogenesis, in Y27632-treated cultures. In contrast, RhoA overexpression in ATDC5 cells suppresses Sox9 mRNA and protein levels. All effects of RhoA overexpression can be reversed by Y27632. Inhibition of actin polymerization by cytochalasin D induces Sox9 gene expression in a similar fashion as Y27632, whereas inhibition of microtubule polymerization by colchicine completely blocks Sox9 expression. Surprisingly, stabilization of the actin cytoskeleton by jasplakinolide also induces Sox9 expression and activity. In summary, we demonstrate that RhoA inhibits Sox9 expression and chondrogenesis through ROCK1/2 signaling and modification of the actin cytoskeleton. These data suggest that the RhoA pathway plays a crucial role in the coordination of the long-known, but poorly understood interdependence of cell shape, cytoskeletal organization and chondrocyte-specific gene expression during skeletal development.

TGF-β1 Regulates ATDC5 Differentiation, and Fibronectin Isoform and SRp40 Expression. F. Han*[1], Z. Tao*[1], C. J. Williams*[2], R. Zaka*[3], R. S. Tuan*[4], P. A. Norton*[5], N. J. Hickok*[1]. [1]Orthopaedic Surgery, Thomas Jefferson University, Philadelphia, PA, USA, [2]Div. Rheumatology, Dept. Medicine, Thomas Jefferson University, Philadelphia, PA, USA, [3]Div. Rheumatology, Dept. Medicine, Thomas Jefferson University, Philadelphia, PA, USA, [4]Cartilage Biol. Orthop Branch, NIAMS, NIH, Bethesda, MD, USA, [5]Biochem.Mol.Pharm, Thomas Jefferson University, Philadelphia, PA, USA.

Chondrogenesis is dependent on cellular condensation and a regulated program of gene expression. During chondrogenesis, regulated splicing of the fibronectin (FN) pre-mRNA results in differential FN isoform expression. Transforming growth factor (TGF)-β alters FN splicing in other systems and induces chondrogenesis. We have asked, using mouse pre-chondrogenic ATDC5 cells, if TGF-β1 affects chondrogenesis in parallel with FN isoform expression. We first assessed if TGF-β1 altered production of a sulfated extracellular matrix,characteristic of cartilage. To prevent chondrocyte maturation, cells were maintained without insulin. By day 5, TGF-β1-treated cultures exhibited more Alcian blue staining than controls. To assess chondrogenesis, we measured by RT-PCR collagen type I and type II mRNA expression. In these first 5 days of culture, representative of the condensation phase, TGF-β1 treatment decreased col α1(I) and increased col α1(II) mRNA expression, suggesting that TGF-β1 accelerated initial stages of chondrogenesis. We next examined inclusion of the EDIIIA (A) and EDIIIB (B) exons in FN mRNA. Inclusion of the A and B exons (A+B+) is characteristic of the pre-chondrocyte, whereas A-B+ form is characteristic of the maturing chondrocyte. TGF-β1 treatment decreased exon A inclusion and increased exon B inclusion, in parallel to effects of TGF-β1 on chondrogenesis. Expression of the short-form of the pre-mRNA splicing protein, SRp40, also correlates with the onset of chondrogenesis. Exclusion of the FN A exon has been directly linked to expression of this short-form. TGF-β1 treatment increased expression of the short-form of SRp40, as assessed by RT-PCR, suggesting a mechanism for the effect of TGF-β1 on FN splicing events. These data indicate that TGF-β1, which increases the commitment of the pre-chondrogenic ATDC5 cells to chondrocytes, decreases inclusion of the FN-EDIIIA exon and increases inclusion of the FN-EDIIIB exon in a time- and dose-dependent manner. These splicing events directly correlate with the increased expression of the splicing factor SRp40. Other extracellular matrix proteins, i.e., collagen type II, undergo regulated splicing during chondrogenesis. Our data suggest that an important effect of TGF-β1 during chondrogenesis involves the regulation of alternative splicing.

The Effect of Pamidronate on Intervertebral Disc and Endplate. S. Moon, H. Kim*, U. Kwon*, K. Lee*, H. Kim*, K. Yang*, J. Jahng, S. Park*, J. Jeon*, H. Lee*. Department of Orthopaedic Surgery, Yonsei Univesity College of Medicine, Seoul, Republic of Korea.

As potent inhibitors of bone resorption, bisphosphonates (BPs) are widely used for the treatment of bone disorders that are due to increased osteoclast activity. BPs also exhibit partial chondroprotective effect, inhibiting breakdown of collagen type II. Nutritional deprivation caused by sclerosis of vertebral end plate provides, in part, a mechanism of intervertebral disc (IVD) degeneration. The fact that BPs have a powerful antiresorptive effect and chondroprotective effect prompts a research for the sum effect of BPs on IVDs, since antiresorptive action can cause hypertrophy of endplate while chondroprotective effect can maintain chondrogenic phenotype of IVDs. Accordingly, the purposes of this experimental study were, firstly, demonstrate the effect of pamidronate, second generation N-containing BPs on in vitro metabolism of IVD cells and secondly, the effect of pamidronate on histologic changes of endplate and IVD. Human lumbar IVD cells were cultured in alginate beads for in vitro test. Pamidronate (10^{-9}, 10^{-6}, 10^{-3} M) was administered to cultures. ^{3}H-Thymidine for DNA synthesis and ^{35}S-Sulfate incorporation for proteoglycan synthesis were performed. RT-PCR for mRNA expression of collagen type I, collagen type II, and aggrecan was also performed. For in vivo test, pamidronate was injected intravenously (30ug/kg, 90ug/kg) to mice (C57BL/6) weekly for 5 and 12 weeks. H-E, Safranin-O stain, and TUNEL assay were done. Histomorphometric data were also collected. Human IVD cell cultures with pamidronate showed significant increase in proteoglycan synthesis, 40% increase with a dose of 10^{-9} M pamidronate ($p<0.05$). In densitometric assay of RT-PCR, cultures showed no significant changes in mRNA expression of type I collagen, type II collagen, and aggrecan. Mice with pamidronate injection showed significant increase in thickness of endplate without evidence of IVD degeneration. Furthermore, Mice with pamidronate demonstrated no significant increase in TUNEL positive cells in endplate and IVD. In conclusion, these in vitro and vivo data confirm that pamidronate, N-containing second generation BPs, is safe to IVD metabolism without causing apoptosis and IVD degeneration.

Osteoprotegerin and Receptor Activator of NF-kB Ligand Were Regulated by Retinoic Acid and Bone Morphogenetic Protein-2 during Chondrogenesis or Osteogenesis of USAC. K. Yagami. Oral and Maxillofacial Surgery, Showa University, Tokyo, Japan.

[Introduction] Several cytokines affect on bone and cartilage resorption at the invasive site of bone tumors. Receptor activator of NF-κB ligand (RANKL) and osteoprotegerin (OPG) are potent regulator of osteoclasts in bone metabolism. At present, however the effect of RANKL and OPG on the differentiation of chondrocyte is unclear. Retionic acid (RA) increases alkaline phosphatase activity and type X collagen synthesis. These stimulatory effects of RA imply the enhancement of chondrocyte maturation. We have newly established a human chondrocytic cell line (USAC) expressing chondrocytic phenotypes. USAC also shows osteogenic differentiation by rhBMP-2 in vivo. In the present study, we examined changes in the expression of RANKL and OPG by RA or rhBMP-2 in the process of maturation and differentiation of USAC.

[Materials and Methods] USAC cells were cultured at a density of 1x106/ml in 2.5%FBS/a-MEM, and were treated with RA (30-300 nM) or rhBMP-2 (10-1000 ng/ml) for several days. RT-PCR was performed with the specific DNA probe for h-RANKL and h-OPG. Cell extracts of parallel culture, containing equal protein concentrations, were electrophoresed on 10% sodium dodecyl sulfate-polyacrylamide gels (SDS-PAGE) for Western blot analysis with anti-human antibody for RANKL and OPG. USAC cells were transplanted into peritoneal cavities of 6-week-old athymic mice using diffusion chambers with or without rhBMP-2. In some chambers, 1000 nM of RA or 5 mg of rhBMP-2 was coated on the inner surface of the membrane filter. The chambers were removed from mice 1-4 weeks after implantation, then fixed and embedded in plastic for undecalcified sections. These sections were stained with anti-human antibody for RANKL and OPG.

[Results] RANKL and OPG mRNAs were expressed in USAC. RANKL mRNA was up regulated and OPG mRNA was down regulated both by the treatment with RA and rhBMP-2. Moreover, the cartilage like tissue formed in DC was mostly stained with OPG. However, RANKL was strongly stained in the calcification portion and the osteoid in DC. These results suggested that RANKL and OPG were regulated by RA and BMP-2 during chondrogenesis or osteogenesis on USAC.

PERK eIF2 Alpha Kinase Regulates Neonatal Bone Development. D. Cavener, J. Wei*, X. Sheng*, B. McGrath*, A. Frank*, M. Teta*. Biology, Penn State University, University Park, PA, USA.

Genetic deficiencies of the PERK eIF2 alpha kinase result in severe neonatal growth retardation, osteopenia, and infantile diabetes in the human Wolcott-Rallison syndrome (WRS) and in mice. Through phosphorylation of the translation initiation factor eIF2 alpha, PERK can regulate either global protein synthesis or translation of specific regulatory genes depending upon the physiological and developmental status of a specific tissue or organ. As an endoplasmic reticulum (ER) transmembrane kinase, we have proposed that PERK acts as multipurpose sensor of secretory activity and modulator of secretory capacity in highly secretory cells such as osteoblasts, chondrocytes, hepatocytes, and insulin-secreting beta cells. Previously we showed that the growth defect in PERK KO mice is caused by an early neonatal deficiency in circulating IGF-1 derived from the liver, whereas the osteopenia is caused by deficiencies in both cortical and trabecular bone formation. To elucidate the underlying molecular and cellular defects associated with the skeletal anomalies in PERK KO mice, we have performed a detailed developmental examination of the skeletal and cellular structure of the axial and appendicular skeleton. In addition we have examined the expression of genes and proteins known to be critically involved in late embryonic and postnatal bone development as well as performed gene profiling experiments comparing wild-type and mutant osteoblasts and fibroblasts. These studies have indicated that PERK plays a crucial role in postnatal synthesis, assembly, and secretion of type I collagen, particularly in osteoblasts.

Gene Expression Microarray-based Hypothesis for Cadmium-Induced Bone Loss. M. H. Bhattacharyya, A. Regunathan*, D. A. Glesne*, A. Ebert-McNeill*. Biosciences Division, Argonne National Laboratory, Argonne, IL, USA.

To identify a mechanism of cadmium-induced bone loss that did not rely on guessing the pathways involved, a whole-mouse genome c-DNA microarray was used to determine changes in bone cell gene expression after a single cadmium gavage to mice. To identify early pathways, time points were 2h and 4h after gavage, for a dose (200 ug Cd/mouse) at which calcium release from bone starts at 8h. Three mouse strains [CF1, metallothionein-normal (MTN), and MT1,2-deficient (MT1,2KO)] were studied to identify a robust mechanism that applied across mouse strains. Results showed that ~18 genes increased significantly in mRNA level in bone cells after Cd gavage in all 4 or in 3 of the 4 microarrays. High to low in Cd responsiveness, these were: cysteine-rich protein 61 (Cyr61), metallothionein 2 (MT2), transferrin receptor (TfR), glutamine synthetase pseudogene 1, MT1, acidic chitinase, RIKEN cDNA 3930401B19, src-like adaptor protein, vacuolar proton pump ATPase, integrin alpha v, aquaporin 1, and p38 MAP Kinase. No genes showed analogous decreases. Concentration increases were small but were validated by Northern analyses. Gene changes fit into the following hypothesis: Cadmium could, by currently unknown mechanisms, increase expression of cysteine-rich protein 61 (Cyr61) in osteoblasts. Cyr61 has been shown to be high in osteoblasts. It is a secreted extracellular matrix-associated protein that binds the integrin dimer, alpha-v beta-3. Cyr-61 secretion from osteoblasts could attract osteoclasts or their precursors and bind to their surface integrin molecules, thus stimulating cell migration, adhesion and osteoclast activation. Activation would stimulate expression of other osteoclast genes, including integrin alpha-v (signaling molecule involved in activation), vacuolar proton pump ATPase (provides acid to dissolve bone calcium and to activate acid proteases that degrade bone matrix), transferrin receptor (provides needed iron), acid chitinase (acidic polyglucosamine hydrolase, maybe involved in degradation of bone matrix glycoproteins, such as osteonectin, decorin, biglycan?), and aquaporin (water pore that enables solute movement to resorption pit?). Osteoclast precursor cells contain high concentrations of p38 MAP kinase compared to other bone cells, and this kinase is required for osteoclast formation. The latter pathways could explain existing evidence that cadmium stimulates bone loss by increasing both osteoclast formation and activation.

Enhanced Bone Regeneration in HIF-1α +/- Mice. D. E. Komatsu[1], D. J. Manalo*[2], G. L. Semenza*[2], M. Hadjiargyrou[1]. [1]Biomedical Engineering, SUNY, Stony Brook, Stony Brook, NY, USA, [2]Pediatrics, Medicine, Oncology, Radiation Oncology, Johns Hopkins University, Baltimore, MD, USA.

Previous work in our laboratory has demonstrated that regional hypoxia subsequent to bone fracture activates hypoxia- inducible factor 1α (HIF-1α) and initiates HIF-1 mediated up-regulation of numerous genes involved in bone regeneration. This study was designed to test the hypothesis that HIF-1α has a functional role in bone regeneration. Fixed femoral fractures were generated unilaterally in 10 female mice heterozygous for HIF-1α (HIF-1α+/-) and 10 wild-type littermates (HIF-1α+/+). The animals were euthanized on post-fracture day 21 and the fractured and unfractured (contralateral control) femurs were harvested and scanned by micro computed tomography (μCT) to determine volumetric and areal properties. In addition, 4-point bending to failure was conducted on the specimens in order to determine stiffness and ultimate strength, quantitative measures of healing. All 10 intact femurs from each group of mice were analyzed, while only 5 fractured femurs from each genotype were analyzed (sample losses due to pin removal and mechanical testing). The μCT scans of the intact femurs revealed no significant differences in femur length or periosteal, cortical and endosteal areas between HIF-1α+/- and HIF-1α+/+ mice. However, mechanical testing demonstrated a significant increase in ultimate strength (17%) in the HIF-1α+/- mice. The μCT scans of the fractured femurs were used to quantify callus volume (including soft tissue, mineralized callus and cortical bone) and mineralization (mineralized callus only) in proximal, central and distal callus regions. These analyses yielded significant increases in mineralization in both proximal (70%) and central regions (57%) as well as callus volume in distal regions (81%) in the HIF-1α+/- mice, as compared to HIF-1α+/+. Since the intact femurs showed significant differences in strength between genotypes, the mechanical testing results for the calluses were normalized to their respective contralateral controls. The results from this analysis identified a significant increase in stiffness (142%) in the HIF-1α+/- mice but no significant differences in ultimate strength. Contrary to our expectation that partial HIF-1α deficiency would lead to impaired bone regeneration, our data surprisingly indicate the reverse. Further experiments are ongoing to verify these data and identify the underlying molecular mechanisms responsible for these observations.

Alterations in Osteoblast-specific Gene Products by Isoflavones in the Context of Soy- and Casein-based Protein in a Rat Model of Male Osteoporosis. D. Y. Soung[1], L. Devareddy*[1], D. A. Khalil[1], E. A. Lucas[1], B. J. Smith[1], S. Juma[2], B. H. Arjmandi[1]. [1]Nutritional Sciences Department, Oklahoma State University, Stillwater, OK, USA, [2]Department of Nutritional Sciences, University of Cincinnati Medical Center, Cincinnati, OH, USA.

Soy and its isoflavones have been shown to increase bone formation. The purpose of this study was to examine the effect of isoflavones on bone matrix protein synthesis and osteoblast activity (i.e. collagen type I, COL: osteocalcin, OC; osteonectin, ON; osteopontin, OP; alkaline phosphatase, ALP) at the mRNA level in male rats. Twenty-four male F344 rats, aged 13 months were either sham-operated (Sham; 1 group) or orchidectomized (ORX; 5 groups). Rats in the Sham and one ORX group were fed a casein-based control diet (AIN-93M) and the remaining four ORX groups were fed one of the two doses of isoflavones in the context of either casein (Iso1 = 600 or Iso2 = 1200 mg isoflavones/kg diet) or soy protein (Soy = 600 or Soy+ = 1200 mg isoflavones/kg diet) for 180 days. Total RNA was extracted from distal femur and Northern blot analysis was used to measure mRNA levels. cDNA of 18S ribosomal RNA was used as an internal control to normalize gene expression. The table below shows the effect of treatments on osteoblast-specific gene products.

Group	COL/18S	OC/18S	ON/18S	OP/18S	ALP/18S
Sham	1.38 ± 0.33^{c}	0.66 ± 0.11^{c}	0.63 ± 0.11^{c}	0.90 ± 0.26	0.68 ± 0.11^{c}
ORX	2.56 ± 0.33^{b}	1.07 ± 0.11^{ab}	1.04 ± 0.11^{ab}	0.99 ± 0.16	0.96 ± 0.11^{bc}
Iso1	2.97 ± 0.38^{b}	1.10 ± 0.12^{ab}	1.01 ± 0.13^{ab}	0.87 ± 0.19	1.08 ± 0.13^{ab}
Iso2	4.13 ± 0.38^{a}	1.32 ± 0.12^{a}	1.31 ± 0.13^{a}	1.06 ± 0.19	1.25 ± 0.13^{ab}
Soy	2.47 ± 0.38^{b}	0.80 ± 0.12^{bc}	0.83 ± 0.13^{bc}	1.17 ± 0.19	0.90 ± 0.13^{bc}
Soy+	3.41 ± 0.38^{ab}	1.29 ± 0.12^{a}	1.11 ± 0.13^{ab}	1.00 ± 0.19	1.41 ± 0.13^{a}

Data are mean ± SE (n=4). Values in a column that do not share the same superscript letters are significantly (P<0.05) different from each other.

Our findings suggest that high dose of isoflavones, irrespective of protein source, have a more pronounced effect on certain osteoblast-specific genes products involved in bone formation.

Orally Administered N-Butyrylated Glucosamine (GlcNBu) Decreases Inflammation in the Streptococcal Cell Wall Rat Arthritis Model and Increases the Bone Mineral Density and Content of the Subchondral Regions of the Femur and Tibia. T. P. Anastassiades[1], M. Grynpas[2], S. Wang*[3], J. R. Carran*[1], D. S. Wainman*[1]. [1]Medicine, Rheumatology, Queen's University, Kingston, ON, Canada, [2]Laboratory Medicine and Pathobiology, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, ON, Canada, [3]Samuel Lunenfeld Research Institute, Mount Sinai Hospital,, Toronto, ON, Canada.

Purpose. Determine the effects of feeding a novel N-acyl glucosamine, GlcNBu, on (i) the inflammatory arthritis in the rat, and (ii) on the bone mineral density in a region of interest (ROI) comprising of the distal part of femur and proximal part of the tibia.

Methods. Female Lewis rats, 150 g, on were injected intra-peritoneally with streptococcal cell wall antigen (15 μg/g) and ankle swelling was measured daily by a standard caliper method. Standard chow was supplemented as follows (mg/kg/day) : Group I - GlcNBu, 200; II - glucose, 200; III - GlcNBu 20; IV - no arthritis induced, no supplementation. At the end of 4 weeks the animals were sacrificed and the dissected femurs and tibias (70 bones of each) were scanned with a micro-DXA technique, standardized at the ROI, to provide normalized bone mineral denisty (BMD) and content (BMC). Statistics were done with SPSS.

Results. Group I, high dose GlcNBu, demonstrated significant reductions in inflammation compared to glucose controls (bottom and top lines, respectively, Fig 1). A smaller reduction in inflammation was seen at 20mg/kg/day (not shown). In Fig 2 the bars show ROI BMDs in the order of I to IV. Group I had the highest BMD and BMC, compared to all other Groups, with statistically significant differences. Group III (low dose GlcNBu) demonstrated the next highest BMD/BMCs, followed by Groups IV and II.

Conclusions. Orally administered GlcNBu at 200mg/kg/day, to rats with inflammatory arthritis significantly reduced the inflammatory response and increased the BMD/BMC in subhondral areas, over controls including normals. The mechaism of these effects has not been elucidated.

A New Technique Using Calcium Phosphate Precipitate Enhances Efficiency of In Vivo Plasmid Gene Transfer. S. Kuroda[1], H. Kondo[1], K. Ohya[2], S. Kasugai[1]. [1]Oral Implantology and Regenerative Dental Medicine, Tokyo Medical and Dental University, Tokyo, Japan, [2]Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan.

Currently, in vivo gene transfer with expression plasmid vector is one of the emerging remedies because gene transfer with plasmid vector is simple and clinically safe compared to the other transfer systems with virus vectors. An expression plasmid vector encoding hBMP-2 was combined with collagen and transplanted to a segmental bone defect of experimental animals, consequently regenerating the bone defect. However, large amounts of plasmid vectors (1 mg or more) have been used in these studies, suggesting the low efficiency of gene transfer. On the other hand, calcium-phosphate (CaP) precipitate, in which plasmid vector is incorporated, has been used for in vitro gene transfer. Since CaP particles stabilize nucleic acid, we speculated that CaP precipitate would be also useful for in vivo gene transfer. In the present study, we combined CaP precipitate with expression plasmid vector encoding BMP-2 and examined whether this formula becomes more effective on gene transfer and bone formation. Twenty μg of pEGFP plasmid vector encoding hBMP-2 was served as several formulas in 1% collagen base in combination with CaP or CaP plus 5% of hyaluronic acid in 400 μl, freeze-dried, and then transplanted on rat calvarias subcutaneously. The animals were killed at 1, 2 and 3 weeks post operation and the calvarias were subjected for EGFP detection and histology. At 2 weeks, fluorescence was observed in "pEGFP-collagen", "pEGFP-CaP-collagen" and "pEGFP-CaP-collagen-hyaluronic acid" groups. Notably, the fluorescence of "pEGFP-CaP-collagen" and "pEGFP-CaP-collagen-hyaluronic acid" groups were much extensive compared to "pEGFP-collagen". Corresponding to these CLSM images, fluorescence measurement of the tissue homogenates revealed intense fluorescence of the "pEGFP-CaP-collagen" and "pEGFP-CaP-collagen-hyaluronic acid" groups. Histological sections from "pEGFP-CaP-collagen" and "pEGFP-CaP-collagen-hyaluronic acid" groups elucidated osteoblast cohesion at 1 to 3 weeks. However, the sections from "pEGFP-collagen"Group suggested that entries of osteoblasts into the matrix area were not as clear as in the other two groups. Additionally, the formula incubation in PBS released more the plasmid from "pEGFP-CaP-collagen" and "pEGFP-CaP-collagen-hyaluronic acid" than from "pEGFP-collagen". Although the safety of the plasmid DNA administration has been speculated, decrease in plasmid DNA dose is obviously ideal. Our formula would reduce the dose of plasmid DNA and impact on experimental and therapeutic fields employing plasmid DNA transfer.

Signal-Dependent and Developmentally Regulated Transcription Factors are Activated During Chondrocyte Differentiation Induced by Demineralized Bone. K. E. Yates. Orthopedic Surgery, Brigham and Women's Hospital, Boston, MA, USA.

The mechanisms that regulate chondrocyte differentiation post-natally are not well understood. In this study, an *in vitro* model of induced chondrocyte differentiation was used to identify changes in transcriptional networks. Human dermal fibroblasts (hDFs) were cultured in three-dimensional, porous collagen sponges with or without chondroinductive demineralized bone powder (DBP). Nuclear extracts were prepared on day 3, before the chondroblast phenotype is evident (i.e., matrix containing collagen type II and aggrecan). Nuclear protein binding to transcriptional enhancer sites (TranSignal Protein/DNA Arrays, Panomics Inc) was measured as a surrogate of transcription factor activity. DBP-induced changes were classified according to transcription factors' roles in cellular regulatory circuits [Science 295: 813, 2002].

1) No changes in activity were found at serum inducible or thyroid hormone receptor binding sites, validating the assay and the specificity of hDFs' response to DBP. 2) Among constitutively active factors, DBP increased activity at TFIID sites (180% of control) and decreased activity at CCAAT-box sites CBF (30%) and C/EBPalpha (30%). 3) Among regulated factors, DBP greatly increased activity at targets of cell surface receptor-ligand activated signaling pathways (Figure). Immunoblotting showed increased (180%) active CREB protein (phospho-CREB) in DBP/collagen sponges, and immunocytochemistry showed intense nuclear staining of phospho-CREB in hDFs in contact with DBP. Quantification of AP-1 proteins by ELISA showed increased JunB (200%) and phospho-Jun (130%). cDNA array analysis documented increased mRNA levels of *NFkB* (290%) and *RelA* (160%). 4) Among developmentally regulated factors, increased or decreased activity was found for several GATA, homeobox, and forkhead binding sites (Figure). Increased expression of *RUNX2* mRNA (200%) in DBP/collagen sponges was detected by real-time PCR.

These changes in transcriptional networks imply upstream activation of cell signaling pathways, including calcium 2nd messengers and serine kinases, in hDFs cultured with DBP for 3 days. Concomitant changes in developmentally regulated factors suggest co-ordination between extracellular and intracellular signals during chondroinduction of post-natal fibroblasts.

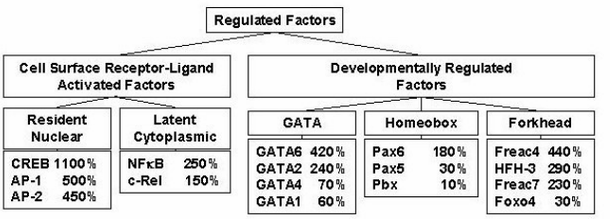

Figure. Classification of DBP-induced changes (% of control) in nuclear extract protein binding activity to enhancer elements.

Multiple Potential of Rat Mandible Marrow Mesenchymal Stem Cells: Isolation, Cultivation, and Induction of Differentiation. C. Shih, J. Shyu. Biology and Anatomy, National Defense Medical Center, Taipei, Taiwan Republic of China.

The regeneration of periodontal tissue apparently depends on differentiation of mesenchymal stem cells migrating into wound which have the potential for osteogenesis, cementogenesis, and formation of periodontal tissues. In addition, successful implant therapy may also be dependent on the differentiation of stem cells arising from the surrounding bone marrow. It is important to establish an in vitro animal study model which deals with cellular aspect of periodontal tissue engineering, regeneration or repair using bone marrow MSCs of mandibular origin. The purpose of this study was to isolate, characterize, and induce cell differentiation into different lineage cells by density gradient separation method, cell culture, CD marker selection, alkaline phosphatase activity(ALP), bone colony formation, light and phase contrast inverted microscopy, H&E stain, oil red O stain, MAP-2 , GFAP and flow cytometry. Rat bone marrow cells were harvested from mandible and MSCs isolated by density gradient separation, cultivation and CD markers (e.g. CD 90 and etc.) selection. Isolated bone marrow MSCs were cultured to semiconfluent and treated with osteogenic differentiation medium(DMEM-LG supplemented with 10% FBS, ascorbic acid, 100 nM dexamethasone, with or without 10 mM beta-GP) or adipogenic differentiation medium (100 nM dexamethasone, indomethacin and insulin) or neurogenic differentiation factor. Appearance of cuboid-shaped osteoblastic cells, unmineralized or mineralized colony was noted approximately 10, 15 and 21 days after osteogenic induction. With adipogenic induction, small sized lipid droplets began to appear within cytoplasm 7 days. More and larger lipid droplets accumulation were noted 10-14 days after induction. We also noted that lipid droplets-containing adipocytes terminally differentiated into round shaped adipocyte and finally became unadherent and floating within the medium. In addition, MAP-2-positive neurons and GFAP-positive glial cells were noted after induction. The results of this study indicated that rat mandible bone marrow MSCs could be isolated, cultured, and induced to become osteogenic, adipogenic and neurogenic cells/tissues.

Changes in Permeability of Osteocyte Lacunar Wall After Ischemia and Reperfusion Injury. S. Qiu[1], D. Rao[1], S. Palnitkar*[1], A. Parfitt[2]. [1]Bone & Mineral Research Lab, Henry Ford Health System, Detroit, MI, USA, [2]Division of Endocrinology and Center for Osteoporosis and Metabolic Bone Disease, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Our objective was to determine the effects of ischemia/reperfusion (I/R) on the permeability of the lacunar wall. Basic fuchsin is able to stain microcracks, unmineralized osteoid and osteocyte lacunae and canaliculi, but unable to penetrate into the mineralized bone matrix. Penetration of basic fuchsin through the lacunar wall indicates that the material property of perilacunar matrix has been changed.

A rubber band tourniquet was applied at the right thigh in 5 rats for 3 hours and then released. The animals were sacrificed 7 days after surgery. Five normal rats were used as controls. The diaphyseal segments were placed in 70% ethanol containing 1% basic fuchsin, embedded in methylmethacrylate, sectioned into 100 µm and examined using fluorescence and confocal microscopy.

In normal bone, 97.6% of osteocyte lacunae were impermeable to basic fuchsin. The thickness of perilacunar labeling was < 1 µm (mean ± SD for 100 normal osteocyte occupied lacunae: *0.43 ± 0.15 µm*) under confocal microscopy. Based on this, a band thicker than 0.8 µm, > 2 SD greater than the mean value for normal lacunae, was taken to define fuchsin permeability. There were many fuchsin permeable lacunae in I/R bone (Fig 1A). However, the small scanning field makes confocal microscopy unsuitable for a large-scale measurement of osteocyte lacunae. Since the fluorescence intensity of basic fuchsin is very strong, the perilacunar band can also be viewed using fluorescence microscopy (Fig 1B). The fluorescence band was not clear around normal osteocyte lacunae. Approximately 98% of the permeable lacunae had a band thicker than 0.8 µm (mean ± SD: *1.71 ± 0.63 µm*). This number was consistent with the value derived from confocal microscopy. There was no significant difference in total lacunar density between I/R and normal bones (1319 ± 98/mm² vs 1384 ± 83/mm²). However, the density of permeable lacunae was about 5 times higher in I/R bone than in normal control (150 ± 24/mm² vs 33 ± 17/mm², $p < 0.001$).

The results show that very few osteocyte lacunae in normal bone are permeable to basic fuchsin. A significant increase in permeable lacunae at 7 days of I/R suggests that the perilacunar matrix may be damaged under certain extreme pathological conditions.

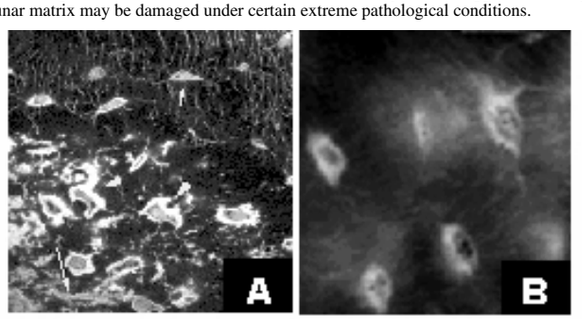

Fig 1. Osteocyte lacunae in bone with I/R injury. A) normal (short arrow) and permeable lacunae (arrowheads) under confocal microscopy, B) permeable lacunae under fluorescence microscopy.

Secreted Phosphoprotein-24 (SPP-24) Reduces Bone Mass in Transgenic Mice Whereas BMP Binding Peptide (BBP), a Polypeptide Deduced from the Sequence of SPP-24, Enhances the Activity of rhBMP-2 In Vivo. S. S. Murray*[1], K. Behnam[2], J. D. P. Silva*[3], M. E. L. Duarte[3], E. J. B. Murray[1]. [1]GRECC/Medicine, VAGLAHS/University of California, Sepulveda/Los Angeles, CA, USA, [2]Physiological Sciences, University of California, Los Angeles, CA, USA, [3]Histology and Embryology, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil.

We have determined by chromatographic separation, MALDI/ToF MS, and peptide fingerprinting analysis that the protein that Marshall Urist referred to as "bone morphogenic protein" is an 18.5 kD acidic fragment of the previously described secreted phosphoprotein-24 (SPP-24). The 18.5 kD protein contains a cystatin- or cysteine-protease inhibitor-like domain similar to that of fetuin. As with fetuin, within this sequence there is a region with sequence similarity to the TGF-beta receptor II called the TRH1 (TGF-beta receptor II homology 1) domain. BMP binding peptide (BBP) is a synthetic 19 amino acid polypeptide deduced from the sequence of Urist's BMP which is similar to the cystatin/TRH1 domain of fetuin. We have investigated the effects of SPP-24 and BBP on bone formation. Transgenic mice expressing full-length SPP-24 under the control of the osteocalcin promoter were created. Five independent strains were generated, though expression could not be quantitated. Femoral, but not vertebral, BMD was 5.7% lower in female, but not male, transgenic mice at 8 months of age. Similarly, quantitative histomorphometric analysis demonstrated reduced bone volume, trabecular thickness, and trabecular separation in female transgenic animals. On the other hand, surface plasmon resonance demonstrated that BBP, like fetuin, binds rhBMP-2. BBP enhanced the activity of rhBMP-2 in the 3-week mouse hindquarter heterotopic bone forming assay. In this assay, 500 ug of BBP increased the activity of 5 ug of rhBMP-2. The area of ectopic bone formed increased by 62%, and bone mineral content increased by 74%. In time-course studies, cartilage was detected earlier in mice who received BBP in addition to rhBMP-2. We conclude that Urist's BMP is an 18.5 kD fragment of SPP-24 and hypothesize that its activity is related to binding BMPs and increasing their residence time at the site of action.

Involvement of the Urokinase Receptor in Bone Homeostasis. F. Furlan[1], N. Jorgensen*[2], J. Jensen*[2], A. Rubinacci*[3], E. Mrak*[3], I. Villa*[3], F. Blasi*[1]. [1]Molecular Gentics, Vita-Salute University, HSR, Milano, Italy, [2]Endocrinology, Osteoporosis Unit, Copenhagen, Denmark, [3]Bone Metabolic Unit, HSR, Milano, Italy.

The plasminogen activator system (PAS) is an intricate system of serine proteases, protease inhibitors, and protease receptors that governs the conversion of the abundant plasma protease zymogen, plasminogen, to the active protease, plasmin. Plasmin directly or indirectly, via the activation of latent matrix metalloproteases, degrades components of the extracellular matrix in the context of tissue homeostasis, tissue remodeling, and tissue repair. In particular, urokinase receptor (uPAR) is actively involved in the regulation of important cell functions like adhesion and migration and it has been shown to interact with integrins.

PAS is also implicated in the pathogenesis of a remarkable array of important human degenerative diseases, tumor dissemination, vessel wall diseases, and rheumatoid arthritis. The skeleton is particularly rich in extracellular matrix, and remodeling is central to skeletal physiology throughout life. Furthermore, it has been previously shown that the major players of bone remodeling, osteoblasts (Obs) and osteoclasts (Ocs), produce urokinase (uPA) and express its receptor (uPAR).

The purpose of this study was to investigate the role of uPAR in bone remodeling. To achieve this aim we analyzed the bone phenotype in uPAR-null female mice. Morphological analysis of the skeleton showed a significant decrease in tibia length in mutant mice as compared to Wt. Bone mass analysis by peripheral quantitative computed tomography (pQCT), reveals that the absence of uPAR determines an increase in bone mass as compared to normal mice ($p<0.02$). Moreover, mechanical test showed a reduction in the capability to sustain a given load in uPAR Ko tibias as compared to normal tibias from female animals ($p<0.02$).

To explore the cellular bases of the bone defect in uPAR Ko mice, we cultured Obs in vitro. The results confirmed these findings showing a proliferative advantage and a higher susceptibility of the matrix to be mineralized as compared to Wt cells. The production of important proteins involved in the mineralization process, like alkaline phosphatase (ALP), is increased only during the first weeks of Ob maturation. After 4 weeks ALP is similar in both genotypes.

Together our preliminary data indicate that uPAR may play an important role in bone physiology.

Regulation of Osteoactivin (OA) Expression by Osteotrophic Factors and its Role in Mediating BMP-2 Effects on Osteoblast Differentiation and Function. S. A. Abdelmagid*[1], E. Nuglozeh*[1], M. F. Barbe[2], S. N. Popoff[1], F. F. Safadi[1]. [1]Anatomy and Cell Biology, Temple University, Philadelphia, PA, USA, [2]Physical Therapy, Temple University, Philadelphia, PA, USA.

Osteoactivin (OA) is a novel osteoblast-related glycoprotein that plays an important role in osteoblast differentiation and function. TGF-β1, BMP-2 and calcitriol are important osteotrophic factors that regulate osteoblast proliferation and differentiation. In this study we first examined the effects TGF-β1, BMP-2 and calcitriol on OA expression. Primary osteoblast cultures treated with TGF-β1 (5 ng/ml), BMP-2 (50 ng/ml) and calcitriol (10^{-8} M) were terminated at different time points and examined for OA expression using Western blot analysis. TGF-β1 treatment showed minimal effect on OA expression, while BMP-2 and calcitriol showed an up-regulate of OA expression especially during the matrix maturation and mineralization stages in culture. BMP-2 maximally induced OA expression (5-fold) during the matrix mineralization stage in culture. Next, we treated primary osteoblast cultures with different doses of BMP-2 (10-200 ng/ml) for 24 hours under serum free conditions. OA protein expression levels reached a maximum at 50 ng/ml. In order to examine whether OA is a downstream mediator of BMP-2 effect on osteoblast differentiation, OA anti-sense oligonucleotide was used to inhibit OA expression in cultures treated with BMP-2. Primary osteoblast cultures treated with BMP-2 (50 ng/ml) stimulated nodule formation and matrix mineralization when compared to non-treated cultures. Cultures treated with OA anti-sense oligonucleotide (0.5 µM) showed a reduction of OA expression associated with decreased nodule formation and calcium deposition. BMP-2 (50 ng/ml) treatment rescued OA expression associated with an increase in nodule formation and matrix mineralization, when compared to OA anti-sense treated cultures. BMP-2 is known to stimulate osteoblast differentiation mainly through the phospho-Smad 1, 5 and 8 path-

way. Cultures treated with BMP-2 showed an up-regulation of phospho-Smad 1 when compared to non-treated cultures. In OA anti-sense treated cultures, phospho-Smad 1 was down-regulated when compared to non-treated cultures, while BMP-2 rescued phospho-Smad 1 expression. These data suggest that OA might be a downstream mediator of BMP-2 in osteoblasts. Future studies are designed to use phospho-Smad 1 inhibitors, to examine whether OA expression is altered. We conclude that OA is regulated by different osteotrophic factors and may act as downstream mediator of BMP-2 effects on osteoblast differentiation.

Disclosures: ***S.A. Abdelmagid****, None.*

IL-3 Stimulates Osteoclast (OCL) Formation and Inhibits Osteoblast (OBL) Differentiation in Myeloma. L. A. Ehrlich*[1], M. Ito[1], S. J. Choi[1], G. D. Roodman[2]. [1]Medicine-Hematology/Oncology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Medicine-Hematology/Oncology, University of Pittsburgh and Dept. of Veterans Affairs Medical Center, Pittsburgh, PA, USA.

Normally, bone resorption is coupled to an increase in osteoblast activity. In Multiple Myeloma (MM), bone remodeling is uncoupled, and bone destruction occurs both by markedly increased osteoclastic bone destruction and severely impaired osteoblastic bone formation. Although several reports have shown that conditioned media from MM cell lines suppress OBL differentiation, the identity of the OBL inhibitor(s) is unknown. A recent report by Tian et al (NEJM 2003) has identified DKK1, an inhibitor of the WNT signaling pathway, as a putative OBL inhibitor in MM. However, it is likely that other inhibitors of OBL differentiation are present in the myeloma microenvironment, just as there are several potent stimulators of OCL formation produced or induced by myeloma cells. We recently reported that IL-3 levels in bone marrow plasma of patients with MM are increased compared to normal controls and that IL-3 in MM marrow plasma stimulates osteoclast formation. We also demonstrated that IL-3 is produced by primary myeloma cells and that it increased MM cell growth in vitro. However the effects of IL-3 on OBL are unknown. Therefore, to determine if IL-3 could affect OBL growth and differentiation, we tested if primary marrow stromal cells and OBL-like C2C12 cells differentiated with BMP2 expressed IL-3 receptor α (IL-3R). Both cells types expressed IL-3R by RT-PCR. Immunostaining for IL-3R in murine marrow stromal cell cultures showed that the IL-3R was present on thirty percent of the cells after treatment with IL-3, confirming the PCR results. Importantly, treatment of primary murine stromal cell cultures with IL-3 (0.01-10 ng/mL) inhibited basal and BMP-2 stimulated osteoblast formation in a dose dependent manner, without affecting cell growth. At 10 ng/mL IL-3 inhibited OBL differentiation by 80%. Time course studies demonstrated that IL-3 affected the later stages of osteoblast differentiation. Further, the inhibitory effects of IL-3 were not due to induction of TNFα. TNFα levels were very low (0-20 pg/ml) in the conditioned media of these cultures, and treating the cultures with anti-mouse TNFα did not block the IL-3 effect. This data suggests that IL-3 may be an important mediator of the bone destruction in MM by both inducing osteoclast formation and inhibiting bone formation.

A New Method for Early *in vivo* Detection of Bone Metastases Using Green Fluorescence Protein (GFP) Expressing A375 Human Melanoma Cells. D. C. Huang[1], G. Ma*[2], A. Belenkov*[2], X. F. Yang*[1], A. Kremer*[1], L. McIntosh*[2], R. Kremer[1]. [1]Medicine, Royal Victoria Hospital and McGill University, Montreal, PQ, Canada, [2]ART Advanced Research Technologies Inc., Saint-Laurent, PQ, Canada.

Nude mice injected into the left cardiac ventricle with A375 human melanoma cells usually develop osteolytic lesions within 2-3 weeks. X-ray analysis is a routine but insensitive method to detect metastatic bone destruction. Histomorphometric analysis is a specific and sensitive method to detect bone metastasis but is labour intensive and consequently not suitable for large scale analysis. A system that would allow early detection of tumor cells colonization within bone prior to detectable bone destruction by X-ray analysis would greatly facilitate research in this area. In the present study, we used a new *in vivo* small animal molecular imager fluorescence scanning system (eXplore Optix) to study the cancer cell dissemination to the skeleton in nude mice injected into the left cardiac ventricle with A375 human melanoma cells expressing green fluorescent protein (GFP). A375 human melanoma cells expressing GFP were established following stable transfection of GFP driven by a CMV promoter. Preliminary quantitative analysis of GFP by eXplore Optix indicated that the minimal detectable specific signal was $3x10^3$ cells. eXplore Optix eliminates non specific fluorescence signals by performing time resolved fluorescence measurements *in vivo*. As a result, the system analyzes fluorescence lifetime, which permits to distinguish fluorophores with similar emission spectra according to their fluorescence lifetime. Fluorescence analysis by eXplore Optix and X-ray detection by Faxitron were done at timed intervals following intracardiac administration of cancer cells. Our analysis indicated that GFP-labeled cancer cells could be detected at 9 days in bone of live animals in the absence of any detectable osteolytic lesions by X-ray. At 3 weeks all animal had detectable lesions by X-ray at the locations previously identified by fluorescence. As predicted, the size of the lesions determined by the intensity of the signals increased progressively with time and correlated with histomorphometric analysis of tumor volume. Taken together these results indicate that fluorescence detection of tumor cells within bone by eXplore Optix is both specific and sensitive and that the signals correlate well with tumor volumes making it a powerful tool for longitudinal analysis of bone metastasis.

Elevated Serum Fibroblast Growth Factor 23 in Patients with Small Cell and Squamous Cell Lung Cancer with Normal Serum Phosphorus. P. Tebben[1], R. J. Singh*[2], A. O. Bungum*[3], R. Kumar[4]. [1]Endocrinology, Mayo Clinic, Rochester, MN, USA, [2]Laboratory Medicine, Mayo Clinic, Rochester, MN, USA, [3]Pulmonary Research, Division of Pulmonary Medicine, Mayo Clinic, Rochester, MN, USA, [4]Nephrology Research, Mayo Clinic, Rochester, MN, USA.

Serum or tissue concentrations of the fibroblast growth factor family of proteins have been studied in relation to several human malignancies including lung cancer. Fibroblast growth factor 23 (FGF23) is a recently discovered member of the FGF family with a distinct carboxy-terminal region that is elevated in the serum of patients with oncogenic osteomalacia and humoral hypercalcemia of malignancy. In order to determine whether FGF23 physiology is altered in malignancies not associated with abnormal phosphate metabolism we measured serum FGF23 concentration in 23 patients with small cell lung cancer and 26 patients with squamous cell lung cancer. Serum samples were collected prior to treatment of their disease. FGF23 values were also determined in 80 healthy controls (41 male and 39 female) to determine a normal range. Patients with elevated serum creatinine were excluded. The mean±SEM serum phosphorus was 3.7±0.1 mg/dL and 3.6±0.2 mg/dL in the small cell and squamous cell groups, respectively. Patients with small cell lung cancer had significantly higher serum FGF23 concentrations compared to the healthy controls (p=0.03). (Figure 1) The patients with squamous cell lung cancer tended to have higher FGF23 concentrations but this failed to meet statistical significance (p=0.1). There was no correlation between serum FGF23 concentrations and serum phosphorus, calcium, creatinine, parathyroid hormone, or 1,25 dihydroxyvitamin D_3. There was no correlation between FGF23 and age in the patients with lung cancer or healthy controls. Serum FGF23 concentrations are elevated in patients with small cell lung cancer and this elevation does not cause hypophosphatemia.

Elevated Serum Fibroblast Growth Factor 23 without Changes in Phosphorus in Women with Advanced Stage Malignant Ovarian Tumors. P. Tebben[1], K. R. Kalli*[2], W. A. Cliby*[3], L. C. Hartmann*[2], R. J. Singh*[4], R. Kumar[5]. [1]Endocrinology, Mayo Clinic, Rochester, MN, USA, [2]Oncology, Mayo Clinic, Rochester, MN, USA, [3]Gynecologic Surgery, Mayo Clinic, Rochester, MN, USA, [4]Laboratory Medicine, Mayo Clinic, Rochester, MN, USA, [5]Nephrology Research, Mayo Clinic, Rochester, MN, USA.

Serum or tissue concentrations of the fibroblast growth factor family of proteins have been studied in relation to human ovarian cancer. Concentrations of fibroblast growth factor 23 (FGF23), a recently discovered member of the FGF family with a distinct carboxy-terminal region, are elevated in some patients with oncogenic osteomalacia and in some patients with humoral hypercalcemia of malignancy. In order to determine whether FGF23 plays a role in other cancers in which fibroblast growth factor physiology is altered such as ovarian cancer, we measured serum FGF23 concentrations in patients with benign and malignant ovarian tumors. Forty patients presenting with an ovarian mass were studied. Twelve patients had stage III or IV ovarian cancer, fourteen had stage I or II ovarian cancer, and fourteen were found to have benign masses. Serum collected preoperatively was analyzed for FGF23, calcium, phosphorus, and creatinine concentrations. FGF23 concentrations were compared between groups and to thirty-nine healthy women. Patients with elevated serum creatinine were excluded from the study. The mean±SEM serum FGF23 concentrations were 31.3±2.7 RU/mL, 30.5±4.2 RU/mL, 16.2±3.7 RU/mL, and 245±115 RU/mL for the healthy, benign, stage I-II, and stage III-IV groups, respectively. Six of twelve women with stage III-IV disease had elevated serum FGF23 concentrations (Figure 1). None of the women with benign masses or stage I-II ovarian cancer had elevated FGF23 concentrations. There was a significant positive correlation between the serum FGF23 concentration and stage of disease ($p<0.02$). FGF23 concentrations also positively correlated with serum phosphorus across all women with ovarian masses ($p<0.001$). There were no differences in serum phosphorus, calcium or creatinine among the three groups of women with ovarian masses. In this series, half of the women with stage III-IV ovarian cancer have elevated serum FGF23 concentrations. These elevations in FGF23 are not associated with hypophosphatemia as is seen in other disorders with abnormal FGF23 physiology.

Breast Cancer Skeletal Metastases affect Osteoblast Function. R. R. Mercer*[1], D. Welch[2], C. V. Gay[1], A. M. Mastro*[1]. [1]Biochemistry, Pennsylvania State University, University Park, PA, USA, [2]Pathology, University of Alabama-Birmingham, Birmingham, AL, USA.

Breast cancer frequently metastasizes to bone, resulting in osteolytic lesions. These lesions, formed by stimulated osteoclasts, cause an increased susceptibility to fractures, pain, and hypercalcemia. It has been shown that breast cancer cells communicate with osteoblasts and subsequently stimulate osteoclast activity; however, little research has focused on understanding the interaction between the breast cancer cells and osteoblasts. To study how cancer cells affect osteoblasts, MC3T3-E1 cells, an immature osteoblast cell line that differentiates *in vitro*, were cultured with conditioned medium from MDA-MB-231 cells, a bone-metastatic breast cancer cell line. We determined that alkaline phosphatase activity and mineralization, two defining characteristics of a mature osteoblast, were completely blocked. Moreover, mRNA expression for both bone sialoprotein and osteocalcin, two genes upregulated during osteoblast differentiation, were not expressed even after 25 days of culture. Together, these data suggested that when cultured with MDA-MB-231 conditioned medium, MC3T3-E1 cells did not differentiate into mature osteoblasts. We speculated that the conditioned medium factor causing this inhibition in differentiation was transforming growth factor β (TGFβ). To test this, MDA-MB-231 conditioned medium was pretreated with a neutralizing antibody to TGFβ. The neutralized conditioned medium was then added to MC3T3-E1 osteoblasts. mRNA expression of alkaline phosphatase, bone sialoprotein, and osteocalcin were all completely restored in the presence of TGFβ-neutralized conditioned medium. While trying to understand how breast cancer conditioned medium affected osteoblast differentiation, we made another key observation: MDA-MB-231 conditioned medium altered MC3T3-E1 morphology and adhesion. Examination with interference reflection microscopy revealed that MC3T3-E1 osteoblasts had fewer focal adhesion plaques when cultured with MDA-MB-231 conditioned medium. Further scrutiny revealed a substantial alteration in actin stress fibers. Instead of forming normal stress fibers, cells cultured with MDA-MB-231 conditioned medium demonstrated thick cortical filaments, as well as areas of large, punctate staining. We determined that the changes in adhesion were not due to TGFβ; thus, another factor present in MDA-MB-231 conditioned medium must be responsible for these effects. These data suggest that osteoblasts are also affected during skeletal metastasis and should be considered as important targets for drug intervention.

Comparison of the Osteolytic Potential of Two Breast Carcinoma Cell Lines MDA-MB-231 and T47D. M. Gallet*, M. Chasseraud*, I. El Hajj Dib*, M. Brazier*, S. Kamel. Faculté de Pharmacie, Amiens, France.

Malignant breast carcinoma metastasizes to the bone and enhances osteoclast bone resorption. It is now well established that breast tumor cell release growth factors and cytokines which stimulate osteoclastogenesis and thus bone resorption. Moreover, we have recently shown that breast cancer cells could also increase osteoclast survival contributing to osteolysis. Herein, we determined the osteolytic potential of two breast carcinoma cell lines T47D and MDA-MB-231, with respectively low and high metastatic potential. The osteolytic potential was defined as the ability of breast cancer to (i) express gene known to target bone resorption, (ii) to induced osteoclastogenesis, (iii) to increase osteoclast survival and (iiii) to up-regulate hyper-resorptive genes in osteoblastic cell.

First, we established that MDA-MB-231 cells transcriptionnally expressed detectable levels of TGFβ1, IL-6, IL-1α, IL-1β, M-CSF, IGF2, GM-CSF, VEGF compared to T47D cells which expressed only TGFβ1, TNFα, IGF2 and VEGF mRNA. None of the two cell lines expressed RANKL mRNA. Then, we demonstrated that conditioned media (CM) prepared from the two cell lines exerted direct and dose dependent effect on osteoclast like cells generation from the monocytic cells RAW264.7. When soluble RANKL was added in the culture media in presence of CM of both cell lines, the effect on osteoclastogenesis was synergistic. Moreover, MDA-MB-231 and T47D CM greatly up-regulated IL-1α, IL-1β and IL-6 mRNA expression in osteoblastic cells MG63. Finally, we studied the effect of CM on mature osteoclasts which were isolated from 10-day-old New Zealand rabbit long bones. Our results showed that 20% MDA-MB-231 CM stimulate significantly bone resorption while 20% T47D CM had no effect. Because osteoclast have a short life span and could undergo apoptosis after bone resorption, we evaluated the effects of MDA-MB-231 and T47D CM on osteoclast apoptosis. We demonstrated that 20% MDA-MB-231 CM inhibited significantly osteoclast apoptosis (-52%) while 20% T47D CM had much less pronounced effect (-15%).Taken together, these results suggest that both breast cancer cell CM could directly induce osteoclast formation with or without RANKL. Furthermore, CM could also stimulate release of osteoblastic factors which are potent enhancers of osteoclastogenesis. In contrast, only the high metastatic cell line could influence the activity of fully differentiated osteoclasts. In conclusion, osteolytic potential of breast cancer cells may be correlated to their gene expression patterns of hyper-resorbing factors. Such studies could be of great interest to predict the aggressive behaviour of breast carcinomas.

Heterogeneous Bone Response to Systemic Therapy (Bisphosphonates and/or Chemotherapy) in Patients with Metastatic Prostate Cancer. M. P. Roudier[1], L. D. True*[2], C. S. Higano*[3], S. M. Ott[4], R. L. Vessella*[1]. [1]GU Cancer Research Lab, University of Washington, Seattle, WA, USA, [2]Pathology Department, University of Washington, Seattle, WA, USA, [3]Oncology Department, University of Washington, Seattle, WA, USA, [4]Medicine and Endocrinology, University of Washington, Seattle, WA, USA.

Effects of cancer on the bone are the major sources of morbidity in prostate cancer patients. To better understand tumor effects and dynamics, we studied a series of 14 patients who died of prostate cancer and underwent a Rapid Autopsy, which involved systematic biopsy, histologic and histomorphometric analysis of 19 separate bones.

Bone biopsies showed a wide variability of tumor-induced bone volume/tissue volume (BV/TV, range from 3.72% [osteopenic pattern] to 73.6% [osteodense pattern], median = 39.4%). New bone was mostly woven with tumor-induced woven bone volume/tissue volume ranging from 0% [osteolytic pattern] to 70.30% [osteoblastic pattern], median = 20%. Qualitative analysis of bone biopsies revealed in 86% of all metastases the presence of an osteoblastic response as defined by the increased presence of osteoid and woven bone. This could occur with a BV/TV as low as 10% [osteopenic pattern with osteoblastic response].

We addressed the following questions, with these respective findings:

Does bisphosphonate therapy, administered for at least 2 months, enhance an osteoblastic state by reducing osteolytic events? In general, we found that bisphosphonate therapy was associated with osteoblastic bone, although some sites in a patient with predominantly blastic changes still had evidence of osteolysis.

Does cancer in a bone have a predictable influence on the response of bone? In general, tumor was associated mostly with osteoblastic bone changes and rarely with osteolytic bone changes. However, there were exceptions, where tumor either had no apparent effect on bone, or where bone was blastic or lytic without identifiable residual tumor.

Does chemotherapy have a predictable response on tumor? Although recent chemotherapy

"caused" tumor necrosis in some patients, the tumor in other patients who did not receive chemotherapy was extensively necrotic.
Do the peripheral bones become sites of hematopoiesis in patients whose central/axial bones are completely replaced by tumor? Ribs, femoral and humeral heads were bones showing hematopoietic bone marrow.
In summary, the effects of end-stage prostate cancer on bone and the effects of systemic therapy on the cancer and on bone vary both between patients and in different bones of each patient. These findings raise the possibility that tumor cells in a given patient may produce a different balance of osteoblastic and osteolytic factors at different sites.

Runx2 Regulates Transcription of Gelatinases (MMP9) in Metastatic Cancer Cell Lines and Functionally Related to Cell Migration. J. Pratap[1], S. Vashi*[1], J. Zhang*[2], L. Languino*[2], A. J. van Wijnen[1], J. L. Stein*[1], J. B. Lian[1], G. S. Stein[1]. [1]Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA, [2]Department of Cancer Biology, University of Massachusetts Medical School, Worcester, MA, USA.

The transcription factor runt-related gene 2, RUNX2 (CBFA1/AML3), regulates osteoblast differentiation and bone formation. We identified matrix metalloproteinase-9 (MMP9) as a novel downstream target of Runx2 using total RNA from Runx2 $^{-/-}$ and Runx2 ΔC mutant mouse on cDNA expression array. MMP9 expression, like MMP13 but not MMP2, is nearly depleted in Runx2 deficient mice. In vivo analysis by chromatin immunoprecipitation assay and in vitro by EMSA revealed recruitment of Runx2 to the MMP9 promoter. A Runx2 motif present in the proximal promoter region of the MMP9 gene was functionally characterized by creating point mutants. We show that Runx2 site mediates transactivation of the MMP9 promoter activity in both osteoblastic cells (MC3T3 E1) and non-osseous (HeLa) cells. Upregulation of MMP9 expression has been implicated in invasion and metastasis of breast and prostate tumors, and Runx2 is ectopically expressed in breast (MDA-MB-231) and prostate (PC3) cancer cells that metastasize to bone. We find that over-expression of Runx2 by adenovirus delivery in both primary and bone metastatic cancer cell lines significantly increase endogenous levels of MMP9. Furthermore knockdown of Runx2 by RNA interference results in decreased MMP9 expression. Importantly, we have demonstrated using a cell migration assay that the Runx2 regulated MMP9 levels are functionally related to the invasion properties of the cancer cell. In conclusion, our findings demonstrate the role of Runx2 in transcriptional regulation of MMP9 and that modulation of MMP9 expression by Runx2 influences cell migration. We suggests that Runx2 is a primary initiator for expression of genes that contribute to the metastatic related properties of cancer cells and their activity in the bone environment.

SELDI-TOF Mass Spectrometry Discriminates PSA-Stable and PSA-Rising Hormone-sensitive Advanced Prostate Cancer. S. Bhattacharyya[1], M. Kohli*[2], E. Siegel*[3], R. Shah*[2], L. J. Suva[1]. [1]Orthopaedic Surgery, UAMS, Little Rock, AR, USA, [2]Pathology, UAMS, Little Rock, AR, USA, [3]Biometry, UAMS, Little Rock, AR, USA.

Prostate cancer is one of the most commonly diagnosed malignancies in the US and is the second leading cause of cancer deaths in males, with bone metastases a common occurance. Protein profiling of clinical specimens to discriminate protein patterns indicative of cancer or non-cancer conditions is a rapidly evolving field. In this study, we collected serum from patients undergoing androgen deprivation therapy (ADT) for hormone-sensitive prostate cancer and determined their respective protein expression fingerprints utilizing surface enhanced laser desorption/ionization time-of-flight mass spectroscopy (SELDI-TOF MS). Group I (n=15), constituted of patients with a stable-PSA response and Group II (n=16) with a rising PSA during ADT. Group II patients had serially rising PSA measurements. Survival data were also collected for all patients. The collected serum samples were fractionated via ion-exchange batch elution into 6 different fractions based on isoelectric point (pI). 1.4 µL aliquots from the most basic fraction (pI≥9) were applied in duplicate to IMAC 30 ProteinChip arrays, and adsorbed material was subjected to SELDI-TOF MS. The resulting spectra were compiled, normalized to total ion current, and mass peaks with mass-to-charge ratios (m/z) ≤20,000 were detected. For each patient, the average intensity per peak was calculated and tested for univariately significant differences between the two groups via the Kruskal-Wallis test. Of 119 peaks having m/z between 2000 and 20,000, seven were statistically significant (P<0.05), with Group II median intensities higher for three peaks and lower for four. An additional eight peaks were marginally significant (0.05=P<0.10), with Group II median intensities higher for five peaks and lower for three. Using SELDI-TOF MS we have identified significantly different serum protein expression profiles in the sequential stages of prostate cancer progression that discriminate between the cancer groups. Additional studies with expanded sample sets are currently ongoing. These data suggest that SELDI profiling may provide critical insights into the rapid diagnosis of prostate cancer progression, and provide a mechanism for evaluating efficacy of treatment regimens. Identification of the specific proteins expressed during relapse may be used to target enhancement of the therapeutic response.

Expression of 25-hydroxyvitamin D_3-1α-hydroxylase (CYP27B1) Is Increased in Breast Tumors Compared to Paired Normals. K. Townsend*[1], M. Guy*[2], M. J. Campbell*[1], J. L. Mansi*[2], K. W. Colston*[2], M. Hewison[1]. [1]Medical Sciences, The University of Birmingham, Birmingham, United Kingdom, [2]St George's Hospital Medical School, London, United Kingdom.

Recent studies have highlighted a role for vitamin D in the prevention and treatment of breast cancer. The active form of vitamin D, 1,25-dihydroxyvitamin D3 ($1,25(OH)_2D_3$), is a potent antiproliferative agent and the vitamin D receptor (VDR) is well expressed in breast tissue. We have investigated whether VDR signaling in breast tumors is due to systemic (renal) $1,25(OH)_2D_3$ or whether there is autocrine/paracrine synthesis of the hormone. Initial analyses using normal breast cells and a panel of breast cancer cell lines showed expression of the vitamin D-activating cytochrome P450 1α-hydroxylase (CYP27B1), highlighting a potential autocrine mechanism by which environmental/dietary vitamin D status can affect breast tumors. Expression of CYP27B1 and other components of vitamin D signalling such as VDR and the inactivating enzyme 24-hydroxylase (CYP24) was then assessed using a panel of 41 matched tumor/normal breast biopsies. Quantitative RT-PCR analyses showed that CYP27B1 mRNA expression was 27-fold ($p<0.001$) higher in tumors compared to controls, which was confirmed by immunohistochemical analyses. Increased expression of the enzyme was accompanied by upregulation of VDR (7-fold, $p<0.001$) and CYP24 (4-fold, $p<0.02$, n=34). These data indicate that breast tumors are able to synthesize and actively respond to $1,25(OH)_2D_3$. However, the resulting sensitive induction of CYP24 may abrogate the anticancer effects of $1,25(OH)_2D_3$ via the generation of inactive vitamin D metabolites. This was demonstrated by in vitro manipulation of CYP24 using antisense cDNA which increased the sensitivity of MDA-MB-231 cells to the antiproliferative effects of $1,25(OH)_2D_3$. Paradoxically, breast cancer cell lines showed lower levels of CYP27B1 and VDR than non-transformed cells highlighting the divergence in vitamin D metabolism and signaling between cell lines and tumor tissue. Further studies suggest that this may be due to immunological responses in the tumors as expression CYP27B1 and VDR correlated with mRNA levels for toll-like receptor 4, an endotoxin receptor and inflammatory marker. These data provide a potential mechanism by which dietary/environmental vitamin D status can influence breast tissue responses via local conversion to active $1,25(OH)_2D_3$ and enhanced VDR expression. The mechanisms involved in upregulation of CYP27B1 and VDR are currently under investigation and appear to be linked to innate immune responses within the breast tumors.

Radiation Therapy Inhibits Tumor-Mediated Bone Destruction and Preserves Bone Mass in a Pre-Clinical Model of Breast Cancer Metastasis to Bone. M. J. Allen, S. A. Arrington*, B. S. Margulies*, J. E. Schoonmaker*, K. A. Mann*, T. A. Damron*. Orthopedic Surgery, SUNY Upstate Medical University, Syracuse, NY, USA.

Pathological fracture is a devastating complication of benign and malignant tumors of the skeleton. It is generally accepted that radiation therapy, which is widely used to palliate bone pain in patients with skeletal metastases, inhibits bone formation and fracture repair. However, in many patients with bone metastases from breast cancer radiation therapy leads to partial or even complete re-mineralization of the lesion. The specific aims of this study were to determine whether (a) radiation is effective in inhibiting tumor-mediated bone loss and (b) whether normal bone and osteolytic bone display different responses to radiation. In a series of IACUC-approved experiments, human breast cancer cells were injected into the right distal femur of female nude mice (n=54); vehicle (medium only) was injected into the left femur as a sham control. Radiation therapy (0 Gy or single dose 20 Gy) was given 3 weeks post-surgery, at which time there is histological evidence of early tumor growth. Radiography and bone density analysis (DEXA) were performed at the start of the study and 3, 6 and 9 weeks later. Groups of animals were euthanized at each time point and their femora were mechanically tested using a novel test method that applies torsional forces through the intact knee. In untreated limbs (0 Gy) tumor was found to cause a statistically significant decrease in bone strength ($p<0.001$ for peak torque, stiffness and energy to failure). Radiation provided moderate but statistically significant protection from the adverse effects of tumor ($p<0.001$ for all parameters) such that 12 of 14 mice (81%) that were irradiated completed the study to 9 weeks as planned compared with only 50% of the untreated mice. Interestingly, radiation had no significant effect on either BMD or mechanical indices in normal bone. These data indicate that radiation *per* se does not stimulate an increase in bone mass in the mouse. We did not observe clinically significant re-mineralization of lesions in this model, probably because irradiation was performed prior to the development of advanced lytic lesions and the follow-up in these animals was relatively short (6 weeks post-radiation). However, our data indicate that radiation therapy is not effective in completely restoring bone mass in bones that have been damaged by tumor. This is consistent with the clinical observation that up to 23% of metastatic lesions may develop pathological fractures after irradiation. New therapies are now needed to try to enhance bone healing after irradiation. The mouse model appears to be a clinically relevant model for evaluating these therapies.

Effects of Osteolytic Bone Metastases on Bone Mass and Bone Strength in the Mouse: Validation of a Pre-Clinical Model of Breast Cancer Metastasis to Bone. M. J. Allen, S. A. Arrington*, B. S. Margulies, J. E. Schoonmaker*, K. A. Mann*, T. A. Damron*. Orthopedic Surgery, SUNY Upstate Medical University, Syracuse, NY, USA.

Skeletal metastases are a common cause of morbidity in patients with malignant disease. The primary goals of therapy for symptomatic osteolytic bone metastases are palliation of bone pain and preservation of skeletal integrity. Although radiation therapy is highly effective in alleviating bone pain, its effects on bone mass and bone strength are less well understood. The specific aim of this study was to determine the temporal pattern of bone loss in a mouse model of tumor osteolysis. Human breast cancer cells were injected into the right distal femur of female nude mice (n=53); vehicle (culture medium) was injected into the left femur as a sham control. All of the experimental procedures in this study were reviewed and approved by the local IACUC. Radiography and bone density analysis (DEXA) were performed at the start of the study and at 3, 6 and 9 weeks post-tumor inoculation. Groups of animals were euthanized at each time point and their left and right femora were mechanically tested using a novel test method that applies torsional forces through the intact knee joint. As expected, DEXA analysis indicated time-dependent increases in BMD in the control (left) femur. Injection of tumor into the femur negated normal bone accrual such that there was no net increase in BMD over time. Analysis of the mechanical test data revealed that there was no significant time-dependent increase in peak torque, stiffness or energy to failure in control femora. However, femora that had been injected with tumor demonstrated a significant time-dependent pattern of decreasing mechanical integrity ($p<0.001$ for all three mechanical test parameters). The clinical significance of this loss of skeletal integrity was underscored by the fact that 10 of 20 mice (50%) that had been injected with tumor developed lameness and/or pathological fractures that necessitated their removal from the study prior to the original scheduled time point of 9 weeks. Taken as a whole, these results confirm the clinical relevance of the mouse model of tumor osteolysis and the utility of DEXA and torsional testing as sensitive indicators of tumor-mediated bone loss. Ongoing studies in this laboratory are now using this model to develop improved therapies for isolated bone metastases from breast and other solid cancers.

High Bone Mineral Density Is a Risk Factor For Prostate Cancer in Older Men of African Descent. C. H. Bunker[1], J. M. Zmuda[2], A. L. Patrick*[3], V. W. Wheeler*[3], J. A. Cauley[2]. [1]Epidemiology, University of Pittsburgh, Pittsburgh, PA, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]Tobago Prostate Survey, Scarborough, Trinidad and Tobago.

Endogenous steroid hormones and growth factors have been linked to prostate cancer but results are not consistent. Bone mass, as a surrogate indicator of lifetime hormone and growth factor exposure, has been associated with prostate cancer risk in Caucasian men but nothing is known about bone mass and prostate cancer risk in men of African descent, a group at high risk of prostate cancer. To test this hypothesis, cases were ascertained in a population-based screening for prostate cancer among Afro-Caribbean men, aged 45-79, on the island of Tobago. Serum prostate specific antigen (PSA) $\geq$ 4 ng/ml, or abnormal digital rectal exam, were the criteria for referral for ultrasound guided sextant biopsy. Hip bone mineral density (BMD) was measured by dual X-ray absorptiometry (Hologic QDR 4500W). Men with body mass index (BMI, kg/m^2) more than 3 standard deviations above the mean (>40 kg/m^2) or prior androgen ablation therapy were excluded. To reduce the likelihood of including men with skeletal metastases, which may modulate BMD, men with PSA >20 ng/ml or highly undifferentiated tumors (Gleason score 8, 9, 10) were also excluded. Analysis of variance was used to estimate age and BMI adjusted BMD between cases and non-cases. Logistic regression, adjusted for age and BMI within each age group, was used to estimate prostate cancer risk in younger (45-59 years) and in older (60-79 years) men categorized by quartile of BMD based on the BMD distribution in each age group.

Over all age groups, adjusted mean hip BMD was higher in 222 cases (1.157g/cm^2, 95%CI 1.138-1.175) than in 1503 non-cases (1.134 g/cm^2 , 95%CI 1.127-1.141) (p=0.02). However, there was an interaction (p=0.055) between BMD and age (Figure). In men aged 60-79, prostate cancer risk was two-fold higher (OR, 2.12; 95%CI: 1.21 - 3.71) in the highest BMD quartile compared to the lowest quartile**.** There was no association in younger men. (Figure).

We conclude that high bone density is a risk factor for prostate cancer among older Afro-Caribbean men, supporting an etiological role for hormone and growth factors. However, other etiologies may be stronger determinants of prostate cancer risk among younger men of African descent.

