Objective: As one of the pathological changes of temporomandibular disorders (TMD), Osteoarthritis (OA) lesion can be caused in many molecular pathways by mechanical loading, especially the traumatic occlusion. Ubiquitin Carboxy Hydro-lase-L1/ protein Gene Product 9.5 (UCHL1/PGP 9.5) is an enzyme with both ubiquitin hydrolase and ubiquitin ligase activity, and plays a pivotal role in the complex mechanism protein metabolism. In the present study, we want to determine the mechanotransduction response of UCHL1/PGP 9.5 in TMJ-OA condylar cartilage induced by unilateral traumatic occlusion. Methods: To establish a unilateral traumatic occlusion rat model by the right bite-raised. The animals were randomised into experimental (Exp) groups received unilateral bite-raised and control (Con) groups received no treatment. Hematoxylin-eosin and immunohistochemical staining were performed on the condylar cartilage at the end of 1, 3, 7, 14 and 28 days, and evaluate histopathological changes and immunohistochemical staining by Colombo scores and average optical density (OD) value respectively. Gene expression was analyzed by SYBR green real-time PCR (RT-PCR). Results: Osteoarthritis-like lesions were detected in Exp groups. The UCHL1/PGP 9.5-positive chondrocytes were mainly located in hypertrophic layer. After exposure, Colombo scores showed increased and significantly higher than those in the Con groups at the end of 3, 7, 14 and 28 days (p<0.05); The average OD-value of UCHL1/PGP 9.5 was increased with peak at the end of 7 days before decreasing, and significantly higher than those in the Con groups at the end of 3 and 7 days (P<0.05); And UCHL1/PGP 9.5 mRNA expression had a transient increasing and significantly higher relative to the Con groups in the first 3 days (P<0.05). Pearson's correlation analysis indicated that the histological scores of condylar cartilage had significantly positive correlations to the average OD-value of UCHL1/PGP 9.5 (r=0.8785, p<0.05), and had significantly negative correlations to the UCHL1/PGP 9.5 mRNA expression (r=-0.8796, p<0.05). Conclusion: Experimentally created unilateral bite-raised can lead to temporomandibular joint OA-like changes. UCHL1/PGP 9.5 is the first to specifically identify involved in initial progressive TMJ-OA induced by traumatic occlusion in condylar cartilage.

Smurf2-Deficient Chondrocytes Exhibit Enhanced Chondrogenic Potential. Henry Huang*, Hong Zhang, David Avers, Jie Song. University of Massachusetts Medical School, USA

Background: Osteoarthritis (OA) is a degenerative joint disease leading to articular cartilage loss, osteophyte formation and subchondral bone thickening. OA is a leading cause of disability and a significant socioeconomic burden. There are no effective disease modifying drugs for OA. Smad ubiquitin regulatory factor 2 (Smurf2) is expressed in human OA cartilage and overexpression of Smurf2 in mouse chondrocytes leads to OA-like changes[1]. We previously[2] showed that Smurf2-deficient mice had similar age-dependent skeletal phenotype as WT. However, after surgical destabilization of the medial meniscus (DMM), Smurf2-deficient mice developed milder OA symptoms than WT. Here, we isolated primary chondrocytes from MT and WT mice and performed in vitro experiments to evaluate their chondrogenic potential.

Methods: A previously reported[3] C57BL/6 Smurf2-deficient MT and WT mice were used. Immature primary articular chondrocytes were isolated from 5-6 day old litters as previously described[4]. Chondrogenesis was evaluated by culturing cells for 4 days and treating them with a combination of TGF- β 3 (10ng/mL) and IL-1 β (5ng/mL). RNA was extracted after 24-hour treatment and RT-PCR was performed to compare the relative gene expression of anabolic (COL2, ACN) and catabolic (MMPs) markers. Dedifferentiation was also evaluated by changes in COL1, COL2 and ACN expression. Changes in growth curves with each passage were also assayed using cell counting kit-8 (CCK-8).

Results: Smurf2-deficient chondrocytes expressed statistically significant higher levels of COL2 and ACN genes than WT. These differences were maintained after treatment with TGF- β 3. Addition of IL-1 β drastically suppressed anabolic gene expression but the level of COL2 expression was still higher in the MT chondrocytes. Upregulation of catabolic genes in response to IL-1 β , including MMP3, were comparable between WT and MT chondrocytes. Smurf2-deficient chondrocytes also showed slower dedifferentiation on 2D TCPS culture, where COL2 and ACN levels remained higher and COL1 expression remained lower in later passages. Impaired metabolic activity (by CCK8) associated with later passages was also less severe in Smurf2-deficient chondrocytes than WT.

Conclusion: Smurf2-deficient chondrocytes express higher levels of chondrogenic markers than WT and undergo slower dedifferentiation during passaging on 2D culture. Future work will evaluate whether and how this difference in chondrogenic potential may contribute to the observed joint articular cartilage phenotype *in vivo* after DMM.

The cell cycle regulation of chondrocyte development. HIROYUKI INOSE¹, MASANORI SAITO², PHILIPP KALDIS³, ATSUSHI OKAWA². ¹Tokyo Medical & Dental University, Japan, ²Department of Orthopedics, Tokyo Medical & Dental University, Japan, ³Institute of Molecular & Cell Biology, A*STAR, Singapore

Cell cycle regulation is known to be important for cell development; however, its importance on chondrocyte development remains unknown. Thus we chose to focus

on the role of cell cycle regulator on chondrocyte development. The regulator we chose was cyclin dependent kinases.

Reverse transcription PCR (RT-PCR) confirmed mRNA expression of Cdk1, Cdk2, Cdk4 and Cdk6 in murine primary chondrocytes. Previously, conventional knockout mice of Cdk2, Cdk4 and Cdk6 were reported to be viable, and do not display any overt skeletal phenotypes. However, the deletion of Cdk1 resulted in embryonic lethality. This led us to generate chondrocyte specific Cdk1 knock out mice using type 2a1 collagen promoter. Unfortunately, these mice died within one day after birth. The spines and hind limbs of Cdk1 cKO were markedly shorter than their Cre-negative littermates. Histological analysis revealed proliferative zone of Cdk1 cKO embryos was significantly reduced with disorganized columnar chondrocyte structure. BrdU labelling revealed that the proliferation on peri-articular chondrocytes was dramatically reduced in Cdk1 cKO. In situ hybridization showed lower expression of chondrocyte marker genes in Cdk1 cKO, which indicated impaired chondrocyte differentiation. In vitro analysis further revealed that knockdown of Cdk1 in ATDC5 cells inhibited chondrocyte proliferation. In addition, over-expression of Cdk1 in ATDC5 cells promoted chondrocyte proliferation. Collectively, our findings suggest that Cdk1 is indispensable for chondrocyte development and further investigations might lead to better understanding of cell cycle regulation of chondrocyte development.

Failed Vertebral Bone Formation in Mucopolysaccharidosis VII is Associated with Aberrant Sox9 Regulation and Altered Wnt Signaling. Sun Peck^{*1}, Eileen Shore¹, Neil Malhotra¹, George Dodge¹, Margret Casal¹, Maurizio Pacifici², Mark Haskins¹, Lachlan Smith¹. ¹University of Pennsylvania, USA, ²Children's Hospital of Philadelphia, USA

Mucopolysaccharidosis (MPS) VII is a lysosomal storage disorder defined by deficient β -glucuronidase activity that results in abnormal accumulation of glycosaminoglycans. MPS VII presents with severe spine disease associated with failed vertebral cartilage-to-bone conversion during postnatal growth. Progressive kyphoscoliosis significantly increases mortality. Our objective was to establish the molecular basis of failed vertebral endochondral bone formation in MPS VII using the naturally-occurring canine model, which exhibits a similar disease phenotype to humans. Our specific aims were to identify 1) the stage of failed chondrocyte differentiation in MPS VII vertebral epiphyses and 2) dysregulation of relevant biological pathways using RNA-Seq.

Previously, we identified the developmental window when failed vertebral bone formation first manifests (between 9 and 14-days of age) in MPS VII dogs. For this study, we collected vertebral epiphyseal cartilage from unaffected control and MPS VII dogs at both ages (n=5, all groups) and measured mRNA levels of chondrocyte differentiation markers using qPCR, and Sox9 protein levels using immunoblotting. RNA-Seq was performed for 14-day samples.

SOX9 mRNA was downregulated at 14 days compared to 9 days in both control and MPS VII dogs, but Sox9 protein expression decreased only in controls (Fig). Expected mRNA increases for subsequent differentiation stage markers (RUNX2, PTH1R, MEF2C, COL10A1) at 14 days were seen only in controls. RNA-Seq identified Wnt/ β -catenin signaling as the top dysregulated bone formation pathway at 14 days, revealing significant downregulation of key inhibitory elements and activating signaling molecules in MPS VII compared to controls. Our data suggest that both unaffected and MPS VII chondrocytes receive regulatory signals to exit the proliferative stage as indicated by downregulation of SOX9 mRNA at 14 days. However, aberrant persistence of Sox9 protein in conjunction with low expression of late-differentiation stage markers in MPS VII suggests that aberrant Sox9 protein processing may contribute to abnormal chondrocyte differentiation. Downregulation of both inhibitory and activating molecules in the Wnt pathway suggests MPS VII cells experience decreased Wnt signaling but are unable upregulate compensatory responses. These results provide the basis for further mechanistic investigations of bone disease in MPS and implicate the Wnt/ β -catenin pathway as a potential therapeutic target.