Reference Data for BMD in the Calcaneus for Healthy Children 4-years of Age by Dual Energy X-ray Absorptiometry and Laser (DXL). A. Söderpalm*[1], R. Kullenberg[2], K. Albertsson-Wikland*[3], D. Swolin-Eide[3]. [1]Dept of Orthopaedics, Sahlgren University Hospital, Inst. for Surgical Sciences, Göteborg, Sweden, [2]Dept of Radiology, Inst. for Radiation Physics, Halmstad, Sweden, [3]Dept of Pediatrics the Queen Silvia Children´s Hospital, Inst. for the Health of Women and Children, Göteborg, Sweden.

There is a growing demand for studying and evaluating pediatric bone status. A debated issue in bone research is the optimal techniques to determine bone mass in growing children. Dual X-ray and Laser (DXL) Calscan measures areal bone mineral density (BMD) by using dual X-ray absorptiometry in combination with laser measurement of the total heel thickness. This technology reduces the uncertainty related to variable composition of soft tissue in adults. The DXL Calscan is portable, easy to use, has a short measurement time and gives a low absorbed dose (<0.12μSv).

The aim of this cross-sectional study was to investigate: if the device was tolerated by young children, if BMD could be measured with good precision, if BMD was related to height, weight and body mass index (BMI) and further to create reference data in healthy 4y old children.

The DXL Calscan was modified for children with a lower absorbed dose and adapted software. 110 strictly healthy Swedish children (49% boys, 51% girls, mean age 4.3y) were included. The left foot was scanned, the actual height, weight and foot length was measured.

The intra-individual CV measured by 2 repeated measurements on 26 subjects was 6.53% for BMD and 8.12 % for bone mineral content (BMC). The mean BMD in the subjects was 0.22 ± 0.003 g/cm^2 (0.14-0.34) and BMC 0.16 ± 0.003 g (0.11-0.25). No significant difference was found in BMD between girls and boys. BMD was significantly correlated to weight ($p=0.007$, $r=0.26$), weight SDS ($p=0.015$, $r=0.24$) and to height ($p=0.03$, $r=0.21$). BMD was not correlated to BMI or foot length.

In conclusion, the measurements were easily performed and well tolerated by these young children. This is the first study to present normative data for BMD and BMC in the calcaneus in 4y old children by DXL. Further studies are required to evaluate this method. The study was approved by the local Ethical Committee of the Medical Faculty Sahlgren Academy at Göteborg University.

SA103

Bone Density in Healthy Spanish Children and Adolescents. L. Del Rio[1], S. Di Gregorio*[1], L. Ibañez*[2], S. Artigas*[2]. [1]Densitometría Ósea, CETIR Centre Médic, Barcelona, Spain, [2]Endocrinología, Hospital de San Juan de Dios, Barcelona, Spain.

Dual energy x-ray absorptiometry (DXA) is the method of choice to measure bone mineral density (BMD) in children, because of low radiation dose, and excellent precision and accuracy. BMD increases during childhood and reaches a peak in early adulthood before declining gradually in later life. Acquisition of adequate bone mass during childhood may influence the risk of fracture in adulthood. Reference data allow comparison of an individual's BMD with the BMD of healthy peers.

We measured BMD using DXA (Lunar Prodigy and DPX-IQ, GE Healthcare) at the spine in 576 children (367 females and 209 males) and at the total body in 537 children (404 females and 133 males) from urban Barcelona. All children were defined as normal based on health history and questionnaire.

Total body BMD showed remarkable similarity between males and females, with BMD nearly congruent throughout most of the age range. Total body BMD was about 5% higher in females than males during the female adolescent growth spurt (ages 11-13 years). Female spine BMD was about 10% higher than males from ages 10 to 16 years, with male BMD catching up at about 17 years of age.

We conclude that total body BMD from age of 4 to 19 years was similar in males and

females, except for differences related to the earlier timing of the female adolescent growth spurt. Spine BMD was generally higher in females during childhood and early teen years, with male BMD approaching female values in the middle to late teen years. These BMD differences demonstrate the need for sepaate gender-based reference data.

Calcaneal BMD with DXL Technique Discriminates Between Postmenopausal Females With and Without a History of Fracture - the CALCOS Study (Calcaneal Osteoporosis Study). T. B. Brismar*[1], C. Nyberg*[2], H. Salminen*[3]. [1]Centre of Surgical Sciences, Division of Radiology, Karolinska Institutet, Stockholm, Sweden, [2]Läkarhuset Hötorget, Stockholm, Sweden, [3]Centre for Family Medicine, Karolinska Instutet, Stockholm, Sweden.

A recently developed technique for assessing calcaneal BMD called dual X-ray and laser (DXL), combines two X-ray energies with a laser measurement of heel thickness. It is theoretically appealing as it allows separation of bone mineral, lean tissue and adipose tissue (a three-component model) instead of using the traditional two-component model (bone mineral and soft tissue). The advantage of this technique does, however, require further evaluation.

We have evaluated whether calcaneal BMD, measured using DXL (Demetech AB, Stockholm, Sweden) can discriminate between females with and without osteoporosis-related fracture. 30 health-care units and outpatient clinics in Sweden participated and 1677 consecutive females over the age of 55 were studied. A standardised questionnaire was used to obtain previous fractures and risk factors. In total 894 fractures were reported by 753 individuals. The mean calcaneal BMD of those with a history of fracture was 313 mg/cm^2 (SD 83), compared with 365 mg/cm^2 (SD 79) in those without a fracture. The best discrimination was observed for hip fractures (area under curve (AUC) 0.72, sensitivity 0.73, specificity 0.58). After correction for age group and other risk factors, the following risk factors were associated with lower BMD: previous fracture (-35 mg/cm^2), significant height decrease (-26 mg/cm^2), low body weight (-2.3 mg/cm^2 and kg), smoking (-12 mg/cm^2) and early menopause (-12 mg/cm^2). Steroid use, gastro-intestinal disease/hormonal disease, weight loss or heredity did not significantly lead to lower BMD. Decrease in height was associated with a 0.42 SD decrease in T-score, and we therefore suggest that this risk factor should be regarded as a strong indication for BMD measurements.

We conclude that calcaneal BMD obtained by the DXL technique has potential to predict osteoporosis-related fractures.

Radiographic Absorptiometry (RA) Assessment of Bone Mineral Density Using a CR-based System Compared to the Film-based System. M. Greenwald[1], L. Al-Dayeh*[2], X. Bi*[2], S. L. Silverman[3]. [1]Desert Medical Advances, Palm Desert, CA, USA, [2]CompuMed, Los Angeles, CA, USA, [3]UCLA, Los Angeles, CA, USA.

Phalangeal BMD assessment using Radiographic Absorptiometry (RA) by means of scanning standard hand radiographs has been in use for years. It is a reliable and inexpensive method for assessing peripheral BMD with high predictability of future fracture risk of the hip and spine. With the recent development and availability of digital radiography platforms, i.e., Computed Radiography (CR), Direct Radiography (DR) and Picture Archiving and Communications Systems (PACS), there exists a need for a reliable Digital Imaging and Communications in Medicine (DICOM) compliant BMD method, such as a DICOM-based RA p study reports the comparison of BMD results between a DICOM-based RA system that utilizes a CR device (ACLxy, Orex, Yokneam, Israel) and a standard film-based RA system.

The 45 Caucasian and Asian volunteers between the ages of 50 to 81 participated in this study. Two consecutive x-rays of the non-dominant hand were acquired for each volunteer, one using a standard film and another using a CR cassette. The standard films were scanned using a flatbed scanner at the resolution of 254 dpi matching the CR resolution. The CR cassette was read at its native resolution of 254 dpi. The images of both x-ray platforms were analyzed for RA results using the OsteoGram® (CompuMed, Inc., Los Angeles, CA) software which performs automated RA analysis.

Regression analysis of the results showed a significant ($p<0.001$) Pearson correlation coefficient of 0.98, between a DICOM-based RA system and a film-based RA system.

We conclude that BMD may be measured using RA on a digital x-ray platform. The availability of DICOM-compliant RA may help improve access to BMD testing in settings where central DXA is not available.

Bone Mineral Density, Vertebral Fracture and Related Factors in Patients with Ankylosing Spondylitis. B. Kuran*, A. Caglilyan*, N. Kotevoglu*, S. Ergan*. Department of Physical Medicine and Rehabilitation, Sisli Etfal Research and Teaching Hospital, Istanbul, Turkey.

PURPOSE : To determine bone mineral density, factors related with bone density and osteoporosis and observe the relation of osteoporosis with depression, fatigue, quality of life and fracture in patients with ankylosing spondylitis (AS).

MATERIAL AND METHOD : 38 men, diagnosed as AS according to Modified New York criteria (Group1) and 30 healthy controls (Group2) were included in this prospective, controlled study.Bone mineral density of proximal femur,tibia and lateral lumbar vertebrae were evaluated in with DEXA. Calcaneal bone assessment was done with quantitative calceneal ultrasound.Results were interpreted according to WHO Study Group recommendations. Dorsal radiographs centered at T7 and lumbar radiographs centered over L3 were obtained for vertebral morphometric measurements. BASFI,BASMI,BASDAI and multidimensional assesment fatigue scale (MAF), Beck Depression Scale (BDS) and SF-36 for quality of life were used to evaluate the impact of AS. Erytrocyte sedimentation rate (ESR), CRP, calcium, phospor,1,25 dihydroxy Vitamin D, parathyroid hormone,follicule stimulating hormone (FSH), Luteinizing hormone (LH) and testosterone levels were analyzed.

RESULTS : Mean age of the patients was 36,8 years and mean disease duration was 7.6 years.L3 t values were significantly lower than controls($p<0,05$).Femur neck and total BMD values (g/cm2,t) were significantly lower in Group I($p<0,01$). In both of the groups tibia measurements were similar ($p>0,05$). Lumbar BMD values were osteopenic in 44,7% and at osteoporotic in 31,6% of the cases. Among the controls, 46,7% of them had osteopenia. Femoral and tibial BMD had good correlation ($r =0.648$; $p<0,01$) with each other. Calceneal QUS was moderately correlated ($r =0.427$; $p<0,05$) with total femoral values. Osteoporosis was strongly associated with CRP,BASMI, duration of disease, age and ESR . 21% of the patients had vertebral fracture but the presence of vertebral fractures was not correlated with BMD. Physical role difficulty subgroup of SF-36 was correlated with BMD of femoral neck ($p<0,05$). There wasn't any correlation between BMD, FSH,LH,testosterone and BDS.

Osteoporosis and vertebral fracture are frequent complications of AS. Calcaneal QUS and tibial BMD values also inform us about femoral bone mass. Vertebral fracture can develope independently from BMD. CRP levels and limitation in movement play significant roles in the development of osteoporosis in AS patients.

Disclosures: ***B. Kuran****, None.*

Ethnic Differences in Bending Stiffness of the Ulna and Tibia. S. B. Arnaud[1], M. T. C. Liang*[2], S. Bassin*[2], W. Braun*[2], D. Dutto*[2], K. Plesums*[2], H. T. Huynh*[2], D. Cooper*[3], N. Wong*[4]. [1]Life Sciences Division, NASA Ames Research Center, Moffett Field, CA, USA, [2]Kinesiology and Health Promotion, California State Polytechnic University, Pomona, CA, USA, [3]Dept. Pediatrics and GCRC, Univ. of California, Irvine, CA, USA, [4]Dept of Cardiology, University of California, Irvine, CA, USA.

There is considerable information about the variations in bone mass associated with different ethnicity, but little on the structural differences in bones from different ethnic groups. We had the opportunity to compare a mechanical property of bone in young college women of Caucasian, Hispanic and Asian descent who gave informed consent to participate in an exercise study. The subjects were sedentary, in good health, eumenorrheic, non-smokers and had body mass indices (BMI) less than 30. Measurements acquired were body weight, kg, and height, cm, calcaneal and wrist bone density, g/cm^2 (PIXI, Lunar GE) and bending stiffness (EI, Nm^2) in the ulna and tibia. EI was determined non-invasively with an instrument called the Mechanical Response Tissue Analyzer (MRTA) that delivers a vibratory stimulus to the center of the ulna or tibia and analyzes the response curve based on the equation EI = k_b L^3/48 where k_b is lateral bending stiffness, L is the length of the bone, E is Young's modulus of elasticity and I, the bending moment of inertia. The error of the test (CV) based on measurements of an aluminum rod with a known EI was 4.8%, of calcaneal BMD, 0.54%, and of wrist bone density, 3.45%.

Averages from each ethnic group

Group	n...BW	Ht.. BMI	WBMD.... HBMD	U EI... T EI
Cauc	19... 63	162.. 24	0.457.... 0.524	31.4...168
Hisp	25... 59	157.. 24	0.472.... 0.538	26.8 ...151
Asn	22... 53*	157.. 21*	0.466.... 0.519	23.7*..123*

Differences (*) were from p<0.001 to p<0.02, ANOVA and Student-Newman-Keuls. For all 3 groups combined, ulnar EI was related to height (r = 0.274, p<0.03) and tibial EI, to HBMD (r = 0.245, p<0.045). Wrist and heel bone densities were similar in all groups. BW, BMI and EI in both the ulna and tibia were lower in Asians than in either Hispanics or Caucasians. Ethnic differences in the tibias and ulnas of young Asian women are revealed as differences in structure, not bone density of the heel or wrist.

Disclosures: ***S.B. Arnaud****, None.*

Assessment of Trabecular Bone Microarchitecture from Conventional X-ray Micro Computed Tomography: Quantification of Effects of Thresholding and Decrease Signal to Noise Ratio. C. Chappard, A. Basillais, B. Brunet-Imbault*, N. Bonnet*, C. Benhamou. Atosep, Université d'Orleans, Orleans, France.

Desktop microcomputed tomography (micro-CT) is available to acquire trabecular bone 3D images. The optimal protocole to analyse bone micro-architecture is not well known. Fourteen subchondral bone samples from femoral heads were obtained in 5 osteoarthritis and 4 osteoporosis patients. All samples were defatted. The micro-CT images (Skyscan® 1072) were acquired at 80keV (voxel size=10.77µm). Two different angular rotation steps were tested 0.23°, 0.9° corresponding respectively to 800, 200 radiographic projections. The increase of rotation step leads to a decrease in signal to noise ratio (S/N) of the image. In all sections of specimens, bimodal histograms were obtained the first peak (low gray levels) corresponding to the background and the second one to bone. In all cases, the two peaks were well identified at 0.23° rotation step and moved very close together at 0.9° rotation step. In the last case, differences between the two peaks were so reduced that it became difficult to use a unique threshold for the whole data set. We tested at 0.9° rotation step to binarize images, a global threshold for the whole data corresponding to the average gray level value between the two peaks and an adapted threshold for each sample located at the minimum between both peaks. Usual morphological bone parameters are measured: Bone Volume/Tissue Volume (BV/TV), Trabecular Number (TbN) derived from the 3D Mean Intercept Length method and Trabecular Thickness (TbTh) from the Hildebrand method.

For each parameter, two types of measurement errors were evaluated by the average absolute percentage deviation: threshold effect (at 0.9° with an adapted or global threshold) and/or S/N effect (by comparison between 0.23° and 0.9° rotation step). The error due to a slice matching variation (visual matching±10 slices) was assessed by the Root Mean Square Coef. of Variation (RMSCV%).

	RMSCV%	*<Δboneparameter$_i$>*		
	slice matching	*threshold*	*decrease S/N*	*threshold + decrease S/N*
BV/TV (%)	1.4%	3.0%	4.7%	5.7%
Tb.Th (µm)	1.0%	3.2%	9.2%	11.5%
Tb.N (1/mm)	1.1%	0.7%	10.5%	11.0%

The error of measurements due to a decrease in S/N is more critical than threshold and slice matching effects for all parameters in particular for TbN likely due to artifactual disconnections of few trabeculae at 0.9° rotation step. Errors of measurements are increased with combination of two effects. Fast scan set at 0.9° rotation steps is not recommendable for trabecular bone assessment.

Disclosures: ***C. Chappard****, None.*

Transiliac Bone Biopsy in Osteoporosis: Indications, Consequences and Complications. P. H. Kann*[1], G. Delling*[2], S. Meyer*[1]. [1]Endocrinology & Diabetology, Philipps University Hospital, Marburg, Germany, [2]Osteopathology, Eppendorf University Hospital, Hamburg, Germany.

Bone biopsy is a diagnostic procedure restricted to untypical, unclear and complicated cases in evidence based guidelines on diagnosis and treatment of osteoporosis. Its relevance has been a topic of recent controverse discussion. This study was performed to evaluate its role and relevance in routine use. A total of 99 horizontal transiliac bone biopsies performed over a time period of 14 years because of an osteological indication in one single centre were analysed, which reflects that bone biopsy followed about 0.003% of patients' consultations. Indications for bone biopsy were osteoporotic males (n = 63) and premenopausal osteoporotic females (n = 18) without endocrine abnormality and normal immunofixation, suspected systemic/malignant disease such as mastocytosis, osteogenesis imperfecta, non secreting plasmocytoma, metastatic infiltration (n = 16) and decreasing bone mineral density under anti-osteoporotic treatment (n = 2). Most frequent diagnoses besides osteoporosis were normal histology, borderline finding towards mild osteoporosis, and osteoporomalacia with relevant osteoidosis. In some cases, pathological findings in bone marrow were detected. In most cases (82/99), bone biopsy led to consequences in medical treatment. Following histopathological diagnosis, sixteen patients did not receive any anti-osteoporotic treatment. In six patients, further diagnostic procedures were initiated because of bone histology. Bone biopsy was well tolerated, complications were rare and mild. In conclusion, despite all progress of non invasive diagnostic procedures in metabolic bone diseases such as osteoporosis, there remains a small but significant subset of patients who may benefit from inclusion of bone biopsy into the diagnostic procedure.

Characterization of Trabecular Micro-Architecture Improvement under Teriparatide by a Fractal Analysis of Texture on Calcaneus Radiographs. C. Benhamou[1], C. Chappard[1], C. Gadois*[1], G. Lemineur*[2], E. Lespessailles[1], M. De Vernejoul[3], P. Fardellone[4], P. Delmas[5], G. Weryha[6], R. Harba*[2]. [1]Atosep, Université d'Orleans, Orleans, France, [2]Lesi, Université d'Orleans, Orleans, France, [3]Rhumatologie, Hôpital Lariboisière, Paris, France, [4]Rhumatologie, Hopital, Amiens, France, [5]Rhumatologie, Hopital, Lyon, France, [6]Rhumatologie, Hopital, Nancy, France.

Teriparatide (parathormone 1-34) is a bone forming drug able to reduce fractures and to increase bone mass. It has been shown to improve trabecular micro-architecture on histomorphometry and micro-computerized tomography. We have developed and validated a fractal analysis of texture on radiographs which is able to distinguish osteoporosis (OP) fracture from control groups. This analysis was performed on a region of interest of the calcaneus after digitizing the radiographs, using a previously described algorithm based on the Maximum Likelihood Estimator of the fractional Brownian Motion. This analysis is correlated with 3D micro-architecture. It has not yet shown in a prospective study its ability to characterize effects of drugs on micro-architecture. We have compared 18 OP women treated by teriparatide plus calcium and vitamin D to 22 OP women under other therapies (7 hormone replacement therapy, 8 calcium vitamin D, 6 bisphosphonates). Patients were post-menopausal women 65.6±5.0 years old for the PTH group and 65.2±7.5 for the control group. They were included on the basis of a T score of BMD at the spine or femoral neck <-2.5 SD. There were no vertebral fracture in the PTH group and 2/22 in the control group. This multicenter study involved 4 centers in France for the PTH therapy (subset of an ongoing open label PTH study, Eli Lilly) and one center for the control group. A calcaneus radiograph was performed at following a very standardized procedure at day 0 (before starting the treatment) then at 1 year. The results were expressed by the Hmean value for each image (H=2-fractal dimension). The average Hmean±SD was measured at 0.790±0.06 at day 0 and 0.826±0.03 at 1 year in the PTH group (p=0.02) versus 0.841±0.02 and 0.839±0.02 in the control group (p=0.38). When the evolution was expressed in % of the initial value of Hmean, it was measured at +5.1 % (PTH) p=0.02 versus -0.3% (controls) p=0.3.

Osteoporosis and aging are characterized by a lower Hmean value. The significant Hmean increase observed under PTH indicates an improvement in the texture analysis corresponding to the micro-architecture improvement described with the other techniques. These data suggest that the fractal analysis of texture on radiographs could be a convenient tool to characterize not only OP changes but also changes induced by bone forming agents such as teriparatide.

Structure Analysis of High Resolution Magnetic Resonance Images of the Calcaneus using the Anisotropic 3D Scaling Vector Method. D. Mueller*[1], R. Monetti*[2], S. Majumdar[3], H. Boehm*[1], C. Raeth*[2], E. J. Rummeny*[1], T. M. Link[3]. [1]Department of Radiology, Technische Universitaet Muenchen, Muenchen, Germany, [2]Max Planck Institute for Extraterrestrial Physics, Garching, Germany, [3]Department of Radiology, UCSF, San Francisco, CA, USA.

The purpose of this study was to use the scaling vector method (SVM) to analyze the trabecular bone structure of high resolution magnetic resonance (HR-MR) images of the calcaneus. The 3D SVM is a non-linear texture measure which takes into account the anisotropic nature of the trabeculae. This new structure analysis technique was compared with BMD in its diagnostic performance to differentiate postmenopausal patients with and without osteoporotic spine fractures.

HR-MR imaging of the calcaneus was performed at 1.5 T in 75 women (35 postmenopausal women with osteoporotic spine fractures and 30 postmenopausal controls) using a receive-only phased-array coil. A three-dimensional gradient-echo sequence was applied with an axial orientation, a slice thickness of 0.5 mm, a TE of 5.7 ms, a TR of 28.1 ms, a flip angle of 30° and in plane spatial resolution of 195x195 µm². After normalization of the images and selection of the region of interest (ROI) structure analysis was performed using algorithms based on the new anisotropic SVM, which is respecting the orientation of the trabeculae of the analyzed bone. In addition BMD measurements of the calcaneus and proximal femur using dual energy X-ray absorptiometry (DXA) were obtained in all patients.

Significant differences between both patient groups were obtained using structure analysis and BMD ($p<0.01$). Receiver operating characteristics (ROC) analyses were used to determine the diagnostic performance in differentiating both groups. In comparison with BMD of the calcaneus (AUC = 0.73) and BMD of the proximal femur (AUC = 0.83) the best results were found for the 3D scaling vector method (AUC = 0.88). By combining structure analysis and BMD a moderate improvement for the diagnostic performance could be achieved (AUC = 0.90), which was, however, not significant ($p>0.01$).

The results of this study suggest that the new anisotropic algorithm based on a local 3D SVM which is respecting the orientation of the trabeculae may improve the diagnostic performance in differentiating postmenopausal women with and without osteoporotic spine fractures.

Age-related Changes in Bone Mineral Density and Trabecular Bone Structure Evaluated by DEXA Imaging. L. Pothuaud*[1], V. Boudouscq*[2], N. Barthe*[3], B. Basse-Cathalinat*[3], J. Leroux[4], P. Kotzki*[2]. [1]A2IOS, Bordeaux, France, [2]CHU - Médecine Nucléaire, Nîmes, France, [3]INSERM U577, Bordeaux, France, [4]CHU - Rhumatologie, Nîmes, France.

The in vivo evaluation of Trabecular Bone Structure (TBS) is a major challenge in bone study. The modern definition of osteoporosis involves low Bone Mineral Density (BMD) and TBS alterations, but TBS cannot be measured in routine at the present time. The aim of the present study is to exploit a new process of analysis of DEXA images for the evaluation of TBS, and to explore the BMD and TBS age-related changes in normal women.

Seventy-eigth normal women from 22 to 83 years were examined on a LEXXOS system (DMS, France), and BMD was evaluated in the standardized neck area of the femoral site. The gray level DEXA images were exported onto a workstation for the evaluation of TBS in the same area. Mean values and standard deviations were evaluated in each ten-year interval. In the two-dimensional (BTS, BMD) representation, mean age-related changes were linked as a continuous variation of both BMD and BTS parameters (see figure). In order to check the complementarity of these two parameters, we have consituted several subgroups with paired BMD values and different ages. The first pairing was constituted of two subgroups of 11 subjects each with mean age of 29.6+/-4.1 years (G_1) and 50.5+/-6.9 years (G_2) and matched neck-BMD: 0.857+/-0.128 g/cm^2 (G_1) versus 0.856+/-0.129 g/cm^2 (G_2). The second pairing was constituted of two subgroups of 7 subjects each with mean age of 33.7+/-3.8 years (G_3) and 65.7+/-4.7 years (G_4) and matched neck-BMD: 0.729+/-0.058 g/cm^2 (G_3) versus 0.726+/-0.058 g/cm^2 (G_4). Significant differences of BTS parameter were obtained in each pairing: 0.501+/-0.101 (G_1) versus 0.632+/-0.089 (G_2), p=0.004 (t-test); 0.466+/-0.079 (G_3) versus 0.631+/-0.080 (G_4), p=0.002 (t-test). At present only BMD is used to evaluate the quality of bone. The prevention strategy then consists into comparing the BMD value of a subject to two "age-matched " and "young normal" standards. Nevertheless, it is well recognized that BMD alone is not sufficient to accurately predict the risk of fracture in individual subject. More accurate normative references of age-related changes including both BMD and TBS parameters, evaluated from the same DEXA exam, would permit to increase the prediction of the risk of fracture.

Change of Biochemical Bone Markers in Korean Postmenopausal Women According to Their Menopausal Period. B. M. Kang*[1], H. Choi*[2], H. M. Park*[3], S. H. Seo*[4]. [1]Obstet & Gynecol, Ulsan University Medical School, Seoul, Republic of Korea, [2]Obstet & Gynecol, Inje University Medical School, Seoul, Republic of Korea, [3]Obstet & Gynecol, ChoongAng University Medical School, Seoul, Republic of Korea, [4]Obstet & Gynecol, Hanlim University Medical School, Seoul, Republic of Korea.

Changes of bone turnover with aging are responsible for bone loss and play a major role in osteoporosis. To investigate the bone turnover pattern in old menopausal women, 674 healthy women including 451 postmenopausal women were classified, according to their menopausal period(less than 5 years, 5-10 years, more than 10 years). Bone formation were assessed by serum osteocalcin(OC) and bone-specific alkaline phosphatase(BSAP). Bone resorption were assessed by the urinary deoxypyridinoline(DPD) and cross-linked N-telopeptide of type I collagen(NTX). All biochemical bone markers, except OC, significantly increased after menopause($p < 0.05$). DPD, NTX and BSAP remained elevated after 10 years of menopause(Table 1). These data indicated that the overall rates of both bone formation and bone resorption increased after menopause and remained high in elderly women.

Table 1. Bone turnover in pre- and postmenopausal women

Bone markers	Premenopause	Postmenopause (n=451)		
	(n=223)	< 5years	5-10 years	> 10 years
DPD(nM/mM)*	4.8±1.3	6.4± 3.1	6.9± 7.3	6.4 ±3.9
NTX(nM BCE/mM)*	31.5±14.0	52.7±26.6	57.8±30.3	57.9±44.3
BSAP(U/L)*	13.2±30.3	19.0± 7.9	19.2 ±9.3	21.8±10.5
OC(ng/ml)	24.1±17.5	24.4 ±9.3	27.2±14.0	27.5±11.1

Interactions of Parathyroid Hormone (PTH) with Markers of Bone Health in a Prospective Study of Perimenopausal Scottish Women. A. J. Black[1], H. M. Macdonald[2], W. D. Fraser[3], D. M. Reid[2]. [1]Department of Rheumatology, Osteoporosis Research Unit, Aberdeen, United Kingdom, [2]Department of Medicine and Therapeutics, University of Aberdeen, Aberdeen, United Kingdom, [3]Department of Chemical Pathology, University of Liverpool, Liverpool, United Kingdom.

While the role of PTH in bone turnover in the elderly is well established, there is little knowledge of the interactions of PTH with bone turnover and bone loss at the time of the menopause.

The Aberdeen Prospective Osteoporosis Screening Study commenced in 1992. All results median ± SD. At the second visit in 1998(6.41±0.9 years later), 3886 subjects had a repeat DXA scan of lumbar spine (LS) and femoral neck (FN), blood and urine samples and risk factor questionnaires performed. The median calcium intake for the group was 1044(+/-257) mg and 4% were pre, 7% peri and 89%postmenopausal.

PTH, P1NP, 25(OH) Vit D_3 and adjusted calcium (Aca) were measured in 2338(75%) and urinary pyridinoline crosslinks in 2771(90%).

Analyte	A Ca Mmol/L	Vit D_3 ug/l	PTH pmol/L	P1NP ug/L	fDPD nmol/ mmol	fPYR nmol/ mmol	Age (yrs)	Height (cm)	Weight (Kg)
Median ±SD	2.35±0.122	0.0±8.7	2.90±2.083	2.0±19.3	5.0±1.96	181±6.4	54.5±2.24	161.1±7.4	67±12.9

Significant but weak correlations with PTH were seen with Vitamin D ,bone turnover markers, height and weight. PTH also negatively correlated with bone loss in the preceding 6 years. These correlations remained significant after adjusting for weight and physical activity. No significant correlations were seen with age or serum Aca.

Pearson correlations with PTH	P1NP	$VitD_3$	fPYR/ creat	Weig ht	LS %change	FN %change
unadjusted	0.11**	0.05*	0.084**	0.11**	-0.08*	-0.06*
adjusted for wt and physical activity.	0.11**	0.05*	0.05*	N/A	-0.063*	-0.07**

*P<0.05**p<0.001, after log transformation of variables

PTH was lower in smokers (2.7±1.9) than non-smokers 2.9±2.12, as was 25(OH) D3 (18.0±7.9, 21.0±8.8 respectively, P<0.05)

The postmenopausal group who had never taken HRT (32%) had the highest bone turnover and PTH when compared to the premenopausal and the oestrogen replete group (premenopausal or on HRT). In none of the menopausal groups nor in the whole group did PTH predict the bone density or bone loss.

PTH has major bone influences in elderly women but only shows minor effects on bone metabolism in women at the menopause. This may be due to the major effects of oestrogen loss at the menopause and the fact that these women are free living with good calcium intakes

Low Performance of Circulating RANKL to Identify Postmenopausal Women with Osteoporosis and Pre-existing Vertebral Fractures. P. Mezquita-Raya*[1], M. de la Higuera*[1], D. Fernandez*[1], G. Alonso*[1], M. Ruiz-Requena*[2], F. Escobar-Jimenez[1], M. Muñoz-Torres[1]. [1]Bone Metabolic Unit. Department of Endocrinology, University Hospital San Cecilio, Granada, Spain, [2]Biochemistry Division, University Hospital San Cecilio, Granada, Spain.

Regulation of osteoclastic activity is critical for understanding bone loss associated with the postmenopausal period. In vitro and animal studies have revealed the role of RANKL on the differentiation and activation of osteoclasts. However, the relationship between serum concentrations of RANKL and bone mass is uncertain, with different studies yielding different results. AIMS: To examine the relationship among circulating levels of RANKL, bone mineral density (BMD) and vertebral fractures in healthy postmenopausal women. SUBJECTS AND METHODS: We determined anthropometric parameters, serum RANKL (Biomedica Gruppe, Vienna, Austria), BMD by dual X ray absorptiometry at lumbar spine and femoral neck (Hologic QDR4500, Waltham, MA), and pre-existing vertebral fractures in 206 ambulatory postmenopausal women. RESULTS: The mean circulating RANKL levels was 3.9±10.7 pg/ml. Serum RANKL concentrations were undetectable in a high percentage of women (n=113, 54,9%). There were no significant differences in clinical variables or prevalent vertebral fractures among women with detectable vs. undetectable RANKL. RANKL were not correlated to clinical variables or BMD. The percentage of women with detectable circulating RANKL was significantly different according to bone status (osteoporosis: 54%, osteopenic 25%; normal bone mass: 14%; p=0.029). However, the association between RANKL and BMD was lost in the multivariate analysis. CONCLUSION: These preliminary results indicate that serum RANKL measurement is of limited practical value at present in the study of bone metabolism.

Serum Gla-type Osteocalcin, Osteoprotegerin, and Urinary Cross-linked N-telopeptide as Markers in Glucocorticoid-Induced Osteoporosis. I. Tanaka, H. Oshima. Department of Laboratory Medicine, Fujita Health University School of Medicine, Toyoake, Japan.

[Objective] Glucocorticoid-induced osteoporosis (GIO) has been increasingly paied attension as a secondary osteoporosis, but valuable markers for outcome such as bone mineral densities and incidental fractures in GIO have not yet available. In this study, we try to clarify a clinical role of serum Gla-type osteocalcin (GlaOC), serum osteoprotegerin (OPG), and urinary Cross-linked N-telopeptide (NTX) levels in GIO.[Subjects & Methods] One hundred patients (75 females and 25 males) with connective tissue diseases under glucocorticoid therapy were enrolled in this study. The mean of age, daily glucocorticoid dosage (prednisolone equivalent), and total glucocorticoid dosage were 46 years old, 19 mg/day, and 7.9 g, respectively. Serum OPG, urinary NTX and serum GlaOC were measured by ELISA, respectively. [Results] 1) Among patients who started to take glucocorticoids (an average dosage of 37 mg/day) but not anti-osteoporosis agents, OPG levels decreased after four weeks significantly (from 3.7+/-1.2 to 2.6+/-1.1 pmol/ml,p<0.05). Anti-osteoporotic agents did not change this decrease. NTX values increased after four weeks (an average of 158% of pre-value, p<0.02). On the other hand, there was no significant change in GlaOC levels. 2) A significant positive correlation was found between OPG and NTX (p< 0.01) before the start of glucocorticoid treatment. In patients under glucocorticoids, however, there was no correlation between these markers. 3) OPG was positively correlated with a change in bone mineral densities of the lumbar spine after 1 year (p<0.02). 4) Among patients (n=12) treated with menatetrenone, a vitamin K analog, GlaOC showed higher values (15.5+/-3.1ng/ml) in 3 cases who had new vertebral fractures in the following 2 years than in 9 cases (7.0+/-4.1) having no fracture in thatpriod (p<0.03).[Conclusion] These results suggest that 1) bone absorption is increased, at least in part, with suppression of OPG by glucocorticoids in the early stage of glucocorticoid treatment, 2) serum OPG level is a predictive marker of change in bone mineral densities, and 3) menatetrenone effectively prevents vertebral fractures in patients with low serum GlaOC values.

Gender and Age Related Changes in Calcaneal Speed of Sound (SOS) in 9,146 Japanese Pediatric Population. T. Yamamoto[1], K. Mimura*[2], H. Morii[3], K. Yoh[4], K. Nonaka*[5], T. Arai*[6]. [1]Pediatrics, Minoh City Hospital, Minoh, Japan, [2]Department of Physical Education, Osaka University of Education, Kashihara, Japan, [3]Emeritus Professor, Osaka City University, Osaka, Japan, [4]Orthopedic Surgery, Hyogo College of Medicine, Nishinomiya, Japan, [5]Department of Health Care, Elk Corporation, Tokyo, Japan, [6]Department of Development, Furuno Electric Co., Ltd., Nishinomiya, Japan.

It seems that the maximum bone quantity in young people will influence a future osteoporosis in the aged. To prevent osteoporosis, it is important for assessment of bone quantity in young people. Previous study was reported to measure calcaneal speed of sound SOS in the elementary school children by using special foot adapter to give more reliable results in ASBMR 2003 by us. The purpose of this study was to assess gender and age related changes for right calcaneal SOS in Japanese pediatric population by using quantitative ultrasound (QUS). A total of 9,146 Japanese children and adolescents (4,352 females and 4,794 males, age range: 6-20 years) at 6 elementary schools, 7 junior high schools, 4 high schools and 4 colleges in 6 provinces from various parts of Japan were , after signing an informed consent, assessed by using QUS device (CM-100, Furuno Electric,Co., Ltd., Japan). To minimize impact of skin temperature, all the measurements in this study were performed in the period during July to October closing to summer season in Japan by the exclusive operators. The age related changes in male: the SOS value increased with age from 12 to 18 years old and showed a peak at age 18. Then it decreased gradually. In contrast, the age changes in female: the SOS values increased with age 12 to 14 years old and showed a peak at age 14. The peak value remained in a plateau until age 18, and then decrease gradually. The SOS value in female was higher than that in male until 16 years old. A significant difference was found between male and female aged 13 and 14. However, the SOS value was becoming similar value in male and female aged 17 to 20. These differences are probably attributed to a different pubertal development.
A detailed reference database for SOS at the calcaneus in Japanese children and adolescents were established. The CM-100 is a useful tool for assessment of pediatric bone quantity.

Inhaled Steroids do not Produce Bone Mass Loss in Asmathic Women. M. Sosa[1], P. Saavedra*[2], and The GIUMO Study Group*[3]. [1]Medicine, University of Las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain, [2]Mathematics, University of Las Palmas de Gran Canaria, Las Palmas de Gran Canaria, Spain, [3]Medicine, Multicentre Cooperative, Study Group, Spain.

Background: Systemic corticosteroid therapy leads to bone loss and increases fracture risk especially with high doses and prolonged use. However it is unclear to what extent inhaled corticosteroids produce detrimental effects on bone mineral metabolism.
Main objective: To study the effect of inhaled steroids on bone mineral density measured by quantitative ultrasound at the heel. To assess the possible influence of menopause as an etiological cofactor on bone mineral loss
Secondary objectives: To study the influence of inhaled steroids on bone mineral density measured by dual X-ray absorptiometry (DXA) at the lumbar spine and the proximal hip.
Subjects and Methods: Cross-sectional study performed on pre and postmenopausal Caucasian women. Group I (patients with oral steroids) was composed by 176 women suffering from asthma and using inhaled steroids for years. They did not use oral steroids. Group II (controls) was composed by 197 women of similar age, height and weight who did not use inhaled steroids. Group III (asmathic) was composed by 72 patients, suffering from asthma and not using any kind of oral or inhaled steroids.
Results: Are shown in tables. We did not find statistical differences in QUS andDXA parameters between the groups.
Conclusions: The chronic use of inhaled steroid in asthmatic pre and postmenopausal Caucasian women, does not produce significative changes in BMD, measured either by QUS at the heel or by DXA at the lumbar spine or the proximal hip.

	Group I Asmathics with inhaled steroids	Group II. Controls	Group III. Asmathic with no steroids	p value
L2-L4 (g/cm^2)	0.936 ± 0.160	0.945 ± 0.152	0.985 ± 0.162	NS

Radiographic Absorptiometry and Quantitative Ultrasound Techniques Are Associated with Vertebral Deformity, but Not with Prior Nonspine Fracture in Japanese Women. Y. Abe*, K. Aoyagi*. Department of Public Health, Nagasaki University Graduate School of Biomedical Sciences, Nagasaki, Japan.

The purpose of this cross-sectional study was to evaluate the association of radiographic absorptiometry (RA) and quantitative ultrasound (QUS) with fractures among 586 Japanese women ages 40 to 89 years (mean age = 64.3, SD = 9.6 years). Bone measurements were performed using RA for metacarpal bone and QUS for calcaneus (stiffness index). Lateral spine radiographs were obtained and radiographic vertebral deformities were assessed by quantitative morphometry, defined as vertebral heights more than 3 SD below the normal mean. Information on previous nonspine fractures after age 45 (due to minor or moderate trauma) was obtained using a questionnaire. The associations of vertebral deformity, previous nonspine fracture, and any (spine or nonspine) fractures with bone measurements were examined using logistic regression analysis, adjusting for age. Both metacarpal bone mineral density (BMD) and stiffness index of calcaneus had significant associations with vertebral deformity. The age-adjusted odds ratio (per 1 SD decrease in bone mass) for vertebral deformity was 1.90 (95% confidence interval [CI]: 1.33-2.71) for metacarpal BMD and 4.03 (95% CI: 2.61-6.22) for stiffness index. However, neither metacarpal BMD nor stiffness index was significantly associated with nonspine fractures; the respective age-adjusted odds ratios were 1.41 (95% CI: 0.99-2.01) and 1.28 (95% CI: 0.89-1.84). Our results suggest that both RA and QUS are significantly associated with existing vertebral deformity, suggesting that peripheral low bone mass contributes to

greater risk of vertebral fracture among Japanese women. Vertebral fractures are rare before age 50, and are typical of osteoporosis in older women. The lack of association of prior nonspine fractures with bone measurements in our study may be partly related to the fact that some fractures occurred much earlier in life, prior to the development of low bone mass or osteoporosis. In addition to bone mass, other factors such as extrinsic energy due to falls may be also important for the occurrence of nonspine fractures. These convenient methods, with portability and relatively low cost, could be in part useful alternatives to conventional bone measurement techniques used for the assessment of fracture risk.

A Family with Osteoporosis-Pseudoglioma Syndrome (OPG) due to Compound Heterozygous Mutation of the LRP5 Gene. L. Y. Jin*[1], H. H. L. Lau[1], D. K. Smith*[2], K. S. Lau*[1], P. T. Cheung*[3], E. Y. W. Kwan*[3], L. Low*[3], V. Chan*[1], A. W. C. Kung[1]. [1]Medicine, The University of Hong Kong, Hong Kong, China, [2]Biochemistry, The University of Hong Kong, Hong Kong, China, [3]Paediatrics, The University of Hong Kong, Hong Kong, China.

Osteoporosis-pseudoglioma syndrome (OPG) is an autosomal recessive disorder due to mutations in the low-density lipoprotein receptor-related protein 5 (LRP5) gene. Here we report two novel missense mutations found in a southern Chinese family from a non-consanguineous marriage. 3 out 4 children had blindness, low bone mineral density (BMD) and multiple fractures in their childhood. The affected subjects were compound heterozygous for W478R and W504C mutations. The father with heterozygous mutation for W478R had low spine BMD while the mother and the unaffected child with heterozygous mutation for W504C had normal BMD. W478R is immediately C-terminal of the third YWTD repeat of the second YWTD/EGF domain in LRP5, while W504C is located between the third and the fourth YWTD repeat of the second YWTD/EGF domain in LRP5. In a model of the LRP5 second YWTD β-propeller domain both W478 and W504 are in close proximity. The two corresponding residues, W515 and W541 in the low-density lipoprotein receptor (LDLR), are involved in contacts with domain R4 of LDLR at endosomal pH. In nidogen W1053 and L1080, which are part of the contact surface with laminin, are the corresponding residues. The observed mutations in LRP5 may affect molecular interactions leading to the observed phenotype. Probable structural perturbation of the β-propeller domain by the charge change of mutation W478R affecting interactions with nearby charged residues may give rise to its apparent greater individual effect.

Spontaneous and Familial Progressive Osseous Heteroplasia (POH), a Human Disorder of Ectopic Bone Formation, Is Dependent on Mutations in the Paternally-Inherited Allele of GNAS. M. Xu*[1], F. S. Kaplan[1], E. M. Shore[2]. [1]Orthopaedics, University of Pennsylvania, Philadelphia, PA, USA, [2]Orthopaedics and Genetics, University of Pennsylvania, Philadelphia, PA, USA.

Progressive osseous heteroplasia (POH) is an autosomal dominant disorder of infantile dermal ossification followed by progressive bone formation within skeletal muscle and deep connective tissue. We previously reported heterozygous inactivating GNAS mutations as a cause of POH. The GNAS gene is transcriptionally complex, initiating mRNA synthesis from multiple promoters and unique first exons that splice into common exons 2-13. Expression of GNAS transcripts is regulated through genomic imprinting. Imprinted genes show a preferential expression of one of the two alleles, dependent on the parent of origin of the allele. The GNAS-Nesp55 transcript is synthesized from the maternally-inherited allele, and the GNAS-XLαs and -1A transcripts from the paternally-inherited allele. The GNAS-$G_s\alpha$ transcript, which encodes a G protein alpha subunit, is bi-allelically expressed in most cells, however, shows preferential expression of the maternal allele and silencing of the paternal allele in some tissues. This tissue-specific imprinting of GNAS-$G_s\alpha$ explains the hormone resistance in patients with pseudohypoparathyroidism type Ia (PHPIa) who have heterozygous inactivating GNAS mutations in their maternally-inherited alleles. POH is a rare condition, with most cases arising as a spontaneous (new) mutation within a family. However, in each of the few families that show inheritance of POH, transmission from fathers to affected children is observed. In this study, we investigated whether POH is dependent on mutations in the paternally-inherited GNAS allele in spontaneous as well as familial cases of POH. To determine whether identified GNAS mutations in POH patients (n= 13; samples obtained following an IRB approved protocol) occurred on the maternally- or paternally-inherited allele, RT-PCR amplification was used to specifically detect the Nesp55 and 1A transcripts followed by DNA sequencing of the cDNAs. If a mutation occurred on the maternal allele, then the mutation would be found in the Nesp55 cDNA but not the 1A cDNA; if a mutation occurred on the paternal allele, the complementary pattern would be observed. In all spontaneous and familial cases of POH examined, GNAS mutations were found to consistently occur on the paternally-inherited allele. These data support that, in contrast to mutations in PHPIa, which occur on the maternally-inherited GNAS allele, POH is dependent on mutations in the paternally-inherited allele of GNAS.

Polymorphisms Within the Osteoprotegerin (OPG) Gene are Associated with both Serum OPG levels and Bone Mineral Density. L. J. Miles*[1], O. Beynon*[1], P. Y. Woon*[1], A. Blumsohn*[2], R. Eastell[2], E. L. Duncan[1], J. A. Wass*[1], M. A. Brown*[1]. [1]Botnar Research Centre, University of Oxford, Oxford, United Kingdom, [2]Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom.

Osteoprotegerin (OPG), a member of the tumour necrosis factor receptor family, plays a key role in the physiological regulation of osteoclastic bone resorption. By virtue of its decoy function, OPG inhibits the binding of RANKL to RANK with a resultant suppression of mature osteoclast activation and inhibition of the terminal stages of osteoclastogenesis. We sought to determine whether polymorphisms within the OPG gene influence bone density (BMD), bone turnover as assessed by serum P1NP, and serum levels of OPG.

This study involved 814 family members (330 men, 484 women) belonging to 164 extended Caucasian pedigrees recruited with probands with extreme low BMD (T-score <-2.5, Z-score <-2.0 at either the lumbar spine (LS) or femoral neck (FN)). Serum OPG was measured by ELISA and P1NP by RIA.

Eleven common single nucleotide polymorphisms (SNPs) spanning the OPG gene were identified from public databases, and previous publications, and confirmed by direct sequencing. SNPs were genotyped by a combination of SNaPshot™, MALDI-TOF mass spectrometry and PCR-RFLP approaches. Two-point linkage disequilibrium was determined using SIMWALK/GOLD, and haplotype estimates using MERLIN/FUGUE. Association was tested between individual polymorphisms and raw BMD using the program QTDT. Proband, age, gender, height and weight were used as covariates.

Significant association was noted between a SNP at the intron2-exon3 boundary (IVS2-4C/T) and LS BMD (p=0.024). Borderline association was found for a SNP within the promoter region (T-847G), and intron 1 (IVS1-865IT/C), with LS BMD (p=0.049 and 0.055, respectively). SNP IVS1-865IT/C was also correlated with OPG levels in serum (p=0.027). No association was found with FN BMD.

Our results suggest that polymorphisms in the OPG gene appear to be important markers for low bone mass and influence serum OPG levels. Further mapping and functional studies will be required to identify the specific variants involved.

High Heritability of Bone Mineral Density in Pedigrees of Men with Idiopathic Osteoporosis. I. Van Pottelbergh*[1], C. Wang*[2], M. Cohen-Solal[3], M. Martinez*[2], A. Ostertag*[3], J. Kaufman[1], M. de Vernejoul[3]. [1]Endocrinology, Ghent University Hospital, Ghent, Belgium, [2]INSERM EMI 00-06, Evry, France, [3]Inserm U606, Hôpital Lariboisière, Paris, France.

Keeping in mind the finding of a high familial resemblance characterising male idiopathic osteoporosis (IO) as observed in 2 independent study groups (1,2), we checked whether pooling of the data was justified. Subsequently we estimated the heritability (h^2) of bone mineral density (BMD) in order to evaluate whether genetic factors influence the familial resemblance for BMD in an extended group of pedigrees ascertained through a male subject with IO, arbitrarily defined as a *Z*-score at the lumbar spine (Z-LS) or at the femoral neck (Z-FN) <= -2, aged 19 to 67. LS- and FN-BMD was measured in IO men (n=89), their first- & second-degree relatives and in their spouses, aged 19 to 85 (n=403). BMD distribution in both the group of IO men and in first-degree relatives was not different for Z-LS and Z-FN between the 2 caucasian study populations (Wilcoxon-testing, P>0.05) indicating that the 2 groups can be pooled. Estimates of h^2 for Z-LS and Z-FN were obtained using the variance component approach taking into account covariate effects as implemented in the Sequential Oligogenic Linkage Analysis Routines (Solar, Version 1.7.3.). The h^2 estimates for Z-LS and Z-FN were highly significant (Table 1). As to covariate effects, BMI had a significant effect on both Z-LS and Z-FN whereas gender significantly affected the variability of Z-LS but not Z-FN (Table 1). Overall, the proportion of phenotypic variance in Z-LS and Z-FN explained by covariates was 18% and 14%, respectively. When the pedigrees were divided in 2 groups according to the probands'age (cut-off 48 yrs), the estimates for covariate effects remained essentially unchanged with slightly higher h^2 estimates for Z-FN in younger probands. In conclusion, our findings confirm that a significant proportion of BMD variability is attributable to additive effects of multiple genes. Considering our findings on BMD h^2 and covariate estimates, a genome-wide search will be performed using non-parametric linkage analyses with adjustment for the identified covariates in this homogeneous group of pedigrees ascertained through men with IO.

Quantitative Genetic Analysis of Hand Skeleton Aging and Biochemical Indices of Bone and Cartilage Metabolism. G. Livshits, I. Malkin*, S. Trofimov*, I. Pantsulaia*, E. Kobyliansky*. Anatomy and Anthropology, Tel Aviv University, Tel Aviv, Israel.

The present study was driven by a clinical problem of chronic degenerative disease of skeleton that includes osteoporosis (OP) and osteoarthritis (OA) related phenotypes. The skeletal phenotypes were assessed from hand radiographs. Our research was carried out on about 150 nuclear and complex three-generational families randomly collected in ethnically homogeneous European pedigrees. The obtained results can be divided into 3 sections: 1.Genetic analysis of bone mass and size characteristics (OP) and traits related to hand OA. 2.Pedigree based investigation of circulating levels of calciotropic hormones, growth factors, cytokines, and biochemical indices of bone and cartilage remodeling. 3.Linkage disequilibrium study of several candidate genes polymorphisms and OP/OA related phenotypes. Model fitting techniques of the genetic analysis were implemented to reveal effects of age, sex, sex hormones, latent environmental, and genetic factors on variation of each of the studied variables and covariation between them. The results indicated strong involvement of the putative genetic factors in determination of variation of the majority of the studied phenotypes. Thus, narrow sense heritability estimates for OP and OA phenotypes, and for biochemical indices such as Leptin, PTH, 25(OH)D, Osteocalcin, PICP, IGFBP-3, TGFb, TNFa, M-CSF, OPG, and TIMPs ranged between 0.30 and 0.80, but were virtually zero for IL6 and soluble RANKL. Genetic relationships between the studied biochemical indices, as well as between them and bone aging traits were complex. Note for example, significant correlations between the OA and OPG (r=0.52, P<0.001) and IGFBP-3 (r=0.46, P0.35, P<0.01) between circulating leptin levels and hand bones size. The search for possible candidate genes revealed that statistically significant portion of OA and OP phenotypes could be attributed to some of these genes. For example, BMD variation, in particular in postmenopausal women maybe accounted for combined effect of ER_a and COLIA1 genes. These effects are likely to be mediated through PTH levels that were significantly related to ER_a polymorphism. Of special interest were results obtained in collaboration with P. Nurnberg's group (Berlin) analyzing ANKH and ENPP1 genes, involved in the control of extra cellular pyrophosphate levels. Each of these genes and in combination was significantly associated (P<0.03-0.006) with hand bone size and proportion. Further extensive research is needed in this field to clarify the situation.

Genome-wide Linkage Analyses of Femoral Neck Density and Strength in Inbred Rats. I. Alam[1], Q. Sun[1], L. Liu*[2], D. L. Koller[2], T. M. Fishburn*[3], M. J. Econs[3], T. Foroud[2], C. H. Turner[1]. [1]Orthopaedic Surgery, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA, [3]Medicine, Indiana University School of Medicine, Indianapolis, IN, USA.

The laboratory rats are the most commonly used animal model for skeletal and aging research. Rats have been used extensively for biomechanical analyses of bone fragility and compared to mice they offer much lower measurement variability, particularly at the femoral neck. Recent progress in mapping of the rat genome and syntenic mapping among different species makes the inbred rats a potentially useful genetic model for skeletal fragility. One of these rat strains, Fischer 344 (F344), has been shown to develop osteopenia similar to humans. Previously, we reported that compared to Lewis (LEW) rats, Fischer (F344) rats have significantly lower (p<0.001) BMD in the femur. In this study, we identified chromosomal regions that contain quantitative trait loci (QTLs) influencing femoral neck density as well as geometric and biomechanical properties in a 595 adult female F2 rats from F344 and LEW progenitors. We performed a whole-genome screen using 100 microsatellite markers at an average density of 20 cM. Skeletal phenotypes were measured by peripheral quantitative computed tomography (pQCT) and femoral neck biomechanical testing. Genetic marker maps were estimated from our own data and compared with published maps. These maps were then used to detect QTLs using interval mapping methods (MAPMAKER/QTL). Our results indicate that a number of different chromosomal linkage regions are linked to femoral neck strength and density. The main QTLs and their synteny to a known QTL region in mice and human are summarized in the following Table.

Marker	Phenotype	LOD score	Mouse Synteny	Human Synteny
D1Rat250	Femur neck BMD	11.6		
D4Rat231	Femur neck BMD	12.3	6, Femur BMD and structure	4q, Hip BMD
	Polar moment of inertia (Ip)	6.8		
	Femur neck width	18.9		
D6Rat39	Femur neck BMD	3.8		
D5Rat159	Ultimate force	3.5	4, Femur and lumbar BMD	1p, Whole body and lumbar BMD
D7Rat64	Ultimate force	6.1	10, Femoral structure and biomechanics	19p, Femoral structure

The results of our study demonstrate novel QTLs for femur neck density and strength and also prove the importance of inbred rat model for genetic linkage analyses for hip fragility.

A QTL with Pleiotropic Effects on Radius Cortical and Trabecular Bone Density in Baboons Maps to a Region Corresponding to Human Chromosome 11q12-13. L. M. Havill, M. C. Mahaney, J. Rogers*. Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX, USA.

We conducted a bivariate statistical genetic analysis of radius bone mineral density (BMD) at two sites, one primarily cortical (dyaphyseal radius (Rad-1/3)) and one primarily trabecular (ultradistal radius (Rad-UD)), to search for genes with pleiotropic effects on both types of bone. BMD was obtained via DXA for 667 pedigreed baboons aged 4.6-30.0 years. We used a maximum likelihood variance decomposition approach to estimate the following parameters simultaneously for both traits: population mean; mean effects of age, age^2, sex, age-by-sex, age^2-by-sex, height, weight, and osteophytosis score; the proportion of the residual phenotypic variance due to the additive effects of genes (heritability (h^2)); unmeasured environmental factors; and the correlations between both traits due to shared genetic effects (ρ_G) and shared environmental factors. Rad-1/3 and Rad-UD BMD showed residual h^2 of 0.42±0.07 (p<0.0001) and 0.35±0.07 (p<0.0001), respectively. The genetic correlation between the two phenotypes (ρ_G=0.63±0.09, p<0.0001) provides strong evidence that 40% of the additive genetic variance in the two traits is attributable to the same gene(s). Initial univariate linkage screens localized QTL for genes influencing Rad-1/3 BMD (LOD=3.00) and Rad-UD BMD (LOD=3.11), to a 20 cM region of baboon chromosome 14 (homologous to human chromosome 11). Maximization of a multivariate multipoint linkage model, parameterized according to the bivariate model (above) and allowing for an additive genetic correlation due to the QTL, improved evidence for linkage (LOD=3.92) in this same region, localizing the QTL to human microsatellite marker D11S916. This region corresponds to human chromosome 11q12-13. Likelihood ratio tests reject the hypothesis of coincident linkage, supporting the pleiotropic effect of a single QTL on both cortical and trabecular BMD in the baboon forearm. This QTL accounts for 31% and 29% of the residual h^2 for Rad-1/3 and Rad-UD, respectively. 11q12-13 harbors the LRP5 gene, known to be influential in Mendelian disorders of BMD and in normal BMD variation in some human populations. The apparent conservation of function to the same genomic region across these two primate species is likely due the effects of the same gene. These results not only provide cross species replication of a BMD QTL on 11q12-13, but also support results of studies in mice and humans showing both pleiotropic and unique gene effects on trabecular and cortical bone. Given the close genetic and physiological similarity of baboons to humans, these results should be highly informative in our search for genes affecting skeletal maintenance and repair.

A Pleiotropic Relationship between Bone Mineral Density and Circulating Leptin Levels in Pedigreed Baboons. L. M. Havill, A. G. Comuzzie*, G. Cai*, J. Rogers*, M. C. Mahaney. Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX, USA.

We conducted preliminary statistical genetic analyses of fasting plasma concentrations of leptin, an adipocyte-derived hormone with known antiosteogenic effects, and dyaphyseal radius bone mineral density (BMD) to search for evidence of shared genetic effects on these two phenotypes. Leptin levels were assayed in frozen plasma samples obtained from 331 pedigreed baboons (*Papio hamadryas*) (231 females, 100 males) aged 6 to 27 years. Radius BMD was obtained via DXA at a point 33% proximal to the styloid process. In initial univariate analyses, we used a maximum likelihood-based variance decomposition approach to estimate heritability and screen for potential covariate effects on each trait. In the subsequent bivariate analysis, we estimated the following parameters simultaneously: population (male) mean; mean effects of significant covariates sex (leptin only), age (BMD), age-by-sex (BMD), weight and osteophytosis score (BMD); the proportion of the residual phenotypic variance due to the additive effects of genes (heritability (h^2)) and unmeasured environmental factors (e^2); and the correlations between both traits due to shared genetic effects (ρ_G) and shared unmeasured environmental factors (ρ_E). Variation in plasma leptin levels and radius BMD showed residual heritabilities of 0.36±0.09 (p<0.0001) and 0.42 ±0.07 (p<0.0001), respectively. We observed a significant positive genetic correlation between these two traits (ρ_G=0.88±0.59, p=0.045), indicating that a significant percentage of the additive genetic variance in plasma leptin levels and BMD is attributable to the effects of the same gene or suite of genes. We estimate (albeit tentatively, given the small sample size in these analyses) that this pleiotropic effect accounts for a minimum of 8% of the additive genetic variance in forearm BMD and a powerful inhibitor of bone formation in this animal model for bone maintenance and turnover. Given the close genetic and physiological similarity of baboons to humans, these results may provide new insights into the role of leptin in regulation of bone mass in our own species.

Macrophage Migration Inhibitory Factor (MIF)Gene Promoter Region Polymorphism and Femoral Neck Bone Density. C. Joseph*[1], K. M. Prestwood*[1], J. A. Burleson*[2], P. K. Gregersen*[3], A. Lee*[3], R. Bucala*[4], G. A. Kuchel*[1], A. M. Kenny[1]. [1]Geriatrics, University of Connecticut, Farmington, CT, USA, [2]Community Medicine & Health Care, University of Connecticut, Farmington, CT, USA, [3]North Shore / Long Island Jewish Research Institute, Long Island, NY, USA, [4]Rheumatology, Yale School of Medicine, New Haven, CT, USA.

Macrophage migration inhibitory factor (MIF), a potent pro-inflammatory cytokine, is elevated in inflammatory conditions like rheumatoid arthritis and sepsis. Polymorphism in numbers of tetranucleotide CATT (cytosine, adenine, thymine, thymine) repeats in the

human *Mif* promoter (5 versus 6,7 or 8) has been linked to lesser MIF expression and lower rheumatoid arthritis disease severity. MIF protein is expressed in osteoblasts and induces metalloproteinase activity. We undertook a pilot study to explore an association between *Mif* CATT polymorphism and bone mineral density.
Methods: Eighty six community dwelling men and women aged 65 and older, with previously determined bone mineral density (BMD), body mass index, and sex hormone levels were recruited. Secondary causes of osteoporosis, hip replacement and high dose corticosteroid use was excluded. Individuals were dichotomized according to CATT alleles into a "low-expressing" genotype (presence of any 5 allele) and a "high-expressing" genotype (no 5 allele). Femoral neck BMD (dependent variable) was compared between the two groups using 2-tail *t* test. Logistic regression was also used to analyze the contribution of *Mif* genotype to femoral neck BMD controlling for age, gender, height and weight.
Results: The distribution of *Mif* genotype was as follows: 5,5 genotype in 5/86 (5.81%); 5,non-5 genotype in 26 (30.2%); and non-5, non-5 in 55 (63.9%) participants. The mean femoral neck BMD for those with any 5 allele (low expressing genotype) was 0.89 ± SD 0.13 and for group with no 5 allele (high expressing genotype) was 0.84 ± SD 0.13 (p= 0.063). There was no significant contribution of CATT genotype to femoral neck bone density (F = 1.64, P=0.204.) when adjusted for age, gender, and Body Mass Index.
Conclusions: In this preliminary pilot study, no difference was seen in femoral neck bone density between individuals with low- and high-expressing *Mif* alleles once potentially confounding variables were controlled. A larger sample cohort will be required to adequately address the study hypothesis

The Effect of *Bsm*I and *Fok*I Genotypes on BMD and Bone Turnover Response to Raloxifene Therapy. A. Rogers, J. A. Clowes, F. Gossiel*, N. F. A. Peel, R. Eastell. Academic Unit of Bone Metabolism, University of Sheffield, Sheffield, United Kingdom.

The vitamin D receptor polymorphism, *Bsm*I, has previously been associated with the efficacy of raloxifene therapy. The aim of this study was to determine the presence of an association between the *Bsm*I and *Fok*I polymorphisms of the vitamin D receptor (VDR) gene and bone density and bone turnover response to raloxifene.
One hundred osteopenic postmenopausal women (ages 52 to 80 years, mean 64 years) were prescribed raloxifene (60mg/day) and calcium carbonate (500mg/day) for 48 weeks. Bone density at the lumbar spine (LSBMD) and total hip (THBMD) was measured in duplicate by DXA (Hologic, QDR 1000W) at baseline and 48 weeks. Urinary N-telopeptides of type I collagen (UNTX), a marker of bone resorption, was measured in quadruplicate at baseline and at 48 weeks using an autoanalyser (Vitros Eci). The *Bsm*I and *Fok*I polymorphisms were assayed using an ABI Prism™ 7200 Sequence Detection System (Taqman®). Adherence to treatment was assessed using electronic monitoring devices. 18 women either withdrew from the study or discontinued treatment before the end of the 48-week study period and were not included in this analysis.
The frequency of genotypes was BB 31%, Bb 47%, bb 22% and FF 31%, Ff 52%, ff 17%. The mean percentage changes in LSBMD, THBMD and UNTX in the whole group bone were +1.5%, +0.83% and -24% respectively. Women who were homozygous for the f allele had a significantly higher increase in THBMD than those who were F homozygous (table, values are % change (SEM)). Women who were homozygous for the b allele had a slightly higher increase in LSBMD than those who were B homozygous, but this borderline association was in the opposite direction to that reported previously.

	BB	Bb	bb	P (ANOVA)	P (BB vs bb)
LSBMD	+1.25 (0.35)	+1.50 (0.37)	+2.41 (0.47)	0.14	0.06
THBMD	+0.97 (0.38)	+0.77 (0.33)	+0.79 (0.50)	0.93	0.82
UNTX	-28.36 (6.78)	-21.41 (4.75)	-28.16 (6.78)	0.61	0.87
	FF	Ff	ff	P (ANOVA)	P (FF vs ff)
LSBMD	+1.83 (0.45)	+1.48 (0.31)	+1.34 (0.66)	0.75	0.59
THBMD	+0.39 (0.34)	+0.84 (0.34)	+1.66 (0.42)	0.16	0.03
UNTX	-30.47 (8.30)	-21.76 (5.25)	-24.78 (5.02)	0.62	0.56

There were no other significant differences in BMD or UNTX response to therapy by *Bsm*I and *Fok*I genotype.
We conclude that in this group of postmenopausal women there is a significant difference between the FF and ff VDR genotypes and THBMD response to raloxifene. However, unlike a previous report, we saw no significant associations between *Bsm*I genotypes and BMD response.

The Catechol-O-Methyltransferase val158met Polymorphism Is Associated with Bone Mineral Density in Young Adult Men. A. Eriksson[1], M. Lorentzon[1], N. Andersson[1], D. Mellström[2], C. Ohlsson[1]. [1]Center for Bone Research at the Sahlgrenska Academy, Department of Internal Medicine, Göteborg University, Göteborg, Sweden, [2]Department of Geriatric Medicine, Göteborg University, Göteborg, Sweden.

Peak bone mineral density (peak BMD) is an important predictor of future risk of osteoporosis. Estrogens influence the accretion of bone mass during puberty. Catechol-O-Methyltransferase (COMT) is involved in the degradation of estrogens. There is a functional polymorphism in the COMT gene (val158met), resulting in a 60-75% difference in enzyme activity between the val (high activity = H) and met (low activity = L) variants. The aim of the present study was to investigate the associations between this polymorphism and peak BMD in young men. 458 healthy men (age 19, SD 0.6) were genotyped and classified as $COMT^{LL}$, $COMT^{HL}$ or $COMT^{HH}$. Bone parameters were measured using both DXA and pQCT.
Regression models using physical activity, height, weight, age and COMT genotype as covariates showed that COMT genotype was an independent predictor of areal BMD in the total body, total femur and trochanter ($p<0.01$) but not in the spine. Areal BMD of the femur was 3.7% lower in $COMT^{LL}$ than in $COMT^{HL}$, while the values for $COMT^{HL}$ and $COMT^{HH}$ were very similar. pQCT analyses demonstrated that COMT genotype was an independent predictor of trabecular vBMD in the tibia, radius and fibula ($p<0.05$). Trabecular vBMD of the radius in $COMT^{LL}$ was 5.4% and 5.1% lower than that of $COMT^{HL}$ and $COMT^{HH}$ respectively. COMT genotype was associated with cortical volumetric BMD ($p<0.05$) but not with cortical cross sectional area in the tibia. These findings demonstrate that the COMT polymorphism is associated with BMD in young adult men.

An Intron 2 Polymorphism at the Serotonin Transporter Is Associated with Reduced Hip Bone Mineral Density. E. M. Haney*[1], L. Marshall[1], L. Lambert[1], J. Zmuda[2], K. Stone[3], E. Orwoll[1], M. Bliziotes[1]. [1]Department of Medicine, Oregon Health Sciences University, Portland, OR, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]University of California, San Francisco, CA, USA.

Functional serotonin transporters have recently been discovered in osteoblasts and osteocytes, and disruption of the serotonin transporter gene in mice results in osteopenia. We investigated whether genetic variation within the serotonin transporter influences BMD in humans. The serotonin transporter has two well-characterized variations: one at the promoter, with 14 or 16 repeats of a 22 base pair unit designated S (14 repeats) and L (16 repeats), and one at intron 2 with 9, 10, or 12 repeats of a 16-17 base pair unit.
We genotyped the serotonin transporter of 431 white men enrolled at the Portland, OR site of the Osteoporotic Fractures in Men (MrOS) study, a longitudinal cohort study of fractures in men. BMD was measured at baseline by DXA (QDR4500W, Hologic, Inc). Genotyping was performed with PCR analysis of DNA from peripheral blood samples using published primer sequences for the polymorphisms of interest.
Table. Frequency of Serotonin Transporter gene polymorphisms at the promoter and intron 2 alleles and mean BMD in the proximal femur according to genotype among 431 US men. BMD=g/cm2 (mean, s.d.).

Promoter Region	**S/S**	**S/L**	**L/L**	
Genotype Prevalence	79 (19.0%)	211 (50.8%)	125 (30.1%)	
Total hip BMD	0.965 (0.151)	0.945 (0.150)	0.967 (0.145)	
FN BMD	0.800 (0.148)	0.771 (0.139)	0.790 (0.132)	
Trochanter BMD	0.764 (0.139)	0.752 (0.137)	0.766 (0.131)	
Intron 2	**9/12**	**10/10**	**10/12**	**12/12**
Genotype Prevalence	6 (1.4%)	90 (21.7%)	164 (39.5%)	155 (37.3)
Total hip BMD	1.05 (0.140)	0.944 (0.152)	0.960 (0.158)	0.955 (0.138)
FN BMD	0.844 (0.142)	0.782 (0.149)	0.784 (0.137)	0.780 (0.137)
Trochanter BMD	0.879 (0.142)	0.749 (0.139)	0.760 (0.139)	0.758 (0.130)

After adjusting for age and lean body mass, the 9-repeat allele was associated with a 12% higher BMD at the trochanter (adjusted means: 0.759 vs. 0.880, P=0.019) and a 10% higher BMD at the total hip (adjusted means: 1.050 vs. 0.955, P=0.08). The L-allele was associated with a 4% lower BMD at the femoral neck (0.777 vs. 0.811, P=0.032). There were no significant differences in BMD noted at the lumbar spine for the other polymorphisms.
These results demonstrate an association between allelic variation at the serotonin transporter locus and BMD in white men. The mechanism for this is unknown, however the association between increased BMD and the 9-repeat allele is consistent with in vitro observations that the 9-repeat allele increases transporter promoter activity, which may lead to increased transporter expression. Additional studies of serotonin transporter polymorphisms and other populations will be required.

Combination of Platelet-Rich Plasma (PRP) and COX-2 Inhibitor Potently Stimulates Mesenchymal Stem Cell Proliferation. D. Chikazu, S. Ohba, T. Ogasawara, M. Katagiri, H. Kawaguchi, T. Takato*. Oral-maxillofacial Surgery & Orthopaedic Surgery, University of Tokyo, Tokyo, Japan.

Platelet-rich plasma (PRP) is a component of blood in which the platelets are concentrated in a limited volume of plasma. PRP contains many growth factors such as PDGF, TGF-β and IGF-I, which are known to show potent osteogenic actions. Although the clinical application of PRP has become prevalent in oral and maxillofacial surgeries, little is known about the mechanism by which PRP leads to bone formation. The present study therefore investigated the effects of PRP on cultured mouse bone marrow mesenchymal stem cells (BMSC) using a double chamber dish separated by a porous membrane with the PRP on the top and cells on the bottom in the absence of serum. Although PRP inhibited mRNA levels of type I collagen, ALP and Runx2 as determined by real-time RT-PCR analysis, it stimulated cell proliferation about 4 fold that of the control culture. Interestingly, PRP potently stimulated cyclooxygenase-2 (COX-2) mRNA level and medium prostaglandin (PG) E_2 accumulation, and endogenous PGE_2 treatment inhibited the proliferation of BMSC. To know the involvement of the COX-2 / PGE_2 induction in the PRP osteogenic action, we added a COX-2 inhibitor, celecoxib, to the BMSC culture. Although celecoxib did not influence the inhibitory action of PRP on osteoblastic markers, it stimulated the mitogenic action of PRP about 2-fold. Moreover, when PRP was added to the culture of BMSC derived from COX-2-deficient mice (KO) or the wild-type (WT) littermates, its mitogenic action in the KO cell culture was about double that in the WT culture. We therefore conclude that PRP induces bone formation from BMSC by stimulating the proliferation, but not the differentiation. Since COX-2 induction by PRP blunts its mitogenic action, the combination with COX-2 inhibitors may reinforce the osteogenic activity of PRP.

ELR^+ CXC Chemokine Production by and Action in Human Mesenchymal Stem Cells. D. S. Bischoff*, N. Makhijani*, J. Zhu*, K. Tachiki*, D. T. Yamaguchi. Research Service, VA Greater Los Angeles Healthcare System, Los Angeles, CA, USA.

Inflammation is the initial phase of bone repair, and recruitment of mesenchymal stem cells (MSCs) to the region of repair has been suggested to occur via a number of growth factors released by injured bone. CXC chemokines bearing the glu-leu-arg (ELR^+) motif have been shown to be released by inflammatory cells and serve as angiogenic factors by stimulating chemotaxis and proliferation of endothelial cells. The potential role of ELR^+ CXC chemokines in early events in bone repair was studied using human MSCs (hMSCs). hMSCs cultured in osteogenic medium (OGM) (containing ascorbate, β-glycerophosphate, dexamethasone) showed a 255-fold and 45-fold increase in mRNA for the ELR^+ CXC chemokines, IL-8 and GROα, respectively, as determined by real-time RT-PCR, compared to hMSCs grown in medium without osteogenic components. OGM also induced an increase in alkaline phosphatase activity, a marker of osteoblastic differentiation, in hMSCs. IL-8 alone but not GROα stimulated alkaline phosphatase activity in the absence of OGM in a dose-dependent manner, with 200 ng/ml (highest concentration of IL-8 tested) showing maximal stimulation. hMSCs exhibited chemotaxis to 10 nM IL-8 but not to lower doses. MC3T3-E1 cells, representative of committed mouse osteoblastic cells were not chemotactically stimulated by KC, the GROα equivalent in mice. Experiments were also conducted to examine CXC receptors on hMSCs. While IL-8 can bind to both CXC receptors (CXCR1 and CXCR2), GROα binds with higher affinity to CXCR2 and much less affinity to CXCR1. Real-time RT-PCR demonstrated that both CXCR1 and CXCR2 mRNA are detected in hMSCs with CXCR1 at much higher levels than CXCR2. FACS analysis showed that CXCR1 and CXCR2 protein levels followed a similar pattern to that shown by the mRNA levels. Preliminary experiments to define signal transduction pathways in hMSCs activated by IL-8 demonstrated that IL-8 treatment induced an increase in cytosolic calcium levels. Additionally, IL-8 stimulated the phosphorylated forms of ERK1/2 (p44/p42) in a pertussis toxin-sensitive manner. Conclusions: 1) hMSCs express ELR^+ CXC chemokines when grown in OGM; 2) hMSCs show significantly more CXCR1 than CXCR2 mRNA and protein expression; 3) hMSCs can respond to ELR^+ CXC chemokines by chemotaxis; 4) IL-8 but not GROα stimulates osteoblastic differentiation in hMSCs, and stimulation of osteogenic differentiation of hMSCs may be related to expression of CXCR1 and not CXCR2; 5) intracellular signaling stimulated by IL-8 include cytosolic calcium and MAPK pathway activation.

Adiponectin Deficiency Partially Protects against Age-related Trabecular Bone Loss in Male Mice. A. Nampei*[1], J. Hashimoto[1], K. Maeda*[2], T. Ono*[1], N. Nakamura*[1], W. Ando*[1], K. Tateishi*[1], H. Tsuboi*[1], K. Shi*[1], K. Hayashida*[1], T. Funahashi*[2], H. Yoshikawa[1]. [1]Orthopaedics, Osaka University Graduate School of Medicine, Suita, Japan, [2]Internal Medicine and Molecular Science, Osaka University Graduate School of Medicine, Suita, Japan.

It is well established that body weight and body mass index are positively associated with bone mineral density (BMD). Obesity also protects against osteoporosis related fracture. Recent studies revealed that adipose tissue secretes various bioactive substances including leptin, tumor necrosis factor-alpha and adiponectin. These adipocyte-derived cytokines shed some light on the relationship between metabolic syndrome and bone metabolism. Many studies focused on leptin to explain the association between fat mass and BMD, however few studies dealt with adiponectin. Adiponectin is known to be associated with type 2 diabetes mellitus and atherosclerosis, but the relation with bone metabolism is still unknown. To investigate the contribution of adiponectin to the positive relationship between obesity and BMD or bone metabolism, we evaluated the morphometrical changes of bone in adiponectin deficient mice radiologically. Radiographs, bone mineral density (BMD), 3-dimensional bone structural architecture of lower extremity of male adiponectin knockout (KO) mice and wild type (WT) mice were analyzed and evaluated at 3 and 9 months old, using dual-energy X-ray absorptiometry (DEXA) and micro-computed tomography (micro-CT). There were no radiographical changes in skeletal frame, i.e. length, and diameter of bone. There were no significant differences of femoral and tibial BMD evaluated with DEXA between WT and KO mice both at 3 and 9 months old. For micro- CT, there were no differences of trabecular bone volume of proximal tibia between WT and KO mice at 3 months old (WT 22.63 ± 0.85 % vs. KO 21.50 ± 1.24 %), but at 9 months old, trabecular bone volume of KO was significantly higher than that of WT (WT 11.66 ± 1.05 % vs. KO 17.48 ± 0.84 % ; $p < 0.005$). Other parameters evaluated with micro-CT also showed the high bone mass and high connectivity of trabecular bone in KO mice than wild mice at 9 months old, although there were no significant differences at 3 month old. Our results revealed that adiponectin is associated with age-related trabecular bone loss and its deficiency protects the age-related trabecular bone loss in male mice, despite the fact that there were no influences upon developmental peak bone mass. These data suggest that adiponectin is one of the biochemical factors to explain the relation between obesity and bone mass.

Regulation of Dickkopf Homolog 1 (Dkk1) Expression by Endothelin-1 (ET-1): Implications in the Pathogenesis of Osteoblastic Metastases. G. A. Clines, K. S. Mohammad, J. M. Chirgwin, T. A. Guise. Internal Medicine, University of Virginia, Charlottesville, VA, USA.

Tumor-produced endothelin-1 (ET-1) is a causal agent in osteoblastic metastases. It stimulates osteoblasts via the endothelin A (ETA) receptor. ET-1 stimulates osteoblast proliferation and new bone formation in neonatal mouse calvariae, effects that are blocked by ETA receptor antagonists. However, the molecular mechanisms through which ET-1 stimulates osteoblasts are unclear.

Downstream targets of ET-1 in osteoblasts were identified by gene array analysis. Calvariae were excised from four-day-old mouse pups and treated with or without 100 nM of ET-1 for 6 hours, 1, 4 and 7 days. Total RNA was isolated and hybridized to mouse Affymetrix GeneChips representing 22,600 genes. Upregulated genes with putative or established roles in osteoblast function included four secreted factors [interleukin 6 (p=.023), Wnt5a (p=.042), tissue inhibitor of metalloproteinase-3 (p=.026), cysteine-rich protein 61 (p=.002)], two signaling molecules [serum/glucocorticoid regulated kinase (p=.016), TGIF (p=.016)] and three transcription factors [TSC-22 (p=.023), C/EBP delta (p=.049) and Twist homolog 2 (p=.039)]. ET-1 significantly downregulated Dickkopf homolog 1 (Dkk1) (p=.019), a secreted inhibitor of the Wnt signaling pathway recently implicated in suppressed bone formation of multiple myeloma. We hypothesized that ET-1 activates osteoblasts by decreasing the tonic negative regulation exerted by autocrine Dkk1. In validation of the gene array data, ET-1 decreased Dkk1 mRNA in calvarial organ cultures and primary osteoblasts.

To test the role of Dkk1 in ET-1-stimulated new bone formation, we utilized the mouse calvarial assay for new bone formation. Recombinant Dkk1 (50 ng/ml) abrogated ET-1-induced osteoblast proliferation and new bone formation in calvarial organ cultures ($p<.05$) but did not inhibit basal osteoblast activity. Dkk1 did not inhibit the osteoblast stimulatory actions of FGF2 or BMP2. These data suggest that Dkk1 may be specific for the ET-1-stimulated pathway rather than a general regulator of new bone formation.

Our data demonstrate that Dkk1 is an abundant product of osteoblasts; and activation of the ETA receptor by ET-1 decreases Dkk1 expression, thereby relieving tonic negative regulation of osteoblast activity. In multiple myeloma bone disease Dkk1 may depress bone formation. The opposite may occur in osteoblastic disease, where ET-1 stimulates osteoblast activity by decreasing autocrine production of the negative regulator Dkk1.

Possible Mechanisms Of TP508, A Synthetic Thrombin Peptide, In Promoting Fracture Healing. H. Wang[1], X. Li*[2], E. Tomin[3], J. Convery*[1], E. Rousseau*[1], S. Doty[3], D. Carney*[4], J. Lane[3], J. T. Ryaby[1]. [1]OrthoLogic Corp., Tempe, AZ, USA, [2]University of Chicago, Chicago, IL, USA, [3]Hospital for Special Surgery, New York, NY, USA, [4]Chrysalis Biotechnology, Inc., Galveston, TX, USA.

TP508, a synthetic 23 amino acid peptide, represents a receptor-binding domain of human thrombin, an important growth factor and immunoregulator of tissue injury. TP508 has been shown to accelerate wound and bone fracture healing, and to promote cartilage repair. In this study, we aim to elucidate the molecular mechanisms of TP508 action using Affymetrix profiling. Closed fractures of the femoral midshaft were created in 10-month-old male Sprague-Dawley rats (3-12 animals/group/time point). TP508 at a dose of 0 (saline control), 1 and 10μg in 100 μl saline was injected percutaneously into the fracture

site one hour post-fracture. For torsion testing, the femurs were collected at 4 weeks post-fracture. For histology, the femurs were collected at week 3. For microarray analysis, the femurs were collected at days 1, 2, and 4. At 4 weeks post-fracture, 1μg TP508 treatment increased mechanical strength 21% relative to the control group, while 10μg caused a 36% increase ($p<0.05$). Histological analysis showed a 41% increase of newly formed blood vessels in 1μg TP508 treated groups in comparison with control. Microarray data showed that major genes involved in the early immune response, including several MHC Class II genes, IL-1β, and IL-1β receptor type 2, were significantly increased in 1μg TP508 treated group relative to controls. The expression of early response factor genes regulating angiogenesis, such as Egr-1, c-Jun and c-Fos, were also significantly increased. In addition, a set of Egr-1 target genes including FGF2 was also positively affected by TP508. This study suggests that TP508 promotes fracture healing through a mechanism that involves an increased induction of a number of growth factors, and enhanced expression of inflammatory mediators and angiogenesis-related genes.

Induction of Bone Repair During Distraction Osteogenesis Requires VEGF Receptor Signaling. R. S. Carvalho, K. Jacobsen*, E. Tsiridis*, T. A. Einhorn, L. C. Gerstenfeld. Orthopaedic Surgery Research Laboratory, Boston University Medical Center, Boston, MA, USA.

The technique of distraction osteogenesis (DO) was developed to correct limb length discrepancies that occur as a result of injury, disease or malformation. Clinically and in animal this is one of the most dramatic means of regeneration of large amounts of osseous tissue and is capable of lengthening a long bone up to ~20% of its length. Despite its wide spread clinical application, very little is understood about the basic biology of bone repair and regeneration induced by DO. Though not mechanistically well understood, the primary descriptive features of DO are that it induces new bone formation through an intramembranous process devoid of extensive cartilage, and the repair tissue is highly vascularized. Due to these observations, we hypothesized that an angiogenic process drives bone regeneration during distraction osteogenesis. In order to test what the role of vascularization was during DO, we examined the functional role of vascular endothelial growth factor (VEGF). VEGF has previously been shown to be responsible for the migration and proliferation of endothelial cells that are essential for the development of new blood vessels. DO was carried out using a monlateral fixator that was applied to the tibia of male mice. The time course of DO was for 35 days. VEGF activity was selectively inhibited by antibody blockade of both receptors, VEGFR1 (Flt-1) and VEGFR2 (Flk-1). Loss of VEGF receptor function lead a failure of bone repair as confirmed by x-ray and histological analysis. Analysis of mRNA expression within the DO regeneration gaps demonstrated a ~50 % reduction in the expression of osteogenic mRNAs (collagen type I, OC and BSP)expression while chondrogenic mRNAs (collagen- type II and X) expression were elevated in the tissues from VEGFR antibody blockaded mice when compared to control DO mice. These results demonstrate that VEGFR signaling is essential for new bone formation during DO, and in the absence of VEGFR signaling a chondrogenic phenotype develops in the regenerating tissues.

The Stimulatory G Protein Signaling Indirectly Increases FGF-23 mRNA Level. M. Takaiwa*[1], K. Aya[1], Y. Yamanaka[1], Y. Seino[2], H. Tanaka[1]. [1]Pediatrics, Okayama Univresity Postgraduate School of Medicine and Dentistry, Okayama, Japan, [2]Pediatrics, Osaka Kousei Nennkinn Hospital, Osaka, Japan.

Background: Fibrobalst growth factor 23 (FGF-23) has been identified as a causative factor in several hypophosphatemia; tumor induced osteomalacia, autosomal dominant hypophosphatemic rickets and X-linked hypophosphatemic rickets. Since the elevation of serum FGF-23 level was also reported among patients with McCune Albright syndrome (MAS)/fibrous dysplasia of bone (FD) and secondary hyperparathyroidism, we hypothesized that the stimulatory G-protein(Gs) - adenylyl cyclase(AC)- cyclic AMP(cAMP) signaling system may positively regulate FGF-23 mRNA expression.
Method: We first measured the serum FGF-23 levels of 3 MAS/FD patients using ELISA in order to confirmed the relationship between serum FGF-23 level and clinical manifestations of MAS/FD. We next investigated the effect of PTH(1-34),forskolin (FSK) and 8Br-cAMP on FGF-23 mRNA abundance in the primary mouse thymic cell culture. We also tested mouse mesenchymal cell line culured with or without the protein kinase A inhibitor H-89. FGF-23 mRNA was quantified using real-time PCR method. To explore molecular regulatory mechanism, 2174bp genomic DNA fragment upstream of FGF-23 gene were cloned into pGL3 basic plasmid (Promega) and transfected to a mouse mesenchymal cell line in order to perform luciferase assay. Transfected mesenchymal cells were cultured for 12 hours with or without PTH(1-34) or FSK and the luciferase activity were measured.
Result: Serum FGF-23 levels were increased in all MAS/FD patients (92-593RU/ml). Serum FGF-23 levels were correlated to serum phosphorus level, the renal threshold phosphate concentration (TmP/GFR), and alkaline phosphatase.
12 hours exposure to PTH(1-34), FSK, 8Br-cAMP increased FGF-23 mRNA abundance of wild type derived thymic cells (2.0-2.2 fold of control ($p<0.05$)) and Hyp mouse derived thymic cells (1.6-2.8 fold of control ($p<0.05$)). Though it required prolonged treatment (20-30 hours), similar effects were observed in a mouse mesenchymal cell line and were suppressed by H-89. Luciferase assay of FGF-23 upstream clone did not show significant change by the treatment of PTH(1-34) or FSK.
<Discussion>
Serum FGF-23 levels indicated that FGF-23 induces hypophosphatemia of MAS/FD patients, and may be produced in FD lesion. The results from the experiment with mouse thymic cells and mesenchymal cell lines suggested that prolonged stimulation of Gs-AC-cAMP signaling may increase FGF-23 mRNA abundance. But, the long duration of cell treatment and the poor results of luciferase assay may indicate that Gs-AC-cAMP signaling sysytem does not directly regulate FGF-23 mRNA expression.

Elevated Expression of *fgf23* in Bone in Primary Hyperparathyroidism *in vivo*. Y. Imanishi[1], T. Kawata*[1], K. Kobayashi*[1], E. Ishimura*[2], T. Miki[3], A. Arnold[4], M. Inaba[1], Y. Nishizawa[1]. [1]Department of Metabolism, Endocrinology and Molecular Medicine, Osaka City University Graduate School of Medicine, Osaka, Japan, [2]Department of Nephrology, Osaka City University Graduate School of Medicine, Osaka, Japan, [3]Department of Geriatrics and Neurology, Osaka City University Graduate School of Medicine, Osaka, Japan, [4]Center for Molecular Medicine, University of Connecticut Health Center, Farmington, CT, USA.

While the importance of FGF-23 is established in the pathogenesis of phosphate wasting disorders, little is known about the mechanisms regulating its circulating level. To investigate the role of calcium metabolism in FGF-23 homeostasis, we investigated the regulation of FGF-23 *in vivo* on PTH-*cyclin D1* transgenic mice (PC2 mice), a model of primary hyperparathyroidism. Studies were approved by the appropriate institutional animal care committees. Serum FGF-23 level was elevated in PC2 mice (PC2: 761 ± 101 vs. WT: 244 ± 51 pg/mL), and the level was significantly correlated with serum PTH ($P= 0.004$), Ca ($P< 0.001$), and P ($P= 0.002$) levels. Expression profile of *fgf23* revealed abundant expression in bone, especially in calvaria by quantitative real-time RT-PCR. The *fgf23* expression in calvaria, significantly increased in PC2 mice compared to WT mice (about 20 times), was well correlated with serum FGF-23 levels ($P<0.001$). Alkaline phosphatase and osteocalcin expression were also significantly correlated with the expression of *fgf23* ($P<0.001$), suggesting the importance of osteoblastic activity in FGF-23 regulation. Serum FGF-23 level was suppressed by parathyroidectomy in PC2 mice, and increased by continuous 1-34 PTH infusion in WT mice. In conclusion, our observations indicate that PTH has a role in the regulation of serum FGF-23 level, likely via osteoblast activation in bone.

FGF-2 Induces Osteoblast Survival Through a PI3-Kinase-Dependent, -Beta-Catenin-Independent Pathway. F. Debiais[1], G. Lefevre*[2], J. Lemonnier*[1], S. Le Mée*[1], F. Lasmoles*[1], F. Mascarelli*[2], P. J. Marie[1]. [1]Laboratory of Osteoblast Biology and Pathology, Inserm U606, Paris, France, [2]Institut Biomedical des Cordeliers, Inserm U450, Paris, France.

Fibroblast growth factor-2 (FGF-2) is an important molecule that controls bone formation through activation of osteoblastic cell replication and differentiation. The role of FGF-2 on human osteoblast survival and the signaling pathway that mediates its effect are not known. We studied the effect of FGF-2 on apoptosis induced by low serum concentration and the signal transduction pathway involved in this effect. Treatment of human primary calvaria osteoblasts or immortalized human immortalized calvaria osteoblastic cells with FGF-2 (10-100 ng/ml) for 24-48 h protected against osteoblast apoptosis induced by low serum concentration. This effect occured through specific inhibition of caspase-2 and caspase-3 activity. Pharmacological inhibition of MEK-1 or p38 MAPK had no effect on the inhibition of caspases-2 and -3 induced by FGF-2. In contrast, inhibition of phosphatidylinositol-3 Kinase (PI3K) with LY294002 abolished the FGF-2-induced inhibition of caspases-2 and -3 in human osteoblastic cells. Using a kinase assay, we found that FGF-2 increased PI3K activity. However, this effect did not induce phosphorylation of the downstream effectors PKB/Akt or p70 S6 kinase. Treatment with FGF-2 induced GSK-3 alpha and beta phosphorylation in osteoblastic cells. However, this effect did not result in beta-catenin accumulation or Lef/Tcf transcriptional activity. In contrast, lithium induced beta-catenin accumulation, Lef/Tcf transcriptional activation and increased caspase-2 and -3 activity. The results indicate that the immediate protective effect of FGF-2 on human osteoblastic cell apoptosis involves PI3K and inhibition of downstream caspases, independently of GSK-3 and beta-catenin-Lef/Tcf-mediated transcription.

Incomplete Glycosylation of Crouzon Mutant FGFR2 Diminishes Protein Stability and Alters Subcellular Localization and Signaling. N. E. Hatch[1], M. Seto*[2], M. Bothwell*[1]. [1]Physiology and Biophysics, University of Washington, Seattle, WA, USA, [2]Pediatrics, University of Washington, Seattle, WA, USA.

Craniosynostosis is a debilitating clinical condition characterized by premature fusion of one or more of the cranial sutures. Mutations in three members of the fibroblast growth factor receptor (FGFR) gene family have been genetically linked to several of the craniosynostosis syndromes and have been shown to be gain of function mutations in terms of ligand binding, dimerization and auto-phosphorylation of the receptor. A commonly accepted hypothesis is that craniosynostosis results from excess mineralization that occurs downstream of overactive FGF/FGFR signaling in the cranial suture environment. Contrary to this idea, we show that a Crouzon mutation of FGFR2 (FGFR2/c278f) diminishes receptor cell surface expression and ligand induced signaling, and that this an effect of inadequate mutant receptor glycosylation. To determine levels of receptor expression/degradation, glycosylation, cell surface expression, and signaling, mammalian expression vectors expressing normal or Crouzon mutant (c278f) FGFR2 were transfected into COS7, NIH3T3 and MC3T3E1C4 cells. Protein expression and degradation was assessed with the use of specific protease inhibitors. FGFR2 cell surface expression was monitored through the use of an N-glycosylation inhibitor followed by streptavidin precipitation of biotinylated cell surface proteins. FGFR2 signaling was induced by treatment of cells with 50 ng/ml FGF2 and 100 mg/ml heparin and monitored through the use of activation-state specific antibodies. Crouzon mutant FGFR2 was found to be degraded to a significantly greater extent than normal FGFR2 protein. Degradation was lysosome and calpain, but not proteasome dependent. FGFR2/c278f was expressed predominantly as the partially glycosylated, 110 kDa form while normal FGFR2 was expressed predominantly as the fully glycosylated, 120 kDa form. Glycosylation of FGFR2 was shown to be essential for cell surface expression. MAPK signaling upon FGF2 treatment was lower in cells expressing the mutant, as opposed to the normal, receptor. The c278f Crouzon mutation in FGFR2 results in diminished glycosylation, increased degradation and dramatically lower levels of cell surface expression. These observations suggest that, although these mutations may induce dimerization and autophosphorylation, it is likely the mutated receptors are trafficked to the lysosome for degradation as opposed to the cell surface for expression, ligand binding and signaling.

Identification and Characterization of a Novel IGFBP-5 Interacting Protein (IGFBP5-IP) by Yeast Two Hybrid Screen of U2 Osteosarcoma cDNA Library: Evidence that IGFBP5-IP Is an Important Regulator of Osteoblast Proliferation and Differentiation. Y. Amaar, D. J. Baylink, B. Tapia*, S. Mohan. JLP VAMC / Loma Linda Univ Dept Med, Loma Linda, CA, USA.

IGFBP-5 (BP-5) is an important bone formation regulator and a multifunctional protein that acts not only as a traditional binding protein but also as a growth factor independent of IGFs. To identify the potential molecular signals that mediate BP-5 effects, we sought to identify proteins that bind BP-5 using BP-5 as bait in a yeast two hybrid screen of U2 human osteosarcoma cell cDNA library. We identified a 0.875 kb partial cDNA clone (clone A) displaying a strong interaction with the bait under high stringency conditions. The Clone A sequence did not match with any known genes in the Genebank, but did show partial sequence identity with a mouse Riken cDNA clone (Accession # BC057304.1) which encodes an ORF of 7 exons. The first segment of the clone A sequence is identical to part of exon 4 and the entire exon 5 sequence of Riken cDNA encoding an ORF of 143 amino acids. The second segment of clone A sequence falls within intron #5 of Riken cDNA clone genomic sequence on mouse chromosome10, suggesting that clone A and Riken cDNA most likely represent alternatively spliced forms of the same gene. Because clone A encodes a previously unidentified novel protein, we termed this protein BP5-IP. If BP5-IP is an important intracellular mediator of BP-5 actions, we expected BP5-IP to be expressed in a variety of osteoblast (OB) cell types that produce BP-5. Accordingly, we found that a number of OB cell types, including normal human OBs, osteosarcoma (U2 and MG63) and MC3T3-E1 mouse OBs, express BP5-IP transcript by Northern blot and RT-PCR analyses. We next determined the role of endogenously produced BP-5-IP on proliferation and differentiation of OBs using small siRNA technology. Treatment of MG63, SaOS-2 and MC3T3-E1 cells with siRNA duplex sequence specific to BP5-IP reduced expression of BP5-IP by >70% and decreased cell number by 20-35% (P<0.01) compared to plasmid control. Furthermore, treatment of high ALP expressing SaOS-2 cells (HSaOS) with siRNA duplex specific to BP5-IP caused a significant reduction in ALP activity compared to plasmid control (65% of control, P<0.01). Conclusions: 1) We identified a novel protein that interacts with BP-5 (BP5-IP) in our yeast two hybrid screen of U2 cell cDNA library; 2) BP5-IP and Riken cDNA clone, BC057304, represent alternatively spliced products of a novel gene located in chromosome 10; 3) BP5-IP is expressed in many cell types that produce BP-5; 4) The findings that inhibition of expression of BP5-IP decreased cell proliferation and ALP activity are consistent with an important role for this novel protein in regulating OB cell functions.

Local IGF-II Expression in Human Bone Is Greater in Women Treated with Teriparatide than with Placebo: A Quantitative Immunohistochemical Study of Bone Biopsies from the Fracture Prevention Trial. E. F. Eriksen, Q. Q. Zeng*, D. W. Donley*, Y. L. Ma*. Eli Lilly and Company, Indianapolis, IN, USA.

Insulin-like growth factors play important roles in the regulation of skeletal remodeling and have been implicated in the anabolic action of teriparatide [rhPTH(1-34)] on bone. PTH induces IGF-1 synthesis in rat calvariae, but the effects on IGF-I or II in humans have not been elucidated. We studied 39 biopsy samples obtained from the Fracture Prevention Trial to quantitatively assess the expression of IGF-I and II in situ (median treatment 18 months, range 12-24 months; 13 posttreatment samples from each group: placebo, teriparatide (TPTD) 20 µg/d & 40 µg/d). Biopsies were embedded at -20ºC in methacrylate to maintain immunoreactivity (Erben 1997). Seven µm sections were stained with specific antibodies against IGF-I and II after pretreatment with 0.1% acetic acid. Immunoreactivity for IGF-I was sparse, while expression of IGF-II on cement lines and bone surfaces was intense, in accordance with previous studies demonstrating higher levels of IGF- II vs. IGF- I in human bone matrix (Mohan and Baylink 1991). The total length of IGF-II positive stained cement lines was measured at the cancellous and cortical envelopes, then normalized to bone area and surface perimeter. There was a dose-dependent relationship in IGF-II immunoreactive expression at all bone envelopes studied. The IGF-II positive cement line length per unit bone surface or area was more than 2 fold greater in the 20 µg group compared with placebo (Table). In conclusion, this study suggests that in situ expression of IGF-II in human cancellous and cortical bone was greater with teriparatide treatment than with placebo. This apparent greater local IGF-II production with teriparatide compared with placebo may play a key role in the positive bone balance and improved cancellous and cortical bone architecture previously demonstrated in these biopsies (Ma et al. 2003).

Quantitative Local IGF-II Expression

IGF-II Expression per unit:	Placebo	TPTD20	TPTD40

High IGFBP-2 Levels Predict Increased Bone Turnover in Aging Men and Women. S. Amin, L. J. Melton, S. Achenbach*, A. L. Oberg*, B. L. Riggs, S. Khosla. Mayo Clinic, Rochester, MN, USA.

Among the insulin-like growth factors (IGF-I, IGF-II) and their binding proteins (IGFBP-1, -2, and -3), we previously found that IGFBP-2, which increases with age, was the strongest predictor of bone density in men and women, with higher age-adjusted levels associated with lower bone density. How IGFBP-2, or other IGF/IGFBPs, affect bone metabolism in aging men and women is unclear.

In an age-stratified, random sample of the adult community population, we assessed serum levels of IGF-I, IGF-II, IGFBP-1, -2 and -3 as well as markers of bone formation (serum osteocalcin (OC)) and resorption (urine & serum NTX). We had measures of serum CTX for women only. We measured body mass index (BMI); serum bioavailable estradiol ($BioE_2$) and testosterone (BioT); and sex hormone binding globulin (SHBG). Associations between IGF/IGFBPs and bone turnover markers were assessed using Pearson correlations, before and after adjustment for covariates. Analyses were stratified by gender and by menopausal status. We studied 344 men (age 23-90) and 276 women, not on any hormones, (age 21-93; 166 postmenopausal). OC, urine & serum NTX in men and women, and serum CTX in women, tended to be greater with age. Adjusted for age, IGF-I was associated with greater OC, as well as urine & serum NTX, in men only (r=0.12, 0.12. 0.14; p<0.05). Higher age-adjusted IGFBP-1 was associated with greater OC in premenopausal women only (r=0.21; p<0.05). No other associations were seen between IGF-I, IGF-II, IGFBP-1 or IGFBP-3 with turnover markers in men or women. In contrast, higher IGFBP-2 was associated with greater OC, urine & serum NTX in men (r=0.30, 0.29, 0.29, respectively; p < 0.001), premenopausal (r=0.20, 0.21, 0.16; p <0.05, but NS for serum NTX) and postmenopausal (r=0.28, 0.37, 0.25; p<0.01) women. Similar results were seen with serum CTX in premenopausal (r=0.29; p<0.01) and postmenopausal (r=0.28; p < 0.001) women. After adjusting for age, BMI, $BioE_2$, BioT and SHBG in multivariate models, IGFBP-2 remained associated with OC, urine & serum NTX in men (r=0.20, 0.25, 0.23, respectively; p<0.001) and postmenopausal women (r=0.23, 0.33, 0.14; p<0.01, except serum NTX (p=0.08)). In similar models, IGFBP-2 was associated with serum CTX in pre- (r=0.29; p<0.01) and post- (r=0.20; p<0.05) menopausal women.

Among the IGF/IGFBPs studied, IGFBP-2 was the strongest predictor of bone turnover. Higher IGFBP-2, which is associated with lower bone density, appears to increase bone resorption in aging men and women independent of sex steroids and body mass. The increased bone formation observed likely occurs from coupling of bone turnover, but does not seem to be adequate to maintain bone density. Results suggest a direct negative influence of IGFBP-2 on bone metabolism.

Localization of Insulin-Like Growth Factor I Gene-Expression in Rat Tibiae. C. M. A. Reijnders*[1], N. Bravenboer[1], M. A. Blankenstein*[2], P. Lips[1]. [1]Endocrinology, VU Medical Center, Amsterdam, Netherlands, [2]Clinical Chemistry, VU Medical Center, Amsterdam, Netherlands.

Growth factors, especially insulin-like growth factor I (IGF-I), have a key role in maintaining skeletal integrity. IGF-I can regulate specific bone cell function. In this study we developed a non-radioactive in situ hybridization (ISH) method in order to localize the mRNA expression pattern of IGF-I in rat bone.

Tibiae of 12-week-old female Wistar rats were dissected, fixed, decalcified and embedded in paraffin. Rat brain tissue was used as positive control. Sections of 5 µm were mounted on aminoalkylsilane-coated glass-slides and hybridized with the IGF-I or the ribosomal RNA probe. As control for degradation of RNA by RNAses the ribosomal RNA probe was used. Hybridization with sense probes was used to investigate the level of non-specific binding.

In the tibiae IGF-I mRNA is expressed in osteoblasts, which are situated against the surface of trabecular and cortical bone, in some osteocytes in the first lamella of the endosteal shaft and in the periosteum. Within the shaft the endosteal osteocytes, which are located within the other lamellae, and the periosteal osteocytes did not express IGF-I mRNA. In the growth plate IGF-I mRNA is located in chondrocytes of the hypertrophic and proliferative zone. The bone marrow cells i.e. megakaryocytes, macrophages and myeloid cells also expressed IGF-I mRNA. The brain showed IGF-I mRNA expression in Purkinje cells of the cerebellum and in neurons of the medulla oblongata. The ribosomal RNA probe exhibited cytoplasmatic expression in every cell type of the tibiae and the brain.

In conclusion, this non-radioactive ISH is a powerful and sensitive method to localize gene-expression within decalcified rat tibiae. During the whole decalcification procedure the RNA is not broken down by RNAses, because all the bone cells, including the osteocytes in the shaft, show ribosomal RNA expression. The osteoblasts and the osteocytes, within the first lamella of the endosteal side of the shaft, synthesize IGF-I mRNA. These bone cells might play a role during bone remodelling. This ISH technique is a useful method to detect acute changes of growth factor mRNA expression levels in bone after stimulation by mechanical stress.

Ghrelin Levels in Osteoporotic Patients. Z. Valkusz*[1], J. Gardi*[1], T. Nyári*[2], J. Julesz*[1]. [1]Dept. of Endocrinology, University of Szeged, Szeged, Hungary, [2]Dept. of Medical Informatics, University of Szeged, Szeged, Hungary.

Ghrelin an endogenous ligand for the growth hormone secretagogue (GHS) receptor, has been reported to stimulate GH secretion and food intake in both humans and animals. Studies have been shown that GH or GHS treatments increase bone mass in rodents and in adult GH-deficient humans, suggesting a stimulatory effect of GH and GHS on bone mass in humans. Objective: To investigate whether a relationship exist between serum ghrelin levels and bone mineral density (BMD) in postmenopausal women and in men with osteoporosis. Methods: 18 women and 6 men with osteoporosis and 22 healthy individuals (17 women and 5 men) were included in the study. Serum ghrelin concentrations were determined by radioimmunoassay (Phoenix Pharmaceuticals, Belmont, CA, USA) Spine and femur BMDs were measured by dual energy X-ray absorptiometry Serum ghrelin concentration in the osteoporotic group was not significantly different from that of the control group (292 ± 36.6 pg/ml and 308 ± 30.2 pg/ml, respectively). Summarized data of all the investigated subjects (osteoporotic plus control groups, serum ghrelin levels correlated with body mass index (BMI) but not with spinal or femoral BMD. However relations were observed between BMI and spinal or femoral BMD. Conclusion: Our results indicate that ghrelin content of the blood serum does not have a direct influence on bone mass in osteoporotic patients.

Genetic Regulation of IGFBP-2 Is Independent of GH and Is Gender Specific. L. R. Donahue, W. G. Beamer, J. Hurd*, V. Guido, C. J. Rosen. The Jackson Laboratory, Bar Harbor, ME, USA.

The importance of the insulin like growth factor (IGF) system in skeletal growth and development is well known, and the genetic determinants of IGF-I and its binding proteins is an active area of study in our lab. We have discovered 3 strong quantitative trait loci (QTL) for serum IGF-I in F2 mice from a cross between 2 inbred strains with normal growth hormone (GH) levels (Rosen, et al 2000). To alleviate the GH influence on genetic regulation of the IGF system, we are using a spontaneous mutation in the mouse growth hormone releasing hormone receptor *Ghrhr^{lit}* that results in smaller mice with disproportionate low bone density and low serum IGF-I, compared to littermates, due to the lack of circulating GH. By transferring the *Ghrhr^{lit}* mutation from its original C57BL/6J (B6) background to the higher density, higher IGF-I, C3H/HeJ (C3H) background, we have produced C3.B6-*lit/lit* mice with higher BMD and increased IGF-I in the presence of GHD. The two GH deficient strains have now been intercrossed and a population of F2 mice, all GH deficient, but with the high and low alleles for BMD and IGF segregating, is being produced. The intention is to find QTLs in these F2 mice that determine a variety of skeletal and IGF phenotypes that are independent of GH influence. IGFBP-2 is of particular interest because serum levels are not affected by the genotype of mice; that is serum IGFBP-2 in *lit/lit* vs *lit/+* mice do not differ on either the C3H or B6 background. However, strain differences within genotype are seen, but only in females. Thus, C57BL/6J-*lit/+* females have lower IGFBP-2 than C3.B6-*lit/+* females, as do C57BL/6J-*lit/lit* females compared to C3.B6-*lit/lit* females. No strain or genotype differences are seen in males. Using this genetic model we will discover chromosomal loci that represent important regulatory genes for IGFBP-2. These loci will give new insight into the pathway through with IGFBP-2 has its biological effect. Data for serum IGFPB-2 in 8 week old male and female mice are shown in the table below (mean ± SEM, n=7-10; p<0.002; * within *lit/+;* @within *lit/lit*).

Serum IGFBP-2 in 8 week old male and female mice

	MALE	FEMALE
C57BL/6J-*lit/+*	854.5 ± 126.0	696.0 ± 33.6*
C57BL/6J-*lit/lit*	769.0 ± 91.1	690.4 ± 50.4@
C3.B6-*lit/+*	898.6 ± 114.2	983.0 ± 52.5*
C3.B6-*lit/lit*	797.4 ± 57.8	956.2 ± 51.9@

Long Term Caloric Restriction Does Not Deleteriously Impact Bone Characteristics or Body Composition in Wildtype and Long-Lived Growth Hormone Receptor/Binding Protein Null Mice. M. S. Bonkowski*[1], R. Pamenter*[2], J. S. Rocha*[2], K. Al-Regaiey*[2], M. M. Masternak*[2], J. A. Panici*[2], A. Bartke*[2]. [1]Pharmacology and Internal Medicine, Southern Illinois University - School of Medicine, Springfield, IL, USA, [2]Internal Medicine, Southern Illinois University - School of Medicine, Springfield, IL, USA.

Caloric restriction (CR) increases lifespan in many species ranging from yeast to dogs. While CR is beneficial in delaying the onset of disease and prolonging life, it is not well known if CR regimens that prolong life detrimentally affect bone health. Growth hormone receptor/binding protein knock out (GHR-KO) mice are long-lived (~50%) compared wildtype (WT) littermates and are GH resistant. GHR-KO mice are smaller, with decreases in bone mineral density (BMD) compared to WT. This research explores the effects of feeding a long term mild CR regimen on body composition and bone characteristics in GHR-KO mice and WT littermates. Starting at 8 weeks of age, WT and GHR-KO mice were placed on either Ad Libitum (AL) feeding or CR (70% of AL). This regiman is previously reported to extend lifespan in rodents. At 30±2 months of age, the mice were mildly anesthetized and body composition and bone characteristics were measured using dual-energy x-ray absorptiometry (DEXA) with a PIXIMUS instrument (LUNAR). Using three-way ANOVA to reveal effects of phenotype, sex, and treatment, CR caused an expected reduction in BW ($P<0.004$) compared to AL. In addition, GHR-KO mice weighed less ($P<0.0001$) than their WT siblings, with females weighing less than males across treatments and phenotypes ($P<0.0001$). CR did not effect % fat or the inversely correlated % lean ($P<0.8415$). In addition, whole animal bone mineral density (BMD), bone area, or bone mineral content did not differ between AL and CR regimen ($P<0.9295$, $P<0.166$, and $P<0.5478$, respectively). Analysis of femur revealed there were no significant effects of CR treatment on femur length ($P<0.9536$) and femur BMD ($P<0.9280$), but femur length and femur BMD were significantly less in GHR-KO mice compared to WT ($P<0.0001$). Surprisingly, lower lumbar (LL) measurements showed that CR treatment increased LL BMD benificially, but results showed an interaction between treatment and phenotype ($P<0.013$). Fisher's post hoc analysis revealed GHR-KO phenotype and CR treatment positively increased femur BMD ($P<0.0001$ and $P<0.011$, respectively), with the exception of GHR-KO female mice which showed overlapping LL BMD results (AL 0.052±0.002, CR 0.049±0.001). These findings suggest that in addition to delaying the onset of disease and prolonging longevity, the employed relatively mild (30%) CR regimen has no deleterious effects on bone health and may even provide a bone health benefit.

Targeted Disruption of IGF-I Gene in Mature Osteoblasts Using Human Osteocalcin Promoter Driven Cre in Mice. S. K. Lee[1], K. Govoni[1], Y. Chung*[1], C. Kesavan*[1], D. J. Baylink[1], D. LeRoith[2], T. Clemens[3], S. Mohan[1]. [1]JLP VAMC / LLU, Loma Linda, CA, USA, [2]NIH, Bethesda, MD, USA, [3]Univ of Alabama, Birmingham, AL, USA.

It is now well established that IGF-I is an important regulator of peak BMD. Accordingly, femur BMD is decreased by 65% in mice lacking functional IGF-I. The anabolic effects of IGF-I on bone are known to be mediated via liver-derived IGF-I which acts as an endocrine hormone and bone-derived IGF-I which acts as an autocrine/paracrine growth factor. Based on the findings that little or no deficit in BMD occurs in mice with disruption of liver-derived IGF-I gene, we predicted that locally produced IGF-I exerts a significantly greater role than circulating IGF-I in regulating BMD. To evaluate the role of mature osteoblast (OB)-derived IGF-I in regulating bone accretion, we used Cre/loxP recombination technology to conditionally disrupt IGF-I gene in mature osteoblasts (OBs). Human osteocalcin (hOC) promoter driven transgenic Cre mice were bred with loxP IGF-I mice to generate mice homozygous for loxP and cre positive (knockout, KO) and cre negative loxP mice (control) for the experiments. Cre expression was verified in the bones of Cre positive mice by real time PCR. Surprisingly, neither total body BMC nor total body BMD measured by DEXA was significantly different in the KO mice compared to control mice at 8 or 16 weeks of age. Furthermore, there were also no significant differences in the total vBMD (717 vs 711 mg/cm^3) or periosteal circumference (4.35 vs 4.45 mm) in the femur of KO mice compared to control mice. One possibility for the lack of phenotypic change in KO mice is that IGF-I is produced by different bone cell types (e.g. stromal cells, pre OBs etc.) and that disruption of IGF-I in mature OBs is not sufficient to reduce IGF-I levels below a thresh hold level that is required to produce an effect on BMD. We, therefore, compared the expression of IGF-I, Cre, osteocalcin and PPIA (control gene) at different time points (days 0, 6, 12, 18 and 24) in bone marrow stromal cells that were induced to differentiate into mature OBs in vitro. We found IGF-I was expressed at high levels throughout OB cell lineage but at much higher levels in pre-OBs (produce no or very low osteocalcin) compared to mature OBs. Accordingly, IGF-I expression was not significantly reduced in the bones of KO mice compared to control mice (30.8±0.9 vs 30.6±0.5, Ct values, Mean±SD). Conclusions: 1) Transgenic disruption of IGF-I gene in mature OBs using hOC promoter driven Cre did not reduce either bone IGF-I expression nor peak BMD. 2) Although hOC driven Cre has been used successfully to disrupt a number of trasngenes, in the case of IGF-I, it appears to be not effective since multiple bone cell types besides mature OBs produce IGF-I.

Determining the Time-Point when TGF-β acts to Promote Lineage Diversion Towards the Osteoclastic Phenotype. S. W. Fox*, A. C. Lovibond*. Cellular and Molecular Medicine, St George's Hospital Medical School, London, United Kingdom.

Transforming growth factor-β (TGF-β) is a multifunctional cytokine that is an essential co-factor for osteoclastogenesis. Exposure to TGF-β within the first few days of culture significantly increases the proportion of uncommitted precursors that form osteoclasts in the presence of receptor activator of nuclear factor-κB ligand (RANKL). However, its actions appear to be bi-phasic since TGF-β may have suppressive effects later on in the culture period. Therefore, the effect of TGF-β is clearly dependent on the time and length of administration.

We have previously shown that TGF-β is able to suppress interferon-γ (IFN-γ) mediated inhibition of osteoclast formation *in vitro*. This finding supports the hypothesis that TGF-β may promote lineage diversion to the osteoclastic phenotype through suppression of pro-inflammatory stimuli. Therefore, to determine the critical time-point at which TGF-β primes non-committed precursors towards the osteoclastic fate, we examined the duration of exposure to TGF-β that was required to overcome the inhibitory effect of IFN-γ.

Murine non-adherent M-CSF dependent precursors were pre-treated with TGF-β for various time-periods (1, 6, 24, 48, 72 hours). After washing thoroughly, cells were incubated with M-CSF and RANKL with or without IFN-γ for 5 days. Alternatively, precursors were cultured with combinations of M-CSF, RANKL, IFN-γ, concurrently with TGF-β for up to 5 days. Osteoclast formation was assessed by staining for tartrate-resistant acid phosphatase (TRAP).

As previously demonstrated, IFN-γ significantly inhibited osteoclast formation compared to RANKL-treated controls. Pre-treatment with TGF-β for 24 hours was able to prevent the suppressive effects of IFN-γ, suggesting that TGF-β acts within this time period to irreversibly commit precursors to the osteoclastic lineage. Longer incubation with TGF-β for 48 and 72 hours did not further enhance osteoclast formation from precursors. In addition to these findings, we found that co-incubation with TGF-β was not able to overcome the inhibitory effect of IFN-γ. This is to be expected since the physiological effects of IFN-γ during an inflammatory response are more pertinent to an organism's survival, than the effect of TGF-β on osteoclasts.

Therefore, our data clearly shows that signalling mechanisms by which TGF-β acts to promote lineage diversion are fully activated within 24 hours. This finding can be used to determine the order and nature of genes up-regulated by TGF-β at this time-point and therefore clarify the mechanism by which TGF-β enables RANKL-induced osteoclast formation.

TGF-β Regulation of Intrinsic Mechanical Properties of Bone. G. Balooch*[1], M. Balooch*[1], G. W. Marshall*[1], S. J. Marshall*[1], R. Derynck*[2], T. N. Alliston[2]. [1]Preventative and Restorative Dental Sciences, University of California San Francisco, San Francisco, CA, USA, [2]Growth and Development, University of California San Francisco, San Francisco, CA, USA.

TGF-β has a vital and complex role in bone. TGF-β binds its cell-surface receptor to activate Smad3, a transcription factor that regulates the expression of defined genes. While TGF-β regulates osteoblast differentiation and gene expression, the effect of TGF-β on bone matrix quality is less clear. To study the effect of TGF-β on bone matrix quality, this study evaluated the intrinsic mechanical properties of bone from mice with altered TGF-β signaling. Intrinsic mechanical properties, including hardness and elastic modulus, are measured using atomic force microscopy with nanoindentation and are independent of bone size or geometry. Previously developed transgenic mouse models show altered TGF-β signaling, ranging from 16-fold (D4 mice) and 2.5-fold (D5 mice) overexpression of TGF-β in bone, to decreased TGF-β signaling due to expression of a dominant negative TGF-β receptor in bone (E1 mice) or deletion of the Smad3 gene (Smad3 +/- or -/- mice). Age- and sex-matched tibias of each mouse model were evaluated. Mice with increased TGF-β signaling (D4, D5) had up to 23% reduced elastic modulus and hardness relative to wild-type littermates ($p<0.05$). However, mice in which TGF-β signaling was impaired (E1, Smad3 +/-, Smad3 -/-) had up to 54% increased elastic modulus and hardness ($p<0.05$). Though both have decreased TGF-β signaling, E1 mice are osteopetrotic whereas Smad3 -/- mice are osteopenic. The similarity in E1 and Smad3 -/- intrinsic mechanical properties suggests that bone matrix quality is independent of other osteoblast-intrinsic effects of TGF-β. Though no phenotype had previously been described for Smad3 +/- mice, these bones also had increased intrinsic mechanical properties. Therefore, partial reduction of TGF-β signaling in bone, either by expression of a dominant negative TGF-β receptor or by heterozygous loss of Smad3, is sufficient to produce bone with increased intrinsic mechanical properties. We are further investigating the Smad3 +/- mouse bone phenotype. We are also employing 3-point bending to determine the relative contribution of bone morphometry and intrinsic mechanical properties to bone resistance to fracture. The current study shows that intrinsic mechanical property testing is a useful tool for the analysis of bone phenotype. We provide the first evidence that growth factor signaling defines bone intrinsic mechanical properties. Finally, the effect of TGF-β on bone matrix quality appears to be independent of other TGF-β effects on osteoblast differentiation and function.

Glitazones, the Anti-Diabetic PPAR-γ Agonists, Suppress Osteoblast Differentiation and the Activity of TGF-β/BMP Signaling Pathways. B. Lecka-Czernik, K. Teng*, O. P. Lazarenko*. Geriatrics, UAMS, Little Rock, AR, USA.

Glitazones, a new class of oral anti-diabetic agents, sensitize cells to insulin through a specific activation of PPAR-γ nuclear receptor. PPAR-γ2 isoform is expressed in marrow mesenchymal stem cells and controls development of both, osteoblasts and adipocytes. As previously demonstrated *in vitro* and *in vivo,* PPAR-γ2 inhibits osteoblast and promotes adipocyte differentiation. In this study, the effects of three different glitazones (rosiglitazone, pioglitazone, and troglitazone) on osteoblast and adipocyte differentiation, phenotype-specific gene expression, and TGF-β/BMP signaling pathways were evaluated. Glitazones activities were tested in U-33/γ2 cells, an *in vitro* model of PPAR-γ2-controled differentiation of marrow mesenchymal cells, and the results were validated in murine primary bone marrow cultures. All tested glitazones simultaneously inhibited osteoblast differentiation and stimulated adipocyte development in a rank order corresponding their binding affinity for PPAR-γ (rosiglitazone>pioglitazone> troglitazone). Glitazones suppressed the expression of osteoblast-specific transcription factors, Dlx5 and Runx2, and phenotype-specific gene markers, osteocalcin and collagen I. Since TGF-β and BMP2/4 cytokines are essential for osteoblast differentiation and bone formation, we assessed the effects of tested glitazones on the expression of components of these signaling pathways using real-time RT-PCR. Glitazones decreased the expression of TGF-β1 and TGF-β3, TβR-II, Smad3, Smad4 and Smad7, as well as BMP4, Smad1 and Smad6. They did not affect the expression of Smad2 and Smad5, TGF-β1 and BMP2 cytokines, and their receptors, TβR-I, BMP-RII, BMPR-IA and BMPR-IB. Decreased expression of components of the TGF-β/BMP pathways resulted in a decreased cell responsiveness to these cytokines as measured by the effects on the expression of genes that are under their control. For example, in a presence of rosiglitazone the BMP4 cytokine effectiveness to stimulate Dlx5 gene expression was reduced by 85%, whereas stimulatory effect of TGF-β on Smad7 and PAI-1 gene expression was reduced by 50%. In conclusion, glitazones affect an activity of TGF-β/BMP signaling pathways which may account for their inhibitory effect on osteoblast differentiation and bone formation.

Increased Prevalence of Osteocyte Apoptosis Precedes Osteoclastic Bone Resorption and the Loss of Bone Mineral and Strength Induced by Lack of Mechanical Forces in a Murine Model of Unloading. J. I. Aguirre, L. I. Plotkin, S. B. Berryhill*, R. S. Shelton*, S. A. Steward*, K. Vyas*, R. S. Weinstein, A. M. Parfitt, S. C. Manolagas, T. Bellido. Endocrinology, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Bone responds to mechanical strains through osteocytes, which detect the need for adaptation and transmit signals to the executive cells of remodeling, the osteoblasts and osteoclasts. Whereas physiological strains sustain bone formation, mechanical unloading causes bone loss. Based on earlier evidence that mechanical stimulation prevents apoptosis of osteocytic cells *in vitro*, we investigated here whether, conversely, reduced mechanical forces increase the prevalence of osteocyte apoptosis *in vivo* and whether this event is linked to bone loss. Adult (5 month-old) Swiss Webster female mice were tail suspended for 1, 3, 7 or 18 days (n=10/group). Global and spinal bone mineral density (BMD) measured by DEXA, and vertebral (L5) compression strength were significantly reduced after 18 days but not at earlier time points compared to fully ambulatory control mice. No differences in BMD or strength, as determined by 3-point-bending, were found in the hind limbs at any time, indicating that the axial skeleton is more sensitive to reduced load than the appendicular skeleton in this mouse strain. Increased prevalence of apoptotic cancellous and cortical osteocytes was found at day 3 and was sustained to day 18, as detected by *in situ* nick-end labeling of undecalcified bone sections. Histomorphometric analysis of vertebral bone indicated that the early increase in osteocyte apoptosis was followed by an increase in the cancellous osteoclast perimeter and number at day 18; and by decreased cortical width at days 7 and 18 with increased cortical porosity at day 18. The vertebral width did not change during the course of the experiment but the width of the bone marrow cavity increased significantly at days 7 and 18, indicating that the decreased cortical width was due to endosteal, rather than periosteal, bone resorption. Indeed, whereas apoptotic osteocytes were randomly distributed in controls, they were preferentially located in the endosteal cortical bone of unloaded animals at day 3 before cortical width was decreased. These findings indicate that reduced mechanical loading leads to osteocyte apoptosis that precedes the removal of bone in the same location by osteoclasts, followed by loss of bone mineral and strength. Furthermore, these results confirm that physiologic levels of strain provide survival signals for osteocytes which maintain the mechanosensory function of the osteocyte network.

Effects of Oscillatory Fluid Flow on RANKL and OPG Expression. C. H. Kim*, C. R. Jacobs. Mechanical Engineering, Stanford University, Stanford, CA, USA.

Physical activity creates bending in the bone which leads to localized pressure gradients that drive interstitial fluid flow, which is oscillatory by nature, within the bone tissue. Oscillatory fluid flow (OFF) may lead to positive bone remodeling through effects on both the osteoblasts and osteoclasts but its effect on the osteoclastogenesis is especially poorly understood. In this study, the effects of OFF on expression of receptor activator of nuclear κB ligand (RANKL) and osteoprotegerin (OPG), two important regulators of osteoclast differentiation, were investigated.

ST-2 murine bone marrow stromal cells (Riken, Japan) were plated on glass slides and cultured with 10 nM 1,25 dihydroxyvitamin D_3 (Sigma, MO) to express RANKL. Two days after plating, cells were exposed to either 1 hour of no flow or OFF resulting in a shear stress of 10 dynes/cm^2. Total RNA was isolated immediately (0 hour) after, 1.5 hours after, or 24 hours after end of treatment. Real-time PCR was used to quantify levels of RANKL, OPG, and 18S mRNA (Applied Biosystems, CA).

Immediately after end of 1 hour OFF, RANKL/OPG ratio was significantly decreased by 60% (p=0.013) compared to no flow controls (Fig. 1). The decline in RANKL/OPG ratio due to OFF weakened after 1.5 hours and even further after 24 hours where the ratio was no longer significantly different (p>0.05).

These results confirm that OFF is a potent regulator of bone remodeling and suggest its effect on RANKL/OPG is maximal immediately after flow. Since RANKL is necessary in osteoclast differentiation, these results also suggest that an OFF induced positive bone remodeling can be achieved via suppression of the formation of osteoclasts.

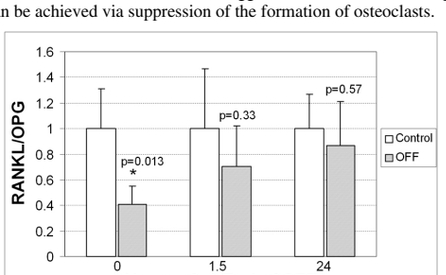

Figure 1. Temporal change in RANKL/OPG ratio after OFF. RANKL/OPG value is normalized to corresponding control values. N=4 for each group.

Five Minutes of Fluid Shear Stress Is Sufficient to Induce Cyclooxygenase-2 in MC3T3-E1 Cells. S. Masatomo, M. Mehrotra, L. G. Raisz, C. Pilbeam. Department of Medicine, University of Connecticut Health Center, Farmington, CT, USA.

Mechanical loading of bone is transmitted to osteocytes and osteoblasts via the flow of interstitial fluid. Cyclooxygenase-2 (COX-2), an enzyme shown to mediate some of the anabolic effects of mechanical loading on bone, has been shown to be transcriptionally induced via a mitogen activated protein (MAP) kinase ERK signaling pathway in MC3T3-E1 and primary murine calvarial osteoblasts by continuous fluid shear stress (FSS), with peak effects at 4-8 h of flow. However, it seems unlikely that cells *in vivo* will see the physiologic equivalent of 4 h of continuous fluid flow. Hence, we examined the response of osteoblasts to short exposure of FSS. MC3T3-E1 cells were subjected to 5-30 min of laminar fluid flow, equivalent to a FSS of 10 dynes/cm^2, in serum free medium (0.1% BSA) and then returned to static culture (post-FSS) in the same medium. All experiments were performed in the presence of NS-398 (0.1 μM) to avoid the auto-amplification of COX-2 by endogenously produced prostaglandins. The induction of COX-2 mRNA following 5, 10 or 30 min of FSS peaked at 30-60 min in post-FSS culture and mRNA levels declined thereafter but remained elevated 4-8 h post-FSS. The induction of COX-2 mRNA by 5 min of FSS followed by 30 min of static culture was greater than or equal to the induction of COX-2 mRNA by 4 h of continuous FSS. Luciferase activity was measured in MC3T3-E1 cells stably transfected with 371 bp of the murine COX-2 promoter fused to a luciferase reporter. Although COX-2 mRNA expression peaked at 30 min post 5 min of FSS, luciferase activity in post-FSS cultures peaked at 2.5 h post-FSS, suggesting that the early COX-2 induction occurs in part by a non-transcriptional mechanism. Bioarray analysis (GenUs Biosystems, Chicago, IL) performed on 2 independent experiments (5 min FSS, 30 min post culture) showed 14 genes that were increased > 2-fold consistently in both experiments. In addition to COX-2, these included IL-6, zinc finger protein 36, a member of nuclear receptor subfamily 4, histone 1, and c-Jun. In other experiments, we have also shown that 5 min of FSS induces MMP-13 and RANKL expression at 4-6 h of post culture. Hence, 5 min of FSS is sufficient to initiate a signaling cascade in osteoblasts that leads to new expression of genes important in the regulation of bone turnover.

Fluid Shear Stress Induces MMP-13 in Murine Osteoblastic Cells. S. Masatomo[1], M. Mehrotra[1], K. Nakamura*[2], H. Kawaguchi[2], C. Pilbeam[1]. [1]Department of Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]Orthopaedic Surgery, University of Tokyo, Tokyo, Japan.

Murine matrix metalloproteinase-13 (MMP-13) degrades interstitial collagen and plays an important role in physiologic and pathologic bone remodeling. A recent study reported that biaxial strain applied to MC3T3-E1 cells increased MMP-13 expression as an early response gene via the MEK-ERK signaling pathway (C-M Yang et al, J Biol Chem, in press 2004). Since mechanical loading may be mediated via shear stresses at cell surfaces generated by the fluid flow, we investigated the regulation of MMP-13 by fluid shear stress (FSS). We used a laminar flow apparatus to apply FSS of 10 dynes/cm^2 to MC3T3-E1 cells or to primary osteoblasts derived from neonatal mouse calvariae. By Northern blot analysis, MMP-13 mRNA levels were low or undetectable in control (no flow) cultures but were strongly induced by various flow regimens, including 4 h of continuous flow or 10 min of flow followed by 4 h in static culture. We subjected MC3T3-E1 cells to FSS for 30 min or primary calvarial osteoblasts to FSS for 60 min, replaced the cells in static culture (post-FSS) for 0-24 h, and measured the expression of MMP-13 mRNA by Northern analysis. In both types of cells, MMP-13 mRNA was increased at 2 h post-FSS; levels peaked at 8-16 h post-FSS and remained elevated at 24 h. In MC3T3-E1 cells subjected to 30 min of FSS and then placed in static culture for 8 h, the protein synthesis inhibitor cycloheximide (CHX) blocked the FSS induction of MMP-13 mRNA, indicating that *de novo* protein synthesis was required for the induction. Since FSS induces both cyclooxygenase-2 (COX-2) and c-Fos by 30-60 min in these cells, these proteins are candidates for mediating the FSS induction of MMP-13. Treatment of cultures with an inhibitor of COX-2 activity, NS398, did not affect the FSS induction of MMP-13. However, preliminary studies indicate that the FSS stimulation of MMP-13 mRNA was reduced 40-50% in primary calvarial cells from *c-fos* knockout mice compared to cells from mice carrying at least one allele for *c-fos*. To examine the role of the MEK-ERK pathway in the FSS stimulation of MMP-13, we used a specific inhibitor of MEK-ERK activation (PD98059, 50 μM). At 6 h post-FSS, PD98059 did not decrease the induction of MMP-13. We conclude that FSS induces MMP-13 mRNA as a delayed response gene, that this induction may depend on the FSS induction of c-Fos, and that the pathway for FSS induction of MMP-13 in osteoblastic cells differs from that for the biaxial strain induction of MMP-13.

Role of TREK Stretch-Activated Potassium Channels in Mechanically-Induced PTHrP Gene Expression in Osteoblasts. X. Chen[1], K. W. Ng[2], L. F. Bonewald[3], A. E. Broadus[1]. [1]Internal Medicine, Yale University School of Medicine, New Haven, CT, USA, [2]University of Melbourne, Melbourne, Australia, [3]School of Dentistry, University of Missouri, Kansas City, MO, USA.

The PTHrP gene is normally expressed in cells of the osteoblastic lineage and is mechanically inducible in smooth muscle cells. N-terminal PTHrP species are equipotent with PTH in bone systems and PTHrP has recently been shown to have an anabolic function in bone in vivo based on conditional knockout of PTHrP in osteoblastic cells (J Bone Min Res 17, S138, 2002). We therefore decided to see whether PTHrP might be mechanically induced in osteoblast-like cells.

Reduction of osmolality from 317 to 240 mosm produced a 3-fold increase in PTHrP mRNA in UMR-201 cells, which have an early osteoblastic phenotype. Addition of either gadolinium or nifedipine had no effect, and removal of extracellular calcium or depletion of intracellular calcium with thapsigargin also had no effect. These findings indicate that neither stretch-activated cation channels, L-type calcium channels, nor intracellular calcium is involved in the induction of PTHrP in response to hypotonicity. TREK family members (two-pore domain potassium channels) are novel stretch-activated channels that can be activated by both stretch and intracellular acidosis. By RT- PCR and direct sequencing, we identified the TREK-2 gene expression in UMR-201cells. We found that intracellular acidification markedly increased PTHrP mRNA expression. Furthermore, we found that siRNA targeted against the TREK-2 gene reduced endogenous TREK-2 expression by 80% and hypotonic induction of PTHrP mRNA by 30% compared with control siRNA transfected cells.

Cell swelling may activate ion channels other than those opened by mechanical force, so we studied UMR-201 cells with Flexercell 4000 apparatus, we found cells exposed to 2% magnitude mechanical strain increased PTHrP mRNA by 2-fold at 24 hours. We also studied MLO-A5 cells, which are phenotypically similar to late osteoblasts-early osteocytes, thought by many to be key targets for mechanical force in vivo, and found a 3-fold Flexercell-induced increase in PTHrP

We propose PTHrP as a candidate mediator of the anabolic effects of mechanical force on bone and that TREK channels maybe involved in the induction of PTHrP.

Increase in Osteoblast-Like Cell Number by Cyclic Strain Is Augmented by Rest-Insertion *In Vitro*. V. J. Armstrong*, D. B. Ong*, G. Zaman*, R. F. L. Suswillo*, J. S. Price, L. E. Lanyon. Veterinary Basic Sciences, The Royal Veterinary College, London, United Kingdom.

In vivo, insertion of a rest period after each load cycle enhances a bone's osteogenic response to cyclic loading [1]. This raises the question as to whether this is an inherent property of the cells, or a feature of the mixed stimulus arising from strain, fluid flow and pressure change to which osteocytes are exposed when bone tissue is cyclically loaded. To investigate this we exposed sub-confluent cultures of ROS 17/2.8 cells to a single short period of cyclic strain by four-point bending of the plastic slides onto which they were seeded (60,000/slide). The cells were then incubated for a further 24 hours before being fixed and counted. Three different straining regimens were used, in each of which the peak strain on the surface of the plastic was 3,400μ. 40 strain cycles at 1 Hz lasting 40 seconds and 600 strain cycles at 1 Hz lasting 10 minutes stimulated a similar statistically significant increase in cell number compared with static (non-strained) controls ($p<0.01$). Insertion of a 14.9 second rest period after each of the 40 strain cycles (0.06 Hz over 10 minutes) stimulated a greater increase in cell number ($p<0.01$) than either 40 strain cycles or 600 strain cycles at 1 Hz. These *in vitro* data confirm that relatively few cycles of strain are needed to stimulate osteoblasts' increase in number. This is consistent with *in vivo* data on the osteogenic effects of loading from mice, rats and birds and from human exercise studies. These data also suggest that the increased osteogenic response to rest insertion [1] is an inherent feature of bone cells' response to cyclic mechanical stimulation (in this case strain and associated fluid perturbation), rather than any effect on fluid flow arising from cyclic strain in bone tissue.

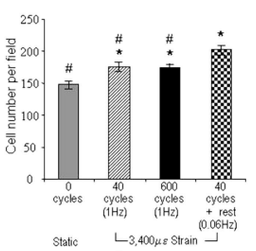

Fig 1. Effect of rest-inserted strain on osteoblast-like cell number. Values = mean +/- SEM; n=6; *P<0.01 vs Static; #P<0.01 vs 40 cycles + rest

Pressure Modulation During Loading of a Trabecular Bone Core in an Ex Vivo Model. E. L. Smith[1], A. Gerson*[1], H. Ploeg*[2], D. B. Jones[3]. [1]Population Sciences, University Of Wisconsin, Madison, WI, USA, [2]Mechanical Engineering, University Of Wisconsin, Madison, WI, USA, [3]Exp. Othopädie & Biomechanik, Phillips- Universität, Marburg, Germany.

It has been hypothesized that bone cell response to mechanical loading is not due to the bending of the bone matrix but to the shear fluid flow. The purpose of this experiment was to determine the degree of deformation on a trabecular bone core that will induce pressure shifts within the morrow cavity. It is difficult to measure shear fluid flow within trabecular bone, however it is possible to measure pressure shifts of fluid within the bone morrow during loading and use this pressure shift as an indicator of changes at the cellular level. Bovine trabecular bone cores 5 mm thick and 10 mm in diameter were prepared using an Exakt diamond band saw and diamond tipped drill. A confocal microscope showed rough surfaces from the saw varying 5 to 10 micrometers. Hemodynamic measurements of pressure shifts were determined using a 1.4 Fr high-fidelity pressure catheter from Millar Instruments in the center of the morrow cavity. The catheter has a pressure range from -50 to +300 mmHg, and a standardized sensitivity of 5 μV/V/mmHg. A hole was drilled through the bioreactor chamber and into the center of the bone cores. The Millar catheter was then placed either just outside the bone core or into the center of the bone core. After stabilization and calibration of the catheter, bone pressure tracings were recorded. Pressure changes were determined while using a 1 Hz loading jump, to induced deformations of 5, 10, 20 and 30 micrometers. Thirty measurements were made at each deformation both with the catheter just outside the bone core and with the catheter resting in the center of the morrow cavity. Pressure changes at the lower deformations were difficult to distinguish from the resting pressure values of about 0.5 mmHg. Figure 1 shows the rise in pressure in the center and outside the bone core bone from 5 to 30 micrometers of deformation (± SD). Pressure modulation was directly related to deformation, with an R^2 value of 0.95 from regression analysis of the inside pressures. Ref. Jones DB, Broeckmann E., Pohl T and Smith EL. Development of a mechanical testing and loading system for trabecular bone studies for long term culture, European Cells and Materials, 5(2003):48-60

Physical Activity Is Associated with the Size but not with the Volumetric Mineral Density of the Cortical Bone in Young Adult Men. M. Lorentzon[1], D. Mellström[2], C. Ohlsson[1]. [1]Department of Internal Medicine, Center for Bone Research at the Sahlgrenska Academy (CBS), Gothenburg University, Gothenburg, Sweden, [2]Department of Geriatric Medicine, Gothenburg University, Gothenburg, Sweden.

Physical activity has been reported to enhance bone mass accretion but little is known about its differential influence on the separate bone compartments, i.e. trabecular and cortical bone.

The *G*othenburg *O*steoporosis and *O*besity *D*eterminants (*GOOD*) study consists of 1075 Swedish men, age 18.9±0.6 yrs, and was initiated with the aim to find both environmental and genetic determinants for bone and fat mass. Questionnaires were used to collect information about current and previous physical activity (hours/week and duration in years), dairy product intake and smoking. 670 men (63%) were currently physically active and 761 (71%) had previously participated in any sports. Bone parameters were measured using both DXA and pQCT.

Both current and previous physical activity were independent predictors (multivariate analysis including age, height, weight, dairy product intake and smoking) of areal BMD of the total body, femoral neck, and lumbar spine as measured by DXA. To determine the associations between physical activity and the different bone compartments pQCT was utilized, demonstrating that current physical activity was an independent predictor of cortical bone mineral content (radius β=0.14, $p<0.001$; tibia β=0.22, $p<0.001$), cortical bone area (radius β=0.15, $p<0.001$; tibia β=0.22, $p<0.001$), and periosteal circumference (radius β=0.16, $p<0.001$ tibia β=0.17, $p<0.001$), but not of cortical volumetric BMD in the long bones. These results demonstrate that physical activity is associated with the size but not with the volumetric mineral density of the cortical bone in young adult men, suggesting that physical activity increases the amount but not the material quality of the cortical bone.