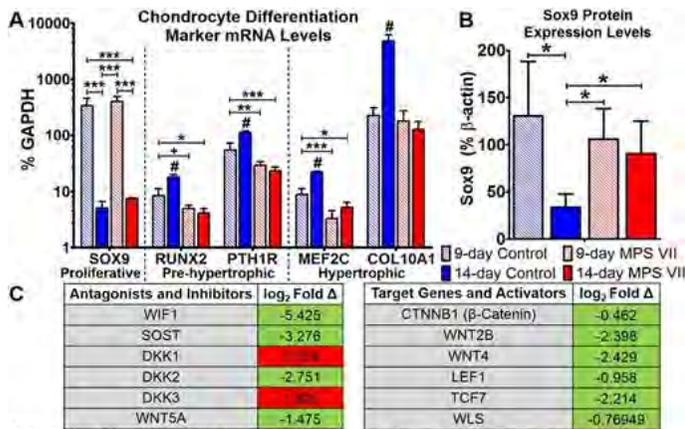

Figure. A) mRNA expression levels of chondrocyte differentiation markers in vertebral epiphyseal cartilage of unaffacted control and MPS VII dogs at 9 and 14-days of age. **B)** Sox9 protein levels in vertebral epiphyseal cartilage of control and MPS VII dogs at 9 and 14-days of age. **C)** Gene expression log₂ fold changes (all $p < 0.05$) of key antagonists and activators of Wnt/ β -catenin pathway in MPS VII vertebral epiphyseal cartilage compared to controls at 14 days, identified by RNA-Seq. Regulation of IL36 α by TBRII Signaling in Articular Chondrocytes: Potential Role in the Osteoarthritic Process. Tieshi Li^{1*}, Joseph temple¹, Alessandra Esposito¹, Arnavaz Hakimiyan², Susan Chubinskaya², Yiwen Zhao³, Richard Loeser³, Daniel Del Gaizo⁴, Christopher Olcott⁴, Anna Spagnoli¹. ¹Department of Pediatrics, Rush University Medical Center, USA, ²Department of Biochemistry, Rush University Medical Center, USA, ³Department of Medicine, University of North Carolina at Chapel Hill, USA, ⁴Department of Orthopedics, University of North Carolina at Chapel Hill, USA

Osteoarthritis (OA) is the most common form of arthritis, affecting millions of people around the world. TGF β signaling and proinflammatory cytokines play essential roles in the pathophysiology of OA. In a mouse model, we have previously reported that the induced conditional postnatal inactivation of TGF β type II receptor, TBRII, (TBRII-ER-Prx1KO) in chondro-progenitors led to OA and demonstrated a functional role for IL36 α and IL36R up-regulation in the process. Increased levels of IL36 α are found in synovial tissues of patients with different forms of arthritis. The present study is aimed at determining whether the TBRII/IL36 α axis is involved in the OA process in humans. To this purpose, chondrocytes were freshly isolated from articular cartilage of human donors (cadavers) that had no documented history or histological signs of OA (normal chondrocytes) and from subjects with histologically proven OA. Cells were treated with either TBRII inhibitor (SB-505124), or IL36 α or IL36 receptor antagonist (IL36Ra). Conditioned medium (CM) or cell lysates were collected for immunoblotting analyses. Isolated mRNA was subjected to qRT-PCR. Untreated cells were used as negative control. We found that in normal chondrocytes, inhibition of TGF β signaling with SB-505124 (5-10 μ M for 24 hrs) induced increases of Mmp13 (28.3 \pm 2.12 fold increase), IL36 α (80.6 \pm 9.04 fold increase) and IL36R (2.68 \pm 0.194 fold increase) mRNA expression ($p < 0.001$; SB-505124 at 10 μ M). An increase of Mmp13 protein was also detected in CM of SB-505124 treated cells. These results suggested that in human normal chondrocytes, TGF β signaling maintains the expression of IL36 α , IL36R at low levels. Next, we found that in normal human chondrocytes, IL36 α treatment (2-200ng/ml) induced a dose-dependent increase of Mmp13 at both mRNA (17.4 \pm 7.23 fold increase, $P < 0.05$; IL36 α at 200ng/ml) and protein levels. Furthermore, in normal chondrocytes, IL36 α treatment (2-200ng/ml for 30 minutes) induced a dose-dependent increase in phosphorylation of ERK1/2, P65, P38, and JNK1/2. These results suggested that IL36 α may regulate articular cartilage homeostasis by regulating Mmp13 expression via NF κ B and MAP kinase signaling pathways. Lastly, treatment of chondrocytes from subjects with histologically proven OA, with IL36Ra (2-10ng/ml) inhibited Mmp13 expressions at both mRNA (0.35 \pm 0.013 fold decrease; $P < 0.01$; IL36Ra at 10ng/ml) and protein levels. Our findings indicate that a TBRII/IL36 α axis is involved in maintaining chondrocyte homeostasis and promotes the development of OA when altered. Our studies provide a novel approach to alter the progression of OA by manipulating the TBRII/IL36 α axis.

Smad3 deficiency leads to mandibular condyle degradation via the Sphingosine 1-phosphate (S1P) /S1P3 signaling axis. Hiroki Mori^{*}, Takashi Izawa, Eiji Tanaka. Tokushima University Grad Sch, Japan

Temporomandibular joint osteoarthritis (TMJ-OA) is a degenerative disease that is characterized by permanent cartilage destruction. Transforming growth factor- β (TGF- β) is one of the most abundant cytokines in the bone matrix and has been shown to regulate the migration of osteoprogenitor cells. It is hypothesized that TGF- β /Smad3 signaling influences cartilage homeostasis by influencing S1P/S1P receptor signaling and chondrocyte migration. Therefore, the molecular mechanisms by which signaling crosstalk could occur between TGF- β /Smad3 and S1P/S1P receptors to maintain condylar cartilage and prevent TMJ-OA were investigated. Abnormalities in the condylar subchondral bone, including dynamic changes in bone mineral density and microstructure, were observed in Smad3^{-/-} mice by micro-computed tomography. Cell-free regions and proteoglycan loss characterized the cartilage degradation present, and increased numbers of apoptotic chondrocytes and MMP-13-positive chondrocytes were also detected in the condylar cartilage of the Smad3^{-/-} mice. Furthermore, expression of S1P receptor 3 (S1P3), and not S1P1 or S1P2 was significantly downregulated in the condylar cartilage of Smad3^{-/-} mice. By employing RNA interference technology and pharmacological tools, S1P was found to transactivate Smad3 in an S1P3/TGF- β type II receptor-dependent manner, and S1P3 was found to be required for TGF- β -induced migration of chondrocyte cells and downstream signal transduction via Rac1, RhoA, and Cdc42. Taken together, these results demonstrate that the Smad3/S1P3 signaling pathway plays an important role in the pathogenesis of TMJ-OA.

Transcriptome landscape of Notch signaling reveals novel canonical and non-canonical targets during chondrogenesis. Yangjin Bae^{*}, Shan Chen, Abhirami Rajagopal, Feng Wang, Hui Wang, Huan-Chang Zeng, Huan-Chang Zeng, Brian Dawson, Terry Bertin, Rui Chen, Brendan Lee. Baylor College of Medicine, USA

Notch signaling, a well conserved pathway across many species, plays critical roles in embryonic development, stem cell maintenance, fate-specification and adult tissue homeostasis. It is activated by direct cell-to-cell physical interaction via Notch receptors and ligands. While Notch signaling pathway has been extensively studied in various cell and tissue types, the mechanism by which Notch governs chondrogenesis in the axial skeleton remains to be elucidated. Our previous studies showed that cartilage specific Notch gain-of-function (Notch GOF) mice exhibited chondrodysplasia and the deletion of *Rbpj* in Notch GOF mice did not fully rescue the axial skeletal deformities. This observation not only demonstrates the importance of canonical *Rbpj*-dependent Notch signaling but also provide interesting evidence for the regulation of Notch targets in a non-canonical (*Rbpj*-independent) manner during chondrogenesis. To further understand the significance of the *Rbpj*-dependent and *Rbpj*-independent Notch signaling during chondrogenesis, we performed ChIP-seq and RNA-seq experiments in chondrocyte cell lines (ATDC5) engineered to overexpress *Notch* alone or both *Notch* and *Rbpj*. These experiments have led to the identification of putative novel *Rbpj*-dependent and *Rbpj*-independent Notch target genes. We have also identified regulatory factors such as Runx1, Nfatc2 and Kid3 that form complex *in silico* and potentially occupy cis-regulatory regions of downstream non-canonical targets in chondrocytes. The functional interactions among these putative regulatory partners during chondrogenesis and novel non-canonical Notch candidate genes are currently under validation. Findings from our study will provide a genome-wide transcriptional network for Notch signaling during chondrocyte differentiation.

The Effects of Endurance Training and Dietary Methionine Restriction on Energy Metabolism, Bone Histomorphometry and Bone Densitometry in Adult Male Rats. Tsang-hai Huang^{*}, Gene Ables², Ming-shi Chang³, Rong-sen Yang⁴. ¹National Cheng-Kung University, Taiwan, ²Orentreich Foundation for the Advancement of Science, USA, ³National Cheng Kung University, Taiwan, ⁴National Taiwan University Hospital, Taiwan

Dietary methionine restriction (MetR) and endurance exercise (EE) have been well-proven in their benefits to metabolic sensitivity and body weight (BW) loss. Simultaneously, MetR and EE also cause reduction in bone mass. The current study aimed to investigate the effects of MetR and EE on energy metabolic and bone quality indices of adult male rats. Animals (26-wk-old male SD rats) were BW matched and assigned to groups subjected to the following interventions: non-treatment baseline group (BA), non-treatment age-matched control (CON) group, dietary methionine restriction (MetR) group, endurance exercise (EE) group, and pioglitazone (PIO) treatment group. By the end of the 10-week intervention, the EE group had lower BW than the CON and PIO group, while the MetR group was lighter than the PIO group ($p < 0.05$). The MetR and PIO groups showed the most efficient performance in

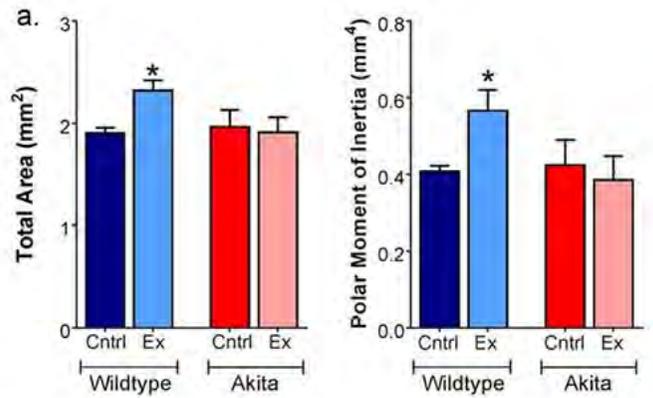

intraperitoneal glucose tolerance test (IPGTT) performance followed by the EE group as compared to the CON group. In serum marker assays, except for a significantly higher procollagen type I amino-terminal propeptide (PINP) and lower leptin, respectively, shown in the BA group, no difference was shown among four experiment groups. In densitometric measurement, a lower total bone mineral density (BMD) was shown in the BA group ($p < 0.05$). In spongy BMD, the CON group was higher as compared to the BA group, MetR and PIO groups, while the EE and MetR groups were higher than the PIO groups ($p < 0.05$). In spongy BMC, the MetR and PIO groups were lower than other groups ($p < 0.05$). In histomorphometry of metaphysis, the BA group showed higher Tb.N and Conn.Dn as compared to other 4 groups. The PIO group showed significantly lower BV/TV and Tb.Th as compared to most of other groups ($p < 0.05$). And, the BA and MetR group had lower Tb.Th compared to the CON group. In summary, EE, MetR and pioglitazone showed benefits to glucose regulation and/or BW control. However, MetR and pioglitazone showed minor or major compromised effects to indices of bone histomorphometry and densitometry. Therefore, in terms of whole body health as well as bone quality, EE might be a better option than diet manipulation or medical intervention.

Type I diabetes altered bone cell purinergic mechanosignaling and anabolic bone response to exercise. Zeynep Seref-Ferlengez¹, Herb B. Sun¹, Mitchell B. Schaffler², Sylvia Suadican¹, Mia M. Thi¹. ¹Albert Einstein College of Medicine, USA, ²City College of New York, USA

Patients with Type 1 diabetes (T1D) exhibit decreased bone density and volume, increased risk for fragility fractures and defective bone healing. Our previous studies demonstrated that the expression of mechanosignaling mediators [purinergic receptors (P2Rs) and pannexin 1 (Panx1) channels] are altered (i) in bone cells exposed to high extracellular glucose levels *in vitro*, and (ii) in bone cells from a T1D mouse model *in vivo*. Given that maintenance of skeletal integrity in response to daily physical activity relies on ability of bone cells to perceive and respond to mechanical loading, we hypothesized that response/sensitivity to mechanical loading is impaired in T1D. In this study we used the Akita (C57BL/6J-Ins2^{Akita}) mouse model of T1D. Young Akita and wildtype (WT) mice (8 wk old, male, n=10/group) were divided into treadmill exercise and cage control groups. The exercise group was subjected to treadmill running for 4 weeks (5 days/wk, 300 m/day, speed up to 10 m/min). All animals were euthanized immediately after the last running exercise. Right hindlimbs were used for histomorphometric study, and lefts were used to examine protein expression. Mid-diaphyseal crosssections from PMMA embedded femurs were used to measure the bone area parameters. Expression level of Panx1 and P2R subtypes (P2Y₁, P2Y₂, P2Y₄, P2X₇) were quantified by Western blotting of osteocytes enriched samples (left femur and tibia diaphyses were cleaned from soft tissues and marrow, pulverized, protein extracted). All experiments were performed under IACUC approval. Histomorphometry studies showed that 4 wks exercise caused radial expansion in femur (increased in Bone Area (~25%) and moments of inertia (~40%), ($p < 0.05$; Fig. 1) in WT mice compared to their cage controls. In contrary, Akita T1D animals did not show anabolic response with exercise. There was no significant difference in bone area parameters between exercised and cage control Akita mice. Western blot analyses showed that mechanosignaling mediators (specifically Panx1, P2X₇R, $p < 0.05$; Fig. 2) were significantly altered in exercised diabetic mice compared to control and exercised WT mice. Our current findings demonstrate that exercise-induced anabolic response of bone is impaired in T1D and likely related to T1D-induced changes in bone cell purinergic mechanosignaling, which is essential for proper response to mechanical loading and maintenance of bone health.

SU0090

VEGF Expression Levels in Human Diabetic and Non-Diabetic Vertebral Bone Tissue. Roberto Fajardo*¹, Jesus Hernandez², Trevor Wait², Ammar Saigal², Elena Geraymovych², Zachary Child². ¹UT Health Science Center, San Antonio, USA, ²The UT Health Science Center at San Antonio, USA

Adults with type 2 diabetes mellitus (DM2) are at increased risk for fractures compared to non-diabetics. Diabetic patients with a prior fracture have increased cortical porosity compared to diabetic subjects without fracture. The porosity suggests a locally acting resorptive process that is independent of hyperglycemia, but so far no mechanisms have been identified.

Micro- and macro-vascular problems are common complications in DM2. Ocular microvascular pathology leads to ischemia that stimulates a neoangiogenic response to restore perfusion. This response is driven by increased vascular endothelial growth factor (VEGF) expression in the diabetic eye. In contrast, in cardiac tissue neoangiogenesis is inhibited in response to ischemia because local cells are unable to secrete VEGF. It is currently unknown what roles ischemia and micro-vascular complications play in diabetic bone.

Spine tissue was collected from human subjects undergoing surgery. Subjects were 50 yrs of age or older and either diabetic or non-diabetic. Exclusion criteria included previous lumbar or thoracic surgeries, use of anti-osteoporosis medications, bone metastases, and other exclusion criteria. Standard of care procedures were used at all times during surgeries. The Institutional Review Board of the University of Texas Health Science Center at San Antonio approved the study.

Bone tissue was harvested and fixed for 5 days under vacuum. Samples were then decalcified and embedded in paraffin. After antigen retrieval sections were treated with 3% hydrogen peroxide treatment to inhibit endogenous peroxidases. Following treatment with a blocking buffer, they were incubated overnight in primary anti-VEGF antibody (Santa Cruz). The tissues were then treated with a secondary antibody (Chicken IgG) and Streptavidin-HRP complex. Sections were stained with a DAB substrate. Figure 1 shows representative images of (A) non-diabetic and (B) diabetic sections. Vascular tissues were intensely stained for VEGF in the non-diabetic sections, with a positive signal focused in cortical bone vascular channels. Evidence indicated that VEGF expression was suppressed in diabetic bone tissue compared to the non-diabetic samples. This decrease in VEGF expression suggests that its protective actions of maintaining the integrity, antithrombotic, anti-inflammatory properties of the endothelium and suppressing apoptotic pathways in endothelial cells and bone cells may be compromised.