The Effect of Reloading on Osteoprogenitor Number, Osteoprogenitor Proliferation, and Bone Histomorphometry: Studies in Hind Limb Unloaded Rats. N. Basso*, C. G. Bellows*, J. N. M. Heersche. Faculty of Dentistry, University of Toronto, Toronto, ON, Canada.

Skeletal unloading associated with space flight results in bone loss. In astronauts the extent to which bone is lost varies greatly between different bones of the skeleton as well as between different individuals. Following return to earth, recovery of bone mass during reloading also varies between different bones and different individuals. Due to this variability between subjects it is difficult to study the effects of unloading/reloading on bone in humans. A viable alternative is to use the rat model of hind limb unloading developed at NASA. We have previously demonstrated that in 6 week old male rats, 14 days of unloading results in a decrease in osteoprogenitor number in cell populations isolated from the proximal femur. The goal of the current study was to determine the numbers of osteoprogenitor cells present in cell populations derived from the proximal femur of young rats after 14 days of unloading followed by 14 days of reloading and to characterize their proliferative capacity. To establish whether the effects of unloading and reloading were specific for cells of the osteoblast lineage, we determined the number of fibroblastic colony forming units (CFU-F), alkaline phosphatase positive CFU (CFU-AP), and osteoblast CFU (CFU-O). Effects of unloading and subsequent reloading on proliferation were evaluated by measuring the size of CFU-O. Neither unloading nor reloading had an effect on the total number of progenitors (CFU-F) in femoral cell populations. Unloading resulted in a 66% reduction in CFU-AP. CFU-O was decreased by 76% and mean colony size was 33% less than controls. The decrease in osteogenic and osteoprogenitor cells in vitro paralleled the decrease in bone volume, trabecular thickness, and trabecular number (which were decreased by 49%, 23%, and 35%, respectively) observed in the proximal tibial metaphysis of unloaded rats. Subsequent reloading restored CFU-AP. CFU-O numbers were only partially restored at 14 days (83% of controls) but nodule size was fully restored to control levels. Serum osteocalcin was unchanged by loading status, however, serum undercarboxylated osteocalcin, levels of which are possibly related to bone quality, was elevated 1.3-fold in unloaded rats and was still elevated following reloading. An assessment of static and dynamic histomorphometric parameters in reloaded animals is currently in progress. Our results indicate that in the 6-week old male rat 14 days of unloading results in a decrease in osteoprogenitor number and that reloading for 14 subsequent days is sufficient to restore osteogenic cell number, if not bone quality, to control levels.

Expression of Insulin-like Growth Factors and Estrogen Receptor Alpha in the Tibia of Ovariectomized Rats after a Single Loading Bout. A. M. Tromp, H. W. van Essen*, M. Koesoebjono*, N. Bravenboer, P. Lips. Department of Endocrinology, Amsterdam, Netherlands.

We examined the influence of a single loading stimulus on mRNA expression of the insulin-like growth factors (IGF-I, IGF-II) and on the expression of type-I IGF-receptor (IGFR) and estrogen receptor alpha (ERα), in the tibia of ovariectomized rats.

Forty female rats, 12 weeks old, were randomly assigned to one of 4 experimental groups (n=10), consisting of sham-loading (SHM-LD), loading (LD), loading and ovariectomy (LD+OVX) or loading and ovariectomy with estrogen replacement (LD+OVX+E2).

Two days after surgery, estrogen replacement was started in the LD+OVX+E2 group and 5 weeks after surgery, rats were subjected to a single loading bout exerted through a four-point bending device. Loading consisted of either bending (LD groups) or compressing the right tibia (SHM-LD group) with 60N, 2Hz, during 300 cycles. The left tibia served as an unloaded internal control (NON-LD). Rats were sacrificed 6 hours after loading. Left and right tibiae were dissected and the diaphyses were prepared for RNA isolation and real-time PCR quantification. Threshold cycles (Ct) of IGF-I, IGF-II, IGFR and ERα were calculated and corrected for the expression of the housekeeping gene PBGD. The Kruskal-Wallis test was used to determine differences between the four groups, analyzed for the right (LD and SHM-LD) and left (NON-LD) tibiae separately. The Wilcoxon test was used to examine differences between the right and left tibiae within the same group. P≤ 0.05 was considered significant. The University Committee on Animal Experiments approved the protocol.

In the left (non-loaded) tibiae, IGF-I mRNA expression differed significantly (p=0.007) between the groups but IGF-II, IGFR and ERa did not. In the right tibiae, both IGF-I (p=0.049) and ERα (p=0.005) mRNA expression differed significantly between the groups, whereas IGF-II and IGFR did not. IGF-I mRNA expression was significantly decreased after loading in the LD+OVX group (p=0.028). IGFR mRNA expression was significantly decreased after loading in the LD+OVX+E2 group (p=0.046). ERα mRNA expression was significantly decreased after loading in the LD group (p=0.043).

We conclude that IGF-I mRNA expression in the tibia was up regulated after ovariectomy; mechanical loading partly counteracted this process. Mechanical loading down-regulated the type-I IGF receptor in the ovariectomized rats with estrogen replacement and the estrogen receptor alpha in the LD group. Since we were not able to detect any effects of IGF-II in this study, we suggest that IGF-I is more sensitive to the effects of mechanical loading and estrogen deficiency than IGF-II in rats.

Disuse-Induced Transcriptional Changes Differ From Morphologic Changes in the Male Skeleton. M. E. Squire[1], L. R. Donahue[2], C. Rubin[1], S. Judex[1]. [1]Biomedical Engineering, SUNY Stony Brook, Stony Brook, NY, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

The loss of functional weight bearing has detrimental consequences on trabecular bone morphology and identifying the molecular basis of disuse-induced skeletal changes will be important for developing effective countermeasures on Earth and in space. Using genetically distinct strains of mice, we recently demonstrated that both male BALB/cByJ (BALB) and C3H/H3J (C3H) suffered moderate losses of trabecular bone averaged across the distal femoral metaphysis and epiphysis with skeletal unloading (-10% and -15% respectively, p<0.05 each). Here, we tested the hypothesis that transcription levels of bone formation-related and bone resorption-related genes will be similarly suppressed by unloading in both mouse strains. Adult (16 wk) *male* BALB and C3H were randomly assigned to control (n=8 BALB and n=4 C3H) and disuse (tail suspension) (n=6 each) groups. After 4d, total RNA was extracted from the whole proximal tibia (including bone marrow and cartilage) and real time RT-PCR assessed expression levels of bone formation-related genes including collagen type Iα1 (col Iα1), core binding factor α1 (CBFA1), alkaline phosphatase, osteocalcin, and osteonectin as well as resorption-related genes including cathepsin K and osteopontin (relative to GAPDH, a housekeeping gene). In disuse BALB, transcription levels of col Iα1, alkaline phosphatase, osteocalcin, and osteonectin were significantly suppressed (-60%, -36%, -65%, and -45%, respectively, p<0.05 each) relative to control. In C3H mice, the extent by which weightlessness suppressed expression levels of col Iα1, alkaline phosphatase, osteocalcin, and osteonectin was much less than in BALB (-23%, -13%, -32%, and -11%, respectively), and only the suppression of osteocalcin was statistically significant (p<0.05). The expression levels of formation-related genes affected by disuse in C3H correlated well (r^2=0.88, p<0.01) with changes in disuse BALB when considering all formation-related genes whose expression levels were suppressed by at least 10%. Transcription levels of CBFA1, cathepsin K, and osteopontin were not affected by disuse in either strain of mice. Relating the molecular level response to disuse to the induced morphologic changes in male BALB and C3H suggests that even though the molecular pathways underlying disuse-induced suppression of bone formation may be similar across different genotypes, similar changes in bone morphology may be accompanied by drastically different changes in the expression levels of some genes. The future development of effective pharmacological and/or biomechanical countermeasures of osteoporosis may need to consider genetic variations.

Gender Influences the Skeletal Sensitivity of F1 BALBxC3H Crossbreds to Mechanical Unloading. M. E. Squire[1], S. Xu*[1], R. A. Garman[1], L. Xie*[1], C. Rubin[1], L. R. Donahue[2], S. Judex[1]. [1]Biomedical Engineering, SUNY Stony Brook, Stony Brook, NY, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

Skeletal morphology as well as sensitivity of the skeleton to the loss of functional weight bearing is under the influence of the genome. Using genetically distinct inbred strains of mice, we have previously demonstrated that the skeleton of female BALB/cByJ (BALB) mice was highly sensitive to the loss of functional weight bearing (-60% loss of metaphyseal trabecular bone) while the skeleton of genetically distinct male C3H/HeJ (C3H) mice was much less responsive (-20% loss of metaphyseal trabecular bone). Here, we subjected F1 crossbreds (BALBxC3H) to hindlimb suspension and hypothesized that the degree of the skeleton's sensitivity to disuse would be intermediate to that of the parental strains. Further, we tested the hypothesis that gender would influence bone morphology and skeletal sensitivity to disuse in these F1 mice. Adult (16 wk) male and female F1 mice (n=20 each) were randomly assigned to control and disuse (tail suspension) groups (n=10 each). After 21d, right femurs were extracted and high-resolution micro-computed tomography (12μm) scanning (μCT) was used to assess indices of trabecular bone quantity and morphology in the distal femoral metaphysis and epiphysis. Comparisons of bone morphology between male and female F1 mice revealed that males had less metaphyseal BV/TV than females (-22%, p<0.01), yet epiphyseal BV/TV was not different across gender. The catabolic effects of hindlimb unloading were seen in both male and female F1 mice, yet female F1 suffered from greater loss of trabecular bone (-29%) averaged across the metaphysis and epiphysis as compared to male F1 (-8%) (p<0.01). Separated into the metaphysis and epiphysis, female F1 mice lost 36% of metaphyseal BV/TV and 15% of epiphyseal BV/TV (p<0.01 each), yet male F1 mice only lost significant amounts of BV/TV from the distal femoral metaphysis (-11%, p< 0.05). These findings demonstrate that male C3H mice/female BALB crossbred mice produce female F1 offspring whose skeletal sensitivity to unloading is intermediate to that of the parental strains. Consistent with data from the female and BALB skeletons, the female F1 mice was more responsive to disuse than the male F1 skeleton. Further, the relatively small response of the male F1 skeleton to disuse more closely corresponds to the responsivity of the skeletons of female and male C3H mice. Taken together, these results suggest that genetics modulates the influence of gender on the sensitivity of the skeleton to altered mechanical loading environments.

Quantitation of an Osteogenic Response to Isometric Mechanical Loading. J. D. Delaney*, D. W. Rowe. Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, USA.

Net bone formation is dependent on remodeling and hence the stimulation and differentiation of multipotent progenitor cells towards an osteogenic lineage. We have been evaluating a strategy to provide a controlled physiologically relevant stress without the volition of the subject sufficent to stimulate osteoblastic activity. A New Brunswick orbital shaker (Model C10) was modified to house up to 16 animals for mechanical loading. Mice transgenic for pOBCol2.3GFP, a visual marker of osteoblasts and osteocytes, were loaded 30 minutes every other day in subsequent three-week intervals of 180, 210 and 240 RPM. Xylenol orange injections were administered to the animals ten and two days prior to sacrifice. Animals were sacrificed at one-week intervals. During sacrifice animals were cardiac perfused with a normal saline solution and then cold 4% paraformaldehyde (PFA). Decalcified and non-decalcified femur and spine were embedded in OCT matrix and cryosectioned. Full-length femurs were viewed on an inverted Zeiss Axiovert 200M and imaged with a digital Axiocam CCD camera. Using Improvision thresholding software we identified and quantitated select sub-populations of high expressing GFP cells (osteoblasts) and low expressing GFP cells (osteocytes) in whole femur sections. GFP expression patterns demonstrated a statistically significant increase in both high expressing and low expressing osteoblast activity at 21, 27 and later at 57 days of loading. Non-decalcified sections revealed marked xylenol orange labeling in the whole femur as the experiment progressed. Extensive xylenol orange labeling was evidenced in the femoral head region as compared to control sections. Results from this study indicate that this mechanical loading protocol is providing an increased stress level particularly in the proximal femur and to a lesser extent along the diaphyseal shaft and metaphysis. Isometric loading protocols should focus examination of boney responses in proximal femur where peak stresses are highest and there is the greatest osteoblastic activity.

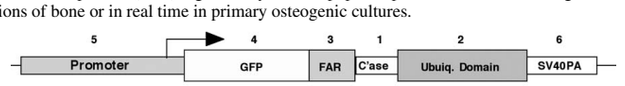
Design and Evaluation of an Apoptosis-Sensitive GFP Reporter Construct. M. B. McKinstry*, Q. F. Yang*, D. W. Rowe. Genetics and Developmental Biology, University of CT Health Center, Farmington, CT, USA.

Apoptosis plays a central role in controlling the number of osteoblasts making and maintaining bone mass. Our goal is to design a reporter system that would initiate a green fluorescent protein (GFP) signal early in the apoptotic process either in histological sections of bone or in real time in primary osteogenic cultures.



Central to our design is a caspase-3 recognition sequence (1) followed by a ubiquitination target (2) downstream of a GFP reporter (4) so that in the absence of apoptosis, GFP is targeted to the proteasome and the cell is "off." Conversely, an apoptotic cell is "GFP on" when caspase 3 is activated and cleaves off the ubiquitination target. Ubiquitination and proteosomal degradation are coordinated within a cell to rapidly prevent expression of intracellular proteins. Two examples of highly regulated and rapidly degraded proteins via the ubiquitination pathway are the hypoxia-inducible factor 1 alpha transcription factor (HIF) and the PRAJA1 protein (PRAJA). Cloning of this construct began with the pEGFP-F1 vector (Clontech), which contains a CMV promoter (5) driving eGFP (4) with a farnyslational domain (FAR, 3) to localize the signal to the cell membrane, followed by a multiple cloning site (MCS), and SV40 polyadenylation signal (6). The farnyslation linker and MCS were modified with an in-frame linker containing the caspase-3 cleavage recognition sequence of DEVD as well as restriction sites for insertion of either HIF or PRAJA. The completed constructs are identified as CMV-EGFP-FAR-DEVD-HIF and CMV-EGFP-FAR-DEVD-PRAJA. Stable cell lines expressing these constructs were generated by LipofectAMINE transfection and selected with G418. Apoptosis was induced with etoposide treatment or by transient transfection with a caspase-3 cDNA. Incubation with etoposide versus vehicle with both HIF and PRAJA clonal lines resulted in GFP-positive cells only with etoposide treatment. Furthermore, overexpression of caspase-3 cDNA resulted in GFP detection in clonal lines expressing the caspase-3 substrate sequence DEVD but not in a line containing a caspase resistant (DEVG) linker sequence. Thus the concept of a visual reporter for a protein cleavage (caspase-3) process appears to be validated by these constructs and justifies further studies on its application as a marker for apoptosis in primary cells and intact animals.

Endogenous COX-2 Gene Expression Does Not Alter Apoptosis in Murine Osteoblastic Cells. S. Choudhary, Z. Xu, L. G. Raisz, C. C. Pilbeam. Dept. of Medicine, Univ. of Connecticut Health Center, Farmington, CT, USA.

Primary calvarial osteoblasts from cyclooxygenase (COX)-2 knockout (KO) and wild type (WT) mice can be used to examine the effects of endogenous COX-2 expression on osteoblastic function. We previously found that cell number and proliferation were significantly increased in primary calvarial osteoblasts cultures from COX-2 KO mice relative to cultures from COX-2 WT mice. The goal of this study was to determine if apoptosis was also affected by the absence of endogenous COX-2. Calvariae from 5-8 wk old mice were sequentially digested, and cell populations 2-5 were pooled, grown to confluence and replated for experiments at 5000/cm^2. We used the same culture conditions that were previously used to study proliferation. Under normal culture conditions, each addition of fresh serum induces COX-2 expression and COX-2 associated PGE_2 production. Little PGE_2 is produced in COX-2 KO cultures. To measure apoptosis and cell death, we used flow cytometry after staining of cells with annexin-V-FITC and propidium iodide, as well as TUNEL staining of fixed cells. Cells were grown for 3 d before measurement. Six independent flow cytometry experiments showed no differences between COX-2 WT and KO cells in percent early (annexin only staining) apoptotic cells (2.7 ± 1.0% vs 2.0 ± 0.8%), late (annexin + PI staining) apoptotic cells (1.0 ± 0.1% vs 0.9 ± 0.2%), or dead (PI only staining) cells (1.0 ± 0.2% vs 1.5 ± 0.1%). On TUNEL staining, there was no significant difference between apoptotic cells in COX-2 WT cultures (14.5 ± 0.9%) and COX-2 KO cultures (16.1 ± 0.5%). Moreover, addition of NS-398 (1 μM) to COX-2 WT cultures, to block prostaglandin synthesis, or of PGE_2 (1 μM) to COX-2 KO cultures had no effect on apoptosis. In order to induce apoptosis, we treated cultures with calcium and phosphate (3 mM each), which also induces COX-2 expression and PGE_2 production in COX-2 WT cells. Cells were grown for 5 days and treated with calcium and phosphate for 6 h. In 3 independent experiments using flow cytometry, calcium and phosphate significantly ($P<0.05$) increased the percent apoptotic cells (early + late) similarly in COX-2 WT cultures (from 2.9 ± 0.3% to 6.3 ± 0.7%) and in COX-2 KO cultures (from 3.3 ± 0.2% to 8.0 ± 0.7%). We conclude that endogenous COX-2 expression has little effect on apoptosis in cultured calvarial osteoblasts. Hence, the increased cell proliferation seen in cultured COX-2 KO calvarial osteoblasts compared to WT cells accounts for the increased cell numbers in KO cultures.

Overexpression of COX-2 in Saos-2 Human Osteosarcoma Cells Increases Apoptosis Via Oxidative Stress. S. Choudhary, Z. Xu, O. S. Voznesensky*, C. C. Pilbeam. Dept. of Medicine, University of Connecticut Health Center, Farmington, CT, USA.

Overexpression of cyclooxygenase (COX)-2 promotes tumor growth in many tissue types, primarily by increasing resistance to apoptosis. To examine the role of COX-2 in osteosarcoma cells, we overexpressed murine COX-2 in human Saos-2 cells, which normally express very low levels of COX-2 mRNA. COX-2 overexpression in Saos-2 cells has previously been shown to reduce cell number and proliferation via cell cycle arrest at G2/M. The goal of this study was to examine effects of overexpressed COX-2 on apoptosis. Two methods of overexpression were used. In the first, we compared cells derived from a single clone stably transfected with neomycin resistance (Neo) and type I Col 3.6-driven murine COX-2 cDNA with cells from a clone expressing only Neo. In the second method, cells were retrovirally transduced with a construct expressing green fluorescent protein (eGFP) and murine COX-2 (CMV-COX-2/eGFP) or with empty vector (CMV-GFP). Expression of COX-2 was confirmed by Northern blot, by Western blot and immunostaining, and by PGE_2 production. Apoptosis was examined by TUNEL staining and by flow cytometry after annexin-V-FITC / propidium iodide (PI) staining. In stably transfected cells examined by flow cytometry, early apoptosis (cells stained only by annexin) increased from 6.6 ± 3.0% in cells with Neo alone to 25.7 ± 4.7% in cells overexpressing COX-2 ($P<0.01$). In retrovirally transduced cells, early apoptosis increased from 14.6 ± 0.4% in cells carrying empty vector to 24.8 ± 0.5% in cells overexpressing COX-2 ($P<0.01$). By TUNEL staining, COX-2 overexpression in retrovirally transduced cells increased apoptosis from 4.0 ± 0.8% to 13.9 ± 3.1 % ($P<0.05$). Effects of COX-2 overexpression could not be reversed by inhibitors of COX activity or mimicked by exogenous PGE_2, indicating that effects were not mediated by prostaglandins. Reactive oxygen species (ROS) may be formed during the catalysis of arachidonate by COX-2 and can potentiate apoptosis. Flow cytometric measurement of intracellular ROS using the fluorescent dye hydroethidine, a marker of superoxide anion, showed increased ROS formation in COX-2 overexpressing cells. Treatment of cells with the antioxidant N-acetyl-cysteine (NAC, 5 mM) for 24 h inhibited both ROS accumulation and apoptosis in COX-2 overexpressing cells. Hence, the increased apoptosis seen with overexpression of COX-2 is likely to be the result of increased ROS. Since overexpression of COX-2 decreases cell proliferation and increases apoptosis in Saos-2 cells, it is unlikely to promote tumor progression in these osteosarcoma cells, in contrast to the findings in other types of malignancies.

The Mechanism of Calcium and Phosphate induced Osteoblast Apoptosis. R. Saunders*, K. H. Szymczyk*, I. M. Shapiro, C. S. Adams. Orthopaedic Surgery, Thomas Jefferson University, Philadelphia, PA, USA.

Our previous work has demonstrated that the $Ca^{2+}$and Pi ion pair is a potent osteoblast apoptogen. The underlying mechanisms by which it activates apoptosis remain unclear. We hypothesize that release of intracellular Ca^{2+} stores causes loss of mitochondrial membrane potential and, subsequently, apoptosis. To establish the mechanism of Ca^{2+}·Pi ion pair induced apoptosis in osteoblasts, MC3T3-E1 osteoblast-like cells were used. Cell death was activated by incubation with 5 or 3 mM Pi and 2.4 or 2.9 mM Ca^{2+}, and measured using the MTT assay. Apoptosome formation was confirmed using Western blot analysis for cytochrome c and Smac/Diablo release. Inhibitors of numerous mitochondrial and endoplasmic reticulum (ER) functions were used to block apoptosis. In addition, neomycin, an inhibitor of phosphoinositide (PI) hydrolysis was also used. Western blot analysis showed that cells treated with the Ca^{2+}·Pi ion pair released cytochrome c and Smac/Diablo from their mitochondria, confirming our previous observation that the ion pair caused a mitochondrial membrane permeability transition (MMPT), and activated an apoptosome in osteoblasts. Blockade of either the electron transfer chain, or induction of the MMPT, inhibits Ca^{2+}·Pi apoptosis in a dose-dependent manner. Pretreating osteoblasts with ruthenium red, a uniporter inhibitor in both mitochondria and the endoplasmic reticulum, also completely abolished Ca^{2+}·Pi -induced programmed cell death. As the endoplasmic reticulum (ER) participates in the propagation of calcium waves and an increase in intracellular Ca^{2+} has previously been observed prior to the MMPT, calcium mobilization from ER stores was examined. Modulation of apoptosis was observed with Dantrolene, a specific inhibitor of the ryanodine receptors in the ER, but not cyclopiazonic acid, an ER Ca^{2+}-ATPase inhibitor. This indicated involvement of calcium stores regulated by ryanodine-receptor channels. Pretreatment with 200 μM neomycin, a general inhibitor of phosphoinositide (PI) hydrolysis also inhibited Ca^{2+}·Pi induced osteoblast cell death while treatment with carbamylcholine chloride, an activator of PI hydrolysis, activated apoptosis in osteoblasts. As calcium sensing receptors utilize PI hydrolysis, these results are consistent with the involvement of those receptors in Ca^{2+}·Pi induced apoptosis. Together, these data demonstrate that Ca^{2+}·Pi induced osteoblasts apoptosis is characterized by the generation of a true apoptosome. Secondarily, calcium release from ER stores may play a major role in the activation of osteoblast apoptosis by the Ca^{2+}·Pi ion pair. Furthermore, such Ca^{2+} release may implicate the involvement of calcium sensing receptors.

Tartrate Resistant Acid Phosphatase (TRACP) in Osteoblasts: Endogenous Expression and Endocytosis of the Enzyme. S. G. Perez*[1], I. Vogels*[2], T. Schoenmaker*[3], S. Alatalo*[4], H. Jussi[5], W. Beertsen[6], V. Everts[7]. [1]Experimental Periodontology, Academic Centre for Dentistry, Universiteit van Amsterdam and Vrije Universiteit, Amsterdam, Netherlands, [2]Cell Biology and Histology, Universiteit van Amsterdam, Amsterdam, Netherlands, [3]Experimental Periodontology, Academic Centre for Dentistry Amsterdam, Universiteit van Amsterdam and Vrije Universiteit, Amsterdam, Netherlands, [4]Finish Red Cross, Helsinki, Finland, [5]Department of Anatomy, University of Turku, Turku, Finland, [6]Periodontology, Academic Centre for Dentistry Amsterdam, Universiteit van Amsterdam and Vrije Universiteit, Amsterdam, Netherlands, [7]Oral Cell Biology, Academic Centre for Dentistry Amsterdam, Universiteit van Amsterdam and Vrije Universiteit, Amsterdam, Netherlands.

TRACP is generally considered as a selective histochemical and biochemical marker of osteoclasts. Yet, several data suggest that other cell types, such as osteocytes and osteoblasts, may also produce the enzyme. Expression of TRACP activity in osteoblasts is particularly obvious at sites were osteoclasts resorb bone. This could suggest that osteoclasts (or their precursors) somehow induce TRACP expression by osteoblasts. In the present study we investigated this by using medium conditioned by osteoclast precursors (monocytes).

Human osteoblasts were obtained from bone samples and cultured with or without medium conditioned by cultured monocytes (MCM). Analysis of TRACP included activity assays, immunolocalization and real time PCR.

Osteoblasts cultured in control medium proved to express TRACP. However, the enzyme was present in an inactive form. Upon culturing with MCM a high level of active TRACP was found. Since this activity could have been due to activation of the inactive enzyme fraction or to endocytosis of TRACP present in the conditioned medium, osteoblasts were cultured in MCM in which the enzyme was depleted by immunoprecipitation. Data obtained from cells cultured with this medium or with non-depleted MCM revealed that (1) a relatively large fraction of TRACP is endocytosed (approximately 80 % of the total level of TRACP activity), (2) endogenous expression of TRACP is stimulated by -yet unidentified- compounds present in MCM, and (3) that this endogenous fraction is activated in the presence of MCM.

The present data show that osteoblasts not only have the capacity to synthesize TRACP, but also to endocytose this enzyme. We propose that osteoblasts endocytose TRACP released by osteoclasts at sites were osteoclastic bone resorption occurs. In the mean time, endogenous TRACP is expressed by the osteoblasts. Osteoblastic TRACP may be used for helping to clean the Howship's lacuna left by the osteoclast.

Paradoxical Regulation of RANKL by Runx-2 in Mature Versus Less Mature Osteoblasts. H. A. Bullock*[1], B. C. Yaden*[1], D. L. Halladay*[1], P. Ducy*[2], V. Krishnan[1]. [1]Bone and Inflammation, Eli Lilly and Company, Indianapolis, IN, USA, [2]Cell Biology, Baylor College of Medicine, Houston, TX, USA.

In an attempt to elucidate the role of runx-2 in mature versus less mature osteoblasts we transfected Saos (mature) and U2OS (less mature) cells with an adenoviral CMV-runx-2 construct. RNA was isolated and hybridized to a human array (SuperArray Bioscience). U2OS cells transfected with adeno-runx-2 showed a 3-fold increase in TNSF11, a 3-fold decrease in MCL-1, and an absence of Nip-3 compared with adeno-CMV-GFP transfected controls. TNFSF11 (RANKL) is a key factor in osteoclast differentiation and is essential in bone remodeling (Fata et al., 2000). Mice deficient in RANKL show severe osteoporosis with a complete absence of osteoclasts and marrow spaces and growth retardation of the skull, limbs, and vertebrae (Kim et al., 2000). RT-PCR analysis was performed using RANKL primers on both U2OS-adeno-runx-2 and Saos-adeno-runx-2 RNA. Runx-2 transfected Saos cells showed an inhibition of RANKL, while runx-2 transfected U20S cells showed an induction of RANKL compared with adeno-CMV-GFP transfected controls. To further explore these differences we utilized a 4.6 kb fragment containing the human RANKL promoter in a βGAL reporter plasmid. This construct contained the TATAA and CAAT boxes as well as several proximal and distal OSE (runx-2 responsive) elements. These striking differences in RANKL regulation can be attributed to the mature versus less mature phenotypes between Saos and U2OS cells, respectively.

Specific Domains of TRAP Control Bone Formation at Sites of Remodeling. M. Matsuzawa*, T. J. Sheu*, R. J. O'Keefe, R. N. Rosier, E. M. Schwarz, M. J. Zuscik, H. Drissi, J. E. Puzas. Orthopaedics, University of Rochester, Rochester, NY, USA.

Purpose: The mechanism by which osteoblasts recognize sites of prior resorption for targeting new bone formation involves a local activation of the TGFbeta and BMP signaling pathways. This occurs through a protein-protein interaction between type 5 tartrate resistant acid phosphatase (TRAP) in the lacuna and TGFbeta receptor interacting protein (TRIP) in the cells. We now show that specific regions of the TRAP molecule are responsible for activating the pathways and describe further characterization of the effect.

Methods: Six domains of human TRAP spanning the signal peptide, catalytic and glycosylation domains were expressed in a Gateway expression system. They were then used in a mammalian two-hybrid system with TRIP to identify the regions of TRAP-TRIP interactions. Immunoprecipitation, Smad reporter assays and RT-PCR experiments for Runx2 and BMP6 further refined the interactions.

Results: Fragment 4, representing overlapping regions in the catalytic and glycosylation domains of TRAP, appears to have the highest affinity for TRIP. It also, i) stimulated TGF-beta/Smad reporter signaling, ii) demonstrated a high specificity for TRIP and iii) induced Runx2 and BMP6 expression by approximately 8 fold over control treatments. These are all features that are consistent with the stimulation of proliferation and differentiation in osteoblasts.

Conclusion: TRAP contains protein recognition domains for TRIP. Upon binding of these fragments to TRIP in osteoblasts, a cascade of signaling pathways is activated involving TGFbeta, Runx2 and BMP6. These effects contribute to the expansion and differentiation of osteoblasts exactly within osteoclast lacunae containing TRAP. This signaling mechanism is a means by which the site-specific formation of bone can be directed to osteoclast lacunae during normal remodeling. It is also identifies another anabolic pathway for the stimulation of osteoblastic activity.

From a clinical perspective, removal of the TRAP signal would be expected to disrupt normal remodeling and may explain the disrupted bone formation that occurs at sites of inflammation and tumor metastasis.

Divergent Effects of Androstene Immune Regulation Hormones (IRH) on RANKL/OPG Ratio and Cell Viability in Osteoblast Cells. N. H. Urban*[1], R. M. Loria*[2], M. J. Beckman[3]. [1]Orthopedic Surgery, Virginia Commonwealth University, Richmond, VA, USA, [2]Microbiology and Immunology, Virginia Commonwealth University, Richmond, VA, USA, [3]Biochemistry, Virginia Commonwealth University, Richmond, VA, USA.

Immune Regulating Hormones (IRH) α androstenediol (5-androstene-3 beta-17 alpha diol, αAED)and β androstenediol (5-androstene-3 beta-17 beta-diol, βAED) have profound effects on the immune system. αAED inhibits tumor cell proliferation and mediates apoptosis via TH_1-type immune pathways. βAED stimulates myelopoesis, strengthens host resistance and counteracts the immuno-suppressive effects of glucorticoids. The emerging concept of osteoimmunity links immune function via T-cell activation to associated bone loss diseases. Recent data suggests that T-cells activate receptor activator of NFκB ligand (RANKL), one of the primary signaling molecules responsible for mediating bone remodeling. RANKL mediates osteoclastogenesis by binding to RANK receptors on osteoclast progenitors, and RANKL potency is balanced by the antagonist (decoy receptor) osteoprotegrin (OPG). We hypothesize that α or β positioning of the C-17 hydroxyl on AED is crucial to the divergent functions of these hormones and their effects on osteoblast signaling and osteoclast recruitment and survival. Using RealTime RT-PCR we determined that αAED significantly increased the RANKL/OPG expression ratio 2-fold in osteoblasts (FOB-9 cells). Confocal immunofluorescence microscopy revealed that αAED altered the morphology and RANKL localization in osteoblasts. Moreover, αAED significantly decreased cell viability (3 fold) as determined in a fluorescent Live/Dead cell assay suggesting a potential for αAED to cause osteoblast apoptosis. However, βAED had no effect on RANKL expression, localization or cell viability. Whereas αAED has recently been shown to increase peroxisome proliferator-activated receptor γ (PPARγ), βAED decreases PPARγ and its genomic effects. In this study, we determined that an increase in PPARγ, via incubation of cells with the known peroxisome proliferator, WY14643, resulted in a significant decrease (4 fold) in viable cells. There was no effect on cell viability upon incubation of osteoblast cells with the PPARγ antagonist GW9662. Co-incubation of cells with αAED and WY14643 also resulted in a decrease in cell viability (6 fold), but co-incubation with αAED and GW9662 had no effect. It is known that a loss of function mutation in CYP17 gene results in decreased growth and osteoporosis which suggests a link between the 17-hydroxylase and bone remodeling. In conclusion, the C-17α hydroxylation on AED regulates both an increase in RANKL and activation of a cell death pathway in osteoblasts.

Oxytocin: an Estrogen-Controlled Autocrine-Paracrine Enhancer of Bone Cell Activity. S. Colucci*, G. Colaianni*, R. Tamma*, A. Di Benedetto*, C. Camerino*, G. Mori*, N. Patano*, M. Grano*, A. Zallone. Human Anatomy and Histology, University of Bari, Bari, Italy.

Oxytocin (OT) is a well known hypothalamic hormone, whose effects in recent years have been demonstrated to be more widespread than previously believed. We recently demonstrated oxytocin receptor expression on both osteoblasts and on mature osteoclasts and their precursors. Here we show that oxytocin is an estrogen-controlled autocrine-paracrine short life peptide that turns on cell activity in bone, stimulating pulses of bone resorption and formation. In fact we demonstrated by immunofluorescence, western blot and RT-PCR that a 6 hours pre-treatment with estradiol up-modulated the receptor both in osteoblasts and in osteoclasts. Simultaneously RNA expression for oxytocin became strongly evident in osteoblasts, as demonstrated by RT-PCR and Northern blot analyses, while with antibodies raised against oxytocin we demonstrated by immunofluorescence that the peptide expression was strongly enhanced in the cells after 6-12 hours and was back to control levels after 24 hours. The presence of OT caused receptor endocytosis within 12hours. OTR stimulation elicited in both cell kinds an intracellular calcium increase, but with different patterns; ERK activation, inhibited by Pertussis toxin, followed after 5' OT treatment and was back to basal levels after 20'. OT stimulated proliferation in growing osteoblast cultures. In more differentiated osteoblasts OT, as seen by Western Blot and RT-PCR, reduced the expression of osteoprotegerin and induced a RANK-L increase. OT on human blood monocytes in the presence of MCSF strongly increased cell proliferation and RANK expression. Osteoclast precursors, cultured in the presence of MCSF and RANK-L, gave rise to a higher number of TRAP-positive cells when OT was added to the medium. In differentiated osteoclasts OT treatment was also followed by AKT phosphorylation. Bone resorption activity was, however, decreased by 40% in the first 48 hour after OT stimulation, but was thereafter back to control levels. All together these results indicate that the Oxytocin acts as an estrogen-mediated switch that keeps up bone cell activity.The increased osteoclastogenesis coupled to decreased bone resorption, considering the cyclic activity of the hormone due to the down regulation of receptors, alternates period of bone formation with resorption performed by the newly differentiate osteoclasts. This fact is particularly important during the final period of pregnancy and during lactation when a high level of circulating calcium is necessary, but can also explain at least part of the protective action of estrogens on the skeleton.

Tibolone Effects on Human Osteoblast Cells in Culture Require Estrogen Receptor. K. L. Shogren*[1], A. Maran[1], M. Zhang*[1], T. C. Spelsberg[2], H. J. Kloosterboer*[3], R. T. Turner[1]. [1]Orthopedics, Mayo Clinic, Rochester, MN, USA, [2]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA, [3]Research and Development Laboratories, NV Organon, 5340 BH Oss, Netherlands.

Tibolone is a Selective Tissue Estrogenic Activity Regulator (STEAR), which expresses estrogenic activity on bone, vagina and brain without stimulating the breast and the endometrium. Clinical studies have proven that postmenopausal loss of bone from the spine and proximal hip can be prevented by tibolone. Animal studies have shown that tibolone can prevent bone loss following ovariectomy and the protective effect of tibolone can be blocked by antiestrogens, suggesting that the effect is estrogen receptor (ER)-dependent. However, direct effects of tibolone on normal human bone cells have not been reported. The effects of two major metabolites of tibolone, 3α-hydroxy tibolone and 3β-hydroxy tibolone were determined on human fetal osteoblast (hFOB) cells that have been stably transfected with ERα cDNA . The effects of these compounds compared to the vehicle control were investigated on bone genes at the level of RNA (alkaline phosphatase, type 1 collagen and osteonectin), protein (type 1 collagen) and enzyme activity (alkaline phosphatase). Both metabolites of tibolone (3α-hydroxy and 3β-hydroxy tibolone) upregulated RNA and protein levels for bone proteins. At 20 μM, 3α-hydroxy tibolone increased mRNA levels for alkaline phosphatase, type 1 collagen and osteonectin by 2.5-fold, 4-fold and 2-fold, respectively, whereas 3β-hydroxy tibolone increased the mRNA levels for the three genes by 2.5-fold, 6-fold and 2-fold, respectively. 3α-Hydroxy and 3β-hydroxy tibolone each increased Type 1 collagen protein levels by 5-fold. When a wide range of doses was used (2-20 μM), tibolone metabolites increased alkaline phosphatase enzyme activity in a dose dependent manner. At 2 μM concentrations, a 4-fold stimulation of alkaline phosphatase activity was observed with both 3α-hydroxy and 3β-hydroxytibolone. A maximum of 6-fold and 7.5-fold stimulation of alkaline phosphatase activity occurred with 20 μM concentrations of 3α-hydroxy and 3β-hydroxy metabolites respectively. In contrast to these results, neither tibolone metabolite had an effect on RNA levels nor protein levels for bone proteins expressed by ER negative hFOB cells. Thus, these results suggest that the direct actions of tibolone metabolites on bone proteins in cultured human osteoblasts are mediated through ER.

Regulation of OPG, RANKL, IL-6 and Growth Factor Expression by Androstenedione, DHEA and Dexamethasone: Potential Usefulness of the Adrenal Androgens in the Prevention of Corticosteroid-induced Osteoporosis. G. Harding*[1], Y. Mak*[1], J. Cheung*[1], B. A. J. Evans[2], I. Fogelman[3], G. Hampson[1]. [1]Chemical Pathology, St Thomas' Hospital, London, United Kingdom, [2]Child Health, University Hospital of Wales, Cardiff, United Kingdom, [3]Osteoporosis Screening Unit, Guy's Hospital, London, United Kingdom.

The adrenal androgens ; dehydroepiandrosterone (DHEA) and androstenedione (ANDI) may have anti-resorptive as well as anabolic effects on bone. The aim was to assess the regulation of cytokines involved in bone remodelling by DHEA, ANDI and Dexamethasone (DEX) in a human osteoblastic cell line (HCC1). Expression of osteoprotegerin (OPG), RANKL, IL-6 was measured following treatment of the cells with DHEA, ANDI (10^{-12} -10^{-6} M) and DEX. The expression of a variety of cytokines and their receptors was assessed using a human cytokine/receptor gene array consisting of 268 cytokine-related cDNAs. An intensity ratio of the cDNA spots between the treated array and control array was set at >1.5 or < 0.66. DEX treatment (10^{-9}-10^{-7}M) reduced OPG (10^{-7}M: 33.7% [4.7] $p < 0.001$). OPG production also decreased with DHEA and ANDI (10^{-7}M) (DHEA 52.5% [7.8] $p < 0.001$, ANDI 51.2% [4.5] $p<0.001$). This was not inhibited by co-treatment with the androgen receptor antagonist, flutamide (10^{-7} M). Co-treatment of ANDI (10^{-8}, 10^{-6} M) with the aromatase inhibitor, ketoconazole (10^{-5} M) reversed the inhibition in OPG production. DEX led to an increase in RANKL production (185% [87.7]) which was abolished by co-treatment with ANDI (77.3 % [12.1] p=0.08) and DHEA (47.4% [8.8] p=0.08). A significant reduction in IL-6 was observed with DEX (14.1[5.4] %, $p < 0.01$), ANDI (28% [9.7], $p <0.02$) and DHEA (10-7 M) (14% [9.8] $p <0.05$). OPG mRNA decreased with DEX (33.3% [1.3], $p <0.001$), ANDI (36% [1.3] $p <0.001$) and DHEA (48% [1], $p<0.02$). DEX increased RANKL mRNA (391.1% [147], p=0.14). DHEA alone or with DEX resulted in a significant reduction in RANKL mRNA (76% [3] p=0.02, 46% [3] $p<0.001$). DHEA and ANDI reversed the DEX-induced increase in RANKL/OPG ratio. In contrast to DEX, DHEA up-regulated over 30 genes; fibroblast growth factor 5 (4.4 -fold), Pleiotrophin (2.5-fold) , Macrophage inhibitory factor (2.0-fold), vascular endothelial growth factor (VEGF 1.7-fold). VEGF up-regulation by DHEA (10^{-7} M) was confirmed by ELISA (133% [9.5] p = 0.1). Our data suggest that the adrenal androgens may slow bone resorption through their conversion to oestrogens. DHEA may also stimulate bone formation through up-regulation of growth factors and may counteract some of the catabolic effects of glucocorticoids on the skeleton.

Anabolic Effects of the Phytoestrogens Genistein, Daidzein, and Resveratrol in Human Osteoblastic MG-63 Cells. A. de Gortázar*, V. Alonso*, P. Esbrit. Bone and Mineral Metabolism Laboratory, Fundación Jiménez Díaz-UTE, Madrid, Spain.

Estrogen deficiency is an important cause of osteoporosis after menopause. The pharmacological effects of soy isoflavones such as genistein and daidzein are of current interest because of their potencial role in the management of osteoporosis. However, there only a few studies so far aimed at evaluating the direct effects of these agents on osteoblastic cells *in vitro*. We assessed here the effects of genistein, daidzein, and resveratrol (another natural phytoestrogen), compared to those of 17β-estradiol (E2), on several osteoblastic markers in human osteoblastic osteosarcoma MG-63 cells. Subconfluent cells were grown in medium with charcoal-treated FBS, with or without the agonists, added every other day for 6 days, and then alkaline phosphatase (ALP) activity and bone nodule formation were determined. In experiments to assess the other markers studied, agonists were added to confluent cells without FBS for 3 days, and then total cell RNA and protein were isolated. We found that genistein, daidzein, and resveratrol, in a similar manner than 17β-estradiol, at 100 nM, inhibited (by 30%) both ALP activity and mineralization in these cells. However, the tested phytoestrogens, at 100 nM, failed to affect either core binding factor-alpha 1 or the PTH1 receptor in MG-63 cells. In contrast, these agonists, within 0.1-100 nM, similarly stimulated (maximal, 2-fold over control, at 100 nM) osteocalcin mRNA and osteoprotegerin (OPG) expression (mRNA and protein; by RT-PCR and western blot, respectively) in these cells. On the other hand, these agents either inhibited (E2) or did not affect receptor activator of nuclear factor (NF)-kappaB ligand (RANKL) protein expression in MG-63 cells. However, in these cells, these agents similarly inhibited (by 50%) basal interleukin (IL)-6 mRNA levels; although daidzein and resveratrol were less efficient than the other agonists in inhibiting PTHrP (1-36)-induced IL-6 gene expression. This inhibitory effect appear to occur by interaction with NF-kappaB activation in MG-63 cells. The stimulatory and inhibitory effects of these agents on OPG and IL-6 expression, respectively, were abolished by raloxifen and ICI182,780, two estrogen receptor antagonists, in these cells.

These findings indicate that genistein, daidzein, and resveratrol can exert similar estrogen-like osteogenic actions on human osteoblastic cells *in vitro*.

Selective Expression of The Soluble or Membrane-Bound Colony Stimulating Factor-1 (CSF-1) Isoform in Osteoblasts Accelerates Estrogen-Deficiency Bone Loss. G. Yao[1], J. Wu*[2], S. Ovadia*[1], N. Troiano*[3], K. Karl. Insogna[2]. [1]Comparative Medicine, Yale University, New Haven, CT, USA, [2]Internal Medicine, Yale University, New Haven, CT, USA, [3]Orthopaedics, Yale University, New Haven, CT, USA.

Osteoblasts express biologically-active soluble (sCSF-1) and membrane-bound (mCSF-1) isoforms of CSF-1. To explore the role of CSF-1 isoforms in estrogen-deficiency bone loss, transgenic mice, selectively expressing either human sCSF-1 or human mCSF-1 in osteoblasts, were engineered using the 2.4 kb rat alpha I collagen promoter. Bone density determined by pQCT at three months was significantly reduced in both mCSF-1 and in sCSF-1 transgenic mice as compared to wild-type animals. For both isoforms, the decrement in bone density in female transgenic animals was greater than the decrement in male transgenic animals when compared to their respective wild-type counterparts (-19.6% vs. -10% for sCSF-1 $p<0.05$ and -11% vs. -3% for mCSF-1 $p<0.05$). Since it has been reported that the relative expression of CSF-1 isoforms changes following estrogen withdrawal, we examined the effect of individual CSF-1 isoforms on rates of bone loss following ovariectomy (OVX). For this purpose, we engineered mice expressing a single CSF-1 isoform on an *op/op* background (e.g. no endogenous CSF-1). This was accomplished by breeding mCSF-1 or sCSF-1 transgenic mice with *op*/+ mice and back crossing the offspring to an *op*/+ genotype to yield mice with an *op/op*-mCSF-1/+ or *op/op*-sCSF-1/+ genotype. Five month-old female mice with these genotypes and their wild-type female littermates underwent OVX or sham-ovariectomy (Sham). One month after surgery, bone density determined by pQCT was reduced by 9% in OVX-wild-type as compared to Sham-wild-type mice. Sham-*op/op* mCSF-1 and Sham-*op/op* sCSF-1 mice showed 6.8% and 7% bone loss respectively compared to Sham-wild-type mice. OVX further reduced the bone density in these two groups such that, compared to Sham-wild type animals, OVX-*op/op* mCSF-1 and OVX-*op/op* sCSF-1 mice showed 20% and 16% reductions in BMD respectively. We conclude that expression of CSF-1 in osteoblasts significantly augments the bone loss associated with estrogen-withdrawal. This effect is not isoform dependent. Therefore, the overall level of CSF-1 expression, rather than the ratio of the two isoforms, seems more important in accelerating estrogen-deficiency bone loss. Since the effects of estrogen withdrawal and CSF-1 expression are additive in this experimental model, it is possible that estrogen and CSF-1 act at different steps in the osteoclast formation/survival pathway. Finally, OVX-*op/op* sCSF-1 and OVX-*op/op* mCSF-1 mice are useful animal models for postmenopausal osteoporosis.

An Isopropanolic Extract of Cimicifuga Racemosa (black cohosh) Stimulates Osteoprotegerin Production by Primary Human Osteoblasts. V. Viereck[1], C. Grundker*[1], S. Blaschke*[2], K. Frosch*[3], M. Schoppet*[4], G. Emons*[1], L. C. Hofbauer[4]. [1]Gynecology and Obstetrics, Georg-August-University, Goettingen, Germany, [2]Nephrology and Rheumatology, Georg-August-University, Goettingen, Germany, [3]Trauma Surgery, Georg-August-University, Goettingen, Germany, [4]Medicine, Philipps-University, Marburg, Germany.

Despite its positive effects on the skeleton, estrogen replacement therapy is no longer recommended for the prevention of postmenopausal osteoporosis because of increased cardiovascular, thromboembolic and breast cancer risks. Recently, certain herbal therapeutics have been shown to exert selective estrogen receptor modulator (SERM)-like effects with positive effects against menopausal symptoms and bone loss, but without adverse effects on the uterus or on breast tissue. Isopropanolic extracts from the rhizomes of *Cimicifuga racemosa* (black cohosh; iCR) have gained acceptance as a herbal alternative in the treatment of menopausal symptoms, although their effect on bone metabolism is unclear. Receptor activator of nuclear factor-κB ligand (RANKL) is essential for osteoclast formation and activation, while osteoprotegerin (OPG) neutralizes RANKL. 17β-estradiol and genistein have been demonstrated to modulate osteoblastic production of RANKL and OPG. In this study, we assessed the effects of iCR on OPG and RANKL mRNA steady-state levels (by semiquantitative RT-PCR) and protein production (by ELISA) in primary human osteoblasts (hOB). Under serum-free conditions, treatment with iCR increased OPG mRNA levels and protein secretion of hOB by 2- to 3-fold in a dose-dependent manner with a maximum effect at 10^6-fold dilution of iCR (0.075 µg/ml) ($P < 0.001$) after 24 - 48 hrs. Time course experiments indicated a stimulatory effect of iCR on osteoblastic OPG protein secretion by 3- to 5-fold ($P < 0.001$) as early as 12 hrs. RANKL expression was very low, and was not found to be modulated by iCR. Moreover, iCR enhanced osteoblastic differentiation markers, alkaline phosphatase activity and osteocalcin expression by up to 4- and 3-fold, respectively ($P < 0.001$). In conclusion, our data suggest that an isopropanolic extract of CR modulates OPG and RANKL production by normal human osteoblasts, which may contribute to the inhibition of osteoclastic bone resorption. Since, OPG production increases with osteoblastic cell maturation, enhancement of OPG by iCR could be related to its stimulatory effects on osteoblastic differentiation.

Osx, an Osteoblast-specific Transcription Factor, Is Mediated by Multiple Signaling Pathways. A. B. Celil*[1], P. G. Campbell*[2], J. O. Hollinger[3]. [1]Biological Sciences, Carnegie Mellon University, Pittsburgh, PA, USA, [2]Institute for Complex Engineered Systems, Carnegie Mellon University, Pittsburgh, PA, USA, [3]Bone Tissue Engineering Center, Carnegie Mellon University, Pittsburgh, PA, USA.

Recent discoveries have revealed the presence of a nuclear transcription factor, Osx, implicated in bone formation. Osx deficient mice lack the formation of cortical bone and bone trabeculae (Nakashima *et al*., 2002). The purpose of this study was to determine the possible mediators of *Osx* expression. Using quantitative real-time PCR, we showed that *Osx* was induced in response to rhBMP-2 and AdBMP-2 in human mesenchymal stem cells (hMSCs) and in NIH3T3 mouse fibroblasts. BMP-2 induced *Osx* expression in a time- and dose-dependent manner in hMSCs. We tested the effect of several different growth factors implicated in osteoblast differentiation and among these factors IGF-I showed a synergistic interaction with BMP-2 in inducing *Osx*. Further, from our studies in Runx2 stably-transfected cells, we showed that Runx2 overexpression is not sufficient to induce *Osx*. BMP-2 and Runx2 display synergistic interactions in upregulating *Osx*. The BMP-2 mediated effect is not direct since it requires *de novo* protein synthesis. These results suggest that *Osx* is not entirely dependent on Runx2 and that a new protein mediator needs to be synthesized downstream of BMP-2 signaling pathway.

We also investigated the possible involvement of MAPK pathway in mediating *Osx* expression. Through our studies, we have determined that the expression of osteoblast marker gene *Alkaline phosphatase* in addition to alkaline phosphatase enzymatic activity is inhibited in response to a block in MAPK signaling pathway in hMSCs. While the inhibition of ERK1/2 seems to have no effect on *Runx2* gene expression, *Osx* expression is inhibited. hMSCs showed an inhibition of BMP-2 mediated *Osx* expression in the presence of p38 inhibitor. We confirmed the results of our MAPK inhibition experiments using chemical inhibitors as well as adenoviral MAPK constructs. As they progress into osteoblastic lineage, hMSCs may utilize MAPK signaling both via ERK1/2 and p38, but in the presence of BMP-2, p38 mediated signaling may be activated for *Osx* regulation.

The αNAC Coactivator must Bind the Promoter to Potentiate the AP-1-Dependent Transcription of the Osteocalcin Gene. O. Akhouayri*, I. Quélo*, R. St-Arnaud. Genetics Unit, Shriners Hospital for Children, Montreal, PQ, Canada.

Tissue-specific gene activation is regulated by a combination of sequence-specific DNA-binding transcriptional activators, general transcription factors, and associated coactivators. The αNAC coactivator was identified in a differential screen for genes expressed in differentiated osteoblasts, and shown to function as a coactivator for the homodimeric c-Jun AP-1 transcription factor. In the course of these studies, it was shown that αNAC can specifically bind DNA in vitro, but it remained unclear whether the DNA binding function of αNAC is expressed in vivo or is required for its coactivating activity. We have identified an αNAC binding site within the murine osteocalcin gene proximal promoter region and demonstrated that recombinant αNAC or αNAC from ROS17/2.8 nuclear extracts can specifically bind this element. Using transient transfection assays, we have shown that αNAC specifically potentiated the c-Jun-dependent transcription of the osteocalcin promoter, and that this activity required the DNA binding domain of αNAC. Our results show that the osteocalcin gene is a target for the αNAC coactivating function and that αNAC is specifically targeted to the osteocalcin promoter as a means to achieve increased specificity in gene transcription.

The Dual Role of Hoxc8 as Transcription Repressor and Activator. N. Wang*[1], M. Wan[1], S. Bai*[2], X. Li*[1], X. Cao[1]. [1]Pathology, The University of Alabama at Birmingham, Birmingham, AL, USA, [2]Pathology, Washington University, St. Louis, MO, USA.

BMPs are potent osteotropic agents that induce osteoblast differentiation and bone development. BMPs transduce their signals into cells through Smad proteins. We have shown that Hoxc8 is a BMP downstream factor by functioning as a transcription repressor to stimulate bone marrow mesenchymal proliferation for their self renewal. Interestingly, Hoxc8 acts as a transcription activator in terminally differentiated cells. There are 39 members within the Hox gene family arranged into four clusters whose activities are essential for tissue patterning and bone development. Our previous data suggest that all of the 39 Hox proteins interact with Smad1, Smad4 and Smad6, not TGF-β specific R-Smads, as major BMP downstream transcription factors. To understand the molecular mechanism that Hoxc8 acts a transcription repressor in stem cells and an activator in differentiated cells, we attempted to characterize the role of Hoxc8 in osteoprotegerin (OPG) and osteopontin (OPN) transcription. We have identified Hoxc8 DNA binding elements in both OPG and OPN promoters and Hoxc8 acts as a transcription repressor in both promoters in C3H10T1/2 mesenchymal cell. Hoxc8 inhibits OPG and OPN expression to prevent C3H10T1/2 mesenchymal cells from differentiation. However, Hoxc8 activates OPN and OPG transcription in 2T3 osteoblastic cells, LNCap prostate cells, MCF-7, MDA-MB-231 breast cells, functioning as a transcription activator. These observation suggests that Hoxc8 contain both activation and repression domains.

To identify such dual function domains, we truncated Hoxc8 into a series of expression plasmids that fused with GAL4 DNA binding domain. The activities of these truncated expression plasmids were examined in C3H10T1/2 cells by using GAL4 reporter plasmid. The results showed that the highly conserved domains in Hoxc8 (Hoxc8PHC) including hexapeptide motif, the homeodomain, and C-terminus mediate its repression and N-terminus of Hoxc8 (Hoxc8N) exhibits transactivation ability. Furthermore, Hoxc8PHC motif only interacts with all class I HDACs, including HDAC1, HDAC2 and HDAC3 in coimmunoprecipitation assay. These data suggests the repressive activity of Hoxc8PHC is mediated by recruiting HDACs. Our data first time demonstrated that Hoxc8 functions as either transcription activator or repressor depending on promoter contexts and the stage of cell differentiation. Based on the conservative nature of Hox transcription factors, these results also imply that dual domains may exist in all of the 39 Hox transcription factors. Thus, this Hox fundamental transcription mechanism may help to understand the mechanisms of BMPs in bone development and remodeling.

Establishment of a Mechanistic Link Between the Osteogenic Function of Runx2 and Its Subnuclear Organization by Intranuclear Informatics. D. Young, S. K. Zaidi*, A. Javed, J. L. Stein*, J. B. Lian, A. J. van Wijnen, G. S. Stein. Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA.

Osteogenesis is controlled by the Runx2 transcription factor through the integration of complex signaling pathways that influence growth and differentiation of mesenchymal progenitor cells. Runx2 is localized in punctate subnuclear domains (foci) and organizes the assembly of supramolecular regulatory complexes that mediate the activation and repression of target genes. A conserved intranuclear targeting signal (NMTS) within the C-terminus of Runx2 directs the protein to matrix-associated subnuclear sites that support transcriptional control during osteoblast differentiation. To understand the relationship between Runx2 subnuclear organization and its physiological roles, we have developed "intranuclear informatics," a multivariate quantitative approach that combines image-processing and statistical tools. This strategy was used to quantify the spatial organization of nuclear protein domains from immunofluorescence microscopic images and provides a framework that establishes a mechanistic connection between nuclear architecture and biological function. We find that Runx2 foci have a distinct non-random organization within the nucleus. Using site-directed mutagenesis, we show that the C-terminal NMTS is a critical molecular determinant for the spatial organization of Runx proteins. Collectively, our results establish that the NMTS contributes to fidelity of Runx subnuclear organization. NMTS mutations affect the number, size and spatial randomness of foci, but not radial position. Further, our experimental strategy has enabled us to discriminate between functional and non-functional Runx proteins based, only, upon their domain organization within the nucleus. Finally, we establish that there is a direct link between Runx2 domain organization and its biological function. We conclude that the architectural organization of the Runx2 transcription factor within the nucleus is obligatory for its osteogenic regulatory function.

Expression of Extracellular WNT Pathway Components in Adult Human Trabecular Bone Cells. V. Trendelenburg*[1], M. Schaeublin*[1], C. Halleux[1], J. A. Gasser[1], S. Guth*[1], J. Porter*[2], D. Curtis*[2], K. Seuwen*[3], M. R. John[1]. [1]Bone Metabolism, Novartis Institutes for Biomedical Research, Basel, Switzerland, [2]Developmental and Molecular Pathways, Novartis Institutes for Biomedical Research, Inc., Cambridge, MA, USA, [3]GPCR Expertise Program, Novartis Institutes for Biomedical Research, Basel, Switzerland.

LRP5 is an important coreceptor in the WNT signaling cascade and has been shown to play a key role in early bone formation. Distinct mutations in the human LRP5 gene can lead to three different diseases: high-bone-mass syndrome, osteoporosis-pseudoglioma syndrome and familial exsudative vitreoretinopathy. Additionally, recent human genetic association studies suggest that LRP5 allelic variation contributes significantly to vertebral bone mass and size determination in males.

To get a comprehensive overview of extracellular human WNT pathway components we have examined the expression of all LRP5/6, WNT, Frizzled (Fzd), sFRP, DKK and Kremen family members in cultured adult trabecular bone cells by RT-PCR and partially by realtime-PCR. As a control, RNA from multiple normal control tissues was included.

Both LRP5 and LRP6 were ubiquitously expressed at comparable levels. Of the 19 Wnt genes, Wnt 1, 2b, 3, 4, 5a, 5b, 9a, 11, and 16 were expressed in trabecular bone as judged by RT-PCR and we could also demonstrate expression of Norrin. Realtime-PCR confirmed particularly strong expression relative to normal tissues for Wnt 2b, 3, 5b and 16 with the highest expression relative to other tissues for Wnt 5b. All Fzd receptors except Fzd 10 were expressed in trabecular bone, but only Fzd 3, 4, 5, 8 and 9 showed some preference for bone. Members of the sFRP and DKK family mainly act as secreted antagonists of Wnt signaling. Expression of these genes in trabecular bone could be shown for sFRP3 and 4, as well as DKK1, 2 and 3 while DKK1 seemed to be most highly expressed in trabecular bone compared to control tissues. Only weak expression of DKK4 and Soggy could be detected in bone tissue. Furthermore, we could demonstrate expression of Kremen1 in human trabecular bone cells.

In conclusion, simultaneous expression of a large number of extracellular WNT signaling components with synergistic but also opposite effects and the capability to activate multiple signaling pathways demonstrates the existence of a complex equilibrium of partially functionally redundant molecules in cultured adult human trabecular bone cells. These data suggest persistent important physiological functions of the WNT pathway(s) in the maintenance of adult human trabecular bone in addition to its demonstrated role during early development.

Evidence For A Role For CCAAT Enhancer Binding Protein β As A Nuclear Coupling Factor For Coordinated Regulation of Osteopontin by 1,25Dihydroxyvitamin D_3 and Parathyroid Hormone. P. Dhawan*, X. Peng*, S. Christakos. Biochemistry, University of Medicine and Dentistry of New Jersey, Newark, NJ, USA.

Osteopontin (OPN), induced in response to $1,25(OH)_2D_3$ in osteoblasts, has been reported to modulate both resorption and mineralization. Parathyroid hormone (PTH) and/or activation of protein kinase A can enhance the $1,25(OH)_2D_3$ induction of OPN expression and transcription in osteoblasts. To understand regulatory mechanisms involved we asked whether C/EBPβ, which is induced by $1,25(OH)_2D_3$ and PTH, may play a role in the regulation of OPN transcription. Northern analysis using UMR 106 osteoblastic cells indi-

cated that PTH (25 nM) potentiates the induction of C/EBPβ, vitamin D receptor (VDR) and OPN mRNAs by $1,25(OH)_2D_3$ (10^{-8}M) as well as the rapidity of the response. In the presence of both PTH and $1,25(OH)_2D_3$ the first significant induction of C/EBPβ mRNA (at 30 min.) precedes the response of VDR mRNA (3h) and OPN mRNA (6h). In UMR 106 osteoblastic cells co-transfected with a C/EBP dominant negative expression construct (DN-CEBP) and the mouse OPN promoter (-777/+79), the cAMP or PTH enhancement of $1,25(OH)_2D_3$ induced OPN transcription was inhibited, suggesting the involvement of C/EBP in PTH enhanced OPN transcription. The OPN vitamin D response element was found to be sufficient to observe the inhibitory effect of DN-C/EBP, indicating that C/EBP is not acting through a site in the OPN promoter. VDR mRNA levels, induced after cAMP treatment in UMR cells (1 mM 8 bromo cAMP, 9h), were inhibited by prior transfection of DN-C/EBP, suggesting that C/EBP may mediate an effect on the PTH and cAMP mediated enhancement of OPN transcription through up-regulation of VDR. Data using the hVDR promoter (-1500/+60) indicate that expression of PKA results in a 3.5 ± 0.5 fold induction of hVDR promoter activity that is further enhanced two fold in the presence of C/EBPβ. DN-C/EBP (100 ng) inhibited the C/EBP enhancement and at higher concentrations (250 ng) DN-C/EBP inhibited the PKA induction of VDR transcription. Basal levels of hVDR transcription were unaffected at these concentrations of DN-C/EBP. 5'Deletion mapping studies indicated that the putative C/EBP sites at -1490/-1480 and at -919/-911are not involved in the response to C/EBP. C/EBPβ, in the presence of PKA, induced transcription from the VDR promoter within -580 and +60 (two CREs at -579/-558 and -367/-347), indicating that the interaction between the effects of PKA and C/EBP β occurs within this region of the hVDR promoter. In summary, the findings presented provide evidence that C/EBP β is a nuclear coupling factor that coordinates regulation of osteoblast function by $1,25(OH)_2D_3$ and PTH, at least in part, by enhancing PKA induced VDR transcription.

Osteogenic Differentiation of Marrow Stromal Cells Induced by Oxysterols Is Associated With the Induction of Cbfa1 Expression and Activity. J. A. Richardson*[1], S. Tetradis[2], C. M. Amantea*[1], T. J. Hahn[1], F. Parhami[1]. [1]Medicine, UCLA, Los Angeles, CA, USA, [2]Dental School, UCLA, Los Angeles, CA, USA.

Identification of anabolic agents that induce osteogenic differentiation and inhibit adipogenic differentiation of osteoprogenitor cells and enhance bone formation is of great importance for improved prevention and management of osteoporosis. Oxysterols are naturally occurring products of cholesterol oxidation, have multiple biologic activities, and are made in part by cellular cytochrome P450 enzymes. We previously reported that specific combinations of oxysterols, namely 22(R)- or 22(S)-hydroxycholesterol with 20(S)-hydroxycholesterol have novel pro-osteogenic and anti-adipogenic effects when applied to osteoprogenitor cells including the pluripotent M2-10B4 (M2) mouse marrow stromal cells (MSC) *in vitro*. In the present report we demonstrate that these osteogenic oxysterol combinations positively regulate Cbfa1, a transcription factor that is a master regulator of osteoblastic differentiation. Treatment of M2 cells with 1-5 μM oxysterol combination 22S+20S (SS) for 4 days caused a dose-dependent increase in Cbfa1 mRNA expression. Treatment of M2 cells for 4 days with 1-5 μM SS also induced a dose-dependent increase in DNA-binding activity of Cbfa1 to mouse OSE2 sequence 5'-AGCTGCAATCACCAACCACAGCA-3', but not to mouse NFκB DNA binding sequence. Antibody specific to Cbfa1, but not irrelevant antibody specific to the nuclear transcription factor Nurr1, caused a supershift in EMSA using nuclear extracts from SS treated M2 cells. Excess unlabelled OSE2 oligo, but not unlabelled NFκB oligo, successfully competed for binding to SS-induced Cbfa1 in M2 nuclear extracts. Other oxysterols and oxidized lipids without osteogenic properties did not induce Cbfa1 expression or DNA binding. Inhibitors of cyclooxygenase 1 and MAPK, SC-560 and PD98059, respectively, partially inhibited SS-induced Cbfa1 DNA binding. We previously demonstrated that osteogenic oxysterols act synergistically with BMP2 and BMP7 to induce osteogenic differentiation of osteoprogenitor cells. This synergy in induction of osteogenic differentiation is associated with synergistic induction of Cbfa1 expression. Altogether these data demonstrate that osteogenic differentiation of cells in response to oxysterols is associated with the induction of previously characterized factors including Cbfa1 that drive osteoblastic differentiation.

Molecular Mechanisms of Bisphosphonate Action on Osteoblasts. G. Tell*[1], A. Pines*[2], A. Costessi*[1], M. Romanello*[2], D. de Feo[3], L. Moro*[2]. [1]Biomedical Science and Technology, Udine University, Udine, Italy, [2]Biochemistry, Center for the Study of Metabolic Bone Diseases, Trieste University, Trieste, Italy, [3]Procter & Gamble, Rome, Italy.

Bisphosphonates prevent osteoblast apoptosis by a mechanism involving extracellular signal-regulated kinase (ERK) activation. However, information regarding molecular targets and mechanisms of bisphosphonate actions are still scanty. ERKs are a family of kinases which play a central role in regulating several biological functions through modulation of the gene expression profile by acting on different transcription factors such as AP-1, Egr-1 and Cbfa-1/Runx-2. With this in mind, we tested the hypothesis that alendronate and risedronate could also act at the genomic level by controlling the activity of those transcription factors acting downstream of ERKs. We recently characterized a signalling pathway in a differentiated human osteoblast cell line (i.e. HOBIT), responsible for the activation of collagen a2 (I) gene expression through activation of Egr-1 transcription factor after mechanical stimuli (Pines et al. *Biochem. J.* 2003 373, 815-824). By using this cellular system, our data suggest that alendronate and risedronate play a role at the transcriptional level, by activating Egr-1 transcription factor itself. Interestingly, the functional activity of risedronate seems more effective and prolonged than alendronate in activating ERKs and Egr-1 and Cbfa-1/Runx-2. To more deeply understand the mechanism of bisphosphonate action at the molecular level, we are using a global approach based on differential proteomics by using hightroughput technologies based on 2-D gel analysis coupled to MALDI-Mass protein identification.These data confirm that bisphosphonate modulate osteoblast function by acting at the genomic level and open new pharmacological perspectives in the treatment of osteoporosis.

Hypoxia Suppresses runx 2 Transcription in Osteoblasts and Osteocytes. R. Irwin*[1], S. Botolin*[1], J. LaPres*[2], L. R. McCabe[1]. [1]Departments of Physiology and Radiology, Michigan State University, East Lansing, MI, USA, [2]Department of Biochemistry, Michigan State University, East Lansing, MI, USA.

Mechanical loading is known to be a major regulator in the promotion and maintenance of normal bone homeostasis. Increasing mechanical load increases bone formation and correspondingly decreasing load decreases bone formation. It remains unclear as to exactly how a bone cell senses load, however interstitial fluid flow (increased with loading and decreased with unloading) is thought to be involved either through direct mechanical stresses on the cell (via shear stress, movement of actin microvilli, etc…) or possibly through its ability to deliver oxygen and nutrients to bone cells in areas of use. We hypothesize that decreased oxygen delivery could contribute to altered osteoblast and osteocyte gene expression, phenotype and function. Previously we identified hypoxia as a key suppressor of runx2 mRNA levels in osteoblasts grown in suspension in a rotating wall vessel. Similarly, when cultured in standard tissue culture dishes under hypoxic (2% oxygen) compared to normoxic (21% oxygen) conditions, osteoblast runx2 mRNA levels are suppressed by 50%. In contrast, VEGF and GAPDH mRNAs (hypoxia responsive genes) are induced 4-10 fold by hypoxic conditions. Live/dead and apoptosis assays indicate that osteoblasts and osteocytes are viable even after greater than 96 hours of hypoxic conditions. Consistent with a transcriptional regulatory component, runx2 promoter-luciferase assays demonstrate, under hypoxic conditions, a 50 and 90% decrease in activity in osteoblasts and osteocytes, respectively. Interestingly, osteocytes were significantly more responsive than osteoblasts. Furthermore, promoter deletion assays indicate that the proximal promoter region of runx2 is critical for this response. Taken together, our data indicate that hypoxia is a key regulator of runx2 expression and could contribute to altered osteoblast and osteocyte function and ultimately bone loss under conditions of decreased oxygenation, interstitial flow and loading.

mSin3a and Multiple HDACs Regulate Runx2 Transcriptional Activity. T. M. Schroeder*[1], J. J. Westendorf[2]. [1]Graduate Program in Biochemistry, Molecular Biology and Biophysics, University of Minnesota, Minneapolis, MN, USA, [2]Orthopaedic Surgery and The Cancer Center, University of Minnesota, Minneapolis, MN, USA.

Runx2 (Cbfa1, AML3) is an essential regulator of osteoblast differentiation and bone development. Runx2 activates or represses osteoblast specific genes through interactions with multiple cofactors. Runx2-mediated transcriptional repression is at least partially dependent on the recruitment of histone deacetylases (HDACs) and associated corepressors (e.g. mSin3A). We previously showed that HDAC3 and HDAC6 interact with amino- and carboxy-terminal Runx2 repression domains, respectively, but mSin3A contact regions have not been defined. Identification of these interaction domains will be important in understanding the regulatory mechanisms that control Runx2 transcriptional activity. Here we show that mSin3A interacts with an amino-terminal portion of Runx2 and represses Runx2-dependent activation of the osteocalcin promoter. The Runx2-mSin3a interacting region contains two serine residues (S286 and S304) that are conserved with Runx1. When these residues are phosphorylated in Runx1, mSin3a interactions are relieved. We have mutated the corresponding serines in Runx2 to alanine (to abolish the phosphorylation site) or to glutamic acid (to structurally mimic a phosphorylated residue). The S>A mutations hinder Runx2's ability to activate transcription, whereas the S>E mutations increase Runx2-dependent transactivation. Unexpectedly, neither set of mutations affected mSin3A or HDAC3 interactions with Runx2. These results suggest that mechanisms regulating Runx2-mediated repression differ from those controlling Runx1 activity. To identify candidate corepressors whose interactions may be dependent on phosphorylation of S286 and S304, we recently found that HDAC7, 9 and 10 form contacts with both the amino and carboxy termini of Runx2. These interactions may be functionally relevant as HDAC7, 9 and 10 messages were detected in osteoblast cell lines. Together these data demonstrate that Runx2 interacts with multiple co-repressors. Identifying the mechanisms regulating these interactions will increase our understanding of how Runx2 regulates gene expression.

Osteopenia in Col3.6-p20C/EBPß Transgenic Mice Is Associated with Reduced Expression of Col2.3-GFP in Vivo and in a Heterotopic Bone Formation Model. L. M. Moranda*[1], P. L. Kelly*[1], J. Delaney*[2], J. He*[3], J. R. Harrison[1]. [1]Orthodontics, University of Connecticut Health Center, Farmington, CT, USA, [2]Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, USA, [3]Medicine, University of Connecticut Health Center, Farmington, CT, USA.

We reported previously that Col3.6 promoter-targeted overexpression of p20C/EBPß, a dominant negative C/EBP isoform, results in osteopenia in transgenic (TG) mice. Stromal cells derived from TG mice in a Col2.3-green fluorescent protein (GFP) genetic background showed a decrease in intensity of GFP expression associated with reduced osteocalcin expression. This suggests that p20C/EBPß overexpression interferes with late osteoblast differentiation or function. To further test this hypothesis, we analyzed Col2.3-GFP expression in vivo and in heterotopic implants seeded with bone marrow stromal cells derived from WT or TG mice. For in vivo analysis, femurs were harvested, fixed, subjected to micro-computed tomography (CT) and frozen sectioned. For heterotopic implantation, WT and TG marrow was flushed from the femur and tibia and cultured in serum-supplemented MEM. After two passages, cells were seeded into Gelfoam sponges and implanted s.c. into athymic nude CD-1 mice. Implants were harvested after 8 weeks, analyzed by micro-CT, and frozen sectioned. GFP was visualized using a fluorescent microscope equipped with a motorized stage, allowing a series of contiguous high-resolution images to be obtained and concatenated into a single image. Heterotopic TG implants showed a 3-fold decrease in bone volume relative to WT controls by micro-CT. This was accompanied by a significant decrease in the area within the implant occupied by GFP-positive cells. Some TG implants were noted to contain skeletal muscle, but the origin of muscle tissue from donor versus host has not been established. In vivo, femurs showed reduced cortical thickness and decreased trabecular bone volume, accompanied by a decrease in the total GFP positive area within the trabecular bone compartment. To determine whether the intensity of GFP expression was altered, Improvision Openlab software was used to threshold GFP-expressing cells into high- and low-expressing populations. In WT femurs, 35% of GFP expressing cells were found to be high expressors, compared to only 15% of TG GFP-expressing cells. These studies demonstrate that TG mice with Col3.6 targeted expression of a dominant negative C/EBP show a cell autonomous decrease in osteogenic capacity that is associated with reduced expression of Col2.3-GFP in vivo. These findings suggest that C/EBP transcription factors may be important determinants of osteoblast differentiation and bone formation.

Transgenic Mice Expressing a Ligand-Inducible Cre Recombinase in Osteoblasts and Odontoblasts: ***A New Tool to Examine Physiology and Disease of Postnatal Bone and Tooth*****.** J. Kim*, K. Nakashima*, B. de Crombrugghe. Molecular Genetics, UT M. D. Anderson Cancer Center, Houston, TX, USA.

Disruption of genes involved in mammalian bone formation often causes embryonic lethality, hence preventing study of these genes's role in adult animals. To develop a usable tool for such study, we generated transgenic mice in which a 2.3-kb mouse *Col1a1* proximal promoter, which is active in all osteoblasts, drives a transgene coding for a polypeptide consisting of Cre recombinase fused to a mutated ligand-binding domain of the estrogen receptor. Cre-mediated DNA recombination was analyzed in the offspring of crosses between these *Col1a1-CreERT2* mouse lines and *ROSA26* reporter mice. Administration of 4-hydroxytamoxifen induced Cre-mediated recombination detected by X-gal staining in osteoblasts in all bones and in odontoblasts in teeth of postnatal mice. Hence, these transgenic mice provide a useful tool with which to study the function of specific genes in bone and tooth in intact animals after birth. We are now using these *Col1a1-CreERT2* mice to study the role of the transcription factor *Osterix* (*Osx*) in bone physiology after birth. *Osx* is needed for bone formation and osteoblast differentiation but *Osx*-null mice die in the immediate perinatal period. We, therefore, generated mice with a conditional allele of *Osx* in which detection of the *Osx* gene is linked to *EGFP* expression. In mice heterozygous for this *Osx* allele, *EGFP* expression recapitulates the expression of *Osx* after Cre-mediated deletion of the *Osx* gene. The characterization of mice in which *Osx* is deleted after birth will be discussed.

Expression of Nitric Oxide Synthase Isoforms in Human Dental Pulp Cells. P. D. Damoulis[1], L. Suri*[2], E. Gagari*[3]. [1]Periodontology, Tufts University, Boston, MA, USA, [2]Orthodontics, Tufts University, Boston, MA, USA, [3]Oral and Maxillofiacial Pathology, Tufts University, Boston, MA, USA.

Cells derived from human dental pulp (HDP) exhibit phenotypic characteristics similar to multipotent bone marrow-derived stromal cells, including the capacity to form mineralized nodules (Gronthos, S. et al, PNAS 97:13625-13630, 2000). Given the recent evidence implicating nitric oxide (NO) as an important mediator in osteoblast differentiation, the goal of this study was to compare the patterns of expression of type III (endothelial) and type II (inducible) NO synthase (NOS) in mineralizing and non-mineralizing (control) HDP cultures. Cells were cultured in αMEM for 44 days with medium changes every 3 days, starting at d2. Mineralization was induced by ascorbic acid and β glycerol phosphate supplementation at every medium change. Assays were performed every 6 days, starting with d14. Since expression of type II NOS requires cytokine stimulation, a cocktail of TNFα (25 ng/mL) + IL-1β (25 ng/mL) + IFNγ (50 ng/mL) was added to the respective groups 48 hours before each assay time point. NOS expression was assessed through Western analysis (for types II and III) and nitrite content in the conditioned media (Griess assay, sensitive for type II activity only). Cell number was evaluated through total protein content. Alkaline phosphatase (AlP) activity was also monitored, whereas mineralization was assessed through alizarin red staining. Control cultures showed relatively stable protein content with low AlP activity and no evidence of mineralization. Expression of type III NOS was constant throughout the culture period with minor fluctuations. Cytokine stimulation in the control cultures did not result in type II NOS expression or any measurable nitrite in conditioned media. Interestingly, cytokines appeared to down-regulate type III NOS expression at d14 and d20 only. In contrast, mineralizing cultures showed a sharp drop in protein content on d32, which coincided with peak AlP activity and the onset of mineralization. At the same time point, type II NOS expression was abrogated. Cytokine stimulation did elicit nitrite release in conditioned media and concomitant type II NOS expression but only after mineralization had been initiated. These results indicate an inverse correlation between type II and type III NOS expression in HDP cultures. This is particularly evident under mineralizing conditions, where the cells appear to be primed for cytokine-mediated type II NOS induction. This interplay in the expression of the two NOS isoforms at various stages of osteoprogenitor cell maturation is a novel finding that could provide significant insight in the role of nitric oxide during bone development and healing.

Plasticity in Adipogenic and Osteogenic Differentiation Pathways using Human Bone Marrow Derived Mesenchymal Stem Cells. T. Schilling*, U. Noeth*, J. Schneidereit*, F. Jakob*, N. Schuetze. Molecular Orthopaedics, Orthopaedic Institute, Wuerzburg, Germany.

Expansion of adipose tissue in bone marrow at the expense of osteogenesis is age-related and may contribute to osteoporosis and osteonecrosis. The molecular basis for this phenomenon is largely unknown. We aimed to establish a cell culture system which allows for reprogramming (transdifferentiation) of osteoblasts into adipocytes and vice versa during differentiation pathways originating from human mesenchymal stem cells (hMSCs). Cells were isolated from the femoral head of patients undergoing total hip arthroplasty. For transdifferentiation of osteoblasts into adipocytes hMSCs were cultured in osteogenic medium for 2 weeks. Alkaline phosphatase (AP) staining revealed a homogenous increase

in expression. Osteocalcin and AP were highly expressed by RT-PCR analysis. These committed osteoblasts were then cultured in the adipogenic medium for 2 weeks resulting in a homogenous oil-red O staining. Direct adipogenic differentiation of hMSCs performed in parallel displayed the same homogenous staining. After adipogenic transdifferentiation of the committed osteoblasts no RNA markers for osteoblasts remained detectable whereas the lipid markers (lipoprotein lipase and peroxisome proliferator activated receptor gamma2) were highly expressed. For transdifferentiation of adipocytes into osteoblasts the hMSCs were cultured in adipogenic medium for up to 2 weeks in which differentiation into adipocytes was controlled by RT-PCR analyses and stainings. Thereafter cells received the osteogenic medium for 4 weeks resulting in marked deposition of mineral (alizarin red staining) and expression of osteoblast markers in RT-PCR analysis. Some adipocytes however, did not respond to the osteogenic medium since residual lipid markers were still detectable. Our results indicate that the plasticity between osteogenesis and adipogenesis extends into the differentiation pathways of osteoblasts and adipocytes . The transdifferentiation process of committed osteoblasts into adipocytes was as efficient and followed the same kinetics as the direct differentiation of adipocytes from hMSCs. Since the molecular mechanisms of this reprogramming phenomenon are unknown, cell culture systems could provide the basis for the elucidation of the underlying molecular pathways. Thereby, novel targets could be detected for therapeutic interventions in order to stimulate osteogenesis.

Low Passage MC3T3-E1 Cells: Proliferation, Alkaline Phosphatase Production And Regulation By Prostaglandins During Osteogenesis In Vitro. W. J. Peterson[1], D. T. Yamaguchi[2]. [1]Grecc 691/11g, Greater Los Angeles Healthcare System and UCLA School of Medicine, Los Angeles, CA, USA, [2]Research Service 691/11g, Greater Los Angeles Healthcare System and UCLA School of Medicine, Los Angeles, CA, USA.

The MC3T3-E1 cell line is a well-known model for studying bone formation in vitro. Since these cells are immortalized but non-transformed, it is commonly assumed that their capacity for proliferation and differentiation is unlimited. However, recent studies revealed that high passage cells show decreased proliferation and differentiation suggesting that MC3T3-E1 cells may go through a form of replicative senescence. It is conceivable that each time these cells are passaged, small changes occur that make them different from their ancestors of previous passages. Thus, even low passage cells would be expected to reveal evidence of small changes during serial passage and assessment of proliferation and differentiation. To test this hypothesis, we initiated experiments to assess passage-related change in cell proliferation and differentiation and to compare the activity and function of 2 selected subpopulations of low passage cells separated by 8-9 passages. In the latter study, we assess the importance of kinetics and seeding density on proliferation and alkaline phosphatase production during osteogenesis in vitro. Also, co-cultures were established to assess suppression and the role of prostaglandins in the suppression. Data are expressed as the mean ±SE. The results show that once MC3T3-E1 cells are placed into culture, decreased proliferation and alkaline phosphatase production are observed in 11-12 passages and 5 passages, respectively. Comparison of p23 and p30-31 cells reveal that: (1) Day 9 is the optimal time for maximal cell number and alkaline phosphatase production in cultures where the seeding density ranged from $0.25 \times 10^4/cm^2$ to $2 \times 10^4/cm^2$; (2) Seeding density does not affect maximal cell number; (3) A direct relationship exists between seeding density and alkaline phosphatase production; (4) P30-31 cells do not suppress proliferation and alkaline phosphatase production by p23 cells in co-culture; (5) The number of cells per cm^2 in cultures of p23 and p31 cells treated with indomethacin reached 78% and 79% of control, respectively; (6) nM of alkaline phosphatase per 10^6 cells in cultures of p23 and p31 cells treated with indomethacin reached 133%and 236% of control, respectively. These results suggest that (a) replicative senescence begins early in the life history of MC3T3-E1 preosteogenic cells; and that (b) the diminishing ability of low passage cells to undergo proliferation and alkaline phosphatase production is mediated by prostaglandins acting through intracellular pathways.

Local Release of a Prostanoid Receptor EP4 Agonist with rhBMP-2 Enhances Bone Morphogenetic Protein-Induced Bone Formation. H. Toyoda*[1], H. Terai[1], R. Sasaoka*[1], K. Oda*[2], K. Takaoka[1]. [1]Orthopaedic Surgery, Osaka City University Graduate School of Medicine, Osaka, Japan, [2]Ono Pharmaceutical Co., Ltd., Osaka, Japan.

Recombinant human bone morphogenetic protein (rhBMP), will tend to be utilized widely to repair damaged bones or bone defects in the fields of orthopedic surgery. However, one major problem is the large amount of rhBMP required for clinical use in human. In order to improve the performance of rhBMP, we have sought agents to enhance the bone-inducing activity of BMP. We have reported the mass of ossicles induced by BMP was significantly augmented by systemic administration of prostaglandin E EP4 agonist, especially administrated in the initial phase of bone formation. We postulated the local release of EP4 agonist with BMP might enhance bone formation without adverse events induced by systemic administration. In this study, we investigated the effects of EP4 agonist when released locally with rhBMP.

As a drug delivery system, a block co-polymer composed of poly-D,L-lactic acid with random insertion of p-dioxanone and polyethylene glycol (PLA-DX-PEG, Taki Chemical Co., Ltd.) was used. The polymer is biodegradable and absorbed within 2 weeks. Polymer disks containing several amounts of rhBMP-2 (Yamanouchi Pharmaceutical Co., Ltd.) and EP4 agonist were prepared and implanted into the left dorsal muscle pouch of the respective mouse. To examine the dose dependent effects of EP4 agonist, total 20 mice were divided into 4 groups (1. BMP 5µg, EP4 0µg, 2. BMP 5µg, EP4 3µg, 3. BMP 5µg, EP4 30µg, 4. BMP 5µg, EP4 300µg). To examine the effect of EP4 agonist alone, 300µg of EP4 agonist was added to the polymer without rhBMP-2 (group 5). One, 2 and 3 weeks after surgery, body weight was measured. Implants were harvested and served for following morphological, radiological and histological analyses at 3 weeks after surgery.

No significant difference in body weight was noted among the groups. Ectopic ossicles induced by BMP were harvested from the implanted site at 3 weeks. However, no bone formation was recognized in the group 5. On DXA analysis, bone mineral contents (BMC) of ossicles were dose-dependently higher in the group 2, 3 and 4 (9.36 ± 1.89 mg, 14.21 ± 1.27 mg, 18.75 ± 2.31 mg respectively) than those in the group 1 (6.52 ± 0.80 mg). The mean BMC value of the group 4 was approximately 3-fold higher than that of the group 1. Conclusively, EP4 agonist can enhance bone-inducing activity of rhBMP-2 without apparent systemic adverse effect when added to the rhBMP delivery system. This approach might be useful tool to improve the performance of the rhBMP-2 in the clinical practice.

High Affinity Leptin Receptors Are Present In Human Mesenchymal Stem Cells (MSCs) Derived From Control And Osteoporotic Donors. J. P. Rodriguez, R. Hess*, A. M. Pino*, S. Ríos*, M. Fernández*. Laboratory of Cell Biology, INTA - University of Chile, Santiago, Chile.

There are disparate observations on central and peripheral effects of leptin, but several studies consistently support its role as a link between fat and bone. Bone marrow stroma contains mesenchymal stem cells (MSCs), which differentiate into osteoblasts and adipocytes, among others cell phenotypes. In this study we assessed the expression of leptin receptors protein in MSCs obtained from control and osteoporotic postmenopausal donors and their change during osteogenic and adipogenic differentiation. Also we assessed the effects of leptin on osteogenic and adipogenic differentiation of these cells. For this, MSCs were isolated from bone marrow obtained from both type of donors and maintained in culture in DMEM suplemented with 10% fetal bovine serum, at 37ºC in an humidified atmosphere of 5% CO_2. Specific binding of ^{125}I-leptin by cells was measured by competition studies using increasing amounts of recombinant human leptin. To determine the effect of leptin on osteogenic and adipogenic differentiation, MSCs were cultured in the presence or absence of 1 µg/ml of leptin in osteogenic and adipogenic culture conditions. In this study, we demonstrated high affinity leptin binding (IC_{50} = 0.4 +/- 0.09 nM) in both types of cells. Binding was very low under basal, but increased significantly (2-3 times) through osteogenic and adipogenic differentiation. Osteoporotic MSCs showed lower leptin binding capacity than control cells at an early osteogenic and adipogenic differentiation time, which could restrict cell sensitivity to the protective action of leptin. In this regard, we observed that leptin significantly inhibited (60%) the adipocyte differentiation in control but not in osteoporotic MSCs, while it exerted a low stimulatory effect on calcium deposition (10-20%) in both types of MCSs. In summary, we report the presence of high affinity leptin receptors on control and osteoporotic MSCs which were modified distinctly by osteogenic and adipogenic stimulation. Also we demonstrated a direct and distinct effect of leptin on both type of cells.

Induction of Multipotent Stem Cells through Dedifferentiation of Mesenchymal Cells by Msx2 Protein Transduction. C. Shinotsuka*[1], A. Hishiya*[1], K. Mizuno*[1], H. Aburatani*[2], K. Ikeda[1], K. Watanabe[1]. [1]Department of Bone & Joint Disease, National Center for Geriatrics & Gerontology, Obu, Japan, [2]Research Center for Advanced Science and Technology, The University of Tokyo, Tokyo, Japan.

Limited availability of stem cells poses a major problem in regenerative medicine and tissue engineering. It has recently been reported that ectopic expression of homeoprotein Msx induces dedifferentiation of terminally differentiated cells (Cell 2000) as well as suppression of adipogenesis (JBC 2003). In the present study we have attempted to generate multipotent stem cells from terminally differentiated cells, such as adipocytes, using Msx protein transduction technology. First, to clarify the underlying mechanism of Msx2-induced dedifferentiation, we employed Msx2-ER (estrogen receptor) system whose activity is controlled by tamoxifen. We generated osteoblastic KUSA-A1 cell lines that express Msx2-ER, and confirmed nuclear import of Msx2-ER fusion protein in response to tamoxifen treatment. Alkaline phosphatase activity was decreased in tamoxifen-treated KUSA/A1 cells expressing Msx2-ER, but not in mock-transfected cells. Total RNA was extracted from Msx2-ER- or mock-transfectants treated either by tamoxifen or ethanol vehicle, and analyzed by GeneChip (Affymetrix). Genes whose expression was decreased after induction of Msx2 function included periostin, sFRP2, osteoglycin and natriuretic receptor 3, whereas mRNA expression of cyclinD1 GADD45 and serpin 6 was upregulated. For application of Msx2, protein transduction (PTD) technique was employed. Msx2 protein with a protein transduction peptide (TAT) was produced as GST fusion protein in bacteria, and GST portion was removed by Precision protease treatment and GSH-Sepharose. Purified TAT-Msx2 protein was added to culture media, and protein transduction was confirmed by indirect immunocytochemistry and western blotting. Within 2 hr of application, TAT-Msx2 protein was readily detected in the nucleus of ~70% of cells. To determine whether TAT-Msx2 possesses dedifferentiation-inducing activity, PTD was applied to myotubes terminally differentiated from C2C12 cells. As a result, the morphology of myotubes changed and some population started proliferating. The PTD of TAT-Msx2 was also effective in inhibiting adipogenesis in vitro. Thus, Msx2-mediated dedifferentiation may be useful for generating multipotent stem cells that can then be diverted to osteogenic or chondrogenic lineages.

Comparison of Bone Marrow Aspiration and Bone Core Biopsy as Methods for Harvest and Assay of Human Connective Tissue Progenitor. C. Nakamoto*, C. Boehm*, J. H. Tao*, K. Powell*, G. F. Muschler. Biomedical Engineering, Lerner Research Institute, The Cleveland Clinic Foundation, Cleveland, OH, USA.

Adult bone marrow and bone tissue contain connective tissue progenitors (CTPs), which can differentiate into a variety of connective tissues. The design and selection of optimal clinical methods for harvest and assay of CTPs has general relevance. Bone or bone marrow harvested from the iliac crest is currently the most commonly utilized tissue source for CTPs. However, little is known about the variation in CTP localization or concentration within human bone and marrow tissue. This study was designed to characterize the location of CTPs within human cancellous bone from the iliac crest.

Bone marrow aspirates (BM fraction) and 7 mm diameter transcortical iliac crest bone core were obtained from 10 human subjects undergoing elective hip arthroplasty procedures. Cells contained within the cancellous bone core samples were separated into those cells that could be easily suspended from the marrow space using mechanical agitation (MS fraction) and those cells that could only be liberated from the remaining trabecular bone surface by collagenase digestion (TS fraction). The number and concentration of cells in the BM, MS, and TS fractions were counted. Cells in each fraction were also assayed to determine the prevalence of CTPs in an established CTP colony formation assay.

Significant variation was seen between subjects, both in the cellularity of bone and marrow tissue and in the prevalence of CTPs among liberated cells. The MS fraction contained roughly six fold more nucleated cells than the TS fraction (MS, $1.3 \pm 0.81 \times 10^8$; TS, $0.18 \pm 0.81 \times 10^8$). However, as the prevalence of CTPs was over 25 fold greater in the TS fraction (TS 306 ± 344 CTPs/10^6 nucleated cells, MS 12 ± 12 CTPs/10^6 nucleated cells), the overall distribution of CTPs was significantly greater in the TS fraction (TS, 3512 ± 2059 /ml sample; MS, 1745 ± 1891 /ml sample). Quantitative analysis of CTP colonies in the three fractions showed no significant difference in proliferation rate, however the TS fraction produced colonies with less density and larger area than the BM and MS fraction.These data suggest that more than 67 % of CTPs within bone reside on or near the trabecular surface. The number of cells and CTPs harvested by aspiration (BM fraction) was poorly correlated with the actual number of cells and CTPs in bone. This suggests that marrow aspiration may be poorly suited as a sampling strategy designed to assess the effect of age, gender, and other clinical variables on the CTP population in human bone, and that a combination of assays applied to transcortical iliac crest biopsies may be better suited to provide quantitative tissue specific information.

Mutations of *TWIST1* Lead to Decreased Proliferation of Calvarial Osteoblasts Derived from Patients with Saethre-Chotzen Syndrome. C. Ratisoontorn[1], M. L. Seto*[2], K. M. Broughton*[2], M. L. Cunningham*[3]. [1]Oral Biology, University of Washington, Seattle, WA, USA, [2]Pediatrics, University of Washington, Seattle, WA, USA, [3]Children's Craniofacial Center, CHRMC, Pediatrics & Oral Biology, University of Washington, Seattle, WA, USA.

Seathre-Chotzen syndrome (SCS) is an autosomal-dominant craniosynostosis syndrome, associated with loss-of-function mutations in *TWIST1*. Naturally occurring mutations in humans and the heterozygous null *Twist* mouse are suggestive of haploinsufficiency as the disease-causing mechanism. *TWIST1* has been implicated in the inhibition of differentiation of multiple cell lineages. Therefore, premature fusion of cranial sutures in SCS might be mediated by altered differentiation of calvarial osteoblasts. To test this hypothesis, we evaluated cells derived from calvarial bone of three patients with SCS compared with those derived from three unaffected individuals as controls to investigate the three principle stages of osteoblast differentiation: 1) proliferation, 2) matrix maturation, 3) mineralization. Using a BrdU-Hoechst flow cytometry assay, we found that the percent of proliferating cells is significantly less in cells derived from patients with SCS compared with those derived from controls ($P \leq 0.05$). In the matrix maturation stage, alkaline phosphatase (ALP) activity, and expression of extracellular matrix genes, collagen I alpha 2 (COL1A2), osteopontin (OPN) and osteocalcin (OCN), were examined by real-time quantitative RT-PCR. The ALP assay revealed that the ALP activity of cells both from SCS and controls are highest at day 3, and continually declined at days 7 and 14. However, the ALP activity of cells derived from SCS patients is significantly lower than controls at days 3 and 7($P \leq 0.05$), and declined to an insignificant difference by day 14, suggesting that cells derived from SCS patients are in a later differentiation stage. There is no significant difference in levels of expression of COL1A2, OPN, or OCN between cells derived from patients with SCS and controls at 3, 7, 14, 21, and 28 days in culture. To evaluate the third stage of differentiation, a quantitative alizarin red-S mineralization assay was performed. Although not statistically significant, we found that osteoblasts derived from patients with SCS have higher levels of alizarin red-S staining at days 21 and 28. Taken together, these results suggest that loss-of-function mutations of *TWIST1* lead to reduced proliferation and increased differentiation of calvarial osteoblasts derived from patients with SCS.

In Vitro and in Vivo Osteogenic Differentiation of FAT Cells Induced by Cbfa1 Overexpression. H. Kojima, T. Uemura. ADRC(Age Dimension Research Center), AIST (National Institute of Advanced Industrial Science and Technology), Tsukuba, Ibaraki, Japan.

As a methodology for bone tissue engineering, a technique for the transplantation of cultured bone has been developed to overcome the disadvantages of autologous bone grafts or the simple implantation of biomaterial into bone defects such as a limited bone supply for bone graft, risk of infection, insuitability for large bone defects etc. The procedure essentially involves the in vivo transplantation of MSC-derived osteoprogenitor cells/ porous ceramic composite, to form bone-like tissue, which can provide applications of tissue engineering to patients with skeletal defects. However, autologous bone marrow cells have potential limitations in the amounts of MSCs and transplantation of cultured bone is difficult for large bone defects. In this study, we examined that a population of stem cells in adipose tissue can be useful as an alternate source of MSCs. Adipose tissue is an abundant, expendable, and easily obtained tissue that may prove to be an ideal source of autologous stem cells for tissue engineering. To accelerate the process of differentiation into osteoblastic cells, we overexpressed the Cbfa1 (Core binding factor alpha-1) gene with adenovirus vector in a population of rat fibroblast like cells obtained from adipose tissue (FAT cell). Cbfa1 is known to be a key osteogenic transcription factor and was found to be indispensable for osteoblast differentiation by the finding that Cbfa1- knockout mice completely lacked osteoblasts. The in vitro results of northern blot analysis revealed that the expression of osteocalcin was induced in Cbfa1 overexpressed FAT cells. Markers of osteoblast differentiation, such as alkaline phosphatase activity, the expression of osteocalcin, and calcium content, in Cbfa1 overexpressed FAT cells were markedly greater than those of uninfected normal FAT cells. Alizarin red staining of the Cbfa1 overexpressed FAT cells showed marked mineralization compared to the infected cells. A subcutaneous implantation of porous scaffolds / Cbfa1 overexpressed cells composite resulted in rich bone formation compared to uninfected composite. These findings suggested that the overexpression of the Cbfa1 gene induced a remarkable and rapid differentiation of FAT cells into osteogenic cells in vitro and in vivo.. Our results implied that Cbfa1 overexpressed FAT cells may become an alternative stem cell source of bone marrow-derived MSCs, and these cells present a potential to provide a practical and instantaneous application for bone tissue engineering.

Calvarial Osteoblasts Transdifferentiate into Adipocytes when Treated with a Combination of PPARγ and α Activators. T. Hasegawa*[1], H. Hatano*[2], K. Tanne*[1], N. Maeda*[2], J. E. Aubin[3], Y. Yoshiko[2]. [1]Orthodontics and Craniofacial Developmental Biology, Hiroshima University, Hiroshima, Japan, [2]Oral Growth and Developmental Biology, Hiroshima University, Hiroshima, Japan, [3]Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada.

While pluripotent mesenchymal stem cells differentiate into osteoblasts, adipocytes and others, considerable evidence also supports the notion that osteoblasts and adipocytes are closely related through a common bipotential progenitor and/or transdifferentiation capacity. The PPARγ nuclear receptor regulates osteoblast-adipocyte fate choice (inducing adipocytic while inhibiting osteoblastic differentiation). However, activation of PPARγ alone appears to be insufficient to convert relatively mature osteoprogenitors such as fetal rat calvaria (RC) cells into adipocytes. To assess whether such cells can convert into adipocytes and, if they do, to determine the cellular events at single cell colony level, RC cells were cultured at very low density in osteogenic medium. Cells from developing and mature single cell colonies were subcultured (secondary cultures) and treated with a combination of PPARγ (BRL-49653) and PPARα (fenofibrate) activators or used for total RNA extraction. Amongst 112 colonies selected, 99 colonies were successfully adapted to secondary cultures and classified into four groups by double staining for osteoblasts (alkaline phosphatase) and adipocytes (oil red O). Single lineage colonies comprised 47% of colonies (osteoblasts 29%; adipocytes 18%), 21% (20 colonies) were bipotential and 32% failed to differentiate into either osteoblasts or adipocytes. To characterize the colonies with adipogenic potential, total RNA from all groups classified by staining (total 44 colonies) was amplified by cRNA synthesis and adaptor primer PCR and then subjected to semiquantitative or real time PCR. Unexpectedly, some colonies expressing osteoblast markers also expressed not only adipocytic markers (LPL and adipsin) but also markers of other lineages (*e.g.*, the chondrocyte marker sox 9), but expression profiles did not correlate with capacity for adipogenesis and osteogenesis in secondary cultures. Adipocyte differentiation was seen in 8 colonies expressing osteoblast markers (osteocalcin and/or bone sialoprotein), but these colonies also expressed high levels of either $PPAR\gamma_1$, PPARα or C/EBPα. Thus, calvarial osteoblasts express considerable potential for transdifferentiation into adipocytes in the presence of PPARγ and α activators, a lineage conversion that may be determined by whether the osteoblasts express relatively high levels of $PPAR\gamma_1$, PPARα or C/EBPα.

Combination of BMP and Runx2 Signalings Constitute the Minimum and Sufficient Unit for Osteogenic Differentiation through Regulation of Cbfb. S. Ohba*[1], T. Ikeda[1], S. Kamekura[1], F. Kugimiya*[1], F. Yano*[1], A. Lichtler[2], T. Ogasawara[1], K. Hoshi[1], K. Nakamura[1], T. Takato*[1], H. Kawaguchi[1], U. Chung[1]. [1]Univ. of Tokyo, Tokyo, Japan, [2]Univ. of Connecticut Health Ctr., Farmington, CT, USA.

Among signaling pathways that have been implicated in the control of osteogenic differentiation from precursor cells, determination of the minimum signaling unit is the most important issue to realize an ideal bone regeneration. We recently established a monitoring system for osteogenic differentiation with EGFP gene driven by bone-specific 2.3 kb rat Col1a1 promoter fragment (COL1A1GFP). Using this system, in the present study we made a comprehensive search for the minimum osteogenic unit among adenovirus-mediated putative signaling pathways: BMP signaling by constitutively active (ca) ALK6, Runx2 signaling by wild-type Runx2, Hedgehog signaling by caSmoothened, Wnt signaling by caTCF/LEF, and IGF-I signaling by wild-type IRS-1. Although no single pathway could induce GFP fluorescence in COL1A1GFP-embryonic stem (ES) cells cultured in a serum-free medium, stimulation of all pathways strongly induced it within a week. When random combinations of all pathways were exhaustively examined, only the co-transduction of caALK6+Runx2 induced GFP fluorescence as strongly as that of all stimulations, indicating that this combination is the minimum and sufficient unit for osteogenic differentiation. The expressions of osteocalcin, BSP and ALP mRNA, and matrix calcification were induced by the caALK6+Runx2 to levels similar to all stimulations in various cells including mouse ES cells, human mesenchymal stem cells, human dermal fibroblasts (DFB), and non-osteoblastic cell lines such as NIH3T3 and HeLa. In addition, transplantation of DFB transduced with caALK6+Runx2 to non-healing critical-sized defects in mouse calvariae induced bone formation *in vivo*. To further investigate the mechanism underlying the synergism of the two pathways, we transduced NIH3T3 cells with caALK6 or Runx2 or both. caALK6 did not affect the expression of endogenous Runx2, or subcellular localization or the DNA binding ability of overexpressed Runx2. Either caALK6 or Runx2 alone moderately stimulated the expression of Cbfb, a heterodimer partner of Runx2, which was not enhanced by the co-transduction. However, chromatin immunoprecipitation analysis revealed that both together, but neither of them alone, recruited Cbfb to OSE2 element in the osteocalcin promoter. These results demonstrate that BMP and Runx2 signalings constitute the minimum and sufficient unit to induce osteogenesis from various cell sources through regulation of Cbfb, suggesting a possible application to bone regenerative medicine.

Correlation Between Bone Mineral Density (BMD) and Gene Expression of OPG-RANKL of Human Osteoblast Cultures from Postmenopausal Women. S. Ruiz-Gaspà*, A. Enjuanes*, J. C. Monllau*, E. Cáceres*, M. Payes*, J. Vila*, L. Mellibovsky*, J. Blanch, I. Aymar*, A. Diez-Perez, X. Nogués. Urfoa, IMIM-Hospital del Mar, Barcelona, Spain.

Postmenopausal osteoporosis is produced by an unbalanced bone remodeling between resorption and formation. OPG-RANK-RANKL is an important regulation system of the process. There are few studies of this regulatory system trying to find a relationship between clinical and in vitro data.

Study of proliferation and OPG-RANKL gene expression in human osteoblast cultures from postmenopausal women and influence of Vitamin D3, 17-beta estradiol in this expression.

22 postmenopausal women (50 to 80 year-old) were included from orthopedic material removed during knee replacement surgery. BMD was measured by HOLOGIC QDR 4500 SL in lumbar spine and femoral neck and patients were classified according to WHO criteria in normal (six cases), osteopenic (six cases) and osteoporotic (ten cases). Human bone cells were obtained from 1 to 2 mm explants of trabecular bone of surgical specimens. Cells were grown in Dulbecco´s modified Eagle medium and 10% fetal calf serum (FCS). Cells were isolated using 0.25% trypsin and then subcultured. Osteoblasts were characterized by alkaline phosphatase activity and osteocalcin synthesis. Confluent culture were treated with: 1) 10% FCS, 2) 10-8M Vitamin D3 (Vit D), 3) 367nM 17-beta estradiol, and a culture without FCS was used as control. OPG and RANKL expression were quantified by real time PCR. Statistical analysis was performed using the SSPS 11.5 software.

Osteoblast proliferation was not different between normal, osteopenic and osteoporotic groups. OPG and RANKL expression levels in human osteoblasts of osteoporotic women were lower than normal and osteopenic women ($p<0.0001$, $p=0.01$). When cultures were supplemented with FCS, OPG expression levels were lower in all cultures ($p=0.012$). After adding Vit D3 and 17-beta estradiol expression levels of OPG were lower but not reached statistically significance whereas expression levels of RANKL were not influenced.

We confirm in vitro the relevance of OPG-RANK-RANKL regulation system since osteoblasts in culture, from osteopenic and osteoporotic postmenopausal women, express decreased levels of OPG and RANKL. Addition of Vitamin D3 and 17-beta estradiol seem not to affect the expression of OPG and RANKL in this experiment.

Subchondral Osteoblasts from Osteoarthritic Patients Show Abnormal Expression and Production of Leptin: Possible Role in Cartilage Degradation. D. Lajeunesse[1], A. Delalandre*[1], J. C. Fernandes*[2]. [1]Medicine, CRCHUM, Hôpital Notre-Dame, Montréal, PQ, Canada, [2]Surgery, Hôpital Sacré-Coeur, Montréal, PQ, Canada.

Leptin is a peptide hormone with a role in body weight regulation, immune response, bone metabolism and possibly in rheumatic diseases. Osteoarthritis (OA) is characterized by cartilage damage and loss, synovial membrane inflammation and bone sclerosis and the formation of osteophytes. It is now evident that the subchondral bone tissue plays a prominent role in the pathophysiology of osteoarthritis (OA), a situation that is related to abnormal osteoblast (Ob) differentiation. Leptin can promote the differentiation of osteoblasts (Ob), however, a direct role for leptin in human OA has yet to be demonstrated. We prepared primay cultures of normal and OA Ob from subchondral bone and OA chondrocytes from articular cartilage from tibial plateaus removed for knee replacement surgery of OA patients or at autopsy. We determined the expression and production of leptin using RT-PCR and ELISA. Our results indicated using two different sets of primers for RT-PCR experiments, that leptin was expressed only in Ob not in chondrocytes. The expression of leptin was also higher in OA Ob compared to normal using real-time PCR and was responsible for the increase in leptin levels noted in conditioned-media from OA Ob. Although leptin was not expressed by chondrocytes, it was present in articular cartilage suggesting that leptin produced in bone tissue reached the overlaying cartilage. The long-form leptin receptor mRNA levels were similar between normal and OA Ob. Since leptin can promote the differentiation of Ob, we next questionned if the observed increase in alkaline phosphatase activity (ALP) and osteocalcin release (OC) observed in OA Ob was linked with their endogenous leptin production. Inactivating antibodies against the leptin receptor reduced both ALP and OC in OA Ob about 35%. Leptin expression was regulated in OA Ob by $1,25(OH)_2D_3$, transforming growth factor-beta 1 (TGF-beta 1) and hepatocyte growth factor (HGF). Indeed, TGF-beta 1 reduced leptin expression whereas both $1,25(OH)_2D_3$ and HGF increased leptin expression. These results indicate that OA Ob produce more leptin than normal, and that leptin found in articular cartilage is derived from bone tissue. The increase in leptin in OA bone tissue is responsible for increased ALP and OC of Ob. Since leptin can promote inflammation and cartilage loss in combination with cytokines, this suggests that subchondral bone production of leptin may be responsible, at least in part, of cartilage loss in OA.

Expression of Voltage Sensitive Calcium Channel (VSCCs) L-type α_{1C} ($Ca_v1.2$) and T-type α_{1H} ($Ca_v3.2$) Subunits during Mouse Bone Development. Y. Shao*, M. Alicknavitch*, M. C. Farach-Carson. Department of Biological Sciences, University of Delaware, Newark, DE, USA.

Plasma membrane VSCCs serve as key regulators of Ca^{2+} permeability including regulation of secretion of paracrine activators of osteoclastogenesis. In osteoblasts, L-type VSCCs consist of a pore forming α_1 subunit, a disulfide-linked $\alpha_2\delta$ dimer, and an intracellular β subunit. Subunit composition plays an important role in fine-tuning of VSCC expression and function. Osteoblasts express as the major L-type channel α_{1C} ($Ca_v1.2$), and two T-type channels α_{1G} ($Ca_v3.1$) and α_{1H} ($Ca_v3.2$). However, only α_{1C} and α_{1H} are regulated by treatment of osteoblasts with 1,25-dihydroxyvitamin D_3. We used a combination of approaches to investigate the α_{1C} and α_{1H} subunit expression in both developing mouse long bones, and in differentiating *in vitro* models of osteogenesis and chondrogenesis, the MC3T3-E1 and ATDC5 cells, respectively. Immunohistochemical studies showed α_{1C} subunits were present in regions of rapid growth, including in the perichondrium, periosteum, chondro-osseous junction and along the surfaces of newly formed trabecular bones throughout various mouse bone developmental stages. Interestingly, α_{1H} subunit expression followed a similar distribution pattern as seen for the α_{1C} subunits, suggesting the coordination of L-type α_{1C} and T-type α_{1H} VSCCs in regulating osteoblastic functions. Western Blot analysis also identified the expression of α_{1C} and α_{1H} subunits in total protein extracts from MC3T3-E1 cells, and the protein level decreased during osteoblastic differentiation. Immunostaining of these cells during growth and differentiated phases confirmed these findings and suggested that subunit assembly is also important. Co-immunoprecipitation and subsequent Western Blot analysis indicated β_2 and β_3 subunits, but not β_1 and β_4, assembled with α_{1C} subunits in growth phase MC3T3-E1 cells. Similar studies are underway with differentiating ATDC5 cells. Our findings support the conclusion that VSCCs in osteoblasts are critical components of growth and development of new bones. Ongoing studies utilize fluorescent resonance energy transfer (FRET) to further investigate the interaction between α_1 subunit and the accessory subunits in functional VSCC complexes in intact bone, as well as in both MC3T3-E1 and ATDC5 cells.

Responses of MC3T3-E1 Osteoblast Cells to Parathyroid Hormone Are Dependent on Differentiation Stage and Duration of Treatment. R. J. Arends*, P. E. J. Langerwerf*, T. M. C. van de Klundert*, M. van Beuningen*, M. van Duin*, A. G. H. Ederveen. Pharmacology, N.V. Organon, Oss, Netherlands.

To select new anabolic drugs for the treatment of osteoporosis, a functional assay is required to predict anabolic effects *in vitro*. Parathyroid hormone (PTH) exerts an anabolic effect *in vivo* when administered intermittently. However, the effect of PTH on mineralization of osteoblasts *in vitro* is less consistent. We studied the effects of different treatments of PTH to various differentiation stages of MC3T3-E1 cells on cAMP signaling and mineralization of extra-cellular matrix in long-term (25 days) cultures, in order to build a functional anabolic assay *in vitro*.

The mRNA expression of the PTH receptor-1 (PTH1R) was quantified using real time PCR. Moderate PTH1R mRNA levels were detected during the culture period and the levels start to increase 3 days after stimulation with 50 μg/ml ascorbic acid (AA) and 10 mM β-glycerol phosphate (βGP) up to 15 times basal levels (day 25). Under these culture conditions MC3T3-E1 cells differentiate and mineralization starts around day 14. Changes in intracellular cAMP levels were found in response to PTH treatment indicating that a functional PTH-induced signaling mechanism is present in differentiating MC3T3-E1 cells.

To study the effects of PTH (10-13 to 10-6M) on mineralization of MC3T3-E1 cells, we exposed long-term cultures for various time periods to different treatments. Cells were cultured in the presence of AA and βGP and exposed to PTH during 1-25, 11-25, 14-25, 17-25 or 21-25 days. The cultures were performed in triplicate and in parallel treated; (a) for 6 h with PTH followed by 42 h fresh medium, (b) 24 h PTH followed by 24 h fresh medium or (c) 48 h PTH. Culture medium was refreshed every 48 h. Mineralization on day 25 was quantified using a calcein method.

A 6 h PTH pulse (a) given from day 1-25 inhibited mineralization around 50%, whereas (a) given from day 11, 14, 17 or 21 had little (<20%) or no effect on mineralization (day 25). A 24 h PTH pulse (b) from day 1-25, 11-25 or 14-25 inhibited mineralization more than 35%. On the other hand, when (b) started on day 17 or 21 no effects were found (day 25). Continuous exposure (c) of MC3T3-E1 cells to PTH from 1-25 days did not change mineralization, whereas when (c) started at day 11 (just before mineralization starts) a 25% inhibition of mineralization was measured. When (c) started on day 14 or 17 it had no effect, whereas when PTH was given on day 21-25 a 20% increase in mineralization was found.

These data indicate that it is unclear how to predict anabolic effects *in vitro* on mineralization by MC3T3-E1 cells. The effect of PTH on mineralization by MC3T3-E1 cell is dependent on the differentiation stage of the cells and on the duration of treatment.

Mice Lacking Phosphatidylinositol Transfer Protein-alpha (PITP-alpha) Display Bone Formation Defect. Z. Zhou*, H. Yang*, X. Feng, W. Xiong. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

Phosphatidylinositol transfer proteins alpha (PITPa) is a protein essential for phosphatidylinositol signaling. Reduction of PITPa expression in mice leads to aponecrotic spinocerebellar disease, hypoglycemia, and intestinal and hepatic steatosis. The role of PITPa and PITPa dependent phosphatidylinositol signaling in bone remodeling is unclear. We have characterized the potential role of PITPa in regulating bone metabolism by using PITPa -/- mice. The reduced bone density and decreased cortical and trabecular bone areas and volumes have been observed in PITPa mutant mice. While osteoclasts derived from PITPa mutant mice show normal bone resorptive function, osteoblasts isolated from the mutant mice exhibit reduced cell proliferation and differentiation. We are in the process to further characterize the phenotype and to understand the underlying mechanism.

Transfer of 128-kb BMP-2 Genomic Locus by HSV-Based Infectious BAC Stimulates Osteoblast Differentiation: A Platform for Functional Genomic Studies. W. Xing, D. J. Baylink, C. Kesavan*, S. Mohan. JLP VAMC/LLU, Loma Linda, CA, USA.

In order to localize chromosomal regions and subsequently identify the genes responsible for musculoskeletal diseases, we previously developed mouse genetic models and discovered quantitative trait loci (QTL) in a number of mouse chromosomes that contribute to phenotypes such as bone density, size and strength. Subsequent analyses of the congenic mice further confirmed and narrowed two predominant QTLs that regulate BMD to < 5 cM regions in mouse chromosome 1. However, these regions contain dozens of genes and are still difficult to clone by time-consuming, expensive positional cloning strategies. A feasible and efficient approach for identifying candidate genes is to transfer the genomic loci of overlapping bacterial artificial chromosomes (BACs) or P1 artificial chromosomes (PACs) encompassing the QTL regions into bone cells in vitro for a high throughput functional screening. In this study, we retrofitted a BAC construct into herpes simplex virus-1 (HSV-1) amplicon and packaged it into an infectious BAC (iBAC) to test gene function in a cell-based system, using a 128-kb clone containing the complete bone morphogenetic protein-2 (BMP-2) gene. We transduced MC3T3-E1 cells with the iBAC bearing BMP-2 and examined transduction efficiency, transgene expression and function. Our experiments revealed that approximately 84% of MC3T3-E1 cells were transduced by the iBAC at a multiplicity of infection (MOI) of 5. The amount of BMP-2 protein was estimated to be 10 ng per 10^6 cells 24 hours after infection of HSV amplicon containing BMP-2 genomic locus. Like the cells treated with 200 ng/ml recombinant human BMP-2, about 20% of the osteoblast cells were differentiated and exhibited positive ALP-staining 9 days post-infection. No ALP-positive cells were seen in the control cells infected with HSV-1 mock amplicon without BMP-2 genomic locus. Our results have indicated that an iBAC can efficiently deliver a BMP-2 genomic locus into preosteoblast cells and express functional BMP-2 protein, stimulating a phenotype of cell differentiation. Therefore, this experimental system provides a rapid, efficient cell-based model of high-throughput phenotypic screening to identify the BAC clones from physically mapped regions that are important for osteoblast differentiation. Because multiple copies of BAC clones can be transferred into the target cells depending on the amount of HSV used, the BAC clone approach also provides a sensitive platform for studies on gene function, gene expression and for identification of gene regulatory elements that are located in the intronic regions.

Osteoblast Differentiation Is Regulated by CaMKII and Mediated by *c-fos* Expression. M. Zayzafoon, J. M. McDonald. Department of Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

CaMKII (Ca^{2+}/calmodulin-dependent protein kinase II) was previously thought to be exclusively expressed in neuronal tissue. However, it has been recently shown that the expression of CaMKII is not limited to the brain and that it plays a critical role in regulating various signaling pathways leading to modulation in several aspects of different cellular functions, including cytoskeleton structure, cell shape and gene expression. The purpose of this study was to examine the expression of CaMKII in osteoblast-like cells (MC3T3-E1) and to elucidate its role in osteoblast differentiation. Here we demonstrate by RT-PCR, Western blotting and immunofluorescence that the alpha-CaMKII gene and protein are expressed in osteoblasts both *in vitro* and *in vivo*. Inhibition of CaMKII by calmodulin or CaMK inhibitors (TFP or KN-93 respectively) resulted in inhibition of osteoblast differentiation, demonstrated by decreased alkaline phosphatase (ALP) activity and mineralization, as well as a 5- and 2-fold decreases in ALP and osteocalcin gene expression, respectively. Incorporation of [^{3}H]-Thymidine was not affected by this treatment, suggesting that the inhibition of differentiation is not due to a decrease in proliferation. We also demonstrate, using the newborn mouse calvaria *in vivo* model, that treatment with TFP and KN-93 causes a 41% and 31% decrease in osteoblast number and mineralization, respectively. In order to elucidate the potential mechanism by which CaMKII regulates osteoblast differentiation, we examined signaling pathways and their downstream transcription factors known to play a role in osteoblast differentiation. TFP and KN-93 decrease the phosphorylation of alpha-CaMKII, ERK and CREB leading to a 31% and 48% decrease in the transactivation of SRE and CRE, downstream response elements of ERK and CREB respectively. The promoter of *c-fos*, a member of the family of activating protein-1 (AP-1), is regulated by SRE and CRE. Inhibition of CaMKII by TFP or KN-93 decreases the expression of *c-fos* and AP-1 transactivation. In addition, EMSA results show that TFP and KN-93 decrease both CRE and AP-1 DNA binding. Supershift analyses confirm that the decrease in AP-1 DNA binding is a result of decrease in c-Fos. Our findings demonstrate that CaMKII is expressed in osteoblasts and is involved in *c-fos* expression through regulation of SRE and CRE. Inhibition of CaMKII results in decrease in *c-fos* expression and AP-1 activation leading to inhibition of osteoblast differentiation.

Diosgenin Stimulates Angiogenesis via Up-regulation of Osteoblast-Derived Vascular Endothelial Growth Factor-A. M. Yen[1], J. Su*[2], W. Chen*[2], M. Kuo*[2]. [1]Departments of Obstetrics and Gynecology , Departments of Primary care Medicine, College of Medicine, National Taiwan University, Taipei,, Taiwan Republic of China, [2]Institute of Toxicology, College of Medicine, National Taiwan University, Taipei,, Taiwan Republic of China.

Diosgenin, a steroidal saponin that is extracted from the root of Wild Yam (Dioscorea villosa), has been reported to have tremendous medical applications. Angiogenesis is a critical process during bone formation and fracture healing and vascular endothelial growth factor-A (VEGF-A) is an important angiogenic factor produced in a regular manner by many cell types, including osteoblasts. The aim of the present study was to examine whether diosgenin modulates VEGF-A expression in osteoblasts and promote angiogenesis. In murine MC3T3-E1 preosteoblast-like cells, we found that VEGF-A expression was significantly elevated in response to diosgenin. Conditioned media of MC3T3-E1 cells treated with diosgenin also induced a strong angiogenic activity in either *in vitro* nor *ex vivo* assay, which were blocked by VEGF-A specific neutralizing antibody. At the mechanistic level, we found that diosgenin treatment activated the Akt and p38 MAPK. The use of pharmacological inhibitors or genetic inhibition by transfection with the dominant-negative (DN)-Akt or DN-p38 plasmids revealed that both Akt and p38 MAPK signalings are involved in diosgenin-mediated VEGF-A up-regulation. Furthermore, we found that diosgenin-treated MC3T3-E1 cells showed an increased hypoxia-inducible factor-1α(HIF-1α) protein in the nucleus. Blockage of HIF-1α activity by transfection with a DN-HIF-1αexpression vector significantly abolished diosgenin-induced VEGF-A up-regulation, suggesting that diosgenin-induced VEGF-A expression was HIF-1α-dependent. Taken together, our results provided evidence that diosgenin up-regulates VEGF-A and promotes angiogenesis in preosteoblast-like cells by a HIF-1α-dependent mechanism involving the activation of Akt and p38 MAPK signaling pathways.

Fluid Shear Stress Synergizes with IGF-I on Osteoblast Proliferation Through Integrin-Dependent Activation of IGF-I Receptor. K. H. W. Lau, S. Kapur, D. J. Baylink. Musculoskeletal Disease Center, Jerry L. Pettis Mem VAMC, Loma Linda, CA, USA.

Mechanical strain increases osteoblast proliferation. Recent studies suggested that mechanical strain has a permissive role in the IGF-I mitogenic action in osteoblasts. The present study tested the hypothesis that mechanical strain interacts with the IGF-I pathway in the stimulation of osteoblast proliferation ([^{3}H]Thymidine incorporation, TdR). Human TE85 osteosarcoma cells were subjected to steady shear stress of 20 dynes/cm^2 for 30 min followed by 24-hr incubation with IGF-I (0 to 50 ng/ml). IGF-I increased TdR (1.5- to 2.5-fold, $p<0.01$) in a dose-dependent manner. Shear stress alone increased TdR by 70% ($p<0.01$). The combination of shear stress and IGF-I stimulated TdR (3.5- to 5.5-fold) much greater than the additive effects of each treatment alone (ANOVA), suggesting a synergistic interaction. IGF-I dose-dependently increased the phosphorylation level of Erk1/2 (1.2- to 5.3-fold) and IGF-I receptor (IGF-IR) (2- to 4-fold). Shear stress alone also increased the phosphorylation Erk1/2 and IGF-IR (2-fold each). The combination treatment resulted in synergistic enhancements in both Erk1/2 and IGF-IR phosphorylation (up to 12-fold for Erk1/2 and 8-fold for IGF-IR). Shear stress did not alter the binding affinity or number of IGF-IR, indicating that the synergy occurred at the post-ligand binding level. Recent studies have implicated a role for integrin in the regulation of IGF-IR phosphorylation and activation of IGF-I signaling mechanism (i.e., integrin activation recruits away SHP-2 from the IGF-IR, allowing sustained IGF-IR phosphorylation and activation). To test the hypothesis that the synergy between IGF-I and shear stress involve integrin-dependent mechanisms, we measured the effect of echistatin (an inhibitor of integrin) on TdR in response to shear stress ± IGF-I. Echistatin reduced basal TdR by 60%, and slightly but not significantly reduced the mitogenic response to the shear stress (173±16% vs. 157±20% of control). However, echistatin completely abolished the mitogenic effect of IGF-I and that of the combination treatment, indicating that the IGF-I action and the synergy between shear stress and IGF-I involves integrin activation. Shear stress also significantly ($p<0.05$ for each) reduced the amounts of SHP-1 and SHP-2 co-immunoprecipitated with IGF-IR, supporting that the synergy involves the integrin-dependent recruitment of SHP-1 or -2 away from IGF-IR. In conclusion, shear stress interacts synergistically with the IGF-I signaling pathway in osteoblast proliferation and this interaction involves integrin-dependent upregulation of IGF-IR phosphorylation and activation

A Novel Target For Calcimimetics In Osteoblasts Lacking CASR. M. Pi[1], D. Martin[2], L. D. Quarles[1]. [1]Internal Medicine, University of Kansas Medical Center, Kansas City, KS, USA, [2]Amgen, Inc, Thousand Oaks, CA, USA.

The phenylalkylamine NPS-568 is an allosteric modulator of the G-protein coupled calcium sensing receptor, CASR. NPS-568R binds to CASR and increases its sensitivity to extracellular calcium, whereas NPS-568S is the less active stereoisomer of this calcimimetic that is often used as a negative control in experiments testing CASR function. There is controversy regarding whether a functional CASR is present in osteoblasts. To determine the response of osteoblasts to calcimimetics, we compared the activation potential of NPS-568R and NPS-568S in MC3T3-E1 osteoblasts and immortalized osteoblasts derived from CASR null mice. Negative and positive controls for CASR activation respectively consisted of non-transfected HEK-293 cells and HEK-293 cells transfected with CASR. NPS-568R at doses of 1 μM stimulated the activity of a serum response element luciferase reporter construct (SRE-luc) in HEK-293 cells transfected with CASR, but not in HEK-293 cells lacking CASR, indicating the requirement of CASR for NPS-568 activation of SRE signaling pathways. NPS-568S failed to stimulate SRE activity in HEK-293 cells with and without CASR overexpression. In contrast, neither NPS-568R nor NPS-568S activated the SRE-luciferase reporter construct in either MC3T3-E1 osteoblasts or immortalized osteoblasts derived from CASR null mice. Consistent with the absence of a functional CASR in osteoblasts, we also failed to detect CASR transcripts by RT-PCR in these osteoblasts cell lines. However, both NPS-568R and NPS-568S caused a dose-dependent activation of ERK1/2 in MC3T3-E1 osteoblasts as well as immortalized osteoblasts derived from CASR null mice, consistent with activation of a non-CASR dependent signaling pathway. The calcium channel blocker, nifedipine, failed to block NPS-568-mediated ERK activation in osteoblasts. These results suggest the presence of a novel target for NPS-568R and its stereoisomer NPS-568S in osteoblasts. Stimulation of this target is not dependent on the configuration of the calcimimetic and is coupled to ERK activation in a manner that does not lead to downstream induction of SRE.

P2 Receptors Are Involved in the Regulation of Proliferation of Human Osteoblastic Cells. M. Solgaard*, Z. Henriksen*, N. R. Jorgensen. Bone Metabolic Unit, Dep.s of Endocrinology and Clinical Biochemistry, Copenhagen University Hospital Hvidovre, Hvidovre, Denmark.

Extracellular nucleotides acting through P2 receptors could be an important factor in the remodeling of bone, affecting the activity of both bone-forming osteoblasts and bone-resorbing osteoclasts. The aim of this study was to investigate the expression of different P2 receptors in human osteoblasts (hOB) and in the osteoblastic cell line SaOS-2, as well as the effect of stimulation with adenosine 5'-triphosphate (ATP) on cell proliferation. Osteoblasts were obtained as stromal cells derived from human bone marrow. Marrow material was collected by puncture of the posterior iliac spine of healthy young volunteers, aged 20-32. Osteoblasts were isolated and cultured in MEM supplemented with 10% fetal calf serum and penicillin/streptomycin for approximately 6 weeks after which reverse transcriptation-linked polymerase chain reactions (RT-PCR) were performed with specific primers in order to detect the expression of different P2 receptors. Cell proliferation was measured by analyzing the number of viable cells, expressed by the cleavage of a tetrazolium salt by a mitochondrial dehydrogenase. Cells were seeded in 96-well plates and assays ran for 5 days. Each day the cells were stimulated with ATP in concentrations ranging from 0,1 μM to 1000 μM. Measurements of cell proliferation were made daily in order to follow proliferation after respectively no, one, two and three stimulations. RT-PCR revealed that hOB expressed mRNA for the following P2 receptors; P2Y 1,2,4,6 and P2X 1,4,6,7 while SaOS-2 cells expressed P2Y 1,2 and P2X 1,4,6,7. Results concerning cell proliferation showed no statistically significant difference in cell proliferation after 2 days stimulation with ATP. However stimulation with ATP each day for 3 days induced an almost significant ($p=0,07$) decrease in cell proliferation for the hOB cells. Only a few assays have been done with SaOS-2 cells so far, but initial results indicate that ATP also acts on osteoblastic proliferation in an inhibitory manner, like in the hOB cells. Thus we have identified, which subclasses of P2 receptors are expressed in human osteoblasts and in SaOS-2 cells. Further, we have shown, that repeated ATP stimulation decreases proliferation of osteoblasts, suggesting an inhibitory function of one or more of the P2 receptors on bone formation. This may be a future target for pharmaceutical modulation of osteoblast numbers and activity in vivo by using specific agonists or antagonists.

Involvement of MAPK Pathways in Phosphorylation of Cbfa1 in Human OsteoProgenitor Cells (HOP) Cultured onto Cyclo-RGD Peptide. S. Pallu*[1], M. Dard*[2], R. Bareille*[1], A. Sewing*[2], A. Jonczyk*[3], M. Vernizeau*[4], J. Amedee[1]. [1]INSERM U 577, Bordeaux, France, [2]Biomet-Merck Biomaterials, Darmstadt, Germany, [3]Merck KgaA Preclinical Research, Darmstadt, Germany, [4]Biomet-Merck France, Valence, France.

Osseointegration of bone substitute materials can be improved by grafting RGD-containing peptides able to stimulate adhesive properties of biomaterials towards osteogenic cells. Modification of materials by grafting a cyclo-DfKRG peptide is based on the affinity of αvβ3-αvβ5 integrins expressed by HOP. Our previous results have shown that cyclo-DfKRG peptide coating stimulates osteoblastic differentiation and provokes early phosphorylation of p^{125}FAK / Erk 1 followed by activation of p38 / Erk 2 / JNK 2 MAPKs after 30 min of cell seeding. As described in the literature, MAPK pathways play a crucial role in cbfa1 activity. The aim of this work is to study phosphorylation of Cbfa1 in HOP cultured onto this cyclo- peptide and furthermore to identify the role of JNK 1/2 and p38 MAPK pathways using specific inhibitors.

HOP were seeded onto different coatings (poly-L-Lysine (PLL), cyclo-DfKRG peptide and plastic culture dishes) and then were treated (or not) for 24 hours with 10 μM SP600125 (JNK 1/2 inhibitor) or with 25μM SB 203580 (p38 inhibitor). Cellular proteins were extracted after 30 to 90 min of culture and phosphorylation of Cbfa1 was investigated by immunoprecipitation using a polyclonal antibody against Phospho-Ser/Thr/Tyr (Cliniscience) and then by Western blot using a monoclonal antibody against Cbfa1 (Tebu-Bio).

The results of these experiments have shown that the cyclo-DfKRG peptide induces a 3 fold increase of phosphorylation of Cbfa1 after 60 min of cell seeding when compared to plastic culture or to PLL coating. JNK 1/2 inhibitor treatment (n =3) did not affected its activity, while a p38 MAPK inhibitor (n=2) seems to inhibit partly Cbfa1 phosphorylation in HOP cultured onto cyclo-DfKRG peptide.

In conclusion, adhesion of HOP onto cyclo-DfKRG peptide promotes cell differentiation (Al-P and cbfa1 mRNA expression), activates MAPK pathways and stimulates phosphorylation of Cbfa1 after 60 min of cell seeding. However, inhibitors of JNK1/2 MAPK pathway fail to inhibit the Cbfa1 phosphorylation induced by cyclo DfKRG, while this last process seems to be dependent of the p38 MAPK pathways.

PTH Regulates IGFBP-5 Transcription through AP-2. M. S. Erclik*, J. A. Mitchell. Pharmacology, University of Toronto, Toronto, ON, Canada.

Parathyroid hormone (PTH) regulates bone remodeling and calcium homeostasis by binding to its G protein-coupled receptor, PTH1R in osteoblastic cells. PTH has divergent effects on bone metabolism; intermittent injections of PTH have an anabolic effect on bone while prolonged PTH exposure causes increased bone resorption. The molecular mechanisms regulating these events remain largely uncharacterized. Previously, we have shown that PTH increases insulin-like growth factor binding protein-5 (IGFBP-5) mRNA levels, a process that occurs through transcriptional mechanisms and that requires PKC-δ activation. IGFBP-5 is secreted by osteoblasts and is thought to bind IGF within the extracellular environment, a process that may favor the anabolic effects of IGFs in bone. We have investigated the molecular mechanisms by which PTH mediates the increase in IGFBP-5 transcription in UMR106-01 osteoblastic cells. To identify specific PTH responsive elements within the IGFBP-5 proximal 5'-flanking region deletion analyses was undertaken by fusing deletion fragments upstream of the luciferase reporter gene. Our studies identified a PTH-dependent regulatory element, 20 base pairs in length, that exists within 40 base pairs of the transcription start site. This 20 base pair region contains a recognition sequence of the transcription factor AP-2 and mutational analysis indicated that AP-2 binding is required to achieve full PTH response. Gel-mobility shift assays demonstrated PTH-induced binding to a DNA segment containing the regulatory region. To investigate the mechanisms by which PTH regulates IGFBP-5 gene transcription, we have examined the effect of PTH on the activity of members of the mitogen activated protein kinase (MAPK) family. PTH stimulates p38 but inhibits JNK and Erk1/2 activity in UMR cells. Luciferase reporter assays demonstrated that activation of p38 was functionally involved in PTH-stimulated transcription of the IGFBP-5 gene. The p38 selective inhibitor, SB203580 and dominant negative mutants of p38, were able to partially block the PTH stimulation of luciferase activity. These findings are the first to demonstrate the involvement of the transcription factor AP-2 in the effects of PTH in the regulation of IGFBP-5.

Osteogenic Effect of Danshensu (D(+)β-3,4-Dihydroxyphenyl-lactic acid) on Bone Marrow Stromal Cells of Intact and Glucocorticoid -treated Rats. L. Cui[1], Y. Y. Liu*[1], L. Y. Zou*[1], C. M. Ai*[2], T. Wu*[1]. [1]Department of Pharmacology, Guangdong Medical College, Zhanjiang, China, [2]Guangdong Key Laboratory for research and development of Natrual Drugs, Guangdong Medical College, Zhanjiang, China.

Our previous study had showed that the danshensu (TSU) had anabolic effects on glucocorticoid(GC)-induced osteoporosis in rats by analyzing bone histomorphometry. The current study was further to investigate the mechanism of molecular biology of danshensu on the abilities of osteogenesis and adipogenesis of bone marrow stromal cells in intact and in GC-treated rats by using cytochemistry and RT-PCT technique. Three-months old SD male rats were received either distilled water, 2.7mg/kg/d of prednisone oral gavage, or prednisone plus danshensu at dose of 25mg/kg/d for 45 days. At the endpoint the bone marrow stromal cells of the rats (rMSCs) was isolated by density-gradient centrifugation and cultured. Compared with intact rats group, the type I collagen (Coll-I) mRNA expression was decreased and the lipoprotein lipase (LPL) mRNA was increased in the first generation of rMSCs from GC-treated group, danshensu treatment group showed a increase in Coll-I mRNA expression and a decrease in LPL mRNA expression when compared with the GC-treated rats. Danshensu at concentration of 0.5μg/ml *in vitro* induced ALP expression, increased ALP activity and Coll-I mRNA expression of rMSCs both in intact and in GC-treated rats, danshensu at concentration of 0.5μg/ml decreased LPL mRNA expression of rMSCs in GC-treated rats (figure shows bellow). Our results illustrate that the increase of osteogenic ability and decreased of adipogenesis in the bone marrow is likely the mechanism of danshensu for protecting bone from glucocorticoid-induced osteoporosis.

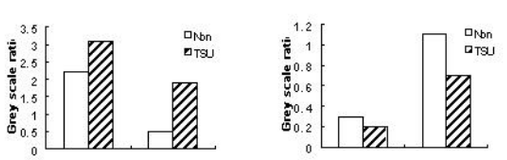

Fig. Effect of TSU on Coll-I (left) and LPL (right) mRNA expression of rMSCs in intact rtas (Cont.) and in glucocorticoid-treated rats (GC).

Successful Engraftment by Donor-derived Osteoblasts Delivered as an Intramarrow but not Systemic Transplantation. L. Wang, Y. Liu*, X. Jiang*, Z. Kalajzic*, P. Liu, D. W. Rowe. Department of Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, USA.

Providing evidence for engraftment of host bone by donor derived osteoprogenitor cells has confounded the interpretation of adult stem cell transplantation studies. We have developed a series of bone specific promoter-GFP reporter transgenic mice to provide a rapid and sensitive method for judging the success of transplantation. The pOBCol3.6GFPtpz and pOBCol3.6GFPcyan construct is expressed in preosteoblasts and early osteoblasts (only a portion of which co-label with injected xylenol orange, XO) while the pOBCol2.3GFPemd construct is active in osteoblasts (that uniformly co-localize with XO) and osteocytes. Marrow stromal fibroblasts (MSFs) derived from any of these transgenic mice and delivered by venous or intracardiac injection fail to show evidence of engraftment in total body irradiated (TBI) and non-transgenic total bone marrow (TBM) rescued mice. However when TBM was derived from pOBCol3.6GFPcyan donor mice, cyan positive cells were located on the trabecular and endosteal bone surface. These cyan positive cells did not prove to be osteoblasts. They never migrated into the bone matrix, failed to co-localize with XO labeling and did not generate bone nodules in MSF cultures derived from the transplanted mice.

When MSFs derived from the pOBCol3.6GFPtpz or pOBCol2.3GFPemd were directly injected into the marrow space of the lethally irradiated non-transgenic mouse along with TBM from a pOBCol3.6GFPcyan donor, clear evidence of local osteoblast differentiation and engraftment were found. GFPtpz and GFPemd positive cells were incorporated into trabecular and endosteal bone and positive cells on the bone surface co-localized with XO. GFPcyan positive cells derived from the TBM co-transplant were found both within the injected bone and at distal bone sites. Again, these cells did not become osteocytes and did not co-label with XO. Further studies indicate that the osteoprogenitors capable of engraftment can be derived from freshly isolated calvarial cells and from primary calvarial or bone marrow stromal cultures. They are capable of making new bone at many sites within the marrow space but lack evidence for osteoblast engraftment other than the bone of injection. The use of the osteoblast lineage restricted GFP markers, coupled with co-localization with a fluorescent label of new matrix formation and recovery of donor osteogenic nodules from the transplanted mice indicate that local osteoblast engraftment with stromal derived progenitors is a feasible strategy for cell therapy at defined sites of the skeleton.

Effect of Raloxifene on the Proliferation and Differentiation of Bone Marrow Stromal Stem Cells in Ovariectomized Rats. S. Hong[1], M. Nam*[1], W. Park*[1], B. Lee*[2], Y. Kim*[1]. [1]Internal Medicine, Inha University, Inchon, Republic of Korea, [2]Obstetrics and Gynecology, Inha university, Inchon, Republic of Korea.