Adiponectin Contributes to Bone Marrow Adipose Tissue Expansion but Not Bone Loss in Calorie Restricted Mice. Theresa Roth¹, Rebecca Hayden², Carolynn Roth³, Linh Ho*², Liping Wang¹, Robert Nissenson¹. ¹UCSF / VA, USA, ²UCSF / NCIRE, USA, ³UCSF, USA

Anorexia nervosa affects up to 1% of American women and is associated with increased fracture risk. Peripheral adipose tissue is reduced in anorexia and bone marrow adipose tissue (BMAT) is increased, but it is unclear why this occurs or whether increased BMAT is responsible for decreased bone density. As circulating adiponectin (APN) levels are known to increase with caloric restriction (CR), we hypothesized that APN may drive increases in BMAT. APN levels are also positively correlated with fracture, suggesting that APN null mice may be resistant to CR-induced bone loss. We subjected male wild type (WT) and global APN null mice to 30% CR from 4 weeks of age until sacrifice at 10 weeks of age and compared these mice with age-matched controls fed ad libitum (AL). Total body fat averages and standard deviations by nuclear magnetic resonance at sacrifice were 1.93 +/- 0.41 grams in AL APN null mice, 1.32 +/- 0.29 grams in AL WT mice, 0.83 +/- 0.30 grams in CR APN null mice, and 0.22 +/- 0.13 grams in CR WT mice. These results demonstrate that endogenous adiponectin limits total body fat in mice maintained on either a normal or a restricted diet. Lean mass was decreased by about 25% in CR mice regardless of genotype ($p < 0.001$). BMAT in the proximal tibia was assessed by osmium tetroxide staining. In AL animals, there was a weak trend towards lower BMAT with deletion of APN. As expected, CR resulted in increased BMAT in WT mice, ($p < 0.05$), and this effect was inhibited in APN null mice. BMAT volume in CR WT mice was approximately twice that of CR APN null mice ($p < 0.05$), indicating a

significant contribution of APN to the increase in BMAT seen with CR. Micro-CT revealed that CR resulted in a 13% decrease in trabecular thickness at the distal femur ($p < 0.01$) and a 14% decrease at the proximal tibia ($p < 0.001$), and a 12% decrease in cortical thickness at the tibiofibular junction ($p < 0.001$) in WT animals. APN deletion did not alter these effects, suggesting that bone loss seen with CR is not dependent on APN. While literature reports on the effect of APN deletion on bone have been varied, we found a trend towards decreased trabecular thickness in APN null mice under AL conditions. Additionally, cortical bone volume was lower in APN null mice than WT mice on either diet ($p < 0.01$). These results indicate that APN contributes to the increase in BMAT that occurs with caloric restriction. However, APN is not required for the negative effects of CR on bone.

Disclosures: Linh Ho, None.

Aging B6 mice are protected from the deleterious effects of calorie restriction on trabecular bone. Casey Doucette*¹, Mark Horowitz², Clifford Rosen¹. ¹Maine Medical Center Research Institute, USA, ²Department of Orthopaedics & Rehabilitation, Yale University School of Medicine, USA

In humans, anorexia nervosa causes a dramatic reduction in bone mineral density (BMD) and visceral adipose tissue with a paradoxical increase in marrow adipose tissue volume. In mice, 30% caloric restriction (CR) during adolescence has similar effects, but studies have also suggested that a CR diet can increase longevity, which could indicate a protective role for CR against age-related bone loss. Here, we investigated the effects of a 30% CR diet on bone in both adolescent and aging mice from two strains with distinct bone phenotypes; one with high bone mass (C3H/HeJ, C3H) and one with low bone mass (C57BL/6J, B6). Male mice from each strain were administered a 30% CR diet daily for a period of 12 weeks from 3-15 weeks of age (adolescent) or 40-52 weeks of age (aging); littermate controls from each strain were fed control diet *ad libitum*. In adolescent mice, areal BMD and bone mineral content (BMC) were reduced in CR mice as compared to controls, which was supported by μ CT analysis demonstrating significant reductions in trabecular BV/TV and cortical BA/TA with CR. Reductions in cortical parameters and femoral length also indicated inhibition of appositional and interstitial growth, respectively, in CR-fed mice. Interestingly, osteoblast numbers (N.Ob/TAR) were significantly increased in CR versus control animals; coupled with μ CT data, these results imply that osteoblast function is reduced during CR in adolescent mice. In aging mice, areal BMD and BMC were significantly reduced in CR-fed C3H mice as compared to controls, but this difference was not observed in CR-fed B6 mice. Analysis of bone microarchitecture by μ CT also indicated that aging B6 mice were protected from the CR-induced reductions in trabecular BV/TV observed in C3H mice. In aging CR mice from both strains, N.Ob/TAR and osteoid volume fraction (OV/BV) were increased as compared to controls, and in calorie-restricted C3H mice, osteoclast numbers were also increased. This increase in osteoblast activity in B6 CR mice without an increase in osteoclast activity may be indicative of the mechanism by which they are protected from CR-induced trabecular bone loss. We conclude that the negative effects of CR on aBMD, BMC, bone microarchitecture, and interstitial and appositional growth during adolescence may be a result of reduced osteoblast function. On the other hand, aging B6 mice may be protected from the effects of CR on trabecular bone through increased osteoblast activity.

Can Magnetic Resonance Spectroscopy Measure Bone Marrow Adipose Tissue Fraction? Ingvild Hogestol*¹, Maziar Shabestari², Hanne Gulseth¹, Tom Mala³, Erik Rud⁴, Erik Eriksen¹. ¹Department of Endocrinology, Morbid Obesity & Preventive Medicine, Medical Clinic at Oslo University Hospital, University of Oslo., Norway, ²Department of Biomaterials, Institute of Clinical Dentistry., Norway, ³Department of Endocrinology, Morbid Obesity & Preventive Medicine, Medical Clinic & Department of Gastrointestinal Surgery, Surgical Clinic at Oslo University Hospital., Norway, ⁴Department of Radiology & Nuclear Medicine, Oslo University Hospital, University of Oslo., Norway

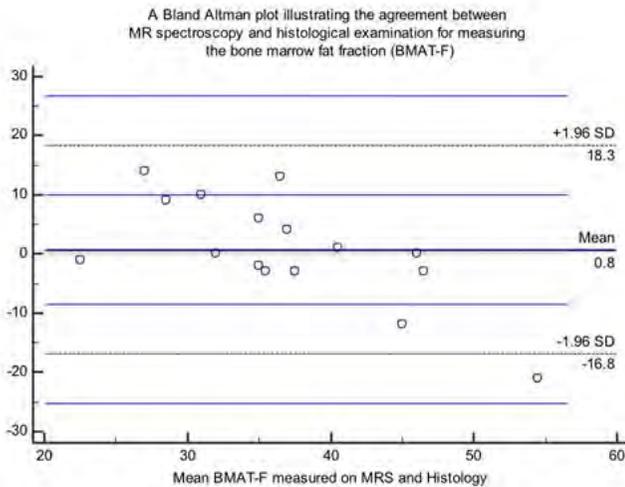

Purpose: Measurement of bone marrow adipose tissue fraction (BMAT-F) may be of prognostic value in a variety of conditions such as osteoporosis, obesity and diabetes. We compared measurement of BMAT-F using bone marrow biopsy (reference) and magnetic resonance spectroscopy (MRS).

Material and methods: Participants were part of a study where we examined bone marrow adipose tissue before and after gastric bypass surgery. The BMAT-F was assessed in trephine needle samples from the posterior iliac crest. Bone marrow biopsies were embedded in methyl methacrylate at -20°C. Subsequently, paired 7 μ m thick sections were stained with Hematoxylin and Eosin. Mosaic images of the sections were analyzed by bone histomorphometric software (BioQuant Osteo). The MRS was performed over the same region using a pelvic phased array with a 1.5 T magnetic resonance imaging scanner (Siemens, Erlangen). MRS values were corrected using the coefficient of variance of duplicate measurements between the two methods. Correlation was evaluated using a Pearson's coefficient. The variability between histology and MRS was estimated as 1.96 x SD of the mean arithmetic difference

according to Bland and Altman. The range between ± 1.96 SD of the mean difference is referred to as 95% limits of agreement. All patient gave informed consent, and the study was approved by the Regional Ethical Committee.

Results: Sixteen patients were included, 8 patients were eligible for gastric bypass surgery and 8 patients had received gastric bypass surgery 1 year prior to study inclusion; mean (\pm SD) age was 41 (\pm 9.1) years, BMI 33.9 (\pm 7.2) kg/m² and 13 (81%) were women. The coefficient of variance of duplicate measurements was 50%. The mean BMAT-F (95% CI) as assessed by histology and MRS was 36.5% (30 to 43%) and 37.2% (34 to 40%), respectively. The two methods correlated positively ($R=0.669$, $p=0.005$). The mean difference and variability was 0.8% (-4 to 5) and 18%, respectively. The 95% limits of agreement ranged from -17 to 18%.

Conclusion: A significant positive correlation between measurements of BMAT-F in bone marrow biopsies and MRS was observed. Significant variability between the two methods was observed and assessment by MRS overestimates BMAT-F. Further studies are needed to assess the clinical utility of MRS in the measurement of BMAT-F.