Since osteoblast and adipocytes originate from a common mesencymal precursor cell, it has been proposed that osteoporosis might in part result from a switch of cell differentiation favoring adipogenesis. Raloxifene, selective estrogen receptor modulator, prevent bone loss. Although it is largely used for the treatment of osteoporosis, the mechanisms by which this compound modulate bone cells are poorly understood. So, We used a rat model in which estrogen depletion was established for a period of 1 months before the treatment. After this period the animals were divided into three experimental groups consisting of sham operated(CON), Ovariectomy(OVX) and OVX-Raloxifene-treated rats(OVX-Ral). All animals received daily treatment of raloxifene 1 mg/kg or placebo for 12 weeks. OVX and OVX-Ral were compared with the CON group and were assessed for the alteration of these cell's proliferation and differentiation. The proliferation of stromal stem cells was measured by CFU-F assay. CFU-F count were not different among 3 groups. But Alkaline phosphatase(ALP)- positive colony count was decreased in bone marrow stromal cells derived from OVX group, was increased in OVX-Ral group. Differentiation of bone marrow stromal cell were assessed in vitro. Marrow stromal cells underwent differentiation in a osteogenic medium containing dexamethasone, ascorbic acid, β-glycerophsphate. In cells of OVX-Ral group, alkaline phosphatase activity and nodule formation were increased compared with one of OVX. The mRNA expression of ALP, osteocalcin were decreased in OVX , but maintained in OVX-Ral. During the adipogenic differentiation, mRNA expresssion of PPAR gamma, FAS of OVX-Ral were decreased than those of OVX group. Oil-red O stains showed similar findings. In conclusion, osteogenic differentiation of bone marrow stromal cells was enhanced after raloxifene treatment. Adipogenic differentiation was negatively regulated in the OVX-Ral group compared to OVX group. Our result might explain the clinical observation that raloxifene treatment decrease fracture incidence.

Osteoclast AlphaVbeta3 Integrin-induced ERK1/2 Activation Is Intracellular Ca2+ and c-Src-Dependent, Shc/Ras/Raf-1-Independent, and Is Triggered by Engagement of PKCalpha. N. Rucci[1], C. Di Giacinto*[1], L. Orrù*[1], R. Baron[2], A. Teti[1]. [1]Department of Experimental Medicine, University of L'Aquila, L'Aquila, Italy, [2]Department of Cell Biology and Orthopaedics, Yale University School of Medicine, New Haven, CT, USA.

The alphaVbeta3 integrin is central to osteoclast function, is engaged by adhesion to bone matrix proteins and activates cytoskeletal reorganization and intracellular signaling. The role of protein kinases C (PKC) in these pathways is still unknown and, to clarify it, mouse primary osteoclast-like cells and beta3-stably transfected CHO cells (CHOalphaVbeta3) were allowed to adhere to immobilized alphaVbeta3-monoclonal antibody, LM609. We observed subcellular redistribution of PKCalpha, with translocation (i.e. activation) of the isoenzyme from the cytosol to the membrane and/or triton-X-insoluble compartments, independent of PLCgamma and PI3-K. Immunoprecipitation assays revealed that alphaVbeta3 integrin was engaged in a complex with PKCalpha and Grb2, as well as with the tyrosine kinases FAK in CHOalphaVbeta3 cells and PYK2 in osteoclasts. AlphaVbeta3 ligation induced ERK1/2 activation, while the JNK and p38 MAPKs were unaffected. Association between ERK1/2 and alphaVbeta3 or PKCalpha was not detectable, suggesting indirect interaction among these molecules. Moreover, the adaptor protein Shc and the canonical Ras/Raf-1/MEK-1/2 signal were not involved in ERK1/2 activation. AlphaVbeta3-dependent ERK1/2 phosphorylation was blunted by pre-treatment with the PKCalpha inhibitor Gö6976 and by downregulation of PKCalpha by long-term treatment with the phorbol ester, TPA. Ligand-induced alphaVbeta3 integrin-dependent ERK1/2 activation was also blocked by c-Src inhibition. However, c-Src and PKCalpha did not appear to interact nor to cooperate to the signal pathway leading to ERK1/2 phosphorylation. Pre-treatment with the intracellular calcium chelator BAPTA inhibited PKCalpha translocation, its recruitment by alphaVbeta3 and ERK1/2 activation, demonstrating intracellular calcium dependence of these events. PKCalpha inhibition did not impair cell adhesion and survival, but significantly reduced migration and osteoclast bone resorption. In conclusion, ERK1/2 activation is central to alphaVbeta3 signaling, and intracellular calcium, c-Src and PKCalpha are key regulators affecting events downstream of the integrin, associated with ERK1/2 activity, cell motility and bone resorption.

Disruption of the Actin-binding Domain of Vacuolar H^+-ATPase Subunit B1 Prevents its Transport to Ruffled Membranes of Osteoclasts. J. Zuo*[1], S. Chen*[1], J. Jiang*[2], M. Kaku*[3], J. Xue*[1], L. S. Holliday[1]. [1]Orthodontics, University of Florida College of Dentistry, Gainesville, FL, USA, [2]Endodontics, University of Florida College of Dentistry, Gainesville, FL, USA, [3]Orthodontics & Craniofacial Development, Hiroshima University, Hiroshima, Japan.

In mammals, two isoforms isoforms of subunit B of vacuolar H^+-ATPase (V-ATPase) exist and both contain F-actin binding sites that can be disabled by minimal alterations[1]. Isoform B1 is normally expressed in kidneys, and isoform B2 is expressed ubiquitously and at high levels in osteoclasts. LLC-PK_1 cells express both B1 and B2, but the two do not co-assemble into the same holoenzyme. In the present study, to test the physiologic relevance of the actin binding domain, we introduced wild type B1 (wtB1) and B1 with the actin binding site disrupted (mutB1) into primary mouse marrow osteoclasts using adeno-associated virus vectors. WtB1 and mutB1 were detected by immunoblotting with anti-B1 antibodies. Both constructs were expressed at similar levels to endogenous B2. Pelleting analysis indicated that wtB1, but not mutB1, associated with the detergent-insoluble cytoskeleton. Localization of B1 in osteoclasts was determined by immunocytochemistry and confocal microscopy. Like B2, wtB1 was targeted to ruffled membranes of resorbing osteoclasts. In contrast, mutB1 was not transported to ruffled membranes, remaining diffusely distributed in the cytosol. In summary, these data show that although the B1 isoform is not normally expressed in osteoclasts, wtB1 has the necessary elements required for proper targeting and transport to ruffled membranes of osteoclasts. Minimal disruption of the actin-binding domain perturbs this transport.

$\alpha_9\beta_1$ Integrin Is Expressed on Osteoclast Precursors and Mediates Osteoclast Formation Though Its Interaction With ADAM8. H. Rao[1], H. Kajiya[1], K. Safran*[1], S. J. Choi*[1], N. Kurihara[1], J. Anderson*[1], G. D. Roodman[2]. [1]Medicine/Hematology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Medicine/Hematology, University of Pittsburgh and VA Pittsburgh Healthcare System, Pittsburgh, PA, USA.

Integrins play an important role in OCL formation. In particular, $\__v\beta_3$ is expressed on OCL, binds osteopontin and is required for normal osteoclastic bone resorption. During OCL precursor differentiation, $\__v\beta_5$ is expressed initially and then is replaced by $\__v\beta_3$ as OCL precursors differentiate to mature OCL. However, the role of other integrins in OCL formation and OCL activity has not been clearly defined. We recently identified ADAM8, a disintegrin and metalloproteinase, as a novel stimulator of OCL formation. Structure-function studies demonstrated that the disintegrin domain of ADAM8 mediated its effects on OCL formation. Since the disintegrin domain of ADAM8 does not bind RGD sequences, we determined which integrin bound ADAM8. Plastic petri dishes were coated with a GST-fusion protein containing the disintegrin domain of ADAM8. CHOK1 cells transfected with various integrin cDNAs were tested for their capacity to bind the disintegrin domain of ADAM8. We found that the $\alpha_9\beta_1$ integrin and not $\alpha_v\beta_3$ bound the disintegrin of ADAM8. Western blot analysis confirmed that the α_9 integrin was present in normal human marrow cultures and was specifically expressed on early human OCL precursors, CFU-GM. The levels of α_9 mRNA expression decreased with progressive OCL precursor differentiation. In addition, α_9 mRNA expression was detectable in mouse bone marrow cultures by immunocytochemistry. Importantly, a blocking monoclonal antibody to α_9 (0.1 and 1 μg/ml) inhibited human OCL formation stimulated by 1,25-$(OH)_2D_3$ in a dose dependent fashion. The antibody also blocked RANKL induced OCL formation by a highly purified CFU-GM. We also found that RAW264.7 cells also expressed α_9 mRNA and that α_9 mRNA expression decreased with subsequent OCL differentiation in the presence of RANKL. Taken together, these data demonstrate that early OCL precursors express $\alpha_9\beta_1$ integrin and that expression of $\alpha_9\beta_1$ integrin decreases with subsequent differentiation. Furthermore, $\alpha_9\beta_1$ integrin appears to be the receptor for ADAM8 and mediates its effects on osteoclastogenesis. These data support an important role for $\alpha_9\beta_1$ integrin in OCL formation.

Osteoclast Podosome Organization Is Dependant of the Maturation of Microtubules under Control of a New Rho/mDIA2/HDAC6 Pathway. O. Destaing[1], F. Saltel*[1], O. Destaing[2], S. Ory*[3], B. Gilquin*[4], S. Khochbin*[5], P. Jurdic[1]. [1]Lbmc, ENS-Lyon, Lyon, France, [2]Cell Biology, School of Medicine, New Haven, CT, USA, [3]Upr 1086, CRBM, Montpellier, France, [4]Inserm U309, Institu Albert Bonniot, Grenoble, France, [5]Inserm U309, Institut Albert Bonniot, Grenoble, France.

By using confocal videomicroscopy, we have previously shown that immature osteoclasts present clusters of podosomes which will evolve later into dynamic, internal and unstable podosome rings (life-span under 30 min). At the end of the differentiation and under controlled of the microtubules network, podosomes rings are stabilized into the classical and peripherical podosome belts, which are reminiscent of the sealing zone in bone resorbing osteoclasts, (*Destaing et al. 2003*, Mol Biol Cell).

However, microtubules are present during all the osteoclastogenesis. To try to understand how microtubules could act only at the end of the differentiation process, we have looked at the post-translationnal modifications of α-tubulin monomers along osteoclast differentiation. Indeed, multiple post-translationnal modifications (phosphorylation, acetylation, detyrosination…) of microtubules are linked with them stabilization and in some specific differentiation process such as myogenesis. We have found that sealing zones and podosome belts are specifically associated with an increase of acetylation of microtubules. In parallel by using TAT-C3 peptide, we have found that Rho inhibition induces a strong stabilization of microtubules which.

It has been shown recently that acetylation is controlled by the histone deacetylase 6, HDAC6. This point lead us to investigate the relationship between Rho and HDAC6 in the context of osteoclast. The expression of constituvely activated form of Rho, RhoA V14, induced deacetylation of microtubules, effect which is blocked by the specific inhibitor of HADC6, trichostatine A. In the osteoclasts, Rho can activate the adaptator mDIA2 which co-immunoprecipitates and activates HDAC6 in an in vitro deacetylase assay. We then defined a new pathway where Rho activation stimulates mDIA2 which is able to interact and activate HDAC6, leading to a decrease of microtubule acetylation. By using differential treatment of trichostatineA and the stabilizing microtubule agent taxol, we have shown that the podosome belt formation is dependant upon microtubule stabilization and acetylation.

Our data suggests the existence of a new pathway leading to decrease Rho activity along osteoclast maturation necessary to allow hyperacetylation and then podosome belt formation. This point opens up new potential strategies to control podosomes and sealing zone properties in bone resorbing osteoclasts.

Vitaxin®, an Alphav Beta3 Blocking Antibody, Inhibits Osteoclastic Resorption by Decreasing the Number of Attached Osteoclasts. A. Gramoun*[1], M. F. manolson[1], J. N. M. Heersche[1], D. P. Trebec*[2], S. Y. Mao*[3]. [1]University of Toronto, Faculty of Dentistry, Toronto, ON, Canada, [2]University of Toronto, Department of Biochemistry, Toronto, ON, Canada, [3]MedImmune, Inc., Gaithersburg, MD, USA.

The integrin $\alpha_v\beta_3$ is an abundant osteoclast surface receptor mediating both cell to matrix and cell-to-cell interactions and is thought to be involved in osteoclast differentiation, attachment and resorption. Vitaxin® is an anti-human $\alpha_v\beta_3$ antibody that blocks the conformational epitope of this integrin. Vitaxin also binds rabbit $\alpha_v\beta_3$, therefore, effects of Vitaxin on osteoclast differentiation, adhesion and resorption using rabbit osteoclasts cultured on plastic surfaces and osteologic discs were studied. After an 18 hour attachment period, osteoclasts were incubated with different concentrations of Vitaxin for an additional 24 or 48 hours. Vitaxin at 30 ng/ml, 100 ng/ml and 300 ng/ml decreased the number of osteoclasts attached to plastic in a dose dependent fashion by an average of 6%, 25% and 35% respectively. This paralleled a decrease in the total number of nuclei in osteoclasts indicating that the decrease in the number of attached osteoclasts was not due to cell fusion. Activation of $\alpha_v\beta_3$ using 2.5 mM $MgCl_2$ in culture did not alter Vitaxin's inhibitory effect on attachment demonstrating that the epitope is not sensitive to activation state of the integrin. Initial attachment (measured at 2 hours) was reduced by 30% when osteoclasts were incubated with 300 ng/ml Vitaxin for 25 minutes prior to plating. However the rate of differentiation of both Vitaxin treated and control groups was equal, indicating that Vitaxin did not interfere with differentiation. Approximately a 50% decrease in the total area of resorption on osteologic slides was seen with Vitaxin at 100 ng/ml and 300 ng/ml. The percentage of large osteoclasts (>10 nuclei) was increased by an average of 1.88 fold in the groups incubated with 300 ng/ml Vitaxin suggesting that it has a greater effect on small osteoclasts (<10 nuclei). The differential sensitivity of large and small osteoclasts to Vitaxin is partially explained by the observation that there was a 4.5 and 2.8 fold increase in the levels of expression of β_3 and α_v respectively on the surface of large osteoclasts compared to small osteoclasts. Our results suggest that in a primary osteoclast culture, the decrease in resorption is a result of Vitaxin impairing osteoclast attachment rather than osteoclast differentiation.

CXCL12 Chemokine Up-regulates Bone Resorption and MMP-9 Release by Human Osteoclasts: CXCL12 Levels Are Increased in Synovial and Bone Tissue of Rheumatoid Arthritis Patients. G. Lisignoli*, F. Grassi, S. Cristino*, S. Toneguzzi*, A. Piacentini*, A. Facchini*. Laboratorio di Immunologia e Genetica, Istituti Ortopedici Rizzoli, Bologna, Italy.

Chemokines has recently emerged as important modulators of osteoclasts recruitment and function. In addition to their chemotactic function, some chemokines have been shown to be able to modulate osteoclasts differentiation and ability to resorb bone. CXCL12 is a chemokine involved in T cells activation during rheumatoid arthritis, but recent findings have revealed that human osteoclasts express high levels of this chemokines at the final stages of differentiation. We hypothesized that CXCL12 may play a role in osteoclasts differentiation and function. Therefore, we evaluated in vitro CXCL12 modulation of osteoclasts development and ability to resorb bone; also, we analysed its expression on synovial and bone tissue biopsies from rheumatoid arthritis (RA) patients. Osteoclasts were obtained by 7 days in vitro differentiation with RANKL and M-CSF of CD11b positive cells in the presence or absence of CXCL12. The total number of osteoclast was analyzed by TRAP staining and bone resorbing activity was assessed by pit assay. MMP-9 and TIMP-1 release were evaluated by ELISA. CXCL12 expression on biopsies from RA patients was analyzed by immunohistochemistry. Osteoclasts obtained in the presence of CXCL12 at 10 nM concentration displayed a highly significant increase in bone-resorbing activity (~ 90% increase relative to control sample) as measured by pit resorption assay, while the total number of mature osteoclasts was not affected. The increased resorption was associated with significant overexpression of MMP-9. Addition of anti-CXCL12 antibody to the culture media suppressed both MMP-9 overexpression and increased resorbtion by osteoclasts. Immunostaining for CXCL12 on synovial and bone tissue biopsies from both rheumatoid arthritis (RA) and osteoarthritis (OA) samples revealed a strong increase in the expression levels under inflammatory conditions.
In summary, CXCL12 chemokine showed a clear activating role on mature osteoclast by inducing bone-resorbing activity and specific MMP-9 enzymatic release. These findings may provide new insights into osteoclasts activation in inflammatory diseases of bone.

TSH Negatively Regulates the TNF Axis During Osteoclast Formation. L. Eldeiry*, Y. Peng*, J. Iqbal*, T. Ando*, T. Davies*, M. Zaidi, E. Abe. Endocrinology, Mt. Sinai School of Medicine and VA Medical Center, New York, NY, USA.

We have shown that the anterior pituitary-derived hormone, thyrotropin (TSH), is a negative regulator of bone remodeling. Even heterozygote mice with 50% TSH receptor (TSHR) deleted display osteopenia due to increased osteoclast formation, function and survival. Here, we establish that the enhanced osteoclastogenesis in the TSHR null mouse results from an up-regulated TNF axis. Real time PCR showed a ~20-fold increase in the expression of both TNF receptors, TNFRI and TNFRII, in $TSHR^{-/-}$ hematopoetic stem cell cultures. Immunoblotting demonstrated a significant increase in the phosphorylated (degradable) form of IκBα, a key TNF signaling inhibitor. In addition to elevated TNF signaling, TNFα levels were increased ~3-fold in $TSHR^{-/-}$ bone marrow supernatants and hematopoetic stem cell cultures. A neutralizing TNFα antibody abrogated the osteoclastogenic response to TSHR deletion, providing direct evidence that the increased osteoclast formation in the $TSHR^{-/-}$ mice resulted from elevated TNF signaling. We next examined the regulation of TNFα expression by TSH in TSHR-positive RAW-C3 osteoclast precursors and bone marrow-derived $CD11b^+$ cells. TSH potently inhibited TNFα expression when cells were co-stimulated by IL-1 and TNFα. Lipopolysaccharide- (LPS-) stimulated TNFα expression was, however, TSH-resistant. To obtain mechanistic insights, we PCR amplified a 1.2 kb murine TNFα promoter sequence containing 3 NFκB binding sites. Exposure to IL-1 and TNFα concomitantly, or to LPS alone enhanced TNFα promoter activity in RAW-C3 cells, by ~3-fold. TSH neither affected basal nor stimulated promoter activity, indicating that the effect of TSH in suppressing TNFα expression was post-transcriptional. Parallel real time PCR studies indicated that TSH reduced basal expression of both TNFRI and TNFRII mRNA by ~30%. Finally, immunoblotting showed that pIκBα and nuclear p65 (but not p50) were inhibited strongly by TSH in RAW-C3 cells. Taken together, the results establish the negative regulation of the TNF axis by TSH during osteoclast formation. The hormone may thus play a more global role in controlling TNF expression and action in tissues other than bone.

The Role of Marrow Stromal Cells in TNF-alpha Induced Inflammatory Arthritis and Osteoclastogenesis In Vivo. H. Kitaura[1], S. Wei[1], P. Zhou[1], K. Aya[1], S. Takeshita[1], Y. Abu-Amer[2], F. P. Ross[1], S. L. Teitelbaum[1]. [1]Department of Pathology, Washington University School of Medicine, St.Louis, MO, USA, [2]Department of Orthopedic Surgery, Washington University School of Medicine, St.Louis, MO, USA.

The marrow stromal cell is the principal source of RANKL and M-CSF and is thus central to physiological osteoclastogenesis. Stromal cells also express receptors for TNF, but the contribution these cells make to the osteolysis associated with excess levels of the cytokine is unknown. To define the role of marrow stromal cells in varying states of TNF-driven osteoclast formation, *in vivo*, we generated chimeric mice using wild type (WT) or TNF receptor deficient (KO) marrow, immunodepleted of T-cells and stromal cells. The samples were reciprocally transplanted into KO or WT mice (i.e. WT→KO; KO→WT) following lethal irradiation to eliminate native marrow. As controls, similarly-treated WT marrow was transplanted into WT mice and KO marrow transplanted into KO mice. Each group was administered increasing doses of TNF and marrow was obtained after five days. Exposure to high dose cytokine, *ex vivo*, induces exuberant osteoclastogenesis irrespective of *in vivo* TNF treatment, or whether the recipient animals possess TNF-responsive stromal cells. In contrast, the osteoclastogenic capacity of marrow treated ex vivo with lower dose TNF requires priming by TNF receptor-bearing stromal cells, *in vivo*. TNF increases the number of marrow macrophages in KO to WT and WT to WT but not WT to KO marrow transfer, suggesting that TNF responsive stromal cells are an essential component of osteoclast precursor proliferation. On the other hand, the osteoclastogenic contribution of cytokine responsive stromal cells *in vivo* diminishes as the dose of TNF increases. At all doses of the cytokine tested, the increase in OC number, *in vivo*, is blunted in mice whose marrow cells are TNF non-responsive. In keeping with a diminishing role of stromal cells as ambient TNF increases, mice with severe inflammatory arthritis accompanied by exuberant TNF production develop profound osteoclastogenesis and bone erosion independent of stromal cell expression of TNF receptors. The direct induction of osteoclast precursor differentiation by TNF is accompanied by their enhanced RANK expression and sensitization to RANKL. These data suggest osteolysis attending relatively modest elevations in ambient TNF depend upon responsive stromal cells. On the other hand, in states of severe periarticular inflammation, such as active rheumatoid arthritis, TNF may exert its bone erosive effects fully by directly promoting the differentiation of osteoclast precursors independent of cytokine-responsive stromal cells and T-lymphocytes.

Regulation of Ca^{2+}-Regulating Enzymes, CD38 and CD157, by TNF-α During Osteoclastogenesis. J. Iqbal*, L. Sun, E. Abe, M. Zaidi. Medicine, Mt. Sinai School of Medicine and the Bronx VA GRECC, New York, NY, USA.

CD38 and CD157 are evolutionary conserved ecto-enzymes that catalyze the conversion of NAD^+ to the Ca^{2+}-releasing molecules, ADP-ribose and cyclic ADP-ribose. We have shown that CD38 is a negative regulator of osteoclast formation. The expression of both CD38 and CD157 is enhanced in severe rheumatoid arthritis, the osteolysis associated with which is TNF-mediated. We therefore examined whether CD38 and CD157 were positively regulated by TNF as a means to control excessive osteoclastogenesis. TNF-α stimulated, by >30- and >8-fold respectively, the expression of CD38 and CD157 mRNA in ficoll-purified bone marrow cells for up to 48 hrs. This was expectedly not seen with $CD38^{-/-}$ cells, confirming specificity. Likewise, FACS analysis showed a ~30-fold increase in CD38 fluorescence of osteoclast progenitors in the presence of TNF-α. Again, $CD38^{-/-}$ progenitors showed no such up-regulation, but did elevate CD157 in response to TNF-α. RANK-L treatment failed to elevate CD38, but did cause a modest increase in CD157. We next investigated the cell-specificity of the CD38 induction by TNF-α. Cells up-regulating CD38 in response to TNF-α were of macrophage/dendritic cell origin, defined as $CD11b^{Hi}$ after ficoll-purification. Double-labeling experiments showed that both CD38 and CD157 were up-regulated in the same cells. This was associated with a TNF-α-induced decrease in proliferation of $CD11b^+/RANK^+$ cells in BrdU incorporation studies. Finally, to understand the mechanism of the TNF-α effect, we carried out (a) half-life experiments and (b) DNA binding assays. Both CD38 and CD157 mRNAs in TNF-α treated cells displayed half-lives at about 3 hrs, excluding effects on mRNA stabilization. Consistent with this, we detected specific binding of a NF-κB responsive element in the murine CD38 promoter to the NF-κB subunit, p50. This binding was abrogated when a G->C point mutation was introduced within the CD38 promoter, confirming specificity. As CD38 negatively regulates osteoclast formation, its up-modulation may provide a primary mechanism for controlling the TNF-α-driven osteoclastogenesis in rheumatoid arthritis.

Ca^{2+}-sensing by Cell Populations in Murine Bone Marrow: Effects on Osteoclast Formation and Gene Expression. T. Chen*, L. Rodriguez*, W. Chang, D. Shoback. San Francisco VA Medical Center, University of California, San Francisco, CA, USA.

Bone formation and resorption are regulated by systemic hormones and local signals including growth factors and ions released from bone matrix. During active resorption, the free $[Ca^{2+}]$ in the bone microenvironment can rise to levels as high as 40 mM. Cells within the marrow, therefore, are exposed to extracellular $[Ca^{2+}]$ ($[Ca^{2+}]_e$) that are many times higher than those of serum. These studies were designed to test the hypothesis that changes in $[Ca^{2+}]_e$ act as a signal in mediating the functions of diverse cell populations in bone marrow (BM). Cells from BM were harvested from 6-week-old male Black Swiss mice and cultured at different $[Ca^{2+}]_e$ (0.5 to 6 mM) for up to 28 days. Alkaline phosphatase activity (APA) and alizarin red (AR) staining for minerals were determined during culture. Osteoclast (OC) formation was assessed by examining cultures after staining for tartrate-resistant acid phosphatase (TRAP) and by measuring TRAP activity. Gene expression was assessed by quantitative real-time PCR (qPCR). In unfractionated BM cells, there was no significant effect of $[Ca^{2+}]_e$ on APA, however, AR staining was 24 +/- 6 fold greater in cells grown at 4 vs 0.5 mM Ca^{2+} (N=4, $p < 0.001$). High $[Ca^{2+}]_e$ promoted (4-6 mM) the development of multinucleated TRAP+ cells in BM cultures. TRAP activity increased by ≈5-fold after culture at 6 mM Ca^{2+} (vs 1.0 mM Ca^{2+}). This effect of high $[Ca^{2+}]_e$ was inhibited (50-90%) by exogenous osteoprotegerin in a dose-dependent manner. Expression of the receptor activator of nuclear factor kappa B ligand (RANKL) was also increased by culturing BM cells at high $[Ca^{2+}]_e$ by qPCR and western blotting. This suggested that high $[Ca^{2+}]_e$ enhanced the formation of OC's in BM by increasing RANKL expression by osteoblastic cells. To define the populations involved in the response to Ca^{2+}, BM cells were separated into macrophages/monocytes and osteoblastic/stromal cells by magnetic cell sorting (MACS) using CD11b/Mac 1 and vascular cell adhesion molecule-1 (VCAM-1, CD106) antibodies, respectively. VCAM+ cells grown at 6 mM Ca^{2+} expressed ≈15-fold more RNA for RANKL vs cells at 1 mM Ca^{2+} (N=2) -- confirming the findings from whole BM. In contrast, in highly purified (>95%) CD11b+ cells, high $[Ca^{2+}]_e$ inhibited RANKL- and macrophage colony stimulating factor-induced TRAP activity in a dose-dependent manner. These findings indicate that the effects of high $[Ca^{2+}]_e$ in bone likely represent a balance between the actions of Ca^{2+} on distinct cell populations. The membrane mechanism(s) responsible for Ca^{2+}-sensing in these populations remain to be identified and offer potential targets for interrupting pathologic bone remodeling.

A Novel Role for Megakaryocytes in the Inhibition of Osteoclast Formation. M. A. Kacena, C. M. Gundberg, M. C. Horowitz. Orthopaedics and Rehabilitation, Yale University School of Medicine, New Haven, CT, USA.

A growing body of evidence suggests that megakaryocytes (MK) or their growth factors may play a role in skeletal homeostasis. We have previously identified a novel regulatory pathway that controls bone formation which is mediated by MK. The co-culture of MK with osteoblasts resulted in increased osteoblast proliferation in vitro, by a mechanism that required direct cell-to-cell contact. Here we examine a second, heretofore unrecognized, MK mediated pathway that regulates osteoclast (OC) generation.

We have begun examining the unique inhibitory effect of MK on OC formation. Spleen or bone marrow cells ($2x10^6$ cells/ml) from C57BL/6 mice, as a source of OC precursors, were cultured with M-CSF (30 ng/ml) and RANKL (50 ng/ml) to induce OC formation. MK were prepared by culturing fetal liver cells with thrombopoietin for 3-5 days which were then separated into MK and non-MK populations by a 1g BSA sedimentation gradient. The MK fraction was 95% pure, whereas the non-MK fraction was comprised of non-MK, MK precursors, and a small number of MK. MK were titrated into the spleen cells and OC were identified as tartrate resistant acid phosphatase positive giant cells with >3 nuclei. There was a significant, dose-dependent reduction (up to 15-fold) in OC formed when MK (0-0.5%) were added to the spleen cell cultures. To rule out the possibility that the inhibition was non-specific, we cultured spleen cells with either thymocytes or the non-MK fraction. We demonstrated that from 0-0.15%, thymocytes and non-MK did not inhibit OC development, whereas comparable numbers of MK inhibited OC formation by up to 5-fold. We determined that MK conditioned media (CM) inhibited OC formation ($ED_{50} \approx 2\%$) in a dose-dependent manner (up to 10-fold), indicating that a soluble factor(s) is responsible, at least in part, for the inhibition. Next, we examined MK CM for known inhibitors of OC formation, using ELISAs. IL-4 was undetectable in both MK and non-MK CM, whereas IL-10 levels were similar in MK and non-MK CM (21±9 and 21±5 pg/ml), respectively. Interestingly, we found a significant increase in the levels of OPG in MK CM compared to the non-MK CM (450±62 and 10±8 pg/ml), respectively, suggesting that OPG could be responsible for the reduction in OC formation in these cultures. Furthermore, the potential of MKs as a heretofore, unrecognized OPG source, implicates a potential physiologic role for MKs in regulating OPG levels. These studies indicate that MK may play a dual role in skeletal homeostasis by stimulating osteoblast proliferation and simultaneously inhibiting OC formation.

In Vitro **Interaction Between Nacre and Mature Osteoclasts and Effects of Nacre Water Soluble Matrix in Osteoclastogenesis Cell Culture Models.** D. Duplat*[1], M. Gallet*[2], L. Bédouet*[1], C. Milet*[1], M. Brasier[2], S. Kamel[2], E. Lopez*[1]. [1]Milieux et Peuplement Aquatique, Muséum National d'Histoire Naturelle, Paris, France, [2]Laboratoire de Pharmacie Clinique (UMRO), Faculté de Pharmacie, Amiens, France.

Nacre is the mother-of-pearl inner layer of the shell of the pearly oyster *Pinctada margaritifera*. It is composed of calcium carbonate crystallized in aragonite form on an organic matrix scaffold. Previously, it has been demonstrated *in vivo* that the nacre implanted in the femur of a sheep is accepted and stimulates bone remodelling at the interface between bone and nacre suggesting that nacre represents a potential newly biomaterial. Furthermore, several *in vitro* studies have confirmed that the nacre water soluble matrix (WSM) stimulates the osteoblasts differentiation but no information is available on the osteoclast lineage.

The objective of our study was to assess the ability of mature osteoclasts to degrade nacre and to evaluate the effect of the nacre diffusible molecules on the osteoclasts differentiation and activity. Two mammalian cell models were used: a murine monocytic cell line RAW263.7 and osteoclasts isolated from long bones from 10-day-old rabbits.

The RAW263.7 cells were cultured during 5 days with RANKL in presence of WSM or fractions of WSM obtained by SE-HPLC. The number of osteoclast-like TRAP positive cells is a measure of the differentiation. On the other hand, rabbit osteoclasts were cultured on bovine cortical bone and nacre slices for 48 hr and 72 hr in presence of WSM. The resorption activity was determined by quantification of the resorption pit area.

Firstly we found that, nacre can be resorbed by rabbit osteoclasts indicating that it exists a bio-interactivity between bone resorbing cells and nacre.

Then we showed that WSM decreases the number of osteoclast-like TRAP positive cells as well as the number of resorption pit area. On RAW264.7 cells, a low molecular weight fraction increases the number of osteoclast-like TRAP positive cells whereas the high molecular weight fractions have a reverse activity.

This nacre matrix can be compared to the bone matrix that contains signal molecules with opposite effects according to the cell type targeted. The opposite effect of the high and low molecular WSM fractions on both osteoblasts and osteoclasts suggested that they contain signal molecules that are involved in a non specific manner in the bone cell differentiation pathway.

This study confirms the previous results obtained *in vivo* and *in vitro* with other bone cell lineage: the nacre organic matrix is the source for the signal molecules responsible for bone cell stimulation in mammals.

Human Microvascular Endothelial Cells (HMVEC) Activated by IL-1 and TNF alpha Selectively Recruit Circulating Human CD14+ Monocytes That Develop Into Functional Osteoclasts. L. Kindle, M. Kriss*, L. Rothe, P. A. Osdoby, P. A. Collin-Osdoby. Department of Biology, Washington University, St. Louis, MO, USA.

Inflammatory diseases such as rheumatoid arthritis and periodontal disease exhibit elevated local cytokine production, monocyte (MN)/macrophage infiltration, and pathological bone erosion due to increases in resorptive osteoclasts (OCs). OC precursors derive from the MN/macrophage lineage and reside in the bone marrow and peripheral circulation, from which they may be recruited to inflammatory sites, develop into OCs, and contribute to localized osteolysis. However, little is known about how pre-OCs may be recruited from the circulation or are influenced by the microvasculature in inflammation. Previously, we showed that IL-1 and TNF alpha upregulate RANKL in HMVEC and thereby promote the co-culture formation and bone resorption of OCs from human peripheral blood mononuclear cells (hPBMC). Here, we analyzed if cytokine-activated HMVEC directly interact with hPBMC to promote adhesion or transendothelial migration (TEM) of precursors that can form bone-resorptive OCs after M-CSF/RANKL culture. Pretreatment of HMVEC with IL-1 and TNF alpha (1 nM, 24h) increased hPBMC adhesion to HMVEC (2-fold in 30 min). Moreover, hPBMC underwent increased TEM (3h) through confluent HMVEC monolayers that were cytokine pre-activated. The majority of hPBMC with OC potential remained attached to the transwell filter after TEM, but were released in 24-48 h of culture with M-CSF/RANKL to form TRAP+ multinucleated OCs by day 7. Antibody neutralization revealed that ICAM-1, VCAM-1, and PECAM-1 cell adhesion molecules were involved in hPBMC TEM through HMVEC. Because pre-OCs are reported to derive from the CD14+ human MN (hMN), but not CD14- lymphocyte, fraction of hPBMC, we isolated and analyzed these fractions. CD14+ hMN displayed increased adhesion to cytokine activated HMVEC, attaining full capture of all CD14+ hMN by 2h, and adherent cells could develop into OCs with M-CSF/RANKL. Cytokine activated HMVEC also caused an increased TEM by CD14+ hMN, which could subsequently be developed into resorptive OCs with M-CSF/RANKL. In contrast, cytokine activation of HMVEC had no effect on CD14- cell adhesion, nor did CD14- cells that had (or had not) undergone TEM through cytokine-activated HMVEC develop into OCs. We conclude that inflammatory cytokine activation of microvascular cells causes the selective adhesion, recruitment and TEM of precursors capable of forming bone-resorptive OCs. Coupled with locally raised levels of pro-resorptive cytokines and RANKL expression by vascular and other cells, such mechanisms may significantly contribute to the bone loss associated with inflammatory diseases.

Synovial Fluid Macrophages Are Capable Of Osteoclast Differentiation. I. Adamopoulos*[1], A. Sabokbar[1], P. Wordsworth*[2], D. Ferguson*[3], N. Athanasou[1]. [1]Department of Pathology, Nuffield Department of Orthopaedic Surgery, University of Oxford, Oxford, United Kingdom, [2]Department of Medicine, Nuffield Department of Orthopaedic Surgery, University of Oxford, Oxford, United Kingdom, [3]Department of Clinical Medicine, University of Oxford, Oxford, United Kingdom.

Bone destruction is controlled by a number of cytokines including RANKL, OPG, M-CSF, TNFα and IL-1α, all of which influence osteoclast differentiation. The balance of these factors is disturbed in pathological joint conditions such as rheumatoid arthritis (RA) where there is formation of marginal erosions and an increase in inflammatory cells and cytokines such as RANKL, M-CSF, TNFα in synovial fluid. In RA, increased numbers of macrophages are present in the synovial membrane and these cells are capable of osteoclast differentiation. In this study we have determined whether synovial fluid macrophages in inflammatory arthritis are similarly capable of osteoclast differentiation. We isolated macrophages from the knee joint synovial fluid of RA, OA, gout and chondrocalcinosis patients and cultured them for 14 days in RANKL (30ng/ml) and M-CSF (25ng/ml) or M-CSF/TNFα (30ng/ml), and IL-1 (20ng/ml). Both RANKL and TNFα/IL-1 treated cultures resulted in the formation of numerous small (10μ) mononuclear and multinucleated $TRAP^+$ and VNR^+ cells capable of lacunar resorption. Many of the mononuclear cells formed small resorption pits (<10μ) when cultured on dentine slices in the presence of RANKL and M-CSF. In TNFα/IL-1-treated cultures, osteoclast formation was also noted, although lacunar resorption was not as extensive as in RANKL-treated cultures. Significantly more resorption was noted in macrophage cultures of RA/Crystal arthritis than OA. Our studies indicate that synovial fluid macrophages in inflammatory arthritic conditions are capable of osteoclast formation and extensive lacunar resorption. RANKL, TNFα and IL-1 are increased in RA synovial fluid and these factors may promote bone loss in inflammatory (RA/crystal) arthritis by enhancing synovial macrophage/osteoclast differentiation.

Strontium Ranelate Decreases *In Vitro* Osteoclastic Differentiation and Bone Resorption. A. Wattel*[1], A. Hurtel-Lemaire*[1], C. Godin*[1], R. Mentaverri*[1], A. Blesius*[2], I. Dupin-Roger*[2], S. Kamel[1], M. Brazier[1]. [1]Laboratoire de Biologie et Pharmacie Cliniques, Faculté de Pharmacie, Amiens, France, [2]Institut de Recherches Internationales SERVIER, Courbevoie, France.

Strontium ranelate dissociates bone remodelling by increasing bone formation and decreasing bone resorption and it has been shown to reduce the risk of vertebral, nonvertebral fractures including the hip-fractures and to increase Bone Mineral Density in postmenopausal osteoporosis. Several studies have already demonstrated strontium ranelate's inhibitory effect on osteoclastic bone resorption.

The aim of the present study was to investigate the effect of strontium ranelate on *in vitro* osteoclastic differentiation. For this purpose, two cellular models were used: a human model using PBMC (Peripheral Blood Monocytic Cells) in the presence of RANKL and M-CSF and secondly, a murine model of RAW 264.7 cells in the presence of RANKL. Strontium ranelate was tested in conditions close to the *in vivo* situation *i.e.* by reproducing the same proportion of strontium ions and ranelic acid present in the plasma of patients. Strontium and ranelic acid were tested simultaneously from 0.1 to 24 mM and from 0.001 to 0.24 mM, respectively. Osteoclastic differentiation was assessed by measuring TRAP activity, by counting the TRAP-positive multinuclear cells or osteoclasts-like (OCLs) and by the assessment of the bone resorption activity. Our results indicate that strontium ranelate inhibits the osteoclastic differentiation in both models. TRAP activity, OCLs counting and bone resorption activity decrease in a dose-dependent manner. Significant differences occur at concentration levels from 6 mM of strontium in the human model: OCLs number was evaluated to 60% of the control, TRAP activity to 60% of the control and bone resorption decreases to 70% ($p < 0.05$). In the murine model, significant results are obtained at lower concentrations (i.e. 2 mM of strontium), TRAP activity decreases to 50% and OCLs number represents 70% of the control ($p < 0.05$). Taken together, these data show that strontium ranelate decreases production of bone resorbing cells. Therefore, osteoclastic precursors are probably important cellular targets of strontium ranelate when given as a treatment for osteoporosis.

Etanercept Suppresses the Number of Circulating Osteoclast Precursors in Psoriatic Arthritis. A. P. Anandarajah*[1], E. Schwarz[2], C. T. Ritchlin*[1]. [1]Rheumatology, University of Rochester Medical Center, Rochester, NY, USA, [2]Orthopedics, University of Rochester Medical Center, Rochester, NY, USA.

Background: Erosive bone lesions occur in up to a third of patients with psoriatic arthritis (PsA). We previously demonstrated osteoclasts at the bone-pannus junction in psoriatic joints. We also found an increased frequency of circulating osteoclast precursors (OCP) in these patients. TNF-blockade rapidly lowered the level of circulating OCP. Thus, we hypothesized that etanercept inhibits bone erosions, in part, by lowering the number of circulating OCP.

Methods: 20 patients with erosive PsA (>1 erosion on plain x-ray) were given 25mg twice a week of etanercept for 24 weeks. Gadolinium enhanced, fat suppressed MRIs (using T1 and T2 weighted spin echo and gradient recall echo sequences) were performed at baseline and after 24 weeks of etanercept. 3 radiologists working independently scored the images for bone erosions and bone marrow edema (BME) on a 6 and 9-point scale respectively. Scoring was based on size/extent, the intensity of T2 signal and contrast enhancement. The circulating osteoclast precursor (OCP) frequency was measured at 0, 2, 12 and 24 weeks. OCP numbers were obtained by counting the number of TRAP positive cells with >3 nuclei present in unstimulated peripheral blood mononuclear cells after 2 weeks in culture.

Results: MRI data was available in 13 patients. BME was present in 81% of patients and the BME score improved from a mean of 5.92 +/- 2.72 to 3.92 +/- 2.69 (p=0.004) at 24 weeks. The erosion score also improved from a mean of 2.54 +/- 0.97 to 2.08 +/- 1.44 but was not significant. The OCP numbers decreased from a mean of 55.45 +/- 73.4 to 11.4 +/- 13.8 cells/ 10^6 ($p<0.01$) at 24 weeks. A significant decrease was noted as early as 2 weeks after starting etanercept. A significant correlation was noted between the erosion scores and the OCP frequency (Spearmans r^2 0.591; p=0.034).

Conclusions: The decrease in BME coupled with the dramatic decrease in OCP frequency following etanercept therapy may provide an additional mechanism to explain how TNF blockade limits joint destruction in PsA. The significant correlation between the OCP frequency and erosion scores supports the concept that the OCP frequency may be used as a biomarker to help determine which PsA patients are at greater risk for bone resorption.

Differentiation of Hydroxyapatite Affinity of Bisphosphonate Analogs For Mechanism of Action Studies. F. H. Ebetino[1], P. Emmerling*[2], B. Barnett*[1], G. H. Nancollas*[2]. [1]New Drug Development, Procter & Gamble Pharmaceuticals, Mason, OH, USA, [2]Department of Chemistry, University at Buffalo, SUNY, Buffalo, NY, USA.

The mechanism of action of bisphosphonates continues to receive attention in models of disease states including osteoporosis, oncology, and arthritis. As these studies progress, it is becoming clear that significant variation in properties can stem from very small structural changes. Thus, no two bisphosphonates possess exactly the same balance of mineral affinity and intrinsic biochemical antiresorptive potency. In vivo, BP's act against osteoclasts, disrupting key biochemical processes within the cell. However, the binding affinity of BP's to bone surfaces may also play an important role in their effectiveness in modulating their loading and release from bone surfaces. Precise methodology is required to completely understand each of these properties. Constant Composition (CC) enables quantitative comparison of BP's at very low concentrations that may be more relevant to clinical studies than in vitro saturation binding data previously reported. (CC) crystal growth kinetic studies were performed at sustained relative supersaturation (9.0 with respect to HAP, pH 7.4) on a wide range of affinity analogs. In the higher affinity series of hydroxybisphosphonates, a surprisingly wide variation of affinity was noted. Risedronate (LED=0.0003 mg P/kg, in vivo growing rat) and structurally similar pyridyl BP's of varying antiresorptive potency including NE-58018 (A) (0.001), and NE58051 (B) (1.0) were studied. Kinetic affinity constants ($X10^{-6}$), K_L= 2.00 (Risedronate), 3.82 (A), ~1.1 (B)] were calculated based on a Langmuir adsorption model. Thus, a key factor influencing the binding of BP's to bone surfaces may be the orientation of the pyridine nitrogen relative to the P-C-P backbone. NE-58018 demonstrated the highest affinity, more similar to pamidronate (K_L =3.3) and alendronate (K_L = 2.93) yet was not the most antiresorptive potent. NE-58051 exhibited lower affinity more similar to risedronate but exhibited a 3,000 fold difference in potency. Two low affinity comparative benchmarks, demonstrate how this property can be even more dramatically modified with studies on phosphonocarboxylate analog NE10790 (LED = 3.0, K_L=0.03) and phosphonophosphinate analog NE-58029 (LED = 1.0, K_L=0.004). Thus, it is more clear that antiresorptive potency stems from both bone affinity and an intrinsic biochemical potency, and that a different structure activity relationship is required for hydroxyapaptite binding than that elucidated for the biochemical target FPPS. This suggests that the clinical consequences should continue to be examined.

Validation of *In Vitro* Human Osteoclast Differentiation Assay and Osteoclast Activity Assay with Antiresorptive Agents: Potential Use for Preclinical Testing of the Effects of Antiresorptive Agents on Human Osteoclasts. J. Rissanen[1], H. Ylipahkala*[2], S. Suutari*[1], J. M. Halleen[1]. [1]Pharmatest Services Ltd, Turku, Finland, [2]Institute of Biomedicine, Department of Anatomy, University of Turku, Turku, Finland.

Despite of the recent development of new techniques allowing culturing of human osteoclasts (OCs) *in vitro*, such culture models for testing antiresorptive effects of drug candidates are not available commercially. Here we have studied the effects of various antiresorptive agents on human OCs in an *in vitro* culture system. We cultured commercially available OC precursor-cells (Poietics™, Cambrex, East Rutherford, NJ, USA) on bovine bone slices in the presence of M-CSF, RANKL and TGF-β_1. Two different assay conditions were validated, a 7-day OC differentiation assay and a 9-day OC activity assay. In the OC differentiation assay, the cells were cultured without added compounds and with osteoprotegerin (OPG) and sodium azide (AZ). After the culture period, the number of TRACP-positive multinucleated OCs formed during the culture period was counted under microscope, and the amount of tartrate-resistant acid phosphatase isoform 5b (TRACP 5b) released into the culture medium was determined with a commercial assay (BoneTRAP®, SBA-Sciences, Oulu, Finland). In the OC activity assay, culture medium was replaced with fresh medium at day 7, and the formed OCs were allowed to resorb bone for an additional 2 days. Cultures without added compounds and with the cysteine protease inhibitor E64 and AZ were included. At day 9, formed resorption pits were visualized with rhodamine-conjugated Wheat Germ Agglutinin lectin, and the amount of C-terminal cross-linked telopeptides of type I collagen (CTX) released into the culture medium was determined with a commercial assay (CrossLaps® for culture, Nordic Bioscience, Herlev, Denmark). Cytotoxicity was determined in both assays after the culture period using a commercial ToxiLight® assay (Cambrex). Both OPG and AZ decreased dose-dependently OC number in the OC differentiation assay, and both E64 and AZ decreased bone resorption in the OC activity assay. As expected, the effects of AZ were caused by toxic effects leading to cell death. OPG and E64 did not show toxic effects. In the OC differentiation assay, TRACP 5b was not released from dying cells and was therefore a reliable index of the number of OCs formed. In the OC activity assay, medium CTX was a reliable index of the amount of bone resorbed. We conclude that we have developed and validated fast and reliable *in vitro* methods for preclinical testing of the effects of new antiresorptive agents on differentiation and activity of human OCs.

Oligomeric RANK Induces the Receptor Signals Ligand-independently. K. Kiyoshi*, A. Kudo. Tokyo Institute of Technology, Yokohama, Japan.

RANK, a member of the TNF receptor family, is essential for osteoclast differentiation. Recently, TNF type I and type II receptors were shown to form a trimer even before ligand binding. Here, we investigated self-assembly of RANK. First, self-assembly was examined by immunoprecipitation assay in 293T cells, which were transfected with mouse RANK tagged FLAG or HA, resulting that the interaction was detected between RANK-FLAG and RANK-HA without RANKL. Next, we generated various RANK constructs to find a domain that mediates ligand-independent self-assembly. RANK-HA was interacted with ΔECD-FLAG that lacks the extracellular domain of RANK, indicating that RANK is self-assembled through the cytoplasmic domain. These results inspired us to investigate whether osteoclast progenitors from mouse bone marrow could differentiate into TRAP positive multinucleated cells (MNCs) when RANK or ΔECD is overexpressed. RANK overexpression induced differentiation of progenitors into TRAP-positive MNCs, demonstrating that self-assembled RANK induces signals for osteoclast differentiation. Moreover, overexpression of ΔECD also induced differentiation, suggesting that RANK, specifically the cytoplasmic domain of RANK, could induce the receptor signals when RANKs themselves assemble on intracellular vesicles. Previously, it was reported that heterozygous insersional mutation in the signal peptide of RANK caused familial expansile osteolysis (FEO), suggesting the mechanism; lack of cleavage of a proper RANK signal peptide results in higher intracellular accumulation of the mutant RANK in compartments of the secretion pathway, leading to receptor-association and increase of constitutive RANK signals. Thus osteoclastogenesis by ΔECD overexpression will help to find the cause of FEO. Therefore, the further analysis of additional RANK mutations may lead to better understanding of the function of RANK and the mechanism of FEO.

Generation and Characterization of Transgenic Mice that Express Cre Recombinase in Osteoclasts. J. D. Zajac[1], W. S. M. Chiu*[1], J. F. McManus*[1], A. J. Notini*[1], A. I. Cassady*[2], R. A. Davey*[1]. [1]Department of Medicine, Austin Health, University of Melbourne, Victoria, Australia, [2]Department of Biochemistry and Molecular Biology, The Institute for Molecular and Bioscience and The University of Queensland, Queensland, Australia.

To aid the study of the physiological control of osteoclasts, we have generated two transgenic mouse lines that express Cre recombinase in osteoclasts under the control of tartrate-resistant acid phosphatase (TRAP) or cathepsin K (Ctsk) promoter.

The suitability of TRAP and Ctsk promoters to drive the expression of Cre recombinase in osteoclasts was determined by the examination of their mRNA levels in normal C57BL/6 mouse tissues by Northern blot analysis. TRAP mRNA was expressed in a number of tissues, however, it was significantly higher in bone compared with brain (14 fold), colon (4 fold), heart (25 fold), kidney (5 fold), liver (4 fold), lung (13 fold), muscle (15 fold) and stomach (11 fold) (P<0.05). Ctsk mRNA was also expressed at significantly higher levels in bone and at lower levels in heart (55 fold), lung (12 fold) and muscle (60 fold) but was undetectable in brain, colon, kidney, liver and stomach ($P < 0.05$).

Two constructs, namely TRAP-Cre and Ctsk-Cre, were generated. Transient transfection of the constructs into RAW 264.7 cells showed that both the TRAP and Ctsk promoters were capable of driving the expression of Cre recombinase *in vitro*. These two constructs were then used to generate transgenic mice. TRAP-Cre and Ctsk-Cre transgenic mouse lines were characterized by breeding with *lacZ* ROSA 26 (R26R) reporter mice and immunohistochemistry for Cre recombinase. Function of Cre was assessed in the mice by the presence of β-Galactosidase activity resulting in blue coloration. Cre recombinase was functional in all lines tested with Cre-mediated recombination occurring primarily in the long bones, vertebrae, ribs and calvaria. Histological analyses of the long bones demonstrated that functional Cre recombinase protein was present in osteoclasts in both TRAP-Cre and Ctsk-Cre mouse lines. In addition in two of the TRAP-Cre lines, functional Cre protein was also detected in proliferating and hypertrophic chondrocytes (Line 4) and round proliferating chondrocytes (Line 3).

In conclusion, we have generated transgenic mouse lines that will enable the deletion of *floxed* target genes in osteoclasts using the Cre/*loxP* system. These genetically modified mouse lines will be valuable tools for studying the regulation of osteoclast function.

Active STAT6 Is a Potent Inhibitor of JNK-mediated Osteoclastogenesis and Bone Erosion. S. Dai*, S. Abbas*, T. Hirayama*, Y. Abu-Amer. Orthopaedics and Cell Biology & Physiology, Washington University School of Medicine, Saint Louis, MO, USA.

Signal transduction pathways transmitted by pro-inflammatory cytokines play a key role in the pathogenesis of inflammatory arthritis. Among these pathways, NF-kB and MAP kinases have been identified as fundamental mediators of inflammatory responses that govern various forms of inflammatory arthritis. The c-Jun N-terminal kinase (JNK) group of MAP kinases are activated by pro-inflammatory cytokines and other stresses. Evidence in recent studies implicates JNK as a potent kinase in the synovium. The kinase is constitutively expressed and activated in synoviocytes and is required for joint destruction in inflammatory arthritis. Destruction of the bony component of the joint is facilitated by recruitment of osteoclasts, cells that necessitate several genes for their formation and tissue destructive function. In this regard, JNK1 was portrayed to be indispensable for osteoclast differentiation and survival. JNK is also activated in response to osteoclastogenic factors, such as RANKL and TNF, and cohorts with c-fos to form the AP-1 complex which is crucial for osteoclastogenesis. It was also noted that inflammatory arthritis concurs with expression of anti-inflammatory cytokines such as IL-4, a component of the response aimed at inhibiting inflammation and tissue destruction. Indeed, recent evidence points out that IL-4 inhibits osteoclastogenesis through blockade of NF-kB and JNK pathways in a STAT6-dependent fashion. Therefore, we reasoned that STAT6 may inhibit JNK and bone erosion in inflammatory arthritis. Using a serum-transfer model of arthritis, we show that JNK phosphorylation/activation is increased in extracts of cells retrieved from joints of arthritic mice. This activation/phosphorylation coincides with activation of the AP-1 complex as shown by electrophoretic mobility shift assay. Because previous observations point out that IL-4-induced STAT6 is required to block JNK activation, we generated a constitutively active form of STAT6, termed STAT6-VT, which does not require activation by IL-4/JAK pathway. Cell-permeable TAT-fusion form of STAT6-VT was effective in blocking JNK phosphorylation/activation in RANKL and TNF-treated osteoclast progenitors. More importantly, while the fusion protein moderately blocks joint swelling, it significantly inhibits in vivo activation of JNK, attenuates osteoclast recruitment to the inflamed joints and leads to a significant decline in bone and cartilage destruction. Therefore, active STAT6-VT presents itself as a novel approach to ameliorate inflammatory arthritis.

Nox4 Participates in Superoxide Production During Osteoclast Differentiation and Bone Resorption. S. Yang[1], Y. Zhang*[1], S. Reddy[2], W. Ries[1], L. Key[1]. [1]Pediatrics, Medical University of South Carolina, Charleston, SC, USA, [2]Dept. of Medicine/Hematology-Oncology,, University of Pittsburgh, Pittsburgh, PA, USA.

Osteoclasts generate superoxide that is involved in osteoclastic bone resorption activity. NADPH oxidase is the enzyme system responsible for osteoclastic superoxide production. Based on the fact that osteoclasts from $p91^{-/-}$ mutants (absence of the catalytic subunit of NADPH oxidase) generate normal amounts of superoxide, we have previously cloned an alternative form of p91 sub-unit, Nox4, which exhibits 58% similarity with the amino acid sequence of p91 subunit of the NADPH oxidase complex. This observation undermined that Nox4 oxidase derived superoxide is essential for osteoclastic function and activity.

We have previously demonstrated that Nox4 is expressed in osteoclasts. Antisense oligos of Nox4 reduced superoxide generation and inhibited bone resorption in p91 knockout mice (Yang et al, 2001). To further study the physiological role of Nox4 in osteoclasts, we have generated RAW 264.7 cells that over express Nox4. A stable transfection technique was applied using the linear Nox4 expression cassette driven by the CMV promoter. After G418 selection, we have established four clonal cell lines (Nox4 RAW cells), which over express Nox4. RANKL stimulation induced osteoclast differentiation of Nox4 RAW cells similar to parental RAW cells. However, Nox4 RAW cells derived osteoclasts demonstrated two fold increase in superoxide production compared to osteoclasts derived from the parental RAW cells. Furthermore, Nox4 over-expression resulted in increased tartrate resistant acid phosphatase (TRAP) activity in osteoclasts compared to osteoclasts formed from control RAW cells. These data suggest Nox4 response to RANKL stimulation and its participation in superoxide production during osteoclast differentiation. Therefore, NADPH oxidase complex sub-unit, Nox4 play important role in osteoclast differentiation and bone resorption activity.

Rac1 Interacts Directly With Rab7. Y. Sun*, K. G. Buki*, J. Vääräniemi*, H. K. Väänänen*. Department of Anatomy, Institute of Biomedicine, University of Turku, Turku, Finland.

Rabs are small GTPase proteins that control many membrane fusion and vesicular trafficking events in various mammalian cells. Most likely each Rab protein functions through multiple effectors thus allowing cell and compartment specific actions. Rab7 has been shown to regulate the late steps of the endocytic pathway from early endosomes to late endosomes or from late endosomes to lysosomes. We have shown earlier that in resorbing osteoclasts, Rab7 is involved in formation of the ruffled border which is a late endosomal-like compartment at the plasma membrane. In order to reveal the molecular mechanisms which are important in the ruffled border formation, we used bacterial two hybrid system and rat trabecular bone derived cDNA library to identify specific effectors for Rab7. We used constantly active form of Rab7 as a bait. We identified P21 Ras-related C3 botulinum toxin substrate 1 (Rac1), another small GTPase protein as a new Rab7 interacting protein. Rac1 is known principally for its regulatory role on actin cytoskeleton, cell polarization, and microtubule dynamics. Rac1 has no homology with RILP or Rabring7, which have been reported earlier as other Rab7 effectors in other cellular system. Our pull down results show that wild type and active GTPase deficient mutant form of Rab7 specifically bind to Rac1. Moreover, we show that this specific interaction doesn't occur with another Small GTPase Rab9 which is also located in late endosomal compartment. More importantly, confocal microscopy images showed that Rab7 colocalises with Rac1 at ruffled border in the resorbing osteoclasts, however, in non resorbing cells, Rab7 and Rac1 colocalises at perinuclear area where the late endosomes and lysosomes are located. These results suggest that Rac1 could act as a downsteam effector of Rab7, thus regulating the late endosomal trafficking in general, and specifically the formation of ruffled border in osteoclasts. As far as we know, this is the first evidence that two small GTPase proteins directly interact with each other. Since Rac1 is known to control actin cytoskeleton directly through its effectors, Rab7-Rac1 interaction may mediate late endosomal trafficking along actin microfilaments to ruffled border.

Normal Human Osteoclasts Formed From Peripheral Blood Monocytes Express PTH Type 1 Receptors and Are Stimulated by PTH in the Absence of Osteoblasts. D. W. Dempster[1], C. Hughes-Begos[1], A. Brandao-Burch*[2], K. Plavetic-Chee*[1], F. Cosman[1], J. Nieves[1], S. Neubort*[1], S. Lu[1], A. Iida-Klein[1], T. Arnett[2], R. Lindsay[1]. [1]Regional Bone Center, Helen Hayes Hopital, West Haverstraw, NY, USA, [2]Department of Anatomy and Developmental Biology, University College London, London, United Kingdom.

The prevailing view for many years has been that osteoclasts (OC) do not express PTH receptors and that PTH effects on OC are mediated indirectly via osteoblasts. However, several recent reports suggest that osteoclasts express PTH receptors. This study tested the hypothesis that human OC formed in vitro express functional PTH Type 1 receptors (PTH1R).

Peripheral monocytes were obtained from healthy donors and were selected for the CD14-positive population (CD14+Mo) by immunomagnetic separation. Cells were cultured on bone slices or plastic culture dishes with RANKL and M-CSF for 16-21 d. At 21 d there was a mixed population of mono-and multi-nucleated cells, all of which stained positively for the human calcitonin receptor. The cells actively resorbed bone, assessed by release of C-terminal telopeptide of type I collagen and the formation of abundant resorption pits.

We obtained evidence for the presence of PTH1R by 4 independent techniques. First, CD14+Mo cultured with M-CSF and RANKL for 21 d were immunocytochemically stained for PTH1R using a goat polyclonal antibody to the human PTH/PTHrP receptor. Positive staining was observed in both mono- and multinucleated cells intimately associated with resorption cavities, whereas staining was markedly reduced in control samples incubated with blocking peptide. Second, Western blot analysis was performed on protein lysates extracted from 4 different samples: 21 d OC cultures, Cos-7 cells transfected with pcDNA1 vector (negative control), Cos-7 cells transfected with the PTH1R and SaOS2 cells (positive controls). PTH1R was detected only in the lysate of OC cultures and positive controls. The band for PTH1R was diminished in the presence of blocking peptide. Third, OC cultures clearly expressed PTH1R mRNA at 21 d and treatment with 10^{-7}M hPTH(1-34) reduced PTH1R mRNA expression by 35%, as detected by RT-PCR. Finally, we tested the effects of PTH(1-34) on unfractionated monocytes, which were cultured with RANKL and M-CSF for 14 d and then exposed to 50 or 100 ng/ml rat PTH(1-34) or vehicle for a further 2 days. Bone resorption was reproducibly increased by 2-3 fold in the presence of PTH(1-34).

These findings provide strong support for a direct stimulatory action of PTH on human OC mediated by PTH1R. This suggests a dual regulatory mechanism, whereby PTH acts both directly on osteoclasts and also, indirectly, via osteoblasts.

Estrogen-Induced Apoptosis Of Osteoclasts Is Delayed By Low-Level Cadmium Exposure. J. Rink*, A. K. Wilson. Biological Sciences, Benedictine University, Lisle, IL, USA.

Low-level cadmium exposure has been demonstrated to induce bone loss *in vitro* and *in vivo* by increasing the bone resorbing activity of osteoclasts. Since osteoclasts undergo apoptosis shortly after they are activated, one possible mechanism is that cadmium may influence the timecourse of apoptosis, allowing the osteoclast more time to resorb bone. To test whether cadmium affects the timecourse of apoptosis, osteoclasts were differentiated from mouse spleen cell cultures in the presence of M-CSF and RANKL. Apoptosis was induced in osteoclasts by the addition of estrogen, mevastatin or etoposide in the presence or absence of cadmium. After incubation for 24 hours, the osteoclasts were stained with DAPI and phalloidin and the percentage of apoptotic cells present was determined by morphometric analysis using fluorescent microscopy. Estrogen, mevastatin and etoposide increased percent apoptosis up to two-fold above control groups. Cadmium alone (100 nM) did not prevent control (baseline) apoptosis. However, when cadmium was added in combination with any of the three inducers of apoptosis, the percent apoptosis values remained constant with control values, indicating that cadmium inhibits induced apoptosis in osteoclasts at 24 hours. A time course indicated that cadmium completely rescued estrogen-induced apoptosis at 12 and 24 hours, with diminishing effects at 36 and 48 hours. These data suggest that cadmium delays the onset of apoptosis for at least 24 hours, giving the osteoclasts more time to resorb bone. Incubation of ICI, an estrogen receptor antagonist, at concentrations that diminish estrogen-induced apoptosis approximately 50% can be further rescued by cadmium to control apoptosis levels. Cadmium could not rescue mevastatin-induced apoptosis when incubated with ICI. These data suggest that cadmium's effect on delaying the onset of apoptosis is via the estrogen receptor.

Syk Is Critical for $\alpha_v\beta_3$ Integrin-Mediated Signal Transduction in Osteoclast. W. Zou, R. Faccio, F. P. Ross, S. L. Teitelbaum. Pathology, Washington University, St. Louis, MO, USA.

Osteoclast $\alpha_v\beta_3$ integrin engagement leads to cytoskeletal reorganization and activates a signaling cascade critical for bone resorption and cell survival. Several downstream pathways, such as c-Src and Pyk2, are known to transduce $\alpha_v\beta_3$ signaling, but the potential role of non-receptor tyrosine kinase, Syk, has not been elucidated. We find Syk-/- macrophage fail to differentiate into mature osteoclasts in the presence of M-CSF and RANKL. Attachment of Syk-/- pre-osteoclasts to the $\alpha_v\beta_3$ ligand, osteopontin, is delayed, and those cells which do adhere, fail to spread properly. These findings suggest that Syk participates in osteoclast differentiation and cytoskeletal organization perhaps by participating in $\alpha_v\beta_3$ integrin-dependent recruitment of signaling and cytoskeletal molecules. In keeping with this hypothesis, adhesion to the $\alpha_v\beta_3$ ligand vitronectin, but not collagen, induces tyrosine phosphorylation of Syk, suggesting that Syk is involved in $\alpha_v\beta_3$ integrin signaling pathway in osteoclasts. In co-immunoprecipitation experiments, Syk, as well as c-Src and Pyk2 bind the cytoplasmic tail of β3 integrin subunit in a matrix adhesion-dependent manner. In this circumstance, Syk forms a complex with c-Src, Pyk2 and Vav3. Consistent with integrin modulation of this complex, association between Syk and c-Src or Pyk2 in β3 integrin deficient osteoclasts is dramatically reduced as compared to wild type although expression of these tyrosine kinases is unaltered. These findings document that syk is critical for $\alpha_v\beta_3$ integrin-mediated signals which prompt cytoskeletal organization in the osteoclast.

Reduced Bone Mineral Density in Men Who were Prescribed Short-term High Dose Steroid Therapy. F. Chan*[1], E. Lau[1], D. Hui*[2], A. Wu*[2], P. Leung*[3]. [1]Jockey Club Center for Osteoporosis Care and Control, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China, [2]Department of Medicine & Therapeutics, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China, [3]Department of Orthopaedics and Traumatology, The Chinese University of Hong Kong, Hong Kong, Hong Kong Special Administrative Region of China.

During the Severe Acute Respiratory Syndrome (SARS) outbreak in Hong Kong in 2003, patients were treated with very high doses of corticosteroid and ribavirin. The detrimental effects of such treatment on bone mineral density (BMD) are unknown. To test the hypothesis that the combination therapy may lower the bone mass, a cross-sectional study was conducted to compare the BMD of SARS patients with normal range data. Two hundred and twenty-four patients with SARS were recruited from the teaching hospital in shatin, where SARS originated. Bone Mineral Density (BMD) at the total hip and spine was measured at around 6 months post SARS by DEXA (Hologic, Inc). Subjects were treated with an average of 2,753mg (SD=2,152mg) prednisolone and 29,344 mg (SD=15,849mg) of ribarivin. When compared to normal range data, 6% of men of had a hip BMD Z-score ≤-2 (P=0.057 for testing the hypothesis that >2.5% of subjects should have a Z-score of ≤-2). The results of BMD at the spine in men, or of the total hip and spine in women, were statistically non-significant. We conclude that high doses of corticosteroid and ribavirin may result in low BMD in male SARS patients.

Bone Mineral Density in Ethnic Norwegians and Pakistani Immigrants - The Oslo Health Study. K. Alver*[1], H. E. Meyer*[2], J. A. Falch*[3], A. J. Sogaard*[1]. [1]Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway, [2]University of Oslo, Oslo, Norway, [3]Aker University Hospital, Oslo, Norway.

Bone mineral density (BMD, g/cm^2) is scarcely studied in immigrants from the Sub-Indian continent. In Oslo, Norway, random samples of the participants in the Oslo Health Study, including also those of Pakistani origin, were invited to a forearm BMD measurement by single x-ray absorptiometry. We have previously shown that Pakistani immigrants in this population have a very high prevalence of vitamin D deficiency. The aim of this study was to compare bone density with and without adjustment for bone size and height among Pakistani immigrants and ethnic Norwegians in Oslo.

BMD was measured at the distal and ultradistal forearm site in 173 Pakistani-born (73 women, 102 men) and 1386 Norwegian-born subjects (678 women, 711 men) aged 30, 40, 45 and 59/60 years, living in Oslo. To account for variation in skeletal size, we computed height-adjusted BMD, BMD/height (g/cm^3) and volumetric bone mineral apparent density (BMAD, g/cm^3). Comparisons were made by both age-specific t-tests and one-way analysis of covariance adjusted for age.

We did not find any differences in distal or ultradistal forearm BMD between Pakistanis and Norwegians in either women or men. We found, however, statistically significant higher values in Pakistani men when BMD was height-adjusted (2% higher at the distal and 5% at the ultradistal site). We also found statistically significant higher bone density values (both distal and ultradistal) in Pakistani women and men compared to their Norwegian counterparts when volumetric measures as BMD/height (7-8% higher in women, 6-7% in men) and BMAD (6% higher in women, 8% in men) were used.

We conclude that Pakistanis living in Oslo have similar BMD as ethnic Norwegians, but they have higher volumetric bone density.

Bone Mineral Density, Muscle Mass and Fat Mass of the Lower Extremities in Independent Ambulators with Chronic Stroke. M. Y. C. Pang*, J. J. Eng*. School of Rehabilitation Sciences, University of British Columbia, Vancouver, BC, Canada.

Community-dwelling individuals with chronic stroke have a high incidence of falls. The loss of bone mass and muscle atrophy, particularly on the paretic side, may be important contributing factors to the much higher risk of fractures resulting from a fall. The purpose of this study was (1) to evaluate the bone mineral density and soft tissue composition of the lower extremities and (2) to identify the stroke-specific impairments that are important determinants of bone mineral density of the lower extremities of fifty-eight community-dwelling individuals with chronic stroke. The bone mineral density, lean mass and fat mass of the lower extremities were measured by dual energy X-ray absorptiometry (DEXA). The results showed that the bone mineral density of the paretic lower extremity was significantly lower than that of the non-paretic lower extremity. The lean mass of the paretic lower extremity was also significantly reduced when compared to the non-paretic leg. The bone mineral density in the paretic leg was positively correlated with the lean mass (r=0.565) and negatively correlated with the fat mass (r=-0.537). Multiple regression analyses revealed that ambulatory capacity and leg strength were significant determinants of the bone mineral density of the paretic lower extremity. The results point to the importance of enhancing mobility and muscle strength to promote bone health of the lower extremities in the chronic stroke population.

Vitamin D Insufficiency in a Racially Diverse Population of Men: Results from BACH/BONE. S. S. Harris[1], T. C. Chen[2], A. B. Araujo[1], M. F. Holick[2], J. B. McKinlay*[1]. [1]New England Research Institutes, Watertown, MA, USA, [2]School of Medicine, Boston University, Boston, MA, USA.

Our aims are 1) to report race and season-specific prevalences of vitamin D insufficiency in a population-based sample of men and 2) to determine whether a 25-hydroxyvitamin D (25OHD) level of 50 nmol/l maximally suppresses parathyroid hormone (PTH) in this group. This information contributes to the current debate about optimal blood levels of vitamin D and the need to reexamine recommended dietary intakes.

We report preliminary, unweighted findings from the Boston Area Community Health Bone Study (BACH/BONE), a study of skeletal health in Boston men aged 30-79 yrs. The platform-based automated Nichols Advantage Specialty System (San Clemente, CA) was used for determinations of 25OHD and PTH. The method uses acridinium ester as the label in its protein binding assay (for 25OHD) or chemiluminescence immunoassay (for PTH).

Age and BMI did not differ by race, and 25OHD was not correlated with age. 25OHD values < 25 nmol/l were more common in Blacks than in others (Table 1). Values < 50 nmol/l were most common in Blacks, intermediate in Hispanics, and least common in Whites. Hispanics and Whites had much lower prevalence of values < 50 nmol/l in summer than winter, but no seasonal difference was seen in Blacks.

Table 1. Prevalence (%) of 25OHD values < 25 and <50 nmol/l

	N	Winter (Nov-Apr)		Summer (May-Oct)	
		< 25	< 50	< 25	<50
Black	106	8.8	43.9	8.2	44.9
Hispanic	128	1.7	30.0	0.0	14.7
White	151	2.1	16.8	1.8	5.4

PTH concentrations were 13% to 29% lower in men with 25OHD values ≥ 50 nmol/l compared with values < 50 (Table 2).

Table 2. Median PTH (pmol/l) by 25OHD (nmol/l)

	25OHD < 50	25OHD ≥ 50	Diff.
Black	3.72	2.65	-29%
Hispanic	2.77	2.41	-13%
White	3.29	2.60	-21%

Over 40% of Black men had low 25OHD levels in both winter and summer. The percentage was lower in Hispanic and even lower in White men, particularly in the summer. A 25OHD level of 50 nmol/l is not associated with maximal PTH suppression in Black, Hispanic or White men, suggesting that a higher 25OHD target may be desirable.

Disclosures: ***S.S. Harris****, None.*

SA327

Variation in Bone Turnover within the Normal PTH Range: Results from BACH/BONE. S. S. Harris[1], T. C. Chen[2], A. B. Araujo[1], M. F. Holick[2], J. B. McKinlay*[1]. [1]New England Research Institutes, Watertown, MA, USA, [2]School of Medicine, Boston University, Boston, MA, USA.

A frequently proposed indicator of optimal vitamin D status is the 25-hydroxyvitamin D (25OHD) level at which parathyroid hormone (PTH) is maximally suppressed. However, although there is clear evidence that above normal PTH is harmful to the skeleton, there is much less evidence, especially in racially/ethnically diverse populations, that suppressing PTH within the normal range is beneficial. We examine the association of serum osteocalcin values (a marker of bone turnover) with normal PTH values in Black, Hispanic and White men. Since reduced bone turnover is generally associated with reduced bone loss, an association of osteocalcin with PTH in the normal range would provide support for maximal PTH suppression as a desirable goal in determining 25OHD targets for skeletal health.

We report preliminary, unweighted findings from the Boston Area Community Health Bone Study (BACH/BONE), a population-based study of skeletal health in a racially/ethnically diverse sample of Boston men aged 30-79 yrs. The platform-based automated Nichols Advantage Specialty System (San Clemente, CA) was used for determinations of serum PTH and osteocalcin. The method uses acridinium ester as the label in its chemiluminescence immunoassays. The normal range and midpoint for the PTH assay are 0.85-5.31 and 3.08 nmol/l, respectively. Primary analyses were restricted to the 346 of 385 men who had PTH values within the normal range (median osteocalcin was 0.97 nmol/l in the excluded men compared with 0.72 in the included men).

Mean age in the six race/ethnic (Black, Hispanic, White) by PTH (low-normal:0.85-3.08, high-normal: 3.08-5.31) groups was 49-54 yrs, and mean BMI was 28-29 kg/m^2. Median serum osteocalcin was higher in the 107 men with high-normal PTH than in the 239 men with low-normal PTH (Figure). Differences in the medians were similar across race/ethnic groups: 22% in Blacks, 22% in Hispanics and 20% in Whites. These data provide preliminary evidence that reducing PTH within the normal range may benefit the skeleton by reducing bone turnover. In addition, they suggest that the benefit may be similar across race/ethnic groups.

Increased Risk of Fractures Is Associated with Acidogenic Food Intake among Post-Menopausal Women Enrolled in the Observational Study of the Women's Health Initiative. U. S. Barzel[1], A. Aragaki*[2], C. Ritenbaugh*[3], J. Wylie-Rosett*[4], M. S. LeBoff[5], J. A. McGowan[6]. [1]Montefiore Medical Center & Albert Einstein College of Medicine, Bronx, NY, USA, [2]Women's Health Initiative, Seattle, WA, USA, [3]Kaiser Permanente Center for Health Research, Portland, OR, USA, [4]Albert Einstein College of Medicine, Bronx, NY, USA, [5]Brigham and Women's Hospital & Harvard Medical School, Boston, MA, USA, [6]Musculoskeletal Diseases Branch, NIAMS/NIH, DHHS, Bethesda, MD, USA.

Human and animal studies demonstrate that an acidogenic diet can cause a negative calcium balance and a reduction in bone mass. The purpose of this study was to test the hypothesis that acidogenic food intake increases fracture risk. Dietary data were collected by a food frequency questionnaire from 93,676 post-menopausal women, ages 50 to 79 years, at baseline. From these data we assessed the consumption by each woman of total animal protein, as surrogate for acid intake (P), and of total potassium as surrogate for alkali intake (K). Fracture data was collected prospectively over an average of 5.5 years. There were 10,875 total fractures, including 616 hip fractures.

In lieu of assessment of actual potential renal acid load, we calculated the ratio of K/P (Frassetto 1998)and arranged the data in quintiles. Statistical models were adjusted for age, ethnicity, education, body mass index, physical activity, hormone replacement therapy, smoking, relevant medications (thiazides, thyroid hormone, corticosteroids, antiestrogens and bisphosphonates), personal and family fracture history, and falls in the past 12 months. Dietary variables included calcium, retinol, vitamin D, vitamin K, alcohol and coffee consumption. All dietary variables, including K/P, were adjusted for total energy intake.

Since our hypothesis was that a very high animal protein diet affects bone metabolism negatively, and it has been shown that a very low protein diet also affects it negatively, we used the middle quintile of K/P as basis for comparison. The lowest K/P was associated with a significant risk for all fractures - hazard ratio (HR) 1.14 (95% 1.05,1.25) p=0.0031. The risk for the lowest half of this quintile was 1.21 (1.08,1.35) p=0.0009. Risk at the highest quintile approached but did not reach significance - HR 1.08 (0.99,1.18) p=0.07. There was a similar, but not statistically significant, trend for hip fractures with lower and upper quintiles of K/P that had HR 1.28 (0.86,1.90) and 1.11 (0.75,1.63), respectively.
This prospective study, with a fracture end point, demonstrates that a relatively high intake of animal protein, unbalanced by alkali supplying foods such as vegetables and fruits, significantly increases the risk of all fractures in post-menopausal women.

Detection of Prevalent Vertebral Fractures Using Historical Height Loss: Comparison of Different Height Measurement Methods. K. Siminoski[1], J. D. Adachi[2], G. Ioannidis, and the CaMOS Research Group[2]. [1]Radiology and Medicine, University of Alberta, Edmonton, AB, Canada, [2]Medicine, McMaster University, Hamilton, ON, Canada.

Previous studies have shown that historical height loss (HHL) >6 cm increases the likelihood of a prevalent vertebral fracture and may serve as a clinically useful diagnostic threshold. Those data were derived from a specialist patient population and employed a stadiometer. In this study we have evaluated HHL in a randomly chosen population to assess the generalizability of a 6 cm HHL threshold, and have compared different methods of height measurement.
We have analyzed HHL for 3,732 women from the Canadian Multicentre Osteoporosis Study (CaMOS), a randomly chosen study population from 9 sites across Canada. Average age was 65.5 years (range: 49 - 93 years). HHL was determined as the difference between the tallest recalled height and current measured height. Four different methods were used to determine height: Method 1 = stadiometer (1 site, n = 320); Method 2 = weight scale attachment (6 sites, n = 2,482); Method 3 = wall-mounted pull-down device (1 site, n = 496); Method 4 = ruler on head with tape measure on wall (1 site, n = 434). Vertebral morphometry was performed on all subjects from T4 to L4, with prevalent fracture defined as any vertebral height ratio >3 SD below the population mean.
The area under the receiver operating characteristics curve (AUC) for the entire population was 0.63 (95% confidence interval [CI], 0.61-0.65; p<0.001). The AUC was similar for the four different height measurement methods (see table). At HHL > 6 cm, sensitivity for the entire group was 30%, ranging from 17% for Method 4 to 33% for Method 2. Specificity for the entire population was 90%, ranging from 88% for Method 2 to 97% for Method 4.
These results confirm previous data that were derived from a specialist referral population and show that HHL >6 cm can be a useful threshold for detecting prevalent vertebral fractures among the general population. The findings also show that different height measurement methods function comparably for determination of HHL, and that the weight scale attachment is acceptable.

Comparison of Height Measurement Methods

METHOD	AUC (95% CI)	Sens for HHL >6 cm (%) (CI)	Spec for HHL > 6 cm (%) (CI)
ALL	0.63 (0.61-0.65)	30 (27-33)	90 (89-91)
1	0.62 (0.57-0.67)	19 (12-29)	96 (92-98)
2	0.63 (0.61-0.66)	33 (29-37)	88 (86-89)
3	0.67 (0.63-0.71)	32 (25-40)	92 (89-95)
4	0.62 (0.57-0.67)	17 (11-25)	97 (94-98)

Meth 1 = stadiometer; Meth 2 = weight scale; Meth 3 = wall-mounted; Meth 4 = ruler

The Use of Height Measurement in Primary Care. K. Siminoski. Radiology and Medicine, University of Alberta, Edmonton, AB, Canada.

Measurement of total body stature is recommended in a number of clinical practice guidelines for two main purposes. The first is to determine body mass index (wt/ht^2) for monitoring obesity and cardiovascular risk. The other is to assess height loss as a means of detecting subclinical vertebral fractures in people with osteoporosis. Since there is no data on current clinical practice in regards to height measurement, we conducted a telephone survey of primary care practitioners.
One hundred primary care physicians randomly chosen from across Canada were questioned on current height measurement perceptions and practice. Physicians (82% male) had been in practice for 20.3±6.3 years (±SD) and saw 185±65 patients per week. Most patients in their practices were female (58.2±11.4%) and 41.0±17.3% were over age 65. Of their patients with osteoporosis, 82.7±14.2% were female.
These physicians regarded height as a useful parameter: it was rated 7.4±2.5 on a 10-point scale. The most commonly used height measurement device was the office weight scale attachment (79%), followed by a flat beam on the head with a tape on the wall (13%), and a wall-mounted sliding arm (6%). Two percent recorded height based on history from the patient. Adequacy of the current height method was rated 7.7±1.8 on a 10-point scale.
Physicians reported that among all female patients, 64.0±36.1% had at least one height measurement on the chart and 47.4 ±35.2% had height recorded on an annual basis (see table). The principle reason for measuring height among all patients was to assess BMI, obesity, or cardiovascular risk. Among females diagnosed with osteoporosis, 76.7±34.8% had at least one height on the chart, and 62.9±37.4% had annual heights. The main reason for doing height in osteoporotics was to detect vertebral fractures. Values were slightly lower in men for both having at least one height on the chart and for having annual heights, but confidence levels overlapped those of women. The reasons for doing height were also similar in men.
These results show that primary care physicians recognize the value of height measurement in clinical practice and do it for the recommended reasons, and that the majority of patients reportedly have at least one height recorded in their medical records. There is room for improvement among both the general patient population and in those patients diagnosed with osteoporosis.

Height Measurements in Different Patient Groups

PATIENT GROUP	At Least One Height On Chart (%) (95% CI)	Annual Height On Chart (%) (95% CI)	Main Reason for Height
All Females	64 (54-73)	47 (37-57)	BMI
Females With Osteoporosis	77 (68-85)	63 (53-72)	Fractures

Seasonal Presentation of Osteoporotic Hip Fracture. M. Larrosa*[1], E. Casado*[1], A. Gómez*[1], J. Gratacòs*[1], E. Fernández*[1], E. Berlanga*[2]. [1]Rheumatology, Hospital Sabadell. University Institute Parc Taulí, Sabadell, Spain, [2]Laboratory, UDIAT, Sabadell, Spain.

Objectives: To analyze if the osteoporotic hip fractures have a seasonal incidence in our area and its relation with serum 25-OHD3 and PTH levels. To evaluate the relation between sunlight exposure and 25-OHD3 serum levels.
Methods: Patients older than 65 years with osteoporotic hip fractures admitted into hospital between March 2002-February 2003. The following data was recorded: date of fracture, degree of sunlight exposure [semiquantitative questionnaire: nil (patients confined to home or institutionalized), poor (1-2 weekly outings), medium (3 or more weekly outings) or high (active sunlight exposure)] and serum 25-OHD3 (25-95 ng/mL, RIA) and PTH levels (10-65 pg/mL, RIA).
Results: 321 patients were included, 258 women (80.4%), age 83+/-7 years old (65-100). The mean 25-OHD3 concentrations were 22.5+/-17.9 ng/mL and PTH 85.0 +/- 59.4 pg/mL. 54 p. (17.0%) had a nil degree of sunlight exposure, 102 p. (32.1%) poor, 151 p. (47.5%) medium and 11 p.(3.5%) high.
During summer we observed a significant reduction of hip fracture incidence, along with an increase of 25-OHD3 levels (Table). 25-OHD3 levels were significantly increased in patients with higher sunlight exposure (p<0.000). Hypovitaminosis D was observed among 85% patients with nil, 74% with poor, 57 with medium and 30% with active sunlight exposure (p<0.000).
Table:

	Number fractures	25-OH-D3 ng/ml (mean+/-SD)	PTH pg/ml (mean+/- SD)
Winter	91	19.7+/-17.0	93.0+/-61.1
Spring	88	20.0+/-16.4	84.6+/-67.7
Summer	54	28.7+/-20.1	73.2+/-37.8
Autum	92	24.1+/-17.9	84.2+/-59.1
P	0.006	0.013	NS

Conclusion: Hip fractures have a seasonal incidence with a reduction during summer and along with higher serum 25-OHD3 levels. Serum 25-OHD3 levels increase with the degree of patients' sunlight exposure.

Sunlight Irradiation, 25-OH-D3 Serum Levels and Osteoporotic Hip Fracture. E. Casado*[1], M. Larrosa*[1], A. Gómez*[1], J. Gratacòs*[1], E. Fernández*[1], E. Berlanga*[2]. [1]Rheumatology, Hospital Sabadell. University Institute Parc Taulí, Sabadell, Spain, [2]Laboratory. UDIAT, University Institute Parc Taulí, Sabadell, Spain.

Background: In a recent study we have observed that hip fracture have a seasonal incidence in our area. In medical literature it has been frequently related to poor weather conditions (snow, ice, rain or minimum daily temperatures), which are not frequent in our area (Barcelona; latitude 41º N)
Objectives: To analyze if osteoporotic hip fracture incidence correlates with mean local sunlight irradiation and serum 25-OH-D3 levels.
Methods: Patients older than 65 years with osteoporotic hip fractures, admitted into hospital between March 2002-February 2003 were included. Patients with vitamin D supplementation and patients without sunlight exposure (confined to home or institutionalized) were excluded. 25-OH-D3 (23-95 ng/ml, RIA) was determined at admission. The number of hip fractures, mean 25-OH-D3 and sunlight irradiation (MJ/m2) (official data of 'Centre meteorologic de Catalunya') were analyzed on monthly basis.
Results: 243 patients, 189 women (77.8%) and 54 men were included in the study, mean age 81.8+/-7.4 years (65-100 years). The mean 25-OH D3 values were 22.8+/-16.0 ng/ml. A significant inverse correlation among fractures incidence and 25-OH-D3 level was observed r= - 0.65 (p=0.02). Every month, serum 25-OH-D3 concentrations correlated with the mean sunlight irradiation recorded two and three months before the fracture r= 0.63 (p=0.02) whereas the monthly incidence of fractures correlated with the mean sunlight irradiation recorded three months before the fracture r= - 0.59 (p=0.04) A tendency to statistical significance with the recorded irradiation 2 months before was observed.
Conclusion: The monthly incidence of hip fracture, among individuals with sunlight exposure, inversely correlates with 25-OH-D3 serum levels and mean sunlight irradiation recorded between 2 and 3 months before the fracture. This data could help to better understanding the seasonal incidence of hip fracture.

Despite Low Bone Mass, Fracture Prevalence Is Low in Post-Menopausal Mayan Women. E. Brudzinski*, N. Binkley. University of Wisconsin, Madison, WI, USA.

Kyphosis and fracture are reputed to be rare in post-menopausal Mayan women. This community-based study investigated self-reported fracture prevalence, known fracture risk factors, physical examination findings of kyphosis and calcaneal bone mass by ultrasonometry.
Thirty-one women age 50 and older were evaluated at a temporary clinic in the Mayan village of Yaxchecu, Mexico. All presented for other health concerns and were directed to the investigator. Language barriers were addressed by both Spanish and Mayan translators. Height, weight, diet, physical activity, fracture and medication history were obtained. Kyphosis was subjectively assessed by physical examination and calcaneal ultrasonometry performed using an Achilles Express (GE Medical Systems, Lunar).
Patient mean age was 69.3 ± 8.7 with menarche at 13.4 ± 1.6 and menopause at 46.2 ± 5.7 years. Age at first childbirth was 18.6 ± 3.7 years and these women were pregnant 8.4 ± 4.3 times. Their mean height, weight and BMI was 4.6 ± 0.2 feet, 116 ± 19.5 pounds and 26.3 ± 3.7 kg/m^2 respectively. None took estrogen, smoked or drank alcohol. They had essentially no dairy intake. All participated in physical labor centered around the home and field, e.g., carrying water from wells and farming in their younger years, and maintained activity by walking around the village. Sun exposure occurred on an almost daily basis and sunscreens are not used in this population. About half (48%) had fallen within the last year, both standing and from heights. Only four women (13%) reported fractures during their adult life: one clavicle, two wrist and one with bilateral humerus fractures. Notably none sustained a hip fracture. Kyphosis was present on examination in none of these women. Their mean calcaneal stiffness T-score was -2.2 ± 1.0, range -4.1 to -0.1. T-scores were lower by 0.04 per year since menopause. There was no effect of BMI or parity on T-score.
In conclusion, despite low calcaneal bone mass and falls, low-trauma fractures are rare, hip fractures absent and kyphosis not observed in this population of Mayan women. Possible explanations for this include maintained physical activity, bone geometry, vitamin D replete status and alterations of bone turnover. Future study in Mayans is necessary and may identify factors contributing to bone strength and fracture resistance.

Quality of Life in Postmenopausal Women: Effects of Bone Mineral Density (BMD) and Subclinical Vertebral Fractures. E. Romagnoli*[1], V. Carnevale*[2], E. D'Erasmo*[1], F. Paglia*[1], S. De Geronimo*[1], J. Pepe*[1], N. Raejntroph*[1], M. Maranghi*[1], S. Minisola[1]. [1]Dpt of Clinical Sciences, "La Sapienza" University, Rome, Italy, [2]Dpt of Internal Medicine, CSS IRCCS, S. Giovanni Rotondo, Italy.

Quality of life (QOL) in postmenopausal osteoporosis has been mainly assessed in patients with clinically recognized vertebral fractures. We investigated the reliability and validity of the Italian version of the quality of life questionnaire of the European Foundation for Osteoporosis (QUALEFFO) in subjects with subclinical vertebral fractures. We also tested its validity in discriminating patients with reduced BMD from normal subjects, independently of vertebral fractures.
We studied 361 healthy ambulant asymptomatic postmenopausal women, sent by their general practitioners to our Mineral Metabolism Center as part of an osteoporosis screening program on healthy postmenopausal women. The QUALEFFO consists of 41 questions divided into five domains, which explore pain, physical function, social function, general health perception and mental function, respectively. All participants underwent BMD measurement by DXA of either the lumbar spine and/or the femoral neck. as well as x-ray examination of the thoraco-lumbar spine. Vertebral deformity was defined when anterior, middle, or posterior height loss was more than 20% in respect to the adjacent vertebra
According to the WHO criteria, when subjects were subdivided by BMD values into three groups (normal BMD, osteopenia, and osteoporosis), a significant difference was found only for the domains exploring general health perception ($p<0.01$) and mental function ($p<0.001$ by ANOVA). Among osteopenic patients, no difference was found between fractured (30) and non-fractured (120) ones for each domain considered. A significant difference was instead found between fractured (52) and nonfractured (93) osteoporotic patients for the domains exploring physical function ($p=0.002$), social function ($p<0.001$), general health perception ($p=0.011$) and total QUALEFFO score ($p=0.008$). Stepwise multiple logistic regression analysis of the whole sample showed that both vertebral fractures and a low femoral BMD impairs QOL perception, while age did not exert a significant influence. ROC curves analysis demonstrated a low discriminating capacity of individual domains and total QUALEFFO score for both vertebral deformities and BMD categorization.
Our results showed that QUALEFFO is not able to discriminate between patients with or without subclinical vertebral fractures. However, some aspects of QOL appear to be impaired in patients with silent vertebral fractures or reduced BMD.

"Occult" Osteoporotic Vertebral Fractures: Vertebral Body Fractures without Radiological Collapse. T. Pham*[1], J. Azulay-Parrado*[1], P. Champsaur*[2], C. Chagnaud*[3], P. Lafforgue[1]. [1]Service de Rhumatologie, la Conception, Marseille, France, [2]Service de Radiololgie, Hôpital la Timone, Marseille, France, [3]Service de Radiologie, Hôpital la Conception, Marseille, France.

Summary of background data: Osteoporotic vertebral fractures are usually diagnosed on plain radiographs on the basis of vertebral deformation, *i.e.* vertebral collapse. There are no data on either the possibility or the features of osteoporotic vertebral fractures without significant vertebral body deformation.
Methods: We retrospectively analyzed cases which presented with acute back pain with initially no vertebral deformity on plain radiographs, and which later proved to be fresh osteoporotic vertebral body fractures. All cases met each of the following criteria: 1) The incriminated vertebra appeared normal (Genant's grade 0 deformation) on initial radiographs. 2) The diagnosis of fresh vertebral body fracture was confirmed by MRI (band-like homogenous bone marrow edema feature , a horizontal linear fracture line parallel to a vertebral plateau or both, and the absence of signs of tumor). 3) The diagnosis of osteoporosis was made by the combination of established osteoporosis, exclusion of another underlying disease, and follow-up.
Results: We observed 21 such fractures in 16 patients (11F/5M, mean age 72 years). Most of these fractures affected the lumbar spine (14/21 occurred at L2 to L5). Osteoporosis was previously known in 9 patients, newly diagnosed in 7. At follow-up, the vertebral fracture worsened in 15 of 19 cases towards a classical vertebral collapse (Genant's grade = 0.5) in a mean of 12.5 weeks (4-24 weeks). In 4 of 19 cases, the vertebra remained normal. All cases have had a clinically favorable outcome.
Conclusion: True osteoporotic vertebral fractures without collapse at presentation exist. They are the equivalent in the spine of occult stress fractures well known in other skeletal sites. They must not be misdiagnosed as malignant lesions.

The Burden and Management of Osteoporosis: A Missed Opportunity. C. J. Metge*[1], W. D. Leslie[2], L. Manness*[3], B. Kvern*[4], M. Yogendran*[5], C. K. Yuen[4]. [1]Faculty of Pharmacy, University of Manitoba, Winnipeg, MB, Canada, [2]Medicine, St. Boniface General Hospital, Winnipeg, MB, Canada, [3]Patient Health Management, Merck Frosst Canada Ltd., Winnipeg, MB, Canada, [4]Faculty of Medicine, University of Manitoba, Winnipeg, MB, Canada, [5]Faculty of Medicine, MB Centre for Health Policy, University of Manitoba, Winnipeg, MB, Canada.

The difference between 'best care' or use of proven interventions and 'usual care' is often large. The Maximizing Osteoporosis Management in Manitoba (MOMM) project is a public/private partnership and includes the province of Manitoba; its sole purpose is to identify gaps in the delivery of osteoporosis care and to promote 'best care'. Using administrative claims data, we performed a panel study (1997-2002) of women aged ≥ 50 years who were residents of Manitoba and had experienced a hip or spine or a non-spine/non-hip fracture. Fracture events were used to identify women at high risk of osteoporosis and fracture. To examine the kinds of care women received 1-year post-fracture we used two data sources and calculated rates of bone mineral density (BMD) testing and pharmacological intervention for each panel. BMD testing is indicated after a non-spine/non-hip fracture in women over 50; the availability of a province-wide BMD database allowed us to identify when BMD investigation was done post-fracture. The use of pharmacological treatment post-spine or hip fracture was determined by examining dispensations of recognized osteoporosis therapies. All years of data show similar results. For example, among the 1802 women fracturing a hip or spine vertebra in 2001/2002, < 18% (n=317)were dispensed a known pharmacological treatment for osteoporosis and < 5% (n=83) had BMD testing in the year post-fracture. The same low patterns of intervention were found in the 4673 women with a non-spine/non-hip fracture in 2001/2002; 15.5% (n=723) were dispensed pharmacological treatment and only 7.0% (n=328) had BMD testing in the year post-fracture. Gaps in the treatment and prevention of osteoporosis in Manitoba women ≥ 50 years old have been identified. Data responsive interventions are currently being implemented in a rural health region of Manitoba.

Development of a Model of Integrated Post-Fracture Care. S. Jaglal[1], G. Hawker[2], E. Bogoch*[3], S. Cadarette[4], J. Carroll*[5], D. Davis*[3], L. Jaakkimainen*[5], H. Kreder*[3], W. McIsaac*[5]. [1]Rehabilitation Science, University of Toronto, Toronto, ON, Canada, [2]Medicine, University of Toronto, Toronto, ON, Canada, [3]Surgery, University of Toronto, Toronto, ON, Canada, [4]Health Policy Management and Evaluation, University of Toronto, Toronto, ON, Canada, [5]Family and Community Medicine, University of Toronto, Toronto, ON, Canada.

The objective of this study was to develop a model for integrated post-fracture care in the province of Ontario, Canada. Both qualitative and quantitative research methodology were utilized to identify barriers and opportunities for post-fracture care interventions. A literature review was first conducted. A provincial telephone survey of all 178 hospitals in Ontario was also conducted to describe the current processes and patterns of post-fracture care in hospitals. Four focus groups were conducted with 26 family physicians to determine the factors influencing post-fracture care, including the diagnosis, treatment and management of osteoporosis. Four focus groups were also conducted with 21 fragility fracture patients to examine their experiences with fracture care, awareness of osteoporosis and information needs. Thirty-four key informant interviews were conducted to validate the findings from the hospital survey, to identify community-based services and programs, to explore roles and responsibilities of various organizations and health care professionals and to identify barriers and facilitators for post-fracture care. Finally, a stakeholder consultation workshop was held to obtain feedback on the feasibility of a proposed model of integrated post-fracture care. Findings suggest that there are gaps in investigation and treatment and a lack of integration between health care professionals who provide fracture care and those who provide osteoporosis management and falls prevention. The development of a model for integrated post-fracture care resulted from triangulating the information. The model reflects the complexity of post-fracture care, from the acute management of the fracture and the role of in-hospital health services (e.g. emergency departments, rehabilitation services, orthopaedic services), through follow-up in the primary care setting (e.g. family physicians, nurse practitioners, pharmacists), and with services and programs provided by community-based organizations. There is an additional telemedicine multidisciplinary osteoporosis clinic component. Interventions were identified for each of the model components. These need to be evaluated for feasibility and outcome effectiveness. A demonstration project is currently underway to implement and evaluate this model in four communities in Ontario, Canada.

Impact of Vertebral Deformities, Osteoarthritis and Other Chronic Diseases on Quality of Life: A Population-based Study. N. M. Van Schoor*[1], J. H. Smit*[2], P. Lips[3]. [1]EMGO Institute, VU University Medical Center, Amsterdam, Netherlands, [2]Department of Sociology and Social Gerontology/ Department of Psychiatry, VU University Medical Center, Amsterdam, Netherlands, [3]EMGO Institute/Department of Endocrinology, VU University Medical Center, Amsterdam, Netherlands.

Vertebral deformities and spinal osteoarthritis are common disorders in elderly persons and are associated with back pain, impaired physical functioning, and loss of quality of life. The objectives of this study were to assess the impact of vertebral deformities and spinal osteoarthritis on quality of life in a population-based sample, and to compare this to the impact of six other important chronic diseases on quality of life.

The study was performed as a substudy of the Longitudinal Aging Study Amsterdam. Vertebral deformities and osteoarthritis were assessed by spinal radiographs in 1998/1999; chronic diseases were assessed by self-report; quality of life was estimated by the physical and mental component summary scales of the SF-12 (PCS-12 and MCS-12) in 1998/1999, and by the EQ-5D (EuroQol) and Qualeffo-41 in 2001/2002 (n=336).

The prevalence of the different diseases was 21.4% for severe osteoporosis of the vertebrae, 42.3% for spinal osteoarthritis, 18.2% for chronic obstructive pulmonary disease (COPD), 26.2% for cardiac disease (CD), 11.0% for peripheral arterial disease (PAD), 8.3% for diabetes mellitus (DM), 7.1% for cerebrovascular accident (CVA) and 15.2% for cancer. Most persons suffered from 2 chronic diseases. In univariate analyses, severe osteoporosis of the vertebrae significantly worsened quality of life as assessed by the PCS-12 (-3.5 points difference in median score; p=0.02) and the total score of Qualeffo-41 (+6.5 points; p=0.04). The impact of osteoarthritis on quality of life was less pronounced and not statistically significant. The other chronic diseases reduced quality of life, although not all changes reached statistical significance. In multivariate analyses, the largest decrease in quality of life, as measured by the PCS-12, was seen for DM (standardized Beta=-1.21), closely followed by PAD (-1.17) and CD (-1.12). Severe osteoporosis of the vertebrae showed a similar worsening of quality of life when assessed by the Qualeffo-41 (+1.12). In conclusion, most persons in an elderly population suffer from one or more chronic diseases, and therefore experience loss of quality of life. After adjustment for age, sex and other chronic diseases, DM, PAD, CD and severe osteoporosis of the vertebrae showed the largest decrease in quality of life. Although the degree of quality of life loss is largest for DM and PAD, the burden of CD and osteoporosis might be higher because of their higher prevalence.

Gender Affects Presentation and Outcome in Osteoporosis and Myeloma Patients Who Undergo Kyphoplasty. S. V. Bukata, J. Koob*, J. M. Lane. Orthopaedics, Hospital for Special Surgery, New York, NY, USA.

Patients with osteoporosis or multiple myeloma suffer vertebral compression fractures with resulting pain and functional disability from biomechanical changes in the spine and residual kyphosis. 45 (36 female/6 male) consecutive osteoporosis patients and 17 (10 female/ 7 male) consecutive myeloma patients with vertebral compression fractures underwent unipedicular balloon kyphoplasty with PMMA stabilization to restore as much normal height and angulation as possible to their fracture site. Patients were evaluated preoperatively and post-operatively with the validated general Oswestry back questionnaire. In the entire population of age, gender, and fracture number matched individuals we found equivalent pain relief and functional improvement between the myeloma and osteoporosis groups. Gender specific analysis within the groups revealed a few important differences. Average pre-operative and post-operative Oswestry scores were greater amongst the female osteoporotic patients (Female 52.9/Male 37.7 pre-operative, and Females 39.1/ Male 22.7 post-operative), but change in the score following surgery was not different (Female 13.8/Male 15.0). With myeloma, male average pre-operative scores were greater than female (Male 53.1/ Female 41.2) but the average post-operative scores were almost identical (Males 32.0 / Females 32.2). Vertebral height restoration was equivalent between all groups, and men and women in both groups experienced good results. In this instance, caution must be used in setting a minimal pre-operative score for consideration for kyphoplasty since osteoporotic men tend to score lower, yet experience equivalent improvement with the procedure. Due to the differences in both presentation and final outcome, gender specific analysis is critical in evaluating outcome data for orthopaedic procedures, including kyphoplasty.

Bone Mass Measurements Are Associated with Cardiovascular Mortality: A 5-year Analysis. M. M. Pinheiro*, C. H. M. Castro, R. E. Heymann*, K. R. B. Oliveira*, C. Ohashi*, V. L. Szejnfeld. Rheumatology, Unifesp, Escola Paulista de Medicina, Sao Paulo, Brazil.

Previous studies suggest that osteoporotic fracture is associated with increased risk of mortality, however the relationship between bone mineral density (BMD), quantitative ultrasound (QUS) and mortality is still controversial. Our aim was to evaluate the ability of BMD and QUS measurements to predict new osteoporotic fracture and mortality. Two-hundred seventy five women were invited to participate in this study. Risk factors for osteoporosis and fracture were evaluated by a questionnaire that included details concerning lifestyle habits, diet, hormonal factors and drug use. Patients with suspected secondary osteoporosis were excluded. Spine and femur BMD (DPX-L, Lunar) and calcaneus QUS (Achilles +, Lunar) were performed in all patients at baseline. Lateral thoracic and lumbar X-ray was taken at baseline and 5-year later to confirm the presence of vertebral fractures. Five-year after baseline visit, all reported deaths were confirmed by review of hospital records and classified according to ICD-10 code. Two-hundred eight (75.6%) women completed the study and 25 (9.1%) lost follow-up. Mean age and weight were 75.2 ± 6.5 years and 60.3 ± 10.2 kg, respectively. Forty-two (15.3%) women died (incidence rate = 36.2/ 1.000 person-years) and 41 patients (19.7%) had new osteoporotic fracture (incidence rate = 41.7/ 1.000 person-years). After adjustments for age, weight, previous fracture, smoking, physical activity, drugs and comorbities, femoral neck BMD, trochanter BMD and stiffness index (SI) were associated with new osteoporotic fracture [standardized HR = 2.0 (95% CI 1.26-3.18), 1.62 (95% CI 1.08-2.42) and 2.2 (95% CI 1.30-3.82), respectively]. Trochanter BMD, SI and femoral neck BMD were the most significant predictors of death in this population [standardized HR = 1.59 (95% CI 1.07-2.36), 1.57 (95% CI 1.10- 2.46) and 1.43 (95% CI 1.06-2.22), respectively]. Cardiovascular mortality was also associated with low femoral neck BMD [RH = 1.28 (95% CI 1.07-2.62)], trochanter BMD [RH = 1.30 (95% CI 1.08-2.18)] and SI [RH = 1.54 (95% CI 1.08-2.79)]. Mortality due to cancer, infectious or pulmonary diseases had no statistically significant association with BMD or QUS measurements. Spine BMD was not related to the risk of new fracture or death. In conclusion, low SI and femur BMD were able to predict the risk of new osteoporotic fracture and were associated with total and cardiovascular mortality, independently of age, health status and other diseases in Brazilian elderly women. These results reinforce epidemiological and biological recent evidence supporting common physiopathological aspects between osteoporosis and atherosclerosis.

Low Bone Mineral Density of Distal Forearm Predicts the Mortality in Elderly Men - the MINOS Study. P. M. Szulc[1], F. Munoz*[1], F. Marchand*[2], P. D. Delmas[1]. [1]Epidemiology of Osteoporosis, INSERM 403 Research Unit, Lyon, France, [2]SSMB, Montceau les Mines, France.

Only limited data on the association between areal bone mineral density (aBMD) and mortality are available in men. We evaluated if cross-sectional area (CSA), aBMD, volumetric BMD (vBMD) and morphologic parameters (external diameter, cortical thickness) predict the risk of death in 792 men aged 50 to 85 belonging to the MINOS cohort. During the follow-up of 7.5 yrs, 134 men died. After adjustment for age, co-morbidity, medication, hormonal levels and professional physical activity, decreased aBMD of distal forearm and ultradistal radius was associated with higher mortality (O.R. = 1.25-1.30 per 1 SD decrease, p < 0.02-0.002). In analyses performed separately for radius and ulna, decreased CSA, aBMD, vBMD and cortical thickness of each bone were associated with increased mortality (O.R. = 1.20 - 1.34 per 1 SD decrease, p < 0.04-0.02) whereas the external diameter was not (p>0.6). In similar multiple adjusted models, hip and lumbar spine BMD were not associated with the increased mortality (p>0.15).

In summary, our data indicate that in elderly men decreased CSA, aBMD, vBMD and cortical thickness of distal radius and ulna, but not of lumbar spine and hip, are associated with a higher mortality. Bone mineral of distal forearm, which is neither a weight-bearing site nor influenced by osteoarthritis, may reflect the deterioration of general health status better than other sites of measurement.

Relationship of Diabetes and Falls in Older Men. T. L. Dam[1], R. Fullman[2], P. M. Cawthon[2], J. Cauley[3], E. Orwoll[4], E. Barrett-Connor[5]. [1]Medicine, UCSD, San Diego, CA, USA, [2]Prevention Studies Group, UCSF, San Francisco, CA, USA, [3]U. of Pittsburgh, Pittsburgh, PA, USA, [4]Medicine, OHSU, Portland, OR, USA, [5]Family and Preventive Medicine, UCSD, San Diego, CA, USA.

Patients with diabetes have increased bone mineral density. Nevertheless, several studies have shown that diabetics also have increased rates of fracture possibly due to an increased risk of falls that may contribute to their increased fracture rates.

We evaluated 5,995 community dwelling men ages 65 years and older enrolled in the prospective cohort study of Osteoporotic Fractures in Men. Self reported diabetes status and multiple covariates were collected at a baseline visit via questionnaire in 2000-2002. Physical, cognitive, visual and neuromuscular functions were measured at the baseline visit. Incidence of falls was ascertained every 4 months by a mailed questionnaire for 2 years (response rate >95%). We compared the prevalence of risk factors for falls and incidence of falls by diabetes status.

The 653 (10.9%) men who reported diabetes had significantly higher BMD scores (at the total spine, total hip, femoral neck, trochanter and intertrochanter) compared to nondiabetics. During each year of follow up, a higher percentage of men with diabetes fell compared to men without diabetes. By the end of year 2, 40% of men without diabetes and 47.4% of men with diabetes had reported at least 1 fall (p=.0003), with an age-adjusted 36% increased fall risk (OR 1.36 (1.15-1.61), p<.0001). More than 10 previously described risk factors for falls were significantly (p <.0001) more prevalent in men with diabetes. After adjusting by logistic regression models for selected covariates (age, weight, history of cataracts or stroke, dizziness, use of benzodiazepine, loop diuretic and tricyclic antidepressant, depth perception and grip strength), the risk of falling associated with diabetes decreased and was no longer statistically significant (OR 1.15 (0.97-1.38), p=.11).

Diabetes was associated with better BMD and an increased risk of falls in these older men. Diabetes co-morbidities and associated medications may explain the higher fall risk, as evidenced by the attenuation of the diabetes fall association in multiply adjusted analyses. These results suggest a multifactorial etiology for the increased risk of fracture despite higher BMD levels observed in diabetics.

Comparison of the OST Versus a Typical Risk-Factor Questionnaire for Evaluating Osteoporosis in Men. C. L. Sybrowsky*, J. G. Skedros. Utah Bone and Joint Center, Salt Lake City, UT, USA.

Although dual-energy x-ray absorptiometry (DXA) is an effective means of determining low bone mineral density (BMD), identifying the appropriate population to screen remains a topic of controversy. This is especially problematic in males, since the majority of osteoporosis risk-assessment models have focused on females. Previous studies have shown that the osteoporosis self-assessment screening tool (OST) is highly sensitive for identifying males at risk for osteoporosis (Adler et al., 2003 Mayo Clin Proc). This value is determined as: [(weight in kg - age in years) × 0.2, truncated to an integer]. The purpose of this study was to determine if the OST more strongly correlated with BMD than responses to a 'typical' risk-factor questionnaire that assessed 30 known or suspected risk factors for osteoporosis or osteoporosis-related fracture in men. This questionnaire has been used in our orthopaedic surgery specialty clinic to determine candidates for DXA and to provide documentation of risk to insurance companies for payment authorization. A population of 158 American Caucasian men with a mean age of 67.5 ± 13.1 years and weight of 85.3 ± 16.0 kg completed the risk-assessment questionnaire and underwent central DXA (total hip, femoral neck, and lumbar spine). T-scores for the population were then correlated with questionnaire responses and OST risk indices. 16.5% of the men had T-scores lower than -2.5 at one or more of the scanned sites. OST indices ranged from -6 to 16 (mean 4 ± 5). Total number of reported risk factors ranged from 0 to 13 (mean 4 ± 2). When defining osteoporosis as a T-score of ≤ -2.5, an OST index of ≤ 3 yielded sensitivity of 92%, specificity of 55%, positive predictive value of 29%, and negative predictive value of 97%. Questionnaire assessment of 3 or more risk factors yielded sensitivity of 65%, specificity of 42%, positive predictive value of 18%, and negative predictive value of 86%. These data confirm the high sensitivity of the OST for detecting osteoporosis in men and demonstrate that it more accurately predicts low BMD than gross quantification of standardized risk factors. However, since the risk-assessment questionnaire assigns equal importance to each of the 30 risk factors, differential weighting of risk factors may improve sensitivity/specificity.

Osteoporosis prevalence determined by OST index and standardized risk-assessment questionnaire

Category	T-score ≤ -2.5	T-score ≤ -2.0
OST ≥ 4	2.7% (2/75)	8.0% (6/75)
OST -1 to 3	26.6% (16/60)	38.3% (23/60)
OST ≤ -2	34.8% (8/23)	56.5% (13/23)
3 or more risk factors	18.1% (17/94)	28.7% (27/94)
5 or more risk factors	22.7% (10/44)	40.9% (18/44)

Predictors of Femoral Neck Geometry in Caribbean Men: The Tobago Bone Health Study. L. M. Semanick*[1], T. Beck[1], J. A. Cauley[2], V. Wheeler*[3], A. Patrick*[3], C. Bunker*[2], J. M. Zmuda[2]. [1]Radiology, Johns Hopkins University, Baltimore, MD, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]Tobago Hospital, Trinidad, Trinidad and Tobago.

Osteoporotic fracture is less prevalent in African Americans than Caucasians suggesting a difference in bone structural strength. Studies of bone differences in African Americans are confounded by their heterogeneity due to their admixture of African, European and other origins. We analyzed the associations between anthropometry, lifestyle factors

and bone cross sectional geometry in 1,886 men of African descent on the Caribbean island of Tobago (age > 39 y; mean 56 y). Femur neck geometry was assessed with Hip Structure Analysis on hip DXA scans. In multiple linear regression models using forward selection, age, body size and composition, indirect measures of physical activity, fracture history, and presence of several health related conditions including coronary heart disease, high blood pressure (HBP), arthritis and diabetes were considered as independent predictors of section modulus (Z), cross sectional area (CSA), BMD and neck width. Standardized beta coefficients for significant predictors ($p<0.05$) of these parameters after adjusting for neck shaft angle, age and neck length are listed in the Table. Multivariate models accounted for over 40% of the variance in Z and CSA. Ever being a farmer was positively associated with CSA and BMD but not Z unless appendicular lean mass (ALM) is taken out of the model indicating that the bone strength effect was mediated through muscle size. Diabetes was associated with all skeletal parameters and requires further investigation. Arthritis was negatively associated with BMD, but not with strength properties or width. Sustaining a fracture after the age of 35 had a significant negative association with BMD apparently due to a positive effect on width but not on the amount of bone (CSA) or Z. Minutes walked per week, smoking, coronary heart disease, or a family history of fracture were not independent predictors of Z, CSA, BMD and width. Offsetting the negative association of age with BMD are opposing trends in femoral neck width and the amount of bone it encloses (CSA); the net effect is that age has no significant association with bending strength (Z). These associations are consistent with a model whereby periosteal expansion might compensate for the loss of bone mass with aging.

	Z	CSA	BMD	Width
Age	-	-0.143	-0.181	0.204
Height	0.239	0.156	-	0.383
ALM	0.441	0.464	0.400	0.133

Risk Factors Associated To Low-Impact Fractures In Men With Ankylosing Spondylitis. R. E. Heymann*, L. Nappo*, R. Vilela*, K. Luz*, M. M. Pinheiro*, V. L. Szejnfeld*. Rheumatology, UNIFESP, São Paulo, Brazil.

Ankylosing spondylitis (AS) is associated with low bone mineral density (BMD). Whether low bone mass in this patients leads to increased fracture rate is still not clear.

The purpose of this study was to determine fracture rate and investigate risk factors associated with low-impact fracture in men with AS.

Eight-Five men were enrolled in this cross-sectional study (40 age matched healthy controls). Clinical risk factors were evaluated by a questionnaire that included details about aspects of lifestyle, diet, drug use and previous fracture. Spine and femur BMD (DPX-L, Lunar) and heel QUS (Achilles +, Lunar) measurements were performed in all the subjects. Lateral thoracic and lumbar radiographs were taken to check for the presence of vertebral fractures, according to Genant's method.

AS patients were thinner and shorter than healthy controls (HC).The mean age, weight and height are 42.6 ± 10.6 vs. 38.4 ± 10 years, 71.7 ± 8.5 vs. 67 ± 17,1 kg, and 1.68 ± 0.08 vs. 1.64 ± 0.08 m, respectively (HC vs. AS). Vertebral deformity (grades II and III) had a significantly 2 fold increase in AS paients compared to HC (identified in 21 AS patients and 12 HC). Patients with AS also had more non vertebral fractures. Spine and femur BMD and QUS measurements were not singnificantly different between AS patients and HC. The mean spine BMD and stiffness index were 1.170 ± 0.17 vs. 1.180 ± 0.24 g/ cm2 and 96,1 ± 17,2 vs. 91,5 ± 19,3, respectively (HC vs. AS) (NS).The most relevant risk factors to discriminate AS patients with low-impact fractures from non-fracture were race and previous history fracture.

In conclusion, the clinical risk factors for fractures were more important than bone mass measurements to discriminate AS patients with low-impact fracture from those without. Interestingly, AS patients had a higher rate of fractures even with BMD and QUS values similar to that observed in the healthy population.

Race/Ethnic Differences in Bone Mineral Density in Men: Preliminary Results from BACH/BONE. A. B. Araujo[1], S. S. Harris[1], M. F. Holick[2], A. Turner*[2], J. B. McKinlay*[1]. [1]New England Research Institutes, Watertown, MA, USA, [2]School of Medicine, Boston University, Boston, MA, USA.

While there are a number of studies on bone mineral density (BMD) in men, few present racial/ethnic differences by skeletal site. Our objective was to estimate racial/ethnic differences in areal BMD in men at the femoral neck, total radius and ulna (forearm), L2-L4 lumbar spine (spine), and whole body. We report preliminary, unweighted BMD data from the Boston Area Community Health/Bone (BACH/BONE) Survey, a population-based study of skeletal health in a racially/ethnically diverse sample of Boston men aged 30-79 y. Data are available for N=538 men. Race/ethnicity was determined by self-report. BMD (g/cm^2) was measured at the hip, forearm, spine, and whole body with a Hologic QDR 4500W, which was calibrated daily with a spine phantom supplied by the manufacturer. Mean age was 50.7±12.7 y. Means for each skeletal site were as follows: 0.867±0.142 g/cm^2 (femoral neck), 0.610±0.063 g/cm^2 (forearm), 1.056±0.159 g/cm^2 (spine), and 1.201±0.129 g/cm^2 (whole body). Compared with Whites, Blacks had 12.6%, 5.9%, 8.6%, and 6.8% higher age-adjusted femoral neck, forearm, spine, and whole body BMD, respectively. None of the Black-White differences were dependent on age. Race/ethnic differences in forearm BMD (Whites and Blacks 1.3% and 7.3% higher, respectively, than Hispanics) and whole body BMD (Whites and Blacks 2.4% and 9.4% higher, respectively, than Hispanics) were constant across age. However, race/ethnic comparisons in femoral neck and spine BMD varied by age, as shown in Table 1. In this population-based study of men, Black/White differences in BMD at various skeletal sites range from 5.9-12.6%. The difference at the hip is of similar magnitude to that reported in previous studies, but few studies provide estimates of Black-White differences at other skeletal sites. Observed Black/White differences suggest a parallel age decline in BMD in the two groups. Comparisons involving Hispanic men are more complex. Forearm and whole body BMD are higher in Whites and Blacks compared with Hispanics. Not noted in previous studies is the age-dependent race difference in femoral neck and spine BMD. Thus, Hispanic men may have steeper age declines in these parameters than observed in White or Black men, suggesting the possibility of a greater increase in fracture risk with age among this group.

Table 1. Whites and Blacks compared with Hispanics in femoral neck and lumbar spine BMD by age.

	White vs. Hispanic (%)		Black vs. Hispanic (%)	
Age	Femoral neck BMD	Spine BMD	Femoral neck BMD	Spine BMD
35 y	-7.8	-1.2	3.8	7.3
45 y	-5.6	1.7	6.3	10.4
55 y	-3.3	4.6	8.8	13.7
65 y	-1.0	7.7	11.3	17.0
75 y	1.4	10.8	14.1	20.4

Osteoporosis: A Silent Epidemic in Male Veterans. R. A. Adler[1], C. A. Hertel*[2], M. I. Williams*[3], V. I. Petkov*[1]. [1]Endocrinology, McGuire Veterans Affairs Medical Center/Virginia Commonwealth University School of Medicine, Richmond, VA, USA, [2]Primary Care, Veterans Affairs Western New York Health Care System - Batavia Division, Batavia, NY, USA, [3]Endocrinology, McGuire Veterans Affairs Medical Center/Virginia Commonwealth University School of Pharmacy, Richmond, VA, USA.

Osteoporosis (OP) is considered a disorder of older women, but we and others have found osteoporosis to be common among male veterans. We used data from screening studies in two Veterans Affairs Medical Centers (VAMC) to estimate the frequency of osteoporosis in men receiving medical care from the Department of Veterans Affairs. At the Richmond VAMC and the VA Western New York Healthcare System, we used the Osteoporosis Self-Assessment Tool (OST), a simple screening method (based on weight and age only) to determine which men in primary care clinics were at moderate or high risk for osteoporosis. The men who were referred by their primary care providers underwent DXA testing. From the DXA data and the distribution of men according to OST, we estimated the total number of male veterans with undiagnosed osteoporosis.

At the Batavia site, spine and hip DXA (Lunar DPX-L) of 612 men revealed 138 (22.5%) with osteoporosis and 265 (43.3%) with osteopenia. In Richmond, DXA testing (Hologic Delphi) of 441 men showed 109 (24.7%) with osteoporosis and 239 (54.1%) with osteopenia. We concluded that 23.5% of men at moderate or high risk by OST have silent osteoporosis.

In the Richmond primary care clinics, 5,645 out of 15,027 men (37.6%) were at moderate or high risk for OP according to OST. There are 4.5 million veterans receiving care from the Department of Veterans Affairs, and we estimated that 3.8 million are men. Using the above data, we calculated that there are 335,768 veteran men with silent osteoporosis. From our studies adding forearm DXA to spine and hip, the estimate would be 475,790.

In conclusion, we estimate that 12.5% of male veterans have osteoporosis and don't know it. It is likely that men followed in the community have a similar prevalence of osteoporosis. We conclude that screening methods such as OST should be used widely to uncover osteoporosis in men.

Family Physician Awareness of Risk Factors For Fracture and the Appropriate Use of Bone Mineral Density Screening in Accordance With The Canadian Osteoporosis Guidelines: Canadian Quality Circles (CQC) Project. A. Papaioannou[1], G. Ioannidis[1], M. Doupe*[2], A. Katz*[2], B. Kvern*[2], A. Hodsman[3], A. Baldwin*[4], D. Johnstone*[5], M. Baranci*[6], J. D. Adachi[1]. [1]McMaster University, Hamilton, ON, Canada, [2]University of Manitoba, Winnipeg, MB, Canada, [3]University of Western Ontario, London, ON, Canada, [4]St. Boniface Hospital, Winnipeg, MB, Canada, [5]Procter & Gamble Pharmaceuticals Inc, Toronto, ON, Canada, [6]Aventis Pharma, Laval, PQ, Canada.

The CQC Pilot Project is a one year, integrated disease management project to disseminate the OSC 2002 guidelines and to improve family physicians (FP) adherence to the guidelines. Fifty-two FP participated in the study and formed 7 quality circles. The FP enrolled a total of 1505 patients. These patients were women age 55 years and over and had attended at least 2 visits in the past 24 months. Data were gathered using the project data collection form.

Our baseline analysis examined the physicians' awareness of thirteen risk factors for fracture (9 major and 4 minor) and the appropriate use of bone mineral density (BMD) screening in accordance with the Canadian Osteoporosis guidelines. The major risk factors included age (>65 yr), prior hip fracture after age 40, prior wrist fracture after age 40, prior vertebral fracture after age 40, family history of fragility fracture, a fall in the previous 12 months, oral prednisone therapy (>3 months), menopause before age 45, and historical height loss (2-4 cm). The minor risk factors included caffeine intake (>4/day), alcohol intake (>9/week), current smoking, and weight (< 57 kg). Patients highly recommended for BMD screening were defined as those with one or more major risk factor, or two or more minor risk factors. Patients with one minor or no risk factors were not recommended for BMD screening in accordance with the guidelines.

Results indicated that 9 of 13 risk factors were identified by over 90% of FP. Four risk factors were identified by only 46-72% of the physicians. Of these, 3 risk factors were major (a family history of fragility fracture [46%], menopause before the age of 45 years [72%] and historical height loss [57%]; and 1 was minor (caffeine intake [57%]). FP reported prevalent hip, wrist, and vertebral fractures in approximately 5% of their patients. BMD screening was conducted in 65% of those highly recommended as compared with 57% for those not recommended.

In conclusion, most risk factors were identified by FP; however, the awareness of a few major risk factors should be strengthened. Given the low prevalence rates of prior fractures (much lower than reported in other studies), it is possible that many prior fractures were not recognized by the FP. Risk factor evaluation did not appear to have an important role in BMD assessment.

High Prevalence of 25(OH)D Deficiency and Secondary Hyperparathyroidism (sHPT) Suggesting "Osteomalacia in Immigrants" in a Turkish Population in Germany (TG) with Diffuse Skeletal Pain. M. Z. Erkal*[1], J. Wilde*[2], Y. Bilgin*[3], C. Algan[3], E. Demir*[3], R. Bretzel*[1], H. Stracke[1]. [1]Medizinische Klinik und Poliklinik III der JLU, Giessen, Germany, [2]Nichols Institute Diagnostika GmbH, Bad Vilbel, Germany, [3]Turkish-German Health Foundation, Giessen, Germany.

Background: the expression "osteomalacia in immigrants" has been used in England during the early 70th to describe a phenomenon observed in Pakistani and Indian immigrants. In 1978 Offermann used the same term in a study including 97 Turkish people living in Germany. During the last years the number of patients in TG complaining of diffuse skeletal pain has constantly increased. Therefore we studied parameters of bone metabolism in TG in comparison to matched groups of Germans (G) and Turks living in Turkey (T).

Methods: 994 apparently healthy volunteers (age 16-70, median 37 years, BMI 16-47, median 23 kg/m^2) were included and divided into 3 groups: (T) 242 female (f) and 85 male (m) Turkish individuals living in Turkey; (TG) 296 f and 270 m Turkish individuals living in Germany and (G): 51 f and 50 m German individuals living in Germany. EDTA blood samples were collected during March to measure 25(OH)D, BioPTH (1-84) and Calcium. Additionally clinical data were obtained by standard questionnaires, including the items age, sex, country, city, BMI, veiled/not veiled, smoking habits, nutritional habits, sun exposure, diffuse skeletal pain, number of children and duration of stay in Germany (TG).

An unconditional logistic regression model was used to calculate relations between different parameters.

Results: Despite similar low 25(OH)D values (75-80% with <20 ng/mL) in all Turkish volunteers only the immigrants in Germany showed elevated PTH values indicating high prevalence of sHPT. Especially veiled female Turkish immigrants were at high risk. In individuals with low 25(OH)D levels the risk of diffuse skeletal pain was increased (x1.8).

Nichols Advantage® 25(OH)D (ng/mL)	Females Median [95% CI]	Males Median [95% CI]	P (females / males)
G	28,7 [20,3; 37,1]	23,4 [17,4; 29,5]	n.s.
T	14,3 [10,7; 18,7]	18,6 [15,6; 22,6]	<0,0001
TG	12,5 [9,5; 17,1]	15,8 [12,6; 19,2]	0,0005
Nichols Advantage® BioPTH (pg/mL)			
G	25,6 [22,8; 28,5]	27,8 [25,1; 30,6]	n.s
T	27,4 [25,8; 29,0]	27,6 [25,4; 29,8]	n.s
TG	37,1 [34,2; 39,9]	34,0 [31,9; 36,1]	n.s

25(OH)D level < 20 ng/mL = deficiency, Bio-PTH reference range: 6-40 pg/mL

Discussion: sHPT due to 25(OH)D deficiency bears the risk of osteomalacia/osteoporosis. Therefore Turkish immigrants in Germany should be regarded as a risk population. In case of diffuse skeletal pains 25(OH)D and PTH levels should be controlled. If "osteomalacia in immigrants" is diagnosed calcium and vitamin D should be substituted.

Gender Differences in Relationships between Body Composition Components, Their Distribution and Bone Mineral Density: An Opposite Sex Twin Study. J. Makovey*[1], P. Sambrook[1], V. Naganathan[2]. [1]Department of Rheumatology, Institute of Bone and Joint Research, Royal North Shore Hospital, University of Sydney, Sydney, Australia, [2]Centre for Education and Research on Ageing, Centre for Education and Research on Ageing,Concord Hospital, University of Sydney, Sydney, Australia.

Background: Numerous studies indicate that bone mineral density (BMD) is closely related to body mass and its components. Most studies have examined these relationships in women with little attention given to how these relationships differ by gender.

Aims: The aims of the present study were to use the opposite sex twin model to determine if there were gender differences in the relationship between body composition and its relation to BMD and how any such differences were influenced by age.

Methods: We measured body composition and bone mass by dual energy x-ray absorptiometry in 93 pairs of opposite sex twins. To examine the effect of age, they were divided into two age groups: under 50 years old (45 pairs) and over 50 years old (48 pairs).

Results: Lean mass (LM) had stronger positive relationships with bone variables in both genders at all ages than fat mass. Fat mass (FM) had positive relationships with total body, lumbar and hip BMD in women under age 50, but not over 50. In general, use of volumetric regional BMD did not improve associations with fat mass or lean mass. There was no significant relationship between FM and total or regional BMD in men under age 50, but men over 50 showed positive relationships between FM measures and total and some regional BMD measures. Central adiposity showed a positive relationship with BMD in men over 50 and women under 50.

Conclusion: Fat mass (FM) and lean mass (LM) and their distribution in the body have different relations with BMD in men and women with ageing.

Key words: Bone mineral density, body composition, fat mass, lean mass

Increased Circulating hsCRP Levels Associated with Low Bone Mineral Density in Healthy Pre- and Postmenopausal Women: Evidence for Links between Systemic Inflammation and Osteoporosis. J. Koh[1], Y. Khang*[2], S. Bae*[1], Y. Chung*[3], G. S. Kim[1]. [1]Division of Endocrinology and Metabolism, Asan Medical Center, University of Ulsan College of Medicine, Seoul, Republic of Korea, [2]Department of Preventive Medicine, Asan Medical Center, Seoul, Republic of Korea, [3]Department of Internal Medicine, Seoul Veterans Hospital, Seoul, Republic of Korea.

Factors involved in inflammation have been associated with bone remodeling. We therefore investigated the association between serum concentrations of high sensitivity C-reactive protein (hsCRP) and bone mineral density (BMD) in 3,662 healthy premenopausal and 1,031 postmenopausal Korean women. At the femoral neck, there was a significant association between the highest hsCRP quintile and low BMD after adjustment for confounding variables in pre- (p=0.0026) and post- (p=0.0006) menopausal women, when compared with the lowest quintile. At the lumbar spine, however, this association was marginal in both groups (p=0.0602 for premenopausal; p=0.0711 for postmenopausal). In premenopausal women with the highest hsCRP quintile, the odds ratio (OR) for osteopenia/osteoporosis was 1.354 (CI=1.018-1.801) at the lumbar spine and 1.377 (CI=1.099-1.726) at the femoral neck. In postmenopausal women, the OR for osteoporosis was high at the femoral neck (OR=3.260, CI=1.546-6.873), but not at the lumbar spine (OR=1.269, CI=0.750-2.149), suggesting a difference that may be due to osteophyte or aortic calcifica-

tion with aging at the spine. These results indicate that hsCRP may be a useful marker in the risk assessment of osteoporosis. In addition, our findings suggest a role of subtle systemic inflammatory processes in the determination of bone mass.

Rapid Weight Loss Related To Gastric Lap-Banding Is Associated With Loss Of Femoral Neck Bone Mass, Predicted By Baseline Truncal Fat. K. M. Sanders*[1], G. K. Kiroff*[2], G. C. Nicholson[1]. [1]Clinical and Biomedical Sciences, The University of Melbourne, Geelong, Australia, [2]St John of God Hospital, Geelong, Australia.

There is evidence that rapid or marked weight loss in the obese also results in bone loss. This study aimed to identify the sites of most significant bone loss accompanying large decreases in body weight following lap-band gastric surgery and to identify the best predictors of bone loss. Subjects (20 women, 4 men) undergoing surgery for morbid obesity had baseline and serial six-monthly DEXA scans for two years (Lunar DPX-L; total body, L2-L4, hip and forearm sites). Biochemistry was measured at baseline. The characteristics of the group were (median, range): age 44, 25-60 years; initial weight 264, 200-387 lbs; initial BMI 42, 34-56; weight loss 51, 16-113 lbs; decrease in BMI 8, 2-20. The median baseline FN T score was +1.1 (range -0.7 to +2.6). The largest bone loss occurred at the femoral neck (FN) BMC -3.0% (-0.17g, -0.89 55to +0.55g) and BMD -2.7%, equivalent to 0.25 SD change. One woman shifted from normal to osteopenic range BMD at this site. Loss of FN BMC was best predicted by baseline truncal fat (R^2 adj 23%, p=0.012). This relationship was not strengthened when males were excluded (p=0.03). Baseline total body fat, and serum SHBG in females, were less strong predictors (R^2 adj 7.2%, p=0.12, 10.4%, p=0.12 respectively). Serum estradiol, PTH, 25-OH vitamin D and C-peptide levels were not significant. Adjusting for age, gender and time between scans (median 12mths) did not change the results. Changes in weight, total body or truncal fat and lean mass were not significant predictors of FN bone loss. BMD changes at other sites were -0.3% L2-L4 and +0.5% UD forearm and +0.8% at mid forearm.

Losses of bone mass associated with lap-band surgery are sufficient to significantly increase risk of fracture, particularly hip fracture, but in this study appear to be more strongly related to baseline measures than change in body composition. Although methodological problems in the serial analysis of body composition using DEXA may influence results, initial BMI was a better predictor of the decrease in FN BMC than change in BMI (p=0.16 and p=0.56, respectively). The amount of FN bone loss accompanying significant weight loss may be partially determined by factors such as common genetic determinants of fat and bone mass and/or dietary changes.

SA376

The Oslo Health Study: Biochemical Markers of Bone Turnover and Their Relation to Parathyroid Hormone Levels in Persons of Pakistani and Norwegian Origin Living in Oslo. K. Holvik*[1], H. E. Meyer*[1], J. A. Falch*[2], A. J. Søgaard*[3], E. Haug*[4]. [1]Department of General Practice and Community Medicine, University of Oslo, Oslo, Norway, [2]Department of Internal Medicine, Aker University Hospital, Oslo, Norway, [3]Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway, [4]Hormone Laboratory, Aker University Hospital, Oslo, Norway.

We have shown that the prevalence of secondary hyperparathyroidism (i.e. low serum 25-hydroxy vitamin D and elevated parathyroid hormone levels) was much higher in Pakistan-born than in Norwegian-born persons attending the Oslo Health Study. In spite of this, bone density in the Pakistanis was at least as high as that in Norwegians. We wanted to explore possible ethnic differences in bone turnover in these groups.

The aim was to study the levels of biochemical markers of bone turnover and the correlation between parathyroid hormone levels and bone marker levels in Pakistanis and Norwegians living in Oslo.

Serum levels of intact parathyroid hormone (s-iPTH), osteoblast markers osteocalcin (s-OC) and bone specific alkaline phosphatase (s-bALP), and osteoclast marker tartrate resistant acid phosphatase (s-TRAP) were measured in a subgroup of Pakistanis and Norwegians participating in the large population-based Oslo Health Study 2000-2001. We here present results for 141 Pakistani men and women aged 30-45 years, and 167 Norwegian men and women aged 45 years.

Mean age-adjusted s-OC was 1.23 nmol/l in Pakistanis and 1.45 nmol/l in Norwegians (p=0.006), a difference corresponding to nearly 1/2 SD. Norwegian women had s-OC levels 0.32 nmol/l higher than Pakistani women (p=0.010), whereas Norwegian men had s-OC levels 0.15 nmol/l higher than Pakistani men (ns). Mean age-adjusted s-bALP was 19.1 U/l in Pakistanis and 17.6 U/l in Norwegians (ns). Mean age-adjusted s-TRAP was 2.30 U/l in Pakistanis and 2.43 U/l in Norwegians (ns).

In Norwegian women there was a positive correlation between s-iPTH and s-bALP (r=0.30, p=0.004), and between s-iPTH and s-OC (r=0.25, p=0.017). In Pakistani women there was a positive correlation between s-iPTH and s-bALP (r=0.29, p=0.020), and a tendency to a positive correlation between s-iPTH and s-OC (r=0.23, p=0.065). S-iPTH was not correlated to s-TRAP in any of the groups. There were no correlations between s-iPTH and bone marker levels in men.

In conclusion, there were no striking ethnic differences in levels of bone turnover markers, although the levels tended to be higher in Norwegians. Although bone marker levels were correlated to parathyroid hormone levels also in Pakistani women, the widespread secondary hyperparathyroidism in Pakistanis does not seem to influence bone turnover adversely at this age.

Osteoporosis Risk Factor Assessment: Comparison of Interviewer-assisted, Patient Self-report and Physician-supplied Data Sources. C. K. Yuen[1], W. D. Leslie[2], C. Metge*[3], B. Kvern*[4], L. Manness*[5]. [1]Obstetrics and Gynecology, Manitoba Clinic, Winnipeg, MB, Canada, [2]Internal Medicine, Nuclear Medicine, University of Manitoba, Winnipeg, MB, Canada, [3]Faculty of Pharmacy, University of Manitoba, Winnipeg, MB, Canada, [4]Family Medicine, University of Manitoba, Winnipeg, MB, Canada, [5]Merck Frosst Canada, Montreal, PQ, Canada.

Clinical risk factor (CRF) and medical risk factor (MRF) assessment has been shown to predict low BMD and fracture when derived from an interviewer-assisted (IA) survey. Our objective was to determine if survey instrument could be adapted to give valid results from patient self-report (SR). We evaluated twelve CRFs (JCD 5(2):117-130, 2002: overall health, physical activity, mobility, current smoking, current weight, height at age 25, height loss, any fracture after age 50, osteoporotic fx in parents/siblings, fall in previous 12 months, previous hyperthyroidism, age) and four MRFs (abnormal menstrual cycling, premature menopause, surgical menopause, steroid use > 3 months). A convenience sample of 63 menopausal women referred for BMD testing was mailed a SR assessment tool three weeks prior to BMD testing. The same tool was completed using IA on the day of BMD testing. Physician supplied (PS) CRF information was extracted from the BMD test requisition which assesses the same items (PS MRF information not available). Agreement between individual items (kappa) and total scores (corr coeff) was determined. Mean total CRF and total MRF were similar for SR and IA (P>0.2) while PS gave a significantly greater total CRF than SA (P=.002) or IA (P=.001). There was excellent agreement between SA and IA for both total CRF (R=0.90, P<.001) and total MRF (R=0.89, P<.001), and also for the individual items (all P<.001). In contrast, only a modest correlation was found between total CRF scores for PS and IA (R=0.39, P=.002) and the individual items. We conclude that interviewer-assisted and patient self-report can provide equivalent CRF and MRF information. Routine physician-supplied CRF information shows a weak agreement and is unlikely to be useful for research purposes.

	SA versus IA	PS versus IA
Total CRF (mean ± SD)	2.8 ± 0.2 versus 2.7 ± 0.2	3.1 ± 0.2 versus 2.7 ± 0.2
Total CRF Correlation (R)	0.90	0.39
Individual CRFs (mean kappa)	0.79 (range 0.49-0.97)	0.37 (range 0.22-0.68)
Total MRF (mean ± SD)	1.0 ± 0.1 versus 1.0 ± 0.1	--
Total MRF Correlation (R)	0.89	--
Individual MRFs (mean kappa)	0.78 (range 0.47-0.96)	--

Differences in Hip Bone Mineral Density and Strength between Glucocorticoid-treated and Glucocorticoid-naïve Postmenopausal Women. K. Lian*[1], T. F. Lang[1], J. H. Keyak[2], G. W. Modin*[1], Q. Rehman*[1], N. E. Lane[1]. [1]University of California, San Francisco, San Francisco, CA, USA, [2]University of California Irvine Medical Center, Orange, CA, USA.

Chronic treatment with glucocorticoids (GC) leads to significant bone loss, osteoporosis, and often results in bone fractures. In GC treated subjects, bone mineral density (BMD) has typically been evaluated by dual-energy X-ray absorptiometry (DXA) to assess fracture risk. However, since GC induce significant trabecular bone loss, DXA may underestimate fracture risk. The purpose of this investigation was to determine if there are differences in trabecular BMD, cortical BMD, volume, and bone strength of the hip between GC treated osteoporotic patients and controls.

Study subjects were GC treated osteoporotic postmenopausal women (PMO) and controls were PMO recruited for separate clinical trials. QCT and DXA of the hip were obtained in all subjects. QCT outcome variables measured included total, cortical, and trabecular BMD of hip subregions (femoral neck, trochanter) and total hip. In addition, finite element modeling (FEM) was performed on a subset of 19 cases and 38 controls, matched on age (± 5yrs), weight (± 5kg), and history of hormone replacement (>1yr use) to assess failure load in stance and fall loading conditions.