Bland Altman plot illustrating the agreement between histology and MRS measurements of BMAT-F

Fate Determination and the Bioenergetics of Osteoblastogenesis and Adipogenesis. Anyonya Guntur*, Victoria DeMambro, Clifford Rosen. Maine medical center research institute, USA

Osteoblastogenesis is an energy consuming process. Signaling mechanisms that control the substrates utilized by osteoblasts during bone formation and the bioenergetic pathways that are employed during mineralization are currently understudied in skeletal biology. To better understand the substrates and the catabolic pathways through which these fuels are metabolized we utilized C3H^{smi/smi} mice which have a loss in IRS1 phenotypically resulting in low bone and fat mass. We isolated calvarial osteoblasts from Wildtype (Wt) and C3H^{smi/smi} mice and compared their bioenergetic response to addition of pyruvate and glucose as substrates. Wt osteoblasts cultured in osteoblast differentiation media for 7 days (ODM) upregulated Oxidative Phosphorylation (OxPhos) compared to Non differentiating osteoblasts and the IRS1 mutant cells showed an attenuated response to differentiation, with 1) decreased basal respiration and 2) decreased spare respiratory capacity compared to differentiating Wt cells, suggesting that loss of IRS1 compromises mitochondrial respiration. Furthermore, Wt calvarial osteoblasts differentiated for 21 days and tested for utilization of pyruvate and glucose showed engagement of both OxPhos and Glycolysis (Glyc) for catabolism compared to Non differentiated cells which were highly OxPhos dependent. Next we wanted to contrast this with the bioenergetic profile of cells undergoing adipogenesis, so we utilized primary ear mesenchymal stem cells (EMSC's) from Wt and C3H^{smi/smi} mice and compared the response of these cells to pyruvate and glucose during adipogenic differentiation. Wt cells after 7 days in differentiation media upregulated OxPhos compared to C3H^{smi/smi} cells and Non differentiating controls, but Glyc compared to Non differentiating cells was lower. This is in contrast to what we observed in differentiated osteoblasts, suggesting that cells of different lineage utilize different catabolic pathways during differentiation. Interestingly, the C3H^{smi/smi} EMSC's undergoing differentiation in contrast to calvarial osteoblasts showed 1) higher spare respiratory capacity compared to Wt cells undergoing differentiation even though they had 2) lower basal respiration, suggesting an important role for IRS1 in modulating adipogenesis. In sum these data suggest that osteoblasts and adipocytes during differentiation utilize different metabolic pathways to generate energy.

Increased Osteocalcin Levels and Bone Mineral Content During Rapid Weight Gain Therapy in Anorexia Nervosa Patients. Bojan Tubic*¹, Cecilia Pettersson², Anna Svedlund³, Heléne Bertéus Forslund⁴, Per Magnusson⁵, Diana Swolin-Eide³. ¹Gothenburg University, Se, ²Department of Internal Medicine & Clinical Nutrition, Sahlgrenska Academy, Gothenburg University, Sweden, ³Department of Pediatrics, Institute of Clinical Sciences, The Queen Silvia Children's Hospital, Sahlgrenska Academy, Gothenburg University, Sweden, ⁴Department of Internal Medicine & Clinical Nutrition, Sahlgrenska Academy, Gothenburg University, Göteborg, Sweden, ⁵Department of Clinical Chemistry & Department of Clinical & Experimental Medicine, Linköping University, Sweden

Purpose: Patients with anorexia nervosa (AN) are at high risk of reduced bone mass. Osteocalcin (OC) reflects bone formation but has also been proposed to act as a link between bone and energy metabolism in mice, however, human data are inconclusive. We investigated how the various forms of OC respond during a 12-week novel intensive nutrition therapy in AN patients during a short period of large changes in energy metabolism. The potential influence of the fat mass and obesity-associated gene (FTO), SNP rs9939609, was also investigated in relation to study parameters.

Methods: Twenty-two female AN patients, mean 20.9 years of age, with a mean body mass index (BMI) 15.5 kg/m² completed the study. Biochemical markers, body composition, bone mass by dual-energy X-ray absorptiometry (DXA) and peripheral quantitative computed tomography (pQCT) were assessed.

Results: Subjects gained in median (minimum-maximum) 9.9 kg (5.5-17.0 kg), and BMI increased from median 15.4 kg/m² to 19.0 kg/m², $p<0.0001$. Fat mass increased from median 11.4% to 26.7%. Total OC, carboxylated OC (cOC), undercarboxylated OC (ucOC) and bone-specific alkaline phosphatase (BALP) increased during the study period. No change was observed for the resorption marker carboxy-terminal cross-linking telopeptide of type I collagen (CTX). Total body bone mineral content increased, but no changes were found for whole body, lumbar spine or femoral neck bone mineral density (BMD). Tibial trabecular density measured by pQCT decreased. Total OC, cOC, ucOC were not associated with BMI, delta BMI or body composition parameters at any time point.

Conclusion: In conclusion, although a small study, this is the first clinical study that contributes to the knowledge how the different forms of OC respond to rapid weight gain. Total OC, cOC, ucOC and BALP increased, but the resorption marker CTX did not change. These biochemical findings corroborate with the findings of increased total body BMC. No associations were found with the measured body composition fat and muscle parameters.

Disclosures: Bojan Tubic, None.

ApoE deficiency in osteoblasts leads to a low bone mass phenotype in mice. Brigitte Müller, Alexander Bartelt, Timo Beil, Till Köhne, Thorsten Schinke, Andreas Niemeier*. University Medical Center Hamburg-Eppendorf, Germany

Objective

Apolipoprotein E (apoE) is an important component of lipoproteins. As a ligand for members of the LDL receptor family, it mediates the endocytosis of these lipoproteins. ApoE deficiency in mice causes an accumulation of remnant lipoproteins but also results in a high-bone mass phenotype with increased bone formation while bone resorption is unaffected. Up to now it is unknown from which cell type the apoE that regulates bone remodeling is derived from. The objective of this study was to explore the role of osteoblast-apoE in the regulation of bone mass in vivo.

Methods

In order to specifically analyze the function of osteoblast-apoE in vivo we generated a conditional ApoE knockout-mouse (Cre-loxP). Runx2-Cre mice were crossed to ApoE^{fl/fl} mice to generate mice lacking ApoE in the osteoblast lineage. Histomorphometry and μ CT was performed on trabecular vertebral and femoral bone of three and six months old females. Bone turnover makers alkaline phosphatase, osteocalcin and DPD/creatinine were measured in the serum and urine by ELISA.

Results

Interestingly, the specific deletion of ApoE in the osteoblast lineage results in an age-dependent bone phenotype which does not reflect the global ApoE knock-out phenotype. Hence, three months old ApoE^{fl/fl}/Runx2-Cre⁺ female mice do not display an altered bone mass phenotype yet, whereas the trabecular bone mass of six months old ApoE^{fl/fl}/Runx2-Cre⁺ females is significantly reduced compared to ApoE^{fl/fl}/Runx2-Cre⁻ littermates. This reduction is caused by an increased number of osteoclasts and increased bone resorption, while the bone formation rate remains unchanged. In addition, these mice exhibit an elevated osteocalcin concentration in the serum.

Conclusion

These findings confirm that apoE has a powerful regulatory function in bone remodeling. The effects of osteoblast apoE and systemic (mostly liver-derived) apoE on the regulation of trabecular bone mass appear to be diverging. The lack of apoE in

osteoblasts triggers a yet to be identified signal that stimulates osteoclastic bone resorption. It is conceivable that apoE, via its effect on osteocalcin production by osteoblasts, plays a relay function in the postprandial energy metabolism at the interface of lipid and glucose metabolism in the osteoblast.

Estrogen Loss Impairs Osteocyte Mitochondrial Electron Transport Chain Activity (oxidative phosphorylation) In Vivo. Dorra Frikha-Benayed^{*1}, Jelena Basta-Plajkic², Robert J. Majeska², Mitchell B. Schaffler². ¹The City University of New York, USA, ²CCNY, USA

Recently we showed that estrogen (E2) loss acutely leads to dramatic accumulation of NADH in osteocytes, indicating oxidative stress. Because E2 has been suggested to directly alter mitochondrial oxidative functions (1), we tested whether E2 loss impairs mitochondrial electron transport chain activity (i.e. oxidative phosphorylation) of osteocytes in vivo. Following IACUC-approved procedures, groups of 17 wk old C57BL/6J mice that had undergone OVX or SHAM surgery were treated either with Methylene Blue (MB, 0.2% in cage water supply) or with normal water beginning at the time of surgery. Methylene Blue is an alternative mitochondrial electron carrier that bridges complexes I and III and has been shown to be neuroprotective against ischemic injury and Parkinson's disease (2). Osteocyte NADH accumulation was monitored in situ by multiphoton microscopy (MPM) at 2 days post-OVX in metatarsal diaphyses of anesthetized mice (3). NADH fluorescence intensities were measured using ImageJ and differences among groups were tested using one-way ANOVA followed by post-hoc testing using the Mann-Whitney U-test. We found that OVX markedly increased osteocyte NADH levels and that this increase was completely prevented by Methylene Blue treatment (Fig 1,2). How E2 loss produces oxidative stress in osteocytes remains obscure. Estrogen depletion is associated with increased ROS (4), but it is not clear how the absence of estrogen's antioxidant effects would so dramatically alter osteocyte NADH levels. Similarly, absence of estrogen's antioxidant effects also would not be expected to alter osteocyte NADH levels (5). In any case, oxidative stresses like those resulting from E2 loss can lead to osteocyte apoptosis or autophagy that trigger and regulate resorption. The present finding that Methylene blue treatment in OVX mice effectively abrogated the increases in osteocyte oxidative stress suggests that E2 loss acts directly on mitochondria. Moreover, since Methylene Blue appears to normalize osteocyte oxidative metabolism after OVX, it may limit some or all of the downstream consequences of estrogen depletion.