Compared with controls subjects, GC treated subjects were significantly ($p<0.05$) younger, weighed less, and had more years of hormone replacement. QCT of the hip in GC treated subjects for total femoral integral, cortical, and trabecular BMD averaged 4.9-23.2% ($p<0.002$) less than controls, and similar results were seen by hip subregion including the trochanter and femoral neck. DXA of the total hip was 17% lower in GC subjects than controls ($p<0.05$).

Compared with controls, FEM failure load in GC subjects was 15% and 16% lower for the stance and fall loading conditions, respectively. Multiple regression analysis demonstrated that a combination of QCT measures was correlated with bone strength as measured by FEM.

Chronic GC treatment in PMO resulted in significantly decreased BMD of the hip, measured by QCT, with loss of both trabecular and cortical bone. In addition, GC treatment also decreased bone strength as determined by FEM. The reduced cortical and trabecular bone mass in the hip may contribute to the disproportionately high hip fracture rates observed in GC treated subjects.

FEM results for stance and fall loading conditions

Failure Load (kN)	Cases (n = 19)	Controls (n = 38)	*p* value
Stance	6.264 (0.942)	7.334 (1.057)	0.004
Fall	1.186 (0.338)	1.410 (0.339)	0.073

Mean ± SD, *p* values unadjusted

The Fat Endocrine Axis And Bone Metabolism In Obese Premenopausal Women. L. Dib*[1], R. Abou Samra*[2], N. Hwalla*[2], N. Torbay*[2], G. El-Hajj Fuleihan[1]. [1]Internal Medicine, American University of Beirut, Beirut, Lebanon, [2]Nutrition and Food Sciences, American University of Beirut, Beirut, Lebanon.

Obesity's protective effect on bone density may be mediated through increased muscle mass, fat mass, increased estrogen, and possibly insulin, and leptin levels. Furthermore, in vitro data suggests a direct role for leptin and the PPARϒ pathway in osteogenesis. The associations between circulating leptin levels and BMD are however debatable and confounded by body composition, insulin levels, and possibly insulin resistance.

48 obese normally cycling premenopausal women were studied: 28 were considered insulin resistant and 20 normoinsulinemic by McAuley index; ISI= exp[2.63-0.28ln(insulin in mU/l)-0.31 ln(triglycerides in mmol/l)], insulin resistance defined as an ISI< 5.8 [1]. Anthropometric, body composition, BMD measurements, serum leptin, insulin, free testosterone, IGF1, bone remodeling markers and calciotropic hormones were obtained.

Subjects were 31± 10 years (mean ± SD), and had a BMI of 35.7± 5 kg/m^2. The baseline characteristics, including age, calcium intake, number of menstrual cycles, BMI, lean mass, fat mass, were comparable between the two study groups. Both groups had comparable serum levels of IGF1, free testosterone, calciotropic hormones, osteocalcin, bony alkaline phosphatase and crosslaps. Hyperinsulinemic subjects had significantly wider waist circumference [101 (10) cm], and higher insulin and leptin levels 31(9) U/L and 69 (26) ng/ml than normoinsulinemic subjects, 95(5) cm, 18.6(3.5) U/L, and 2(26) ng/ml respectively. Despite higher circulating insulin and leptin levels, hyperinsulinemics had mean values of biochemical markers of bone remodeling and BMD at all skeletal sites that were comparable to the normoinsulinemic group. In the hyperinsulinemic group, fat mass but not lean mass, serum leptin, insulin, testosterone, and IGF1 levels correlated positively with hip, and/or total body BMD/BMC, R=0.2-0.61, P< 0.05, depending on the hormone and skeletal site. Conversely, in the normoinsulinemic group, lean mass but not fat mass, and only IGF1 correlated with hip BMD/total body BMC, R= 0.49-0.69, p< 0.05.

In conclusion, there is a dichotomy in the impact of body composition parameters, insulin and leptin levels on bone parameters in obese individuals. The interaction between the fat related endocrine system and bone seems to be complex and may be modulated by local resistance to the putative protective effect of insulin and leptin on bone.

Similar Trunk Length but Shorter Leg Length in Chinese than Caucasians: Implication for Racial Differences in Hip Fracture Rates. X. Wang*, Y. Duan, E. Seeman. Endocrinology and Medicine, the University of Melbourne, Heidelberg, VIC 3084, Australia.

The basis for the lower hip fracture rate in Chinese than Caucasians is unknown. We asked: (i) are there racial differences in trunk length or leg length? (ii) Do Chinese have shorter femoral neck axis length (FNAL) after adjustment for femur length? We measured standing and sitting height, leg length, femur length and FNAL in 239 healthy Chinese (162 females) and 542 Caucasians (403 females) aged 18-45 years living in Melbourne, Australia. In both women and men, Chinese had a 5.8-6.3cm (~3.5%) shorter stature than Caucasians due to their shorter leg length (~85%) not sitting height. There was a lower ratio of leg length/standing height in Chinese than Caucasians in both sexes. In a subgroup of Chinese and Caucasians matched by standing height, Chinese had shorter leg length but greater sitting height than Caucasians. FNAL was shorter in Chinese than Caucasians before (~7.4%) and after (~3.8%) adjusted for their shorter femur length in both sexes. In a subgroup of Chinese and Caucasians matched by femur length, Chinese had 3.5% shorter FNAL than Caucasians in both sexes. Racial differences in standing height is predominantly on the leg, not trunk, length. Chinese have a shorter FNAL relative to their femur length. We infer that the lower body segment length and shorter FNAL in Chinese may contribute to the lower hip fracture rates in Chinese than Caucasians.

Bone Tissue Quality Is Differently Altered by PTH and Bisphosphonates. P. Ammann[1], S. Barrauld*[1], P. Zysset[2], R. Rizzoli[1]. [1]Department of Rehabilitation and Geriatrics, Division of Bone Diseases, Geneva, Switzerland, [2]Swiss Federal Institute of Technology, Laboratory of Bone Biomechanics, Lausanne, Switzerland.

Treatment with inhibitors of bone resorption or stimulators of bone formation reduces fracture risk. Bone strength, hence the resistance to fracture, depends on bone mineral density, bone geometry, micro-architecture, bone turnover rate and intrinsic bone tissue quality. Despite comparable antifracture efficacy, bone resorption inhibitors and bone formation stimulators are likely to modify quite differently these various determinants of bone strength. To address this issue, we treated 8-month old osteoporotic ovariectomized (OVX) rats with either pamidronate (APD, 0.6 mg/kg 5 days/month s.c.), PTH(1-34) (10microg/day s.c.) or the vehicle for 16 weeks, and measured proximal tibia areal BMD (g/cm2), ultimate strength (N), stifness (N/mm) and energy (N*mm) with an axial compression test, micro-architecture by microCT, and bone intrinsic quality by nanoindentation. This latter test allows the calculation of the elastic modulus and tissue hardness (mPa). The markers of bone turnover deoxypyridinoline (Dpd) and osteocalcine were also determined. Values are tabulated as means± SEM, * P<0.05 vs OVX, ° P<0.05 vs OVX/APD.

	SHAM	OVX	OVX/APD	OVX/PTH
Ultimate Stength	303.5±27.3*	215.8±11.3	321.1±18.1*	404.9±25.0 *°
Stiffness	662.6±54.5	563.8±29.6	825.2±43.9*	720.8±53.5*
Energy	108.7±21.8	68.1±12.9	78.3±8.8	170.6±19.0*°
BMD	187.1±4.2*	153.5±3.8	177.3±3.3*	201.4±2.8 *°
Hardness	975±22*	878±15	921±20	872±18
Dpd	29.1±4.3	34.4±2.9	16.2±1.26*	46.2±3.2 *°
Osteocalcine	11.1±0.7	14.9±1.3	8.2±0.5*	23.4±1.2*°

The higher bone strength induced by PTH as compared with APD was associated with a greater absorbed energy, BMD, and bone turnover markers. Furthermore, PTH, but not APD markedly increased trabecular bone volume and connectivity. Tissue hardness was identical in PTH-treated and OVX untreated controls. In contrast, the correction of bone strength by APD was accompanied by reduced bone turnover, and increased hardness. Elastic modulus was similar in all groups. These results illuminate the different mechanisms by which inhibitors of bone resorption and stimulators of bone formation reduce fracture risk. PTH influences micro-architecture and bisphosphonate intrinsic bone tissue quality, with probable opposite effects on remodeling space.

The Relationship Between Bone Morphology and Bone Quality: Implications for Stress Fracture Risk in Young Adult Male Tibiae. S. M. Tommasini[1], P. Nasser*[2], K. J. Jepsen[2]. [1]CUNY Graduate School, New York, NY, USA, [2]Mt Sinai School of Medicine, New York, NY, USA.

Stress fractures occur among persons with normal bones, no acute injury, and are most common among elite runners and military recruits [1]. Having a narrow or slender tibia has been shown to be a major predictor of stress fracture risk and fragility [2]. Previous studies revealed that inbred mice with slender bones had increased mineral content. Although increased mineral content may have compensated for the smaller morphology by increasing tissue stiffness and strength, the increased mineral had the adverse effect of increased bone brittleness and tissue damageability under fatigue loading [3]. It is unknown whether a similar reciprocal relationship between bone geometry and bone tissue level mechanical

properties also exists in the human skeleton. We assessed the biomechanical properties of tibiae from young adult males in order to determine whether whole bone geometry is a predictor of tissue fragility. Tibiae from 17 male donors (age 17-46 yrs) were measured for bone geometry [length, cortical area (CtAr), AP and ML width, moments of inertia (I_{AP}, I_{ML}, J)]. A slenderness index was defined as the inverse ratio of the section modulus to tibia length and body weight [4]: S=1/[(J/width)/(L*BW)]. The diaphyses were cut into rectangular beams and tested for monotonic properties in 4-point bending [modulus (E), strength, post-yield strain (PYε), work] and tissue damageability (*D*) in 4-point bending using the methods of Jepsen and Davy [5]. Partial correlation coefficients were determined between each geometrical parameter (CtAr, width, I_{AP}, I_{ML}, J, S) and each tissue level mechanical property (E, strength, PYε, work, *D*) while taking age into consideration.
Significant correlations ($p < 0.05$) were observed between AP width and two mechanical properties related to tissue brittleness (PYε, work) indicating that the tissue of individuals with narrow tibiae was less ductile. Further, there was a significant correlation between tissue damageability and tibia slenderness ($p = 0.05$) consistent with the mouse model suggesting that slender bones may have more damageable tissue. This data indicated that not all bone is made the same way. Having a more slender tibia was associated with tissue that was less ductile and more susceptible to damage accumulation. Thus, under extreme loading conditions (e.g., military training), variation in bone quality may be a contributing factor for increased stress fracture risk in individuals with a more slender bone. [1] Milgrom et al, 1989 J Biomech 22 [2] Beck et al, 2000 Bone 27 [3] Jepsen et al, 2001 JBMR 16 [4] Selker and Carter, 1989 J Biomech 22 [5] Jepsen and Davy, 1997 J Biomech 30.

High Resolution Spiral-CT for the Assessment of Osteoporosis: Which Site of the Spine and Region of the Vertebra Is Best Suited to Obtain Trabecular Bone Structural Parameters? J. S. Bauer*[1], D. Mueller*[2], M. Fischbeck*[3], F. Eckstein*[4], E. J. Rummeny*[2], T. M. Link[1]. [1]Radiology, University of California, San Francisco, CA, USA, [2]Radiology, Technical University, Munich, Germany, [3]Anatomy, Ludwig-Maximilian-Universität, Munich, Germany, [4]Anatomy, Paracelsus Private Medical University, Salzburg, Austria.

Objectives: In osteoporosis, bone demineralization is heterogeneous: There may be major differences between different skeletal sites, as well as between different regions within one bone. The purpose of this experimental study was to investigate which site of the spine and region of the vertebral body is best suited for analysis of trabecular bone structure in the assessment of osteoporosis resp. biomechanical strength.
Material and Methods: 133 vertebrae (63 thoracic vertebrae, 70 lumbar vertebrae, all with adjacent intervertebral discs and vertebrae as motion segments) were harvested from 73 human spines. All specimens were examined with Spiral-CT using a slice thickness of 1 mm and an in plane spatial resolution of 0.4 mm. Quantitative structure parameters, analogous to bone histomorphometry, were determined in those specimens for a superior (below the endplate), mid-vertebral and inferior (superior to the endplate) region of interest (ROI). Additionally BMD was measured using quantitative CT (QCT) with a standard protocol. In all specimens maximum compressive strength (MCS) was determined using axial loading.
Results: The standard BMD measurement correlated significantly with the MCS ($r^2 = 0.55$, $p < 0.01$). For the structural parameters the highest correlation with the MCS was obtained using the structure parameter app. (apparent) BV/TV (bone volume/ total volume) in the inferior region of the lumbar vertebrae ($r^2 = 0.72$, $p < 0.01$). It could be improved using a multi regression model with app. BV/TV, app. trabecular separation and cortical BMD (r^2=0.77, $p < 0.01$). This correlation was significantly higher than the correlation between MCS and BMD ($p < 0.05$).
Conclusion: Compared to clinical BMD measurements the prediction of MCS was significantly improved using a structure parameter measured in the inferior region of excised vertebral bodies. This indicates that histomorphologic parameters measured at skeletal sites with higher bone turn-over, such as the part near the endplate of the vertebral body, may improve the assessment of biomechanical strength of bone.

Idiopathic Inflammatory Bowe Disease and Decreased Bone Mineral Density in Children and Adolescents. S. Kutilek[1], J. Sykora*[2], V. Vyskocil[1]. [1]Bone disease center, Charles University Hospital, Plzen, Czech Republic, [2]Department of Pediatric, Charles University Hospital, Plzen, Czech Republic.

Idiopathic inflammatory bowel diseases (IBD) are characterised by weight loss, abdominal pain and diarrhea, often mixed with blood. Skeletal changes, in particular osteopenia, osteoporosis or osteomalacia, have been observed in almost 70% of adult patients with IBD. We evaluated 13 patients (9 girls and 4 boys) with IBD, aged 5-22 years (mean age 13.6 ± 4.5 SD). Calcium and vitamin D intake was maintained as adequate according to the recommended daily allowance. The mean values of body height and weight (expressed as Z-scores) didn´t differ from age- and sex-related reference values ($p = 0.8$ and 0.7, respectively), however the body mass index (BMI) was decreased ($p< 0.02$). The spinal (L1-L4) bone mineral density (BMD, g/cm^2; expressed as Z-score) was low in comparison to reference values ($p< 0.02$). When calculated as volumometric BMD (BMDvol, g/cm^3), and expressed as Z-scores, we observed even higher difference in comparison to age- and sex related reference values ($p< 0.0001$). We found high and significant correlation between BMD and body height ($r = 0.67$, $p< 0.01$). There was no significant relationship between BMD and body weight or BMI. The estimation of areal BMD is influenced by bone size and can be underestimated in smaller individuals. However, our results of low BMDvol further confirm the low bone mass in patients with IBD, as volumometric bone density gives more reliable information than areal data. Low bone mass and consequent risk of developing osteoporosis must be taken into consideration in pediatric patients with IBD.

Nutritional Assessment in a Sample of Brazilian Post-Menopausal Osteoporotic Women. T. M. Aniteli*[1], C. M. Z. Carnevalli*[1], R. M. Pereira[2], M. M. Madureira*[3], L. A. Martini[1]. [1]Nutrition, Sao Paulo University, Sao Paulo, Brazil, [2]Medicine, Sao Paulo University, Sao Paulo, Brazil, [3]Rheumatology, Sao Paulo University, Sao Paulo, Brazil.

Diet is one of the main approach therapeutic in the Osteoporosis. The relationship of calcium deficiency and osteoporosis is the most studied one and it is well known that women affected by this illness need an adequate diet in calcium for preservation and maintenance of bone mass. The objective of the present study was to evaluate the dietary intake of calcium, phosphorus, energy and percentile distribution of protein, carbohydrates and lipids using the 24 hour diet recall and body composition by DEXA of osteoporotic women. Twenty-nine women, mean age 75 ± 5 years old (X ± SD), body mass index 24 ± 6.3 kg/m^2 were evaluated. The mean fat mass percentage measured by DEXA was 38 ± 8%. The mean calcium intake was of 875 ± 374 mg/day. From these, 83% of patients had an intake lesser than the proposed intake (AI) of 1200mg/d. However, it is a value of intake bigger that the average for the Brazilian population (633 ± 320 mg/d). The mean phosphorus intake was 993 ± 307 mg/d and 21% of them had lower intakes than the RDA recommendation (700 mg/d). None of the patients reached the upper limit levels (UL) for both nutrients. The percentile distribution of carbohydrates, protein and lipids was of 53.2 ± 8.6 %, 18.5 ± 4.8 % and 28.1 ± 8.2 %, respectively. All the women were in according to the recommended standards of protein intake (10-35%), 80% adequate for carbohydrate (45-60%), and 21% presented higher values of fat intake (20-35%). Multiple linear regression analysis showed that calcium intake and percentage of fat mass are responsible for 36% of the BMD in lumbar spine L1-L4 [L1-L4 = 6.104 + 0.001 (calcium intake) + 0.065 (% FM) R^2=0.358]. This study demonstrate the importance of an adequate calcium intake in bone mass of postmenopausal women, exerting an important role in calcium retention and therefore prevention loss of bone mass and fractures.

Effect of Pinealectomy on Bone Remodeling in Sheep. M. Egermann*[1], C. Gerhardt*[1], A. Barth*[2], E. Schneider[1], M. Alini*[1]. [1]AO Research Institute, Davos, Switzerland, [2]Neurosurgery, University of Berne, Berne, Switzerland.

Osteoporosis and associated fractures are a major public health burden. Osteoporosis is a multifactorial disease and the causes are yet not fully understood. New literature data have shown, that melatonin, the hormone of the pineal gland, seems to influence the bone metabolism. This study aims to evaluate whether absence of melatonin due to pinealectomy (Px) affects the bone microarchitecture and remodeling comparable to the absence of sex hormones subsequent to ovariectomy (Ovx) using an ovine animal model.
Following approval of the appropiate ethical committee, 26 female sheep (3.1±0.5 yrs) were arranged into four groups: Control (C) (n=8), Ovx (n=6), Px (n=6), Ovx+Px (n=6) and surgically pinealectomized or ovariectomized respectively. Pinealectomy was confirmed by absence of nocturnal melatonin secretion. Before and 6 months after surgery, bicortical iliac crest biopsies (∅8.4mm) were harvested and structural parameters (BV/TV, Tb.Sp, Tb.Th, Tb.N) were determined using µCT. Deoxypyridinoline (DPD) was determined from urine samples three times before surgery as baseline level and at 6 month. All parameters are expressed relative to baseline. Statistical analysis tested for difference to control group (*= $p<0.05$).
The complete removal of the pineal gland and the ovaries was tolerated well by all animals without drop out or notable side effects. The changes of the structural parameter in cancellous bone after 6 months are shown in the table. Compared to baseline, increased levels of DPD were found in all treated groups, with significant differences for the combined Ovx+Px group only (C: +1±63%, Ovx: +8±55%, Px: +10±36%, Ovx+Px: +69±47%*).

Group	BV/TV	Tb.Sp	Tb.Th	Tb.N
C	7 ±14%	-11 ±12%	26 ±18%	7 ±13%
Ovx	-4 ±22%*	3 ±21%	-6 ±13%	1 ±14%
Px	-13 ±9%*	12 ±8%*	-6 ±7%*	-8 ±6%*
Ovx+Px	-18±14%*	21±22% *	-7 ±9% *	-11±17%*

The changes of structural parameters in the treatment groups are indicative of bone loss, although these data could have been influenced by several factors like site of biopsy, short term follow up or seasonal variation, particularly in penealectomized sheep. However, a similar trend is observed for the biochemical resorption marker, DPD. This also suggests that in the treated groups there is an increased bone resorption activity. Overall, these preliminary findings suggest that the pineal gland may influence bone metabolism, although, large number of animals and long term follow up are needed to draw final conclusions.

Disclosures: ***M. Egermann****, AO Foundation 3.*

Is the Effect of Raloxifene and Estrogen on Bone Mediated by a Differential Expression of Estrogen Receptors? M. Naves*, A. Rodríguez-Rodríguez*, C. Gómez, A. González-Carcedo*, N. Carrillo-López*, J. B. Cannata-Andía. Bone and Mineral Research Unit, Hospital Universitario Central de Asturias, Oviedo, Spain.

The protective effect of estrogen and raloxifene on bone metabolism is well established. However, the cellular and molecular mechanisms of their actions are still not fully understood.

The aim of this study was to measure changes in bone histomorphometric parameters and the expression of estrogen receptors on proximal tibial segment in rats with mild kidney insufficiency and ovariectomy treated with raloxifene and estrogen, alone or combined with calcitriol.

Six-month old female Sprague-Dawley rats (n=48) were ovariectomized and nephrectomized (7/8). One week after surgery, the rats were divided into 6 groups and treated with: 1) Placebo, 2) 17-β-estradiol 10 µg/kg/day, 3) raloxifene 1 mg/kg/day 4) calcitriol 10 ng/Kg/day, 5) 17-β-estradiol plus calcitriol and 6) raloxifene plus calcitriol. A group of non-treated animals with normal ovarian and kidney function was used as the control group (n=8). The rats were sacrificed after 8 weeks of treatment.

Total RNA was extracted from bones and mRNA levels of alpha (ERα) and beta (ERβ) estrogen receptors were measured by quantitative RT-PCR. The relative amount of ERα and ERβ mRNA adjusted for 18s rRNA was calculated.

Bone loss, measured by densitometry and histomorphometry, was partially prevented in the groups treated with 17-β-estradiol, raloxifene and calcitriol (table). However, the best response was observed in the groups treated with raloxifene plus calcitriol and 17-β-estradiol plus calcitriol, achieving a similar bone mineral density and trabecular bone volume to the control group (0.40±0.03 g/cm^2 and 32.5±8.6 % respectively).

Compared with the placebo group, the ERα expression decreased significantly in those rats treated with raloxifene alone or combined with calcitriol and in the rats treated with 17-β-estradiol plus calcitriol. Although the treatments either 17-β-estradiol or calcitriol also decreased the ERα expression, the changes were not significant. No statistical differences in ERβ expression were found in either group (table).

* p<0.05 compared with placebo

Groups	Proximal tibia BMD (g/cm2)	Trabecular bone volume (%)	Relative quantity of ER a mRNA	Relative quantity of ER b mRNA
Placebo (n=7)	0.33±0.01	16.9±3.5	21.0±6.6	14.0±7.1
17-b-estradiol (n=8)	0.35±0.01*	28.8±6.4*	14.3±3.4	6.9±4.1
Raloxifene (n=9)	0.35±0.03*	29.8±12.2*	5.7±2.2*	18.8±27.9
Calcitriol (n=8)	0.36±0.02*	26.7±4.6*	14.9±4.5	7.9±4.8
17-b-estradiol+Calcitriol (n=8)	0.40±0.05*	32.8±10.7*	11.8±2.2*	6.5±3.7
Raloxifene+Calcitriol (n=8)	0.42±0.02*	46.8±12.7*	12.5±3.2*	11.9±9.7

In conclusion, the best response to treatment was always accompanied by a significant decrease in the ERα expression, suggesting a down-regulation of the estrogen receptor. By contrast, there was no relationship with the ERβ expression.

Estrogen Deficiency Causes Bone Loss through Induction of TNF-alpha by Hydrogen Peroxide. C. J. Jagger*, J. M. Lean*, J. T. Davies*, T. J. Chambers. Cellular Pathology, St George's Hospital Medical School, London, United Kingdom.

We recently found that antioxidant defenses fall substantially in rodent bone marrow after ovariectomy, and are rapidly normalised by exogenous estradiol. Moreover, administration of N-acetyl cysteine or ascorbate, antioxidants that increase tissue antioxidant levels, abolish ovariectomy-induced bone loss, while buthionine-(S,R)-sulfoximine (BSO), a specific inhibitor of the synthesis of glutathione, the major intracellular antioxidant, cause substantial bone loss. These results suggest that estrogen deficiency causes bone loss by lowering antioxidant defenses in bone marrow.

How does lowering of antioxidant defenses cause bone loss? All cells generate reactive oxygen species (ROS), and osteoclasts in particular produce them in large amounts. If thiol antioxidant defenses are lowered, this will increase the half-life of ROS. Amongst ROS, hydrogen peroxide is sufficiently stable and membrane-permeant to transmit both intra- and inter-cellular ROS signals. Hydrogen peroxide also increases expression of TNF-alpha in many cell types, including osteoclasts. Blockade of TNF-alpha signaling has been reported to prevent estrogen-deficiency bone loss in mice.

We therefore tested the role of hydrogen peroxide in estrogen-deficiency bone loss. We found that catalase, which destroys hydrogen peroxide, prevented osteopenia in ovariectomised mice. This shows that hydrogen peroxide is essential for bone loss in response to estrogen deficiency, and is consistent with the notion that the lowering of antioxidant defenses observed after ovariectomy cause bone loss through an increase in hydrogen peroxide. We also found that the bone loss caused by both BSO and ovariectomy was reduced by administration of TNF-alpha, and abrogated in mice deleted for TNF-alpha gene expression. Furthermore, in mice treated with soluble receptors, antioxidant defenses remained low, despite inhibition of bone loss.

These experiments are consistent with a model for bone loss in which estrogen deficiency lowers antioxidant defenses in bone marrow and thereby increases hydrogen peroxide levels, which in turn induces expression of TNF-alpha, which causes bone loss.

Oral Contraceptive Users Have Lower Bone Density than Nonusers. H. C. Almstedt*, C. M. Snow. Exercise and Sport Science, Oregon State University, Corvallis, OR, USA.

Osteoporosis is a skeletal disease affecting 44 million Americans. A primary strategy to prevent osteoporosis is to develop a high peak bone mass in youth. Oral Contraceptives (OCs) alter hormones in women and could affect bone mass development. Forty percent of American women between the ages of 18 and 24 use OCs. However, the interaction between OCs and skeletal mineralization is poorly understood. Our aims were to 1) compare bone mass (BMD) of young women who have a history of OC use with eumenorrheic controls and 2) evaluate whether years on oral contraceptives predict BMD among those with a history of use. We recruited 98 women who were 18 to 25 years of age and had a history of OC use (n=44, 3.4 + 1.9 years of OC use) and controls (n=54). BMD at the hip, whole-body, and spine (AP, g/cm^2 and width-adjusted lateral, g/cm^3) was measured by dual-energy x-ray absorptiometry (DXA). Physical activity (METs) was measured via questionnaire and grip strength was evaluated using an isometric dynamometer. Groups were similar in body mass index (BMI), fat mass, grip strength, and physical activity but controls were older than OC users (21.3 ± 1.9 vs. 20.3 [[Unsupported Character - Codename]]± 1.6, $p < .05$). In analysis of covariance, controlling for age and BMI, controls had significantly greater BMD than OC users at the AP and lateral spine, femoral neck, greater trochanter, total hip, and whole-body ($p < .05$). We conducted stepwise regression of the OC users that included the following independent variables: 1) years on oral contraceptives, 2) BMI, 3) calcium intake, 4) grip strength, and 5) physical activity. Results indicated that history of oral contraceptive use was a negative independent predictor only at the femoral neck BMD. Specifically, physical activity (β=.47), BMI (β=.34), and years of OC use (β= -.28) predicted 32% of the variance in femoral neck BMD. At the trochanter, BMI (β=.31) and physical activity (β=.30) predicted 15% of the variance in BMD, while, at the total hip, physical activity (β=.40) and BMI (β=.37) accounted for 26% of the variance in BMD. Twenty-eight percent of the variance in total body BMC was predicted by BMI (β=.42) and grip strength (β=.34). At the spine, BMI was the only independent predictor of BMD and accounted for 9-30% of the variance in volumetric, lateral and AP areal BMD. We conclude that, in this cross-sectional analysis, oral contraceptive use by young women may compromise bone health during a time when mineral is still accruing. Further longitudinal analysis will corroborate these findings.

Additive Stimulatory Effects of Estrogen and Androgen Receptor Activation on Trabecular Bone in Ovariectomized Rats. S. Moverare[1], Å. Tivesten*[2], A. Chagin*[3], K. Venken[4], P. Salmon*[5], D. Vanderschueren[4], L. Sävendahl*[3], A. Holmäng*[2], C. Ohlsson[1]. [1]Internal Medicine, Center for Bone Research at the Sahlgrenska Academy, Gothenburg, Sweden, [2]Cardiovascular Institute at the Sahlgrenska Academy, Wallenberg Laboratory for Cardiovascular Research, Gothenburg, Sweden, [3]Karolinska Institute, Pediatric Endocrinology Unit, Stockholm, Sweden, [4]Katholieke Universiteit Leuven, Laboratory for Experimental Medicine and Endocrinology, Leuven, Belgium, [5]Skyscan N. V., Aartselaar, Belgium.

Sex steroids are important regulators of trabecular bone mass. Both estrogen receptor (ER) and androgen receptor (AR) activation results in increased trabecular bone mass. The aim of the present study was to investigate if combined ER and AR activation might be beneficial in the treatment of trabecular bone loss. Twelve-week-old female rats were ovariectomized (ovx) and treated with vehicle (V), 17β-estradiol (E2; ER activation), dihydrotestosterone (DHT; AR activation) or the combination (E2+DHT) for six weeks. The skeletal phenotype was analyzed by peripheral quantitative computerized tomography (pQCT), micro-computerized tomography (micro-CT), histomorphometry of growth plates and serum levels of biochemical bone markers. Both E2 (+121% over V) and DHT (+34%) increased the trabecular volumetric bone mineral density (tvBMD) in ovx rats. The effect of E2 and DHT was additive, resulting in a 182% increase in tvBMD of the rats given E2+DHT. Micro-CT analyses of the trabecular bone microstructure revealed that the effect of E2 and DHT was additive onboth the number and the thickness of trabeculae. E2 treatment reduced serum markers of both bone resorption (collagen C-terminal telopeptide) and bone formation (osteocalcin), indicating a reduced bone turnover. Addition of DHT to E2 treatment did not modulate the effects of E2 on the marker of bone resorption while it attenuated the inhibitory effect of E2 on the bone formation marker, which might explain the additive stimulatory effect of E2 and DHT on trabecular bone mass. In contrast, DHT partially counteracted the suppressive effect of E2 on longitudinal bone growth and the E2-induced alterations in growth plate morphology. These findings demonstrate that a combined ER and AR activation results in additive stimulatory effects on trabecular bone in ovx rats. Our data suggest that a combined treatment with selective ER and AR modulators might be beneficial in the treatment of osteoporosis.

The Effect of Ovariectomy on Aromatase Bone Expression in Rat. C. Potrel-Burgot*[1], H. Mittre*[2], J. Sabatier*[3], R. Levasseur[1], M. Kottler*[2], C. Marcelli[1]. [1]Medicine/Rheumatology, University of Caen, Caen, France, [2]Ea 2608 usc inra, University of Caen, Caen, France, [3]Nuclear Medicine, University of Caen, Caen, France.

The origin of the decrease in bone loss observed in woman a few years after the menopause remains unknown at yet. Aromatase is the enzyme responsible for the peripheral conversion of androgens into estrogens. The aim of this study was to analyse the aromatase bone expression in rats after ovariectomy with or without estrogen replacement therapy.

45 female wistar rats 12-week-old were randomized into 3 groups : bilateral ovariectomy plus subcutaneous injection of 20 µg/kg estradiol three times per week (OVX+E2), ovariectomy plus vehicle injection (OVX+VH) and the sham-operated control group (SHAM). BMD was measured on day 0 and day 30 at both distal femurs in all rats using dual X-ray absorptiometry. Transcripts for aromatase were measured in the right distal femur of all animals using competitive and quantitative RT-PCR. Immunohistochemistry was also performed at the left femur in order to localize aromatase in bone. Vaginal smears were performed daily in SHAM during the 10 days before the end of the study. Bones were also sampled from five 8-week-old male rats.

At day 30, a 9 % decrease in BMD was observed in OVX+VH (p=0.0012), a 10 % increase in SHAM (p=0.0010) and a non significant 2 % increase in OVX+E2. At day 30, the aromatase mRNA level (mean ± SE) was significantly lower in OVX+VH (0.11 ± 0.07 fg) than in OVX+E2 (0.49 ± 0.26 fg, p=0.0004) and SHAM (0.29 ± 0.24 fg, p=0.014). In SHAM, the mRNA level was low on the day of proestrus (0.16 ± 0.03 fg, n=3), an increase was observed on the day of estrus (0.29 ± 0.04 fg, n=5) and the highest mRNA level was measured on the day of diestrus (0.42 ± 0.25 fg, n=3). In male rats mRNA level was 0.49 ± 0.20 fg. Aromatase immunoreactivity was localized in osteocytes and in some bone lining cells.

In rats, ovariectomy results in a fast decrease in BMD as well as a decrease in aromatase mRNA bone expression, both being prevented by estrogen replacement therapy. The decrease of aromatase mRNA expression seems to be related to the important bone loss induced by ovariectomy. The variable mRNA levels observed in control rats and the high levels observed in males suggest a negative control of aromatase bone expression by circulating estradiol levels which could modulate ovariectomy-induced bone loss.

Vitamin D Status, Risedronate and Bone Turnover in Nursing Home Residents. D. Krueger[1], L. Nest*[2], P. Krause*[2], P. Drinka*[2], N. Binkley[1]. [1]University of Wisconsin, Madison, WI, USA, [2]Wisconsin Veterans Home, King, WI, USA.

Though osteoporotic fractures and hypovitaminosis D are extremely common among nursing home (NH) residents, studies of optimal vitamin D (D) repletion approaches and/or antiresorptive therapy in this population are quite limited. The purpose of this study was to assess the effect of supplementation with a commonly used D dose (400 IU daily) and risedronate (RIS) administered once weekly using a flexible dosing schedule on serum bone turnover markers. This randomized double-blind placebo-controlled trial involved 60 skilled nursing home residents (46 men/14 women) who received RIS 30 mg or matching placebo (PBO) once weekly for 12 weeks. All participants received calcium and D (315 mg/200 IU) twice daily. Participant mean age and weight (SD) were 76 (6) years and 190 (40) pounds respectively; 68% were independently ambulatory and 57% had sustained a prior fracture. Serum was obtained following an overnight fast between 0600-1000 at baseline, after 6 and 12 weeks of therapy. Research nurses administered study preparation at least 2 hours from any food or drink. Fifty-three participants completed the study, discontinuations were evenly divided (4 PBO/3 RIS). As expected in NH residents, adverse events (AE's) were extremely common, but there was no difference in AE occurrence between RIS and PBO groups. Compared to PBO, RIS reduced BSAP by 8% ($p < 0.05$) at 6, but not 12 twelve weeks; no effect on serum NTx was observed. If hypovitaminosis D were defined as a serum 25OHD concentration below 32 ng/ml, 50/53 (94%) of study participants had D insufficiency at baseline with the mean serum 25OHD concentration being 19 ng/ml. Though 12 weeks of supplementation increased mean 25OHD concentration to 25 ng/ml, D status remained insufficient in 74% of participants.

In conclusion, hypovitaminosis D was extremely common and not reliably corrected by daily administration of 400 IU cholecalciferol in this population of NH residents. Weekly RIS administered using a flexible dosing schedule reduced serum BSAP at six, but not 12, weeks of treatment. These results differ from previously reported studies demonstrating RIS efficacy in older adults. Potential explanations for this discordance include the high prevalence of hypovitaminosis D, inadequate correction of this deficiency despite supplementation, the flexible dosing schedule chosen where RIS absorption may have been impaired by delayed gastric emptying, or other unidentified factors specific to this NH population. Additional study is required to evaluate approaches to optimally diagnose and subsequently conduct D repletion in NH residents and determine under which conditions bisphosphonate treatment is efficacious in this population.

Oral Risedronate at High Doses Demonstrates Upper Gastrointestinal Tolerance in an NSAID-using Population. W. Benson*[1], G. Cline*[2], M. Hosterman*[2], S. Adami[3]. [1]St. Joseph's Hospital/McMaster University, Hamilton, ON, Canada, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA, [3]Rheumatologic Rehabilitation, University of Verona, Verona, Italy.

Five (5) mg daily oral risedronate, used in the treatment of osteoporosis, has demonstrated favorable gastrointestinal (GI) tolerance in a clinical database involving over 10,000 patients. Approximately two-thirds of patients in this database had either a history of GI tract disease, or prospectively received non-steroidal anti-inflammatory drugs (NSAIDs). We now have experience on the GI tolerance of risedronate from an osteoarthritis patient population receiving 3 times the dose used in the treatment of osteoporosis. Two, Phase III placebo-controlled studies in 2483 patients with a diagnosis of medial compartment knee osteoarthritis have been completed. Patients received orally placebo, daily risedronate at doses of 5 mg or 15 mg, or weekly risedronate at doses of 35 mg (in Europe) or 50 mg (in North America) for 24 months. This report will focus on adverse event profile of placebo, 5 mg risedronate, and 15 mg risedronate, since these were the common doses across both studies. The average age of the study population was 62 years with the majority (60%) being postmenopausal women. Forty-one percent of patients had a history of GI disease. The incidence of NSAID use during the study period was 87%. Approximately 87% (2154) of the patients completed the month 24 visit. Withdrawals due to AEs were low and comparable for the placebo (12%), 5 mg (9%), and 15 mg (11%) groups. Upper GI adverse event (AE) data are presented in the table for the placebo, 5 mg, and 15 mg groups.

Treatment (n)	Placebo (622)	Ris 5 mg daily (628)	Ris 15 mg daily (609)
Upper GI AEs	18%	20%	17%
Moderate to Severe Upper GI AEs	8%	10%	7%

The GI tolerability of risedronate was comparable to placebo with regard to incidence of upper GI AEs and severity of upper GI AEs. Weekly doses of 35 and 50 mg were also similar when compared to their respective placebo groups (data not shown). In summary, risedronate, even when given at higher doses, is well-tolerated in a population at risk for increased GI side effects. In addition, this study confirms previous observations of the favorable tolerability of 5 mg daily and 35 mg weekly risedronate used in the treatment of osteoporosis.

TNF Protects Osteoclasts from Alendronate-Induced Apoptosis by Stimulating Bcl-xL Expression through the Transcription Factor, Ets 2. Q. Zhang*, I. Badell*, E. M. Schwarz, B. F. Boyce, L. Xing. University of Rochester, Rochester, NY, USA.

Bisphosphonates prevent bone resorption in osteoporosis, but clinical trials have reported that they fail to prevent bone loss around joints in patients with rheumatoid arthritis, suggesting that they may be less effective for inflammation-induced osteolysis. Based on the known functions of TNF in inflammatory arthritis and osteoclast (ocl) survival, we hypothesized that TNF protects ocls in inflamed joints from bisphosphonate-induced apoptosis by inducing the expression of cell survival genes. We previously found that: TNF stimulates Bcl-xL expression in ocls; ocls at the erosion front in joints of TNF-Tg mice express high levels of Bcl-xL and are resistant to high doses of alendronate (ALN); and Bcl-xL protects ocls from ALN-induced cell death. Here, we attempted to identify the molecules that mediate TNF-induced Bcl-xL expression and have focused on NF-κB (p65), c-Fos and Ets members because they are known to regulate Bcl-xL transcription. We also studied if RANK signaling is required for TNF-mediated ocl survival. By real time PCR, we found that TNF significantly increased the expression of NF-κB, c-Fos and Ets 2, but not PU.1 and Ets 1 (fold increase at 8 hr over 0 hr: NF-κB, 7+/-0.1; c-Fos, 8+/-2; Ets2, 14+/-1; PU.1, 1+/-0.1; Ets1, 0.2+/-0.1) in M-CSF-treated bone marrow cells. To examine if over-expression of these proteins could protect ocls from ALN-induced apoptosis, we infected bone marrow cells with NF-κB, c-Fos, Ets2, Bcl-xL or GFP retroviral supernatant and cultured with M-CSF/RANKL to form ocls. The mature ocls that formed were treated with ALN for 24 hr and the % apoptotic ocls was counted. Only Bcl-xL and Ets2 over-expressing ocls had a 50% reduction in ALN-induced cell death (% apoptotic ocls: GFP, 76+/-5; Bcl-xL, 36+/-2; Ets 2, 39+/-5; c-Fos 75+/-1; NF-κB 80+/-2). Ets2 infected ocls had 1.6 fold increased Bcl-xL expression. To study if RANK mediates TNF's survival effect, we treated RANK-/- mature ocls (generated from RANK-/- splenocytes with TNF/M-CSF) with TNF for 24 hr and counted ocl numbers. TNF supported RANK-/- ocl survival. Accordingly, Etanercept, but not RANK:Fc, blocked TNF's survival effect on wt ocls. In summary, we found that: TNF increases the expression of Ets 2 in ocl precursors; over-expression of Ets2, but not NF-κB or c-Fos, protects mature ocls from ALN-induced cell death; Ets2 increases Bcl-xL expression in ocls; the survival effect of TNF on ocls is RANK independent. In conclusion, in inflammatory bone disease where TNF levels are high, local TNF triggers survival signals that render ocls more resistant to bisphosphonate-induced cell death by up-regulating Bcl-xL and Ets2 expression, thus reducing bisphosphonate efficacy.

Efficacy and Safety of Long-Term Alendronate in Male Solid Organ Transplant Recipients. R. C. Christian[1], M. E. Elliott[1], N. Vallarta-Ast[2], K. Hansen[1]. [1]University of Wisconsin, Madison, WI, USA, [2]Radiology, Wm. S. Middleton VAMC, Madison, WI, USA.

Background: Solid organ transplant recipients are at high risk for osteoporosis and fragility fractures. Many clinicians are reluctant to prescribe bisphosphonates, as reduced renal function is common in transplant patients. Outcomes data on bisphosphonate use in transplant patients is limited to short term (≤12 month) trials.

Objective: This retrospective study compared efficacy and tolerability of long- term alendronate therapy in male solid organ recipients and a comparable group of non-transplanted men (controls).

Methods: Among 900 veterans filling at least one alendronate prescription between 1997 and 2002, 17 male transplant recipients and 44 male controls had bone density studies bracketing use of alendronate. Demographic and anthropometric data, fracture incidence, adverse events and therapy duration were obtained from medical and pharmacy records. We calculated annualized BMD change by dividing total change in BMD by days between DXA scans, and multiplying by 365.25 days.

Results: Mean duration of alendronate therapy was 34 months in both groups, with a notable average delay of 36 months between organ transplant and onset of alendronate therapy. Glucocorticoid use was more common (100% vs. 41%, $p < 0.001$), and creatinine clearance was lower (32 vs. 48 cc/minute, $p = 0.004$) in transplanted than in control men. Transplanted men were younger (59 vs. 72 years, $p < 0.001$), and no more likely to experience adverse events (12% vs 27%, NS) than controls. Fracture rates, hypogonadism, alcohol abuse and smoking did not differ between groups. Neither initial BMD nor change in BMD differed significantly between groups at either site ($p > 0.05$).

Conclusions: Alendronate increased spine BMD and stabilized hip BMD in transplanted men comparable to non-transplanted men, despite delayed therapy initiation. Transplanted men were no more likely to experience adverse effects, despite compromised renal function and ongoing glucocorticoid therapy. This retrospective study suggests that chronic alendronate therapy is both safe and effective at stabilizing or increasing bone mass in male veterans following solid organ transplant.

Bone Mineral Density Results

BMD (gm/cm2)	Transplant (mean BMD ± SD)	Non-transplant (mean BMD ± SD)
Initial Lumbar Spine	1.032 ± 0.144	1.044 ± 0.212
Initial Total Hip	0.859 ± 0.135	0.828 ± 0.134
Annualized Spine Change	0.028 ± 0.074	0.030 ± 0.061
Annualized Hip Change	0.005 ± 0.013	0.006 ± 0.041

Medication Persistence Is Better With Weekly Bisphosphonates, but It Remains Suboptimal. R. Recker[1], R. Gallagher*[2], M. Amonkar*[3], J. Smith*[3], P. MacCosbe*[3]. [1]Creighton University, Omaha, NE, USA, [2]NDCHealth, Pheonix, AZ, USA, [3]GlaxoSmithKline, Durham, NC, USA.

Persistence on bisphosphonates (BPs) for the treatment of osteoporosis is necessary to prevent bone fractures. An indicator of treatment persistence is medication possession ratio (MPR). It has been reported that the risk of bone fractures increases significantly among osteoporosis patients with MPR <80% (Caro et al. *Osteoporosis Int.* 2003:14 (Suppl 7);S2). The objective of this study was to compare MPR between women receiving daily BPs vs. women receiving weekly BPs.

A HIPAA-compliant, longitudinal patient database of prescriptions dispensed from ~25% of US retail pharmacies was used to assess MPR in women at least 50 years old receiving risedronate (5, 35mg) or alendronate (5, 10, 35 or 70mg). Data were assessed for a 12 month study period (10/02-9/03). MPR was defined as the total days of supply from all prescriptions for a brand and strength filled or refilled during the study, divided by 365 potential days of therapy. Adequate persistence was defined as MPR at least 80% and inadequate persistence was defined as MPR less than 80%. Pre-study data (10/01-9/02) were used to classify patients as new to therapy (no osteoporosis prescription in the pre-study) or receiving existing therapy (at least one prescription in the pre-study for the same brand and strength as in 10/02).

A total of 33,767 patients were receiving daily BPs and 177,552 were receiving weekly BPs. Most patients were classified as receiving existing therapy; 91% of patients receiving daily BPs and 84% receiving weekly BPs. The percent of patients with adequate persistence vs. inadequate persistence were as follows:

	New Patients*		Existing Patients*		All Patients*	
MPR Category	Daily	Weekly	Daily	Weekly	Daily	Weekly
Adequate Persistence	13.2%	25.2%	35.2%	48.1%	33.3%	44.8%
Inadequate Persistence	86.8%	74.8%	64.8%	51.9%	68.7%	55.2%

*daily vs. weekly, P<0.0001, Cochran-Mantel-Haenszel test; data source: NDCHealth

In all patient groups, less frequent dosing of BPs was associated with a higher percent of patients who had adequate persistence (MPR at least 80%). The highest percent of patients with adequate persistence was among those classified as receiving existing therapy with weekly BPs. However, only ~48% of these patients had adequate persistence. Thus, medication persistence and fracture protection with weekly BPs appear to be suboptimal.

Cost-Effectiveness Of Alendronate In The Treatment Of Postmenopausal Women In Spain- An Economic Evaluation Based On The Fracture Intervention Trial. F. Borgström*[1], Å. Carlsson*[1], O. Johnell*[2], G. Nocea*[3], S. S. Sen*[4], B. Jönsson*[5]. [1]Stockholm Health Economics AB, Stockholm, Sweden, [2]Department of orthopaedics, Malmö General Hospital, Malmö, Sweden, [3]Merck Sharp & Dohme, Madrid, Spain, [4]Outcomes Research, Merck&Co., Inc., Whitehouse Station, NJ, USA, [5]Centre for Health Economics, Stockholm School of Economics, Stockholm, Sweden.

The Fracture Intervention Trial (FIT) showed that the bisphosphonate alendronate reduces the risk of fractures in women with low bone mass, with and without prior fractures. The objective of this study was to estimate the cost-effectiveness (cost per quality-adjusted life-year, QALY, gained and cost per life-year gained) of treating women with vertebral fracture in Spain with alendronate, compared with no treatment.

A further development of a Markov model earlier used in the economic evaluation for Sweden, Denmark and the UK was adapted to fit a Spanish setting. This Markov model depicted patients progressing through healthy (with existing vertebral fracture) state, spine fracture state, post spine fracture state, wrist fracture state, hip fracture state and post hip fracture state over time until the patient reached 100 years of age or died with a cycle length of 1-year. In the base-case scenario alendronate was assumed to have a fracture-risk reducing effect as shown in the vertebral fracture arm of FIT. Patients were assumed to receive treatment for 5 years as it was in the FIT population, followed by 2 years with maintained full effect and thereafter a 3-year period where the effect declined linearly to zero.

The cost-effectiveness ratios of treating a 71-year old (the mean age in the vertebral fracture arm of the FIT) woman with one prior vertebral fracture with alendronate were found to be associated with a cost of €4 341 per life year gained and €3,147 per QALY gained, well below the threshold of €30,000/QALY gained generally accepted as bench mark for cost-effective interventions in Spain.

The results of this study indicate that treating post-menopausal women with vertebral fracture with alendronate in Spain is projected to be cost-effective.

Is Alendronate Effective on BMD and Metabolic Markers of Postmenopausal Osteoporotic Patients with Normal to Mildly High Turnover? Comparison with High Turnover Bone. T. Miki[1], H. Naka*[1], H. Masaki*[1], T. Koumo*[2], Y. Imanishi[2], M. Inaba[2], Y. Nishizawa[2]. [1]Geriatrics, Osaka City Univerisy Graduate School of Medicine, Osaka, Japan, [2]Department of Metabolism, Endcrinology, and Molecular Medicine, Osaka City Univerisy Graduate School of Medicine, Osaka, Japan.

Aim: We investigate whether basal bone metabolism influences on the effectiveness of alendronate on lumbar BMD (L-BMD) increase and suppression of metabolic markers of bone.

Methods: Postmenopausal osteoporotic patients (n=58, mean age=69 years old) were divided in to two groups depending on median basal urinary NTX. High turnover group (H group, mean u-NTX=79.3nmolBCE/mmol.cre) consists of 30 patients and normal to moderately high turnover group (N group, mean u-NTX=40.6, $p<0.01$ vs. H-group) consists of 28 patients. These patients were treated with alendronate for 18 months. L-BMDs were followed every 6 months, and metabolic markers of bone (u-NTX, serum NTX, u-βCTX, BAP) were evaluated before, 1, 3, 6, 12 months after initiation of the treatment.

Results: L-BMD in H-group was 7.3% lower than that of L-group ($p<0.04$), although mean age was not different between these groups. The % suppressions at 3rd, 6th, and 12th month of u-NTX were significantly higher in H-group than that of N-group ($p<0.03$), but the absolute difference between these groups was decreased. The initial BAP in H-group was significantly higher than that of N-group ($p<0.05$), but significant differences between these groups were not found in % suppression at 6th and 12th month. The similar findings were also observed in both serum NTX and u-βCTX. The increment of L-BMD was 4.9% in H-group and 5.2% in N-group at 6th month, and 6.6% and 7.3% at 12th month respectively, and the differences between H and L-group were not significant. The differences of absolute increases($\Delta g/cm^2$) of every 6th month between these groups were not significant.

Summary and Conclusion: The ffectiveness of alendronate on the L-BMD and bone metabolism is similar in both u-NTX high group and normal to moderately high turnover group, This suggests alendronate is not contra-indication to postmenopausal osteoporosis without high turnover bone metabolism up to 18 months.

Intravenous Pamidronate Therapy for Treatment of Osteoporosis. What Is the Optimum Dose? S. J. Wimalawansa. Dept. Medicine, Div. Endocrinology, Robert Wood Johnson Medical School, New Brunswick, NJ, USA.

Rationale: Oral bisphosphonate therapy is highly effective in prevention and treatment of osteoporosis, but the compliance is poor due to the inconvenience, and the responses take a year or so. These issues including compliance and upper gastrointestinal problems are overcome by administering a bisphosphonate intravenously. This is particularly true for patients who cannot adhere to, or tolerate oral bisphosphonates, or patients with severe osteoporosis. However, the optimum dose or the frequency of administration of this agent is not known.

Method: A dose-response study was carried out using bone mineral density (BMD) and biochemical markers (BCM) as the end points. Doses of pamidronate between 30 and 120 mg were compared over a 3-year duration. Pamidronate was administered 10 mg/30 min as infusion in normal saline. Two separate infusions of pamidronate were administered a week apart at the onset (loading dose), and single doses were repeated at 6-monthly intervals. BCM were checked prior to each administration of pamidronate.

Results*:* Doses of 90 and 120 mg pamidronate administered at 6 monthly intervals were able to keep the BCM (hydroxyproline/creatinine) suppressed (Table 1), while significantly increasing BMD over the three-year period (Fig 1).

Table 1	Months				
Dose	6	12	24	36	n
30 mg	-18%	-9%	-5%	10%	21
60 mg	-22%	-12%	-10%	-13%	25
90 mg	-40%	-38%	-36%	-39%	29
120 mg	-46%	-44%	-40%	-42%	21

Discussion: Evaluating the BCM and BMD changes, it is concluded that the optimum doses of pamidronate for the treatment of osteoporosis is 90 mg given at 6 monthly intervals. Due to the inability of keeping the BCM suppressed, doses below 90 mg are recognized as sub-therapeutic and unlikely to have beneficial effects on fracture reduction. There was no serious drug-related adverse effect noted in any of these patients. Conclusion: Intravenous pamidronate therapy is a practical and highly effective way of administering a bisphosphonate to improve BMD and fracture reduction, provided that the appropriate doses are used

Dose Response Study of Soy Isoflavones on Bone Resorption in Postmenopausal Women. J. M. K. Cheong*[1], J. R. Nolan*[2], G. S. Jackson*[3], B. R. Martin[1], D. Elmore*[3], G. P. McCabe*[2], S. Barnes*[4], M. Peacock[5], C. M. Weaver[1]. [1]Foods and Nutrition, Purdue University, West Lafayette, IN, USA, [2]Statistics, Purdue University, West Lafayette, IN, USA, [3]PRIME Lab, Purdue University, West Lafayette, IN, USA, [4]Pharmacology, University of Alabama, Birmingham, AL, USA, [5]School of Medicine, Indiana University, Indianapolis, IN, USA.

The purpose of this 3-way crossover study was to identify the effective dose of soy protein isolate enriched with isoflavones for suppressing bone resorption in postmenopausal women. Thirteen postmenopausal women (≥ 6 years since menopause) were pre-dosed with ^{41}Ca intravenously. After a 100-day baseline period, subjects were given 40 grams of soy protein per day that contained either 0, 97.5, or 135.5 mg of total isoflavones in randomized order. The soy protein isolate powder was incorporated into baked products and beverages. Each 50-day treatment phase was followed by a 50-day recovery phase. Serum isoflavone levels and biochemical markers were measured at the end of each phase. Twenty-four hour urine collections were performed every ~10 days during each phase for ^{41}Ca/Ca analysis by Accelerator Mass Spectrometry. Serum isoflavone levels reflected the amount of isoflavones consumed in a dose-dependent manner. None of the isoflavone levels had a significant effect on biochemical markers of bone turnover, urinary cross-linked N-teleopeptides of type I collagen (NTx) and serum osteocalcin (OC), or bone turnover as assessed by urinary ^{41}Ca/Ca. In conclusion, soy isoflavone doses of up to 135.5 mg per day did not suppress bone resorption in postmenopausal women.

Results of a 5 year Double Blind, Placebo Controlled Trial of Calcium Supplementation (CAIFOS); Bone Density Outcomes. A. Devine[1], R. L. Prince[1], S. S. Dhaliwal*[2], I. M. Dick[1]. [1]School of Medicine and Pharmacology, University of Western Australia, Western Australia, Australia, [2]School of Public Health, Curtin University of Technology, Western Australia, Australia.

Osteoporotic fracture is a major public health problem in elderly women. Another presentation demonstrates a 34 % reduction in clinical non vertebral fractures in patients receiving calcium supplementation (calcium carbonate 600mg b.d.) compared to identical placebo in women over 70. In this presentation we examine the hypothesis that calcium supplementation prevents fractures by reducing bone mass loss.

1460 women mean age 75 were recruited from the whole population using a recruitment letter strategy. Responders were excluded if they were on bone active treatment, calcium supplementation or if they had diseases that may have prevented them completing the study. Bone mineral content (BMC), area and BMD were measured using an Hologic 4500A at years 1 and 5. The BMD cv was 1.4 % for the femoral neck and 0.82% for the whole body. Outcomes for those patients completing the per-protocol study were assess using GLM procedures in SPSS version 11.

194 patients had whole body BMD measured at 1 and 5 years. There was no significant treatment group difference in the 1 year BMC (1851 ± 260 g), area (1871 ± 134 cm^2) or BMD (986 ± 90 mg/cm^2). At 5 years the age and BMI adjusted changes in BMC for calcium vs placebo was -19 ± 6 vs -42 ± 6 g (P=0.01); area -18 ± 5 vs -34 ± 5 cm^2 (P=0.025); BMD -0.60 ± 2.6 vs -5.4 ± 6 gm/cm^2 (P=0.20).

In a cross sectional analysis of 692 patients measured at 5 years, the whole body BMC for calcium vs placebo was 1855 ± 15 vs 1782 ± 15 g (P < 0.001); area was 1864 ± 8 vs 1829 ± 8 cm^2 (P < 0.001) and BMD was 990 ± 5 vs 970 ± 5 mg/cm^2 (P=0.007), after adjustment for age and BMI.

741 patients had femoral neck BMD measured at 1 and 5 years. There was no significant treatment group difference in the 1 year BMC (3.56 ± 0.59 g), area (5.13 ± 0.34 cm^2) or BMD (694 ± 103 mg/cm^2). At 5 years the age and BMI adjusted changes in the femoral neck BMC for calcium vs placebo was -49 ± 14 vs -111 ± 14 mg (P =0.002); area 0.008 ± 0.014 vs -0.034 ± 0.014 cm^2 (P=0.027); BMD -10.7 ± 2.0 vs -17.9 ± 2.0 mg/cm^2 (P =0.01). No effects at other hip DXA sites were detectable.

In a cross sectional analysis of 812 patients measured at 5 years, the femoral neck BMC for calcium vs placebo was 3.53 ± 0.03 vs 3.42 ± 0.29 g (P=0.009); area was 5.13 ± 0.02 vs 5.09 ± 0.02 cm^2 (P = 0.094) and BMD was 688 ± 5 vs 672 ± 5 mg/cm^2 (P=0.025) after adjustment for age and BMI. No effects at other hip DXA sites were detectable.

Therefore calcium supplementation reduces the loss of bone mass and area occurring with aging. This effect may explain at least in part the reduction in clinical osteoporotic fracture outlined described in this study.

Racial Differences in Calcium Retention in Adolescent Girls on a Range of Controlled Calcium Intakes. M. Braun[1], Z. Jiang*[2], C. Palacios*[1], K. Wigertz*[1], L. A. Jackman*[1], R. J. Bryant*[1], B. R. Martin[1], G. P. McCabe*[2], M. Peacock[3], C. M. Weaver[1]. [1]Foods & Nutrition, Purdue University, West Lafayette, IN, USA, [2]Statistics, Purdue University, West Lafayette, IN, USA, [3]Indiana University School of Medicine, Indianapolis, IN, USA.

Calcium balance studies were conducted in adolescent females aged 11-13, matched for weight and post-menarchal age. A range of calcium intakes (760-2195 mg Ca/day) were tested in the 3-week controlled feeding studies. Some subjects were studied repeatedly; total observations were sixty-eight for whites and eighty-two for blacks. Diet composites and all urine and feces were collected during each 3-week period in 24-hour pools and analyzed for calcium. All procedures were approved by the Purdue University and Indiana University School of Medicine Institutional Review Boards. Non-linear regression analysis indicated that blacks had higher calcium retention than whites at all intakes. Higher calcium retention during adolescence may play a role in the development of higher bone mineral content observed in blacks compared to whites in adulthood.

Significant Reduction of Risk of Fall in Osteoporotic Women: A Four-Week Proprioceptive Dynamic Program. M. Sinaki[1], R. Brey*[2], C. Hughes*[3], D. Larson*[4], K. Kaufman*[5]. [1]Physical Medicine and Rehabilitation, Mayo Clinic, Rochester, MN, USA, [2]Vestibular Laboratory, Mayo Clinic, Rochester, MN, USA, [3]Motion Analysis Laboratory, Mayo Clinic, Rochester, MN, USA, [4]Biostatistics, Mayo Clinic, Rochester, MN, USA, [5]Biomechanics Laboratory, Mayo Clinic, Rochester, MN, USA.

Twenty-six women ages 60 and older, 13 osteoporotic/kyphotic (O/K) women with thoracic kyphosis of 50 to 65 degrees (Cobb angle) and 13 healthy controls without hyperkyphosis (C) were enrolled in a study to assess risk of falls. Measured parameters included kyphosis, balance, muscle strength, gait, and height.

Computerized Dynamic Posturography (CDP) testing of the two groups at baseline demonstrated a significant balance disorder in the O/K group as compared with the C group ($p < 0.001$). Isometric strength testing of the lower extremities revealed that the O/K group had significantly lower strength ($p < 0.05$) than the C group in all muscle groups except for the right plantar flexors. Objective gait evaluation showed significant differences in various temporal-distance parameters between the O/K and C groups including right and left step length, stride length, forward velocity and average cadence ($p < 0.03$).

Following baseline evaluations, a specific 4-week proprioceptive dynamic program (PDP) was initiated for the 13 O/K subjects. This program consisted of application of a specially designed weighted back support while performing prescribed balance exercises. Twelve subjects completed the program.

At follow-up, balance improved significantly ($p = 0.003$) on CDP testing. Height also improved significantly ($p < 0.001$). Gait parameters showed statistically significant improvement relative to the baseline evaluations. The average increase for forward velocity was 5.7 cm/s ($p = 0.04$) and anteroposterior maximum velocity of the center of mass during level walking improved 0.1 m/s ($p = 0.02$). Cadence improved 3.9 steps/min ($p = 0.02$). Total support time decreased an average of 1.2% on the left and 1.7% on the right ($p = 0.02$, $p = 0.001$, respectively). Swing phase increased for both left (1.2%) and right (1.7%) ($p = 0.02$, $p = 0.001$, respectively). The double support time decreased 1.2% on the right side ($p = 0.04$). Lower extremity strength was not significantly changed from baseline.

Risk of falls in O/K individuals can be successfully reduced with a specific proprioceptive dynamic program without increasing muscle strength. This is the first controlled proprioceptive trial for reduction of risk of falls (in addition to our pilot study) that has been significantly effective without increasing muscle strength in the lower extremities. These results indicate that balance can be improved without strenuous strengthening exercises.

Yaktrax® Walker Reduces Outdoor Winter Falls and Injurious Falls in Fall-Prone Elderly. F. E. McKiernan. Center for Bone Diseases, Marshfield Clinic, Marshfield, WI, USA.

Falling is an oft-overlooked target for fracture reduction strategy. In elders (>65y) 5-10% falls result in soft tissue injury, 3-5% in fracture, 1-2% in hip fracture. An expert panel on fall prevention recently identified 12 high priority research questions including "What is the safest footwear for people who have fallen or are at risk for falling?"

The objective of this IRB approved study was to determine whether Yaktrax® Walker (YW; a non-medical, gait stabilizing device) reduced outdoor winter slips, falls or injurious falls in the fall-prone elderly. Ambulatory, community dwelling elders who had fallen at least once during the previous year were randomized by independent numerical assignment to wear either YW or usual winter footwear (UWF) during the winter of 2003-4 under appropriate environmental conditions. Both groups maintained daily diaries of all indoor/outdoor slips/falls and injurious falls. Injurious falls were rated mild (no medical attention), moderate (medical attention) or serious (hospitalization). Indoor slip/fall occurrences served as the control for fall tendency.

113 subjects (46 M/67F) were randomized. 2 UWF subjects met tests for exclusion (indoor slip/fall rate >3 SD group mean) and were not analyzed. 2 YW subjects were excluded from analysis; 1 withdrew consent, 1 completed only 10 diary days. Mean subject age was 74.2 yrs (range 65-96). Throughout 10,724 observation-days there were 93 indoor slips, 13 indoor falls, 714 outdoor slips and 62 outdoor falls. The YW group RR for indoor slip was 1.46 (p=0.45) and for indoor fall was 1.17 (p=0.78). Thus the tendency for YW and UWF groups to slip or fall appeared comparable. By intention to treat analysis the RR of outdoor slip for YW was 0.50 (p<0.04) when all diary days was the exposure variable and 0.62 (p=0.14) when only days walked on snow and ice was the exposure variable. By intention to treat analysis the RR of outdoor fall for YW was 0.44 (p<0.02) when all diary days was the exposure variable and 0.49 (p<0.03) when only days walked on snow and ice was the exposure variable. About 1/3 of outdoor slips and 2/3 outdoor falls occurred when YW were not wearing their assigned device. Falls resulted in 10 injuries (8 mild, 2 moderate) in UFW and 1 mild injury in YW. No serious injury or fracture occurred in either group. RR of injurious fall for YW was 0.10 (p=0.004). RR of injurious fall per day walked on snow and ice for YW was 0.12 (p<0.02). NNT for the Yaktrax Walker® to prevent 1 injurious fall per winter was 6.

Under appropriate environmental conditions YW prevents falls and injurious falls in fall-prone elderly. Fewer falls should result in fewer serious injuries, fractures and fatalities.

Effects of Reducing Intensity of Back-Strengthening Exercise on Strength of Back Extensors in Healthy Young Women: A Preliminary Study. M. Hongo*[1], E. Itoi*[1], N. Miyakoshi[1], M. Sinaki[2], Y. Shimada*[1]. [1]Orthopedic Surgery, Akita University School of Medicine, Akita, Japan, [2]Mayo Clinic, Rochester, MN, USA.

We reported that back-strengthening muscle exercise using a specific backpack was effective in increasing back extensor strength (BES) and decreasing risk of vertebral fractures. The same intensity of exercise, when performed by patients with osteoporosis, may cause back pain or even vertebral fractures. A reduction in intensity of the exercise may thus be beneficial for osteoporotic patients. We have shown that reduction in intensity from 30% of BES to 15% had similar effect in terms of increasing the back extensor strength. However, we do not know how much reduction in intensity of back exercise would still be effective in increasing the BES. The purpose of the present study was to determine the least effective intensity of back exercise in increasing the BES in healthy young volunteers. Fifty-four healthy young female volunteers with a mean age of 21 years were enrolled in this study. Participants were instructed to lift the upper trunk in prone position with or without a backpack. The protocol was to perform the exercise 10 repetitions per day, 5 days per week. Subjects were randomly assigned to one of the following five groups: control group (Control; n=11) without exercise prescription; 30% of the BES weighted group (30%-W:average weight=9.0kg; n=11) with a standard protocol that has been shown to increase BES and decreasing the risk of vertebral fractures; 15% weighted group (15%-W:average weight=4.4kg; n=13); 2kg weighted group (2kg-W; n=9); and no-weighted exercise group (No-W; n=9). The isometric BES was measured at baseline, 4, 8 and 12 weeks using a dynamometer. Of the original 54 subjects, 47 completed the study. Two subjects in the 30%-W group and one in the No-W group dropped out because they experienced low back pain. The BES increased significantly in all groups except in the Control by 12 weeks. The maximum increase in the BES at 12 weeks was observed in the 30%-W group (39%), followed by the 15%-W (22%), 2 kg-W (32%), No-W (17%), and Control (5%). The increase in BES of the 30%-W was greater than that of Control (p=0.0001), No-W (p=0.0176), and 15%-W (p=0.0337). The percent change of Control was smaller than that of 2 kg-W (p=0.0017) and 15%-W (p=0.0026). There was no significant difference in the change of BES between 30%-W and 2 kg-W. We conclude that either a load of 2 kg or 15% of maximum back extensor strength is effective in increasing the back extensor strength when this amount of load is used during back strengthening exercise.

Comparison of the Extraskeletal Effects of Lasofoxifene and Raloxifene. M. McClung[1], D. Portman*[2], R. Emkey*[3], J. McKenny*[4], M. Ettinger[5], V. Somayaji*[6], A. Lee[6]. [1]Oregon Osteoporosis Center, Portland, OR, USA, [2]Columbus Center for Women's Health Research, Columbus, OH, USA, [3]Radiant Research, Wyomissing, PA, USA, [4]National Clinical Research Inc, Richmond, PA, USA, [5]5Regional Osteoporosis Center of South Florida and Radiant Research, Stuart, FL, USA, [6]Global Research and Development, Pfizer, New London, CT, USA.

Estrogen effectively prevents bone loss after menopause but has recently been shown to have adverse extraskeletal effects. SERMs bind to estrogen receptors to display a variety of estrogen-like and antiestrogen effects in different tissues. Evaluating the extraskeletal effects of new SERMs such as lasofoxifene that prevents bone loss is important.

This 2-yr, phase 2 study was compared the bone density responses to lasofoxifene, a next generation SERM with raloxifene and placebo. 410 women (mean age 58 y and 9 y post-menopausal) were randomized: 82 each to 0.25 mg/d and 1.0 mg/d lasofoxifene, 83 to placebo, and 163 to raloxifene 60 mg/d. All women received daily calcium 1000 mg and vitamin D 250IU. BMD and biochemical markers of bone turnover (data presented in another abstract), markers of lipid metabolism, selected coagulation factors, and gonadotropins were measured.

Both doses of lasofoxifene resulted in greater reductions ($p \leq 0.05$) in LDL-C when compared to raloxifene and placebo. At month 24, median LDL-C reductions of 20.6% and 19.7% were observed for the lasofoxifene 0.25 mg/d and 1mg/d dose groups, respectively, compared to 12.1% and 3.2% reductions observed for raloxifene and placebo, respectively. Lasofoxifene-treated women had significantly ($p \leq 0.0049$) greater decreases as compared to raloxifene in TC (11.3% vs 6.7%), Apo B100 (11.7% vs 5.0%), and Lp(a) (37.7% vs 25.6%), and a significantly ($p<0.05$) greater increase in Apo A1 (5.5% vs 1.6%).There were no consistent treatment effects on HDL-C and TGs. Lasofoxifene was effective in reducing levels of coagulation factors (fibrinogen, PAI-1, and antithrombin III activity), and in reducing serum LH and FSH, compared to placebo ($p<0.05$).

Overall, lasofoxifene was well tolerated. Similar adverse events, including hot flushes and leg cramps, were reported more often with lasofoxifene and raloxifene than placebo. More urogenital symptoms were observed with lasofoxifene compared to raloxifene. This finding was driven largely by leukorrhea (increased vaginal lubrication) - which was considered a beneficial effect by some women.Lasofoxifene was efficacious as compared to raloxifene not only in preventing bone loss, but also showed positive effects on LDL-C and other lipid parameters, no deleterious effects on coagulation markers, and was well tolerated, supporting its use in the management of the postmenopausal woman.