NGF-BDNF-Osteocalcin and oxytocin genes interaction in brain, bone, fat stores and reproductive organs. Claudia Camerino^{*1}, Maria Cannone², Elena Conte², Domenico Tricarico². ¹School of Medicine, University of Bari, Italy & ²University of Cincinnati, USA, ²Dept. of Pharmacy – Drug Sciences, University of Bari, Italy

Bone mass, metabolism and reproduction require a coordinated regulation. The bone-derived osteocalcin (Ost) favors insulin sensitivity, male fertility and neurogenesis. The neurotrophins BDNF/NGF and oxytocin(Oxt) are involved in energy and bone metabolism. NGF regulates fertility elevating LH in female, *Ost*^{-/-} mice show obesity and high LH in spite of decreased testosterone. To investigate the NGF-osteocalcin- BDNF-Oxt interaction we analyzed by RT-PCR the mRNA levels of NGF, BDNF, Oxt, Ost and their receptors p75NTR/NTRK1, TRKb, OxtR and Gprc6a in brain and bone, adipose WAT/BAT and reproductive organs, of 3 months old female and male mice. Brain and bone were used as positive controls respectively.

The mRNA levels of NGF and p75NTR are 50% higher in BAT than brain. NGF and its receptors are downregulated in WAT and bone in both genders. Ost and Gprc6a are upregulated in bone and brain, down-regulated in BAT/WAT. BDNF and TRKb expression in bone is higher than brain, but lower in BAT/WAT; TRKb is downregulated in bone and up-regulated in adipose tissue. NGF is up-regulated in ovaries/uterus, but down-regulated in the testes. The mRNA levels of p75NTR is respectively 300%, 100% and 50% higher in testis, ovaries and uterus than brain. NTRK1 is downregulated in all tissues. The Gprc6a is expressed in testes, not in ovaries and uterus. BDNF and TRKb are downregulated in the sexual organs. The Oxt gene is markedly expressed in brain and with minor extend in bone in either genders, while the OxtR in ovaries although a significant level of expression is observed in adipose tissues and bone. The up-regulation of NGF and related-receptors in fat are consistent with NGF as an energy regulator. The inverse correlation of NGF and BDNF in fat and bone, shows these exerting opposite effects on leptin with BDNF regulating bone. The up-regulation of p75NTR in testes match the Gprc6a expression, and may be responsible for the higher LH in the *Ost*^{-/-} mice. The pattern of expression of these molecules and their receptors show a similar trend with Ost, NGF, Oxt and BDNF genes highly expressed in brain of both male and female mice, while their receptors were instead expressed in the reproductive organs showing a gender expression profile. This is consistent with the fact that these molecules have limited or no access through the blood brain barrier and add evidences that the signalling of bone metabolism and fertility are released from CNS to act on peripheral tissues.

Peripheral Leptin Stimulates Bone Formation at Very Low Circulating Levels. Russell T. Turner^{*}, Kenneth Philbrick, Carmen Wong, Amida Kuah, Dawn Olson, Adam Branscum, Urszula Iwaniec. Oregon State University, USA

Leptin is produced by adipocytes and enters peripheral circulation where it may act directly on bone cells. Leptin is also transported across the blood brain barrier via a saturable transport system where, in addition to regulating appetite and thermogenesis, it may indirectly regulate bone metabolism. Leptin levels in peripheral circulation greatly exceed those in the central nervous system. Thus, the direct peripheral actions of leptin should be evident at lower concentrations than the hormone's centrally mediated actions. We performed a dose response study in which leptin was continuously infused (0, 4, 12, 40, 140, and 400 ng/hr) for 12 days into 6-week-old leptin-deficient female *ob/ob* mice (n=8/group) using s.c. implanted osmotic pumps. Additional controls consisted of *ob/ob* and wild type (WT) mice sacrificed at the start of leptin infusion and WT mice sacrificed at study termination. Changes in energy metabolism in response to leptin administration were evaluated by measurement of food consumption, body composition, blood glucose, uterine weight, and UCP-1 gene expression in brown adipose tissue. Bone response to leptin was evaluated by imaging, dynamic histomorphometry, gene profiling and biochemical markers of bone turnover. As expected, longitudinal bone growth, osteoblast-lined bone perimeter, mineralizing perimeter and bone formation rate were depressed in distal femur in *ob/ob* mice. Subcutaneous infusion of leptin into *ob/ob* mice resulted in a dose-dependent increase in serum leptin levels, with WT levels achieved at 140 ng/hr. Leptin treatment increased osteoblast-lined bone perimeter, mineralizing perimeter and bone formation rate at the exceptionally low level of 4 ng/hr and longitudinal growth rate and mineral apposition rate at 12 ng/hr. Leptin replacement in *ob/ob* mice increased mRNA levels for bone matrix proteins and BMP signaling in tibia. Higher dose rates of leptin (40 to 140 ng/hr) were required for leptin to increase UCP-1 gene expression in brown adipose tissue, and to decrease food consumption, blood glucose levels, body weight and adipose tissue weight. These findings suggest that the bone anabolic effects of leptin are primarily mediated through peripheral leptin signaling. The exquisite sensitivity of the skeleton to peripheral leptin suggests caution should be made in interpreting results obtained by direct administration of the hormone into the hypothalamus because of efflux from the brain into peripheral circulation.

Phosphate Restriction Leads to Global Inhibition of Mitochondrial Oxidative Function in Fracture Healing. Amira Hussein^{*1}, Serkalem Demissie², Kyle Lybrand¹, Heather Matheny¹, Brenna Hogue¹, Anthony DeGiacomo¹, Louis Gerstenfeld¹. ¹Orthopaedic Surgery, Boston University School of Medicine, USA, ²School of Public Health, Boston University, USA

Introduction: Phosphate is essential for healthy bone development and fracture repair. Although phosphate deficiency has been shown to impair fracture healing, the mechanisms involved in impaired healing are unknown. The goal of this study was to determine the effects of phosphate restriction on the biologic functions identified from the transcriptomic analysis of fracture calluses.

Methods: Closed stabilized fractures were generated in the femora of three strains of male mice: A/J, C57BL/6J, and C3H/HeJ. Phosphate deficiency was initiated 2 days prior to fracture and maintained for 15 days by supplying the mice with a low phosphate diet. Matching control groups were given a normal diet. Microarray analyses of the exomic transcriptome were performed using total RNAs isolated from fracture calluses across the 35 day time course. Gene expression values were compared

between Pi and control groups using analyses of covariance with strain and time-point as covariates to examine the effect of diet. The biologic functions of genes with FDR q-value ≤ 0.005 were assessed.

Results: Many biologic functions were affected by phosphate deficiency. Metabolic-related functions such as oxidative phosphorylation and mitochondrial dysfunction were the top pathways affected by the phosphate deficiency. Mice with phosphate deficient diet had significantly lower expression levels compared to controls, indicating impairment in the metabolic functions ($p < 0.0001$).

Discussion: Oxidative metabolic functions were those most affected by phosphate deficiency within all strains of mice. The effect of phosphate deficiency was more pronounced in the C57BL/6J strain of mice, which interestingly, is the most sensitive to dietary oxidative stress, which is associated with obesity and diabetic condition. Comparative studies with cardiac tissue microarray data using hearts obtained from diet induced cardio-myopathies showed similar alterations in oxidative functions. These findings provide a crucial link between genetic variability or life style factors that affect system wide metabolic activity and fracture healing outcome.

The Phosphate Hypothesis: Thyroid Disease and the Skeleton. Robert Fredericks¹, Ilka Nemere². ¹Endocrine Associates, USA, ²Utah State University, USA

Translation of basic science to clinical care is dependent upon understanding the nature of variance in the expression of human disease. Anticipation that the human genome project would clarify this question has been a dominant influence on healthcare policy. It is now recognized that all human beings are compound mutants, including those considered healthy. This discovery explains the dissonance between observations made in inbred animals and clinical care. Personalization of healthcare delivery will require recognition that each individual is profoundly unique. Based on the assumption that phosphate is a primary signal in the organization of heat and that calcium serves as an organizing signal for phenotypic expression, highly influenced by the calcium sensing receptor, we have developed physiologic/metabolic models based on existing data from both animal and human studies, in the context of practice, engaging oral calcium challenge and immersion in water (gravitational subtraction) to explore the nature of human variance. The intestinal MARRS 1-25 D receptor appears to interface with the T3 alpha/beta receptor signaling and the models predict that paricalcitol would have a favorable effect on hyperthyroidism when pathogenically influenced by a T3alpha receptor gain of function, mediated by an antagonistic effect on the 1-25D MARRS receptor. Ten consecutive cases of refractory hyperthyroidism, considered obligate candidates for radioactive iodine or surgical intervention, have been managed with paricalcitol resulting in either complete remission or effective management with concomitant thioamides. In addition an association with spinal BMD and the balance between T3 alpha and beta receptor function as predicted by the models is readily demonstrated. The physiologic/metabolic models serve as a template for understanding the phenotypic expression of compound mutant influences on the heterostatic organization of heat that is the foundation of the general theory of metabolism and serves to clarify fundamental organizational principles operative in the organization of biology and healthcare.

Uncontrolled glucose significantly impairs trabecular and cortical micro-architecture and delays bone callus formation in type 1 diabetic rats, which are ameliorated by insulin administration. Ariane Zamarioli¹, Maysa Campos², Ana Paula Frantini², Mariana Butezloff², Francisco de Paula², José Volpon². ¹School of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil, ²University of São Paulo, Brazil

We assessed the microstructural changes in the bone tissue and in the bone callus in both uncontrolled and controlled glucose level of diabetic rats. Sixty female Wistar rats weighing approximately 200g were given single intravenous injection with streptozotocin to induce diabetes (DM). Control rats (CON, n=12) were injected with citrate buffer alone. Diabetes was diagnosed on the basis of blood glucose concentrations (≥ 250 mg/dL on two consecutive days). Rats from groups DM+INS received daily insulin treatment. Thirty days after diabetes induction (or buffer injection), half of the animals were anesthetized and a closed bone fracture was produced in the right mid-femur (CON+FRA, DM+FRA and DM+INS+FRA, n=16/group). Then a surgical procedure with a 1-mm-diameter Kirschner wire was conducted for bone fragments stabilization. The status of the fracture was radiographically confirmed immediately after surgery and then followed-up weekly. On both days 14 and 28 post-surgery, eight rats from each group, respectively, were killed and the femurs harvested in preparation for three-dimensional analysis, where a micro-CT system was used to quantify the BMD and the 3D microarchitecture parameters in the femurs. In the non-fractured bone, two regions of interest were made, one at the femoral distal metaphysis, which mainly contains trabecular bone and, another at the mid-diaphysis, which mainly contains cortical bone. Callus was analyzed by calculating the volume. Uncontrolled glucose (DM rats without treatment) significantly impaired trabecular and cortical micro-architecture and mass and, delayed bone callus formation in type 1 diabetic rats. On the other hand, these deleterious changes were ameliorated by insulin administration. We concluded that uncontrolled diabetes leads to dramatic changes in both trabecular and cortical bone mass and microstructure. Additionally, bone healing was negatively affected by uncontrolled diabetes; with deficit of 80% in callus volume and mineralization. On the other hand, the administration of insulin mitigates the deleterious effects of diabetes not only on the bone tissue (trabecular and cortical), but also on the bone healing process.

Conserved Dynamics in Genes Associated with Human BMD and Bone Disorders During Zebrafish and Rat Bone Formation. Leah Worton¹, Arden Chew¹, Claire Watson¹, Edith Gardiner¹, Dobrawa Napierala², Amarjit Virdi³, D. Rick Sumner³, Cole Trapnell¹, Yi-Hsiang Hsu⁴, Ronald Kwon^{*1}. ¹University of Washington, USA, ²University of Alabama at Birmingham, USA, ³Rush University Medical Center, USA, ⁴Harvard Medical School & BROAD Institute of MIT & Harvard, USA

Zebrafish have emerged as a valuable model for human disease modeling due to their genetic tractability, optical properties, and amenability to *in vivo* screening. While zebrafish hold potential to open novel avenues for bone genetic research including rapid gene function mapping, mutant allele testing, and prioritization of candidate GWAS genes, the degree to which zebrafish and mammalian bone physiologies transcriptionally resemble each other is unknown. In this study, our goals were to 1) develop a cross-species framework for comparative analysis of zebrafish and rat gene expression, and 2) identify genes whose temporal dynamics are conserved during osteogenesis in both systems. For this, we used a custom meta-analysis pipeline [1] to analyze two microarray datasets: zebrafish fin regeneration (a model of intramembranous ossification that we have found to exhibit the physiochemical hallmarks of mammalian bone formation, Fig 1A), and rat marrow ablation-induced bone regeneration. To align profiles across species, we developed a three-step strategy in which we ordered the zebrafish and rat datasets within a principal component basis (adapting an approach based on [2]) (Fig 1B), correlated each pair of zebrafish and rat profiles (Fig 1C), and identified the rat ordering subset whose endpoints had the highest correlation with the endpoints of the zebrafish ordering. Using a L2 norm-based distance measure *q* (Fig 1D), we identified orthologs exhibiting similar (and differential) dynamics in zebrafish and rat (Fig 1E). Within this analysis, we isolated a number of genes with low *q* values (i.e., similar in both species) that have previously been implicated in human bone disorders [3] (Fig 1F). Using qPCR we analyzed genes previously identified in BMD GWAS studies, and identified two genes (*trps1* and *wnt16*) significantly elevated during zebrafish fin regeneration (Fig 1G). Similar patterns of expression were found during rat bone regeneration (Fig 1H), validating the predictive potential of this system. Collectively, this study develops a novel framework for cross-species gene expression analysis, identifies clinically-relevant genes conserved during rat and zebrafish bone formation, and advances zebrafish fin regeneration as a functional testbed for skeletal gene analysis.

Cortical bone phenotypes observed in *Mmp8* and *Prokr1* null mice produced by the Knock Out Mouse Project. Douglas Adams¹, Renata Ryzdik¹, Li Chen¹, Zhihua Wu¹, Seung-Hyun Hong¹, Gaven Garland², Pujan Joshi¹, Caibin Zhang¹, John Sundberg², Dong Guk Shin¹, David Rowe¹, Cheryl Ackert-Bicknell³. ¹The University of Connecticut, USA, ²The Jackson Laboratory, USA, ³University of Rochester, USA

The Knockout Mouse Program (KOMP) is part of a larger effort to generate transgenic mice carrying a null mutation for every gene, and many of the targeted genes are uncharacterized. We are examining the bone phenotype of approximately 80 KOMP lines per year. We have implemented a comprehensive, high-throughput, high-resolution phenotyping pipeline based on 3-D X-ray microtomography (μ CT) and dynamic histomorphometry of frozen sections to quantify bone physiology within the peripheral (femur) and axial (lumbar vertebrae) skeleton of knockout mice. All transgenic mice are homozygous global knockouts on a C57BL/6NJ (B6/N) strain background with B6/N mice serving as controls. Groups of 8-10 male and female null and control mice are raised to 12 weeks of age for phenotyping. Some genes, but not all, affect bone in one sex. Herein we present 2 new lines that exhibit a cortical bone phenotype, but do not have an impact on the trabecular compartment. The first of these is matrix metalloproteinase 8 (*Mmp8*), a gene highly expressed by the osteoclast, which has been studied for its role in periodontal disease and osteoarthritis. While *Mmp8* null male mice had a lower body weight than controls, femur length was equivalent ($P = 1.00$). Male mice had a lower cortical bone area fraction (Ct.Ar/Tt.Ar) (null = 37.9 ± 1.4 vs control = $40.6 \pm 1.7\%$, $P=0.007$) and this is driven primarily by a decrease in cortical area (Ct.Ar). No phenotype was observed in females. Mice lacking prokineticin receptor 1 (*Prokr1*) presented with a reduction in cortical bone area fraction in both males (null = 37.3 ± 1.4 vs control = $40.6 \pm 1.7\%$, $P=0.002$) and females (null = 37.6 ± 0.8 vs control = $40.8 \pm 1.4\%$, $P<0.001$), due to a concomitant increase in total area (Tt.Ar) and decrease in Ct.Ar. This gene is expressed in both osteoblasts and osteoclasts, but is otherwise unstudied in the skeleton. In total, approximately 25% of the genes that we have studied have an impact on at least one compartment of bone (trabecular versus cortical). These 2 strains represent two manners in which cortical bone mass can be impacted, emphasizing the benefit of careful and comprehensive phenotyping to determine the role of genes in bone. A greater understanding of all genes that impact skeletal disease, and the degree and manner in which they do so, is a current gap in knowledge that our project seeks to fill. Additional findings from this study can be found at bonebase.org.

Exercise Capacity of Mice with Genetically Induced Hypophosphatemia. Daniel Caballero¹, Dominik Pesta², John Sterpka¹, Ali Nasiri¹, Michael Jurczak¹, Gerald Shulman³, Clemens Bergwitz¹. ¹Yale School of Medicine, USA, ²University of Innsbruck, Austria, ³Yale School of Medicine/HHMI, USA

Mutations in the sodium phosphate co-transporters, NPT2a and NPT2c, have been reported in kindreds with hypophosphatemic rickets. In addition to a mineralization defect of their bone matrix, growth plate abnormalities and renal calcifications due to high circulating levels of 1,25(OH)₂D and hypercalciuria, hypophosphatemia causes muscle weakness in these individuals. In this study we examined the potential role of blood phosphate on muscle function in *Npt2a* knockout mice. These mice become hypophosphatemic on a diet containing 0.02% phosphate (LP-diet) because they are unable to conserve phosphate in their kidneys. Normophosphatemia is restored when these mice are fed a diet containing 1.2% phosphate (HP-diet). Spontaneous activity monitored in metabolic cages over 72 hrs. of mice maintained on LP-diet for 8 weeks was reduced, when compared to mice maintained on HP-diet. Likewise, forced exercise capacity in a metabolic treadmill assembly was reduced in these mice, when compared to HP-diet. However, HP-diet was unable to restore critical speed and anaerobic exercise capacity to values previously reported for wild-type C57Bl6 mice. Oxygen consumption and carbon dioxide production was reduced in *Npt2a* knockout mice on LP-diet when compared to HP-diet during spontaneous and forced exercise, albeit not significantly. These *in vivo* findings parallel our observation *in vitro* that the oxygen consumption rate (OCR) is stimulated by phosphate in cultured 3T3 fibroblast cells using a Seahorse XFe24 analyzer and previous observations by us indicating that myocyte and isolated mitochondrial ATP-flux is dependent on cellular and mitochondrial phosphate uptake (Pesta et al. in preparation). In conclusion, exercise capacity of hypophosphatemic mice is decreased, which may be due to decreased mitochondrial respiration.

Identification of sub-populations within Diversity Outbred mice representing differing states of bone turnover. Cheryl Ackert-Bicknell¹, Douglas Adams², Seung-Hyun Hong³, Renata Ryzdik³, Li Chen², Zhihua Wu², Laura Mello⁴, Caibin Zhang², Shin Dong Guk², David Rowe². ¹University of Rochester, USA, ²The University of Connecticut, USA, ³University of Connecticut, USA, ⁴The Jackson Laboratory, USA

The majority of genetic studies for bone have focused on bone mineral density (BMD). At its simplest, BMD is the sum of formation and resorption, yet even limited to these two processes, there are multiple ways that high bone mass can be achieved. The complex nature of BMD has impeded the transition from identification of a genetic locus to an understanding of the biological implications of a locus. To explore the genetic regulation of bone turnover, we are using the Diversity Outbred (DO) population of mice. The DO was generated by interbreeding 8 strains of inbred mice, such that each DO mouse is genetically unique from all other DO mice. We phenotyped femurs from 65 male and 54 female 6 month old DO mice. After splitting the population by gender, we conducted bottom-up Unweighted Pair Group Method with Arithmetic Mean (UPGMA) hierarchical clustering. After iterative modeling multiple combinations of formation and resorption phenotypes, the combination of trabecular bone mass (BV/TV), mineralizing surface (MS/BS) and TRAP over bone surface (TRAP/BS) yielded the most robust clustering. This allowed us to identify 4 male and 4 female sub-populations within this DO cohort, with each subpopulation containing 7 or more mice. For the males, 2 clusters with low BV/TV were identified (cluster1 mean = 11.8 ± 4.4 and cluster 2 mean = $11.9 \pm 7.0\%$, male mean = $16.4 \pm 8.9\%$), but these clusters did not differ for BV/TV ($P = 1.00$). However, these clusters did differ for MS/BS (cluster1 = 15.3 ± 5.3 vs cluster 2 = $24.4 \pm 4.5\%$, $P<0.0001$, male mean = $20.4 \pm 7.6\%$) and TRAP/BS (cluster1 = 8.7 ± 4.4 vs cluster2 = $17.7 \pm 5.5\%$, $P=0.0002$, male mean = $18.0 \pm 10.3\%$). Similarly, 2 of the clusters for females had low BV/TV (6.2 ± 4.4 , $8.5 \pm 3.7\%$, population mean BV/TV = $9.4 \pm 7.4\%$) and were not different from each other ($P=0.91$). The 1st cluster presented with high TRAP/BS ($27.2 \pm 3.3\%$ vs female mean = $21.6 \pm 6.8\%$) and normal MS/BS ($23.0 \pm 3.9\%$ vs female mean = $23.0 \pm 9.3\%$). In contrast, the 2nd presented with low TRAP/BS ($18.4 \pm 3.9\%$ vs female mean = $21.6 \pm 6.8\%$) and high MS/BS ($30.3 \pm 1.8\%$ vs female mean = $23.0 \pm 9.3\%$). These sub-populations appear to represent different states of bone turnover. These data highlight that within a population, individuals presenting with similar bone mass may have differing statuses of formation or resorption. Moving forward, we will use clustering to map genes for states of bone turnover to improve identification of important genes controlling bone physiology.

Mouse with substitution of type I collagen 3-hydroxylation site has altered ECM but does not recapitulate the bone dysplasia of types VII/VIII Osteogenesis Imperfecta. Wayne Cabral¹, Nadja Fratzi-Zelman², Joseph Perosky³, Adrienne Alimasa³, Rachel Harris³, Peter Backlund⁴, Paul Roschger², Klaus Klaushofer², Antonella Forlino⁵, Kenneth Kozloff³, Joan Marini¹. ¹Bone & Extracellular Matrix Branch, NICHD, NIH, USA, ²Ludwig Boltzmann Institute of Osteology at Hanusch Hospital of WGKK & AUVA Trauma Centre Meidling, 1st Med. Dept. Hanusch Hospital, Austria, ³Orthopaedic Research Laboratories, Department of Orthopaedic Surgery, University of Michigan, USA, ⁴Biomedical Mass Spectrometry Facility, NICHD, NIH, USA, ⁵Department of Molecular Medicine, Biochemistry Unit, University of Pavia, Italy

Recessive types VII and VIII osteogenesis imperfecta (OI) are severe bone dysplasias caused by null mutations in the genes that encode prolyl 3-hydroxylase 1 (P3H1) or cartilage-associated protein (CRTAP), two mutually supportive components of the prolyl 3-hydroxylase (P3H) complex expressed in bone and cartilage. Individuals with types VII or VIII OI lack both the P3H complex components and post-translational hydroxylation of its collagen substrate at residue a1(I)P986. This primary modification defect leads to increased post-translational lysine hydroxylation of the type I collagen helix, consistent with delayed folding and loss of complex chaperone function. Several potential functions of the substrate modification have been proposed, including modulating collagen helical stability, fine-tuning the alignment of collagen monomers within fibrils, and regulating bone matrix mineralization. We therefore sought to clarify the role of the P986 substrate modification in bone dysplasia and collagen overmodification by generating a knock-in mouse model with an a1(I)P986A substitution that cannot be 3-hydroxylated. Exclusive expression of a1(I)A986 collagen in murine-derived tissues and cellular transcripts and protein was confirmed by cDNA sequencing and mass spectrometry. Neither heterozygous (986P/A) nor homozygous (986A/A) mice recapitulate critical features of types VII and VIII OI. Mutant mice exhibited normal growth rates, femoral mechanical properties (stiffness, ultimate load, brittleness) and collagen folding kinetics. However, the P986A substitution affected collagen biochemistry, matrix organization and mineralization. Despite normal P3H complex levels in cell lysates, 986P/A and 986A/A osteoblast type I collagen was moderately overmodified on PAGE analysis. Dermal fibrils of 986A/A displayed decreased diameters and heterogeneity. Skeletal staining and radiographs revealed flared rib cages, delayed

calvarial mineralization and kyphosis by 2 months in 986A/A pups. Interestingly, although femoral aBMD and TMD was reduced in 986A/A versus WT femora, bone matrix mineral density distribution assessed by qBEI was normal. Together, these data suggest that 3-hydroxylation of a1(I)P986 is important for regulating type I collagen modification, crosslinking and mineral organization in bone, but does not cause the severe bone pathology of collagen 3-hydroxylation defects, which likely result from absence of the ER complex and cartilage a1(II)P986 3-hydroxylation.

Positive Effects of Pamidronate on Bone and Muscle in a Mouse Model of Duchenne Muscular Dystrophy. Sung-Hee Yoon^{*1}, Kim Sugamori¹, Marc Grynblas², Jane Mitchell¹. ¹University of Toronto, Canada, ²Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Canada

Patients with Duchenne muscular dystrophy (DMD) often present with decreased bone mineral density and are at increased risk of peripheral fractures while ambulatory. Bisphosphonates have been used to treat bone pain and recurrent fractures in patients with DMD with positive outcomes. In this study we used a well characterized mouse model of DMD, the Mdx mouse, to assess the effects of early and brief treatment with the bisphosphonate pamidronate during a period of rapid bone growth from 5 to 13 weeks of age.

Mdx mice were injected subcutaneously with pamidronate at a dose of 2mg/kg body weight twice per week at 5 and 6 weeks of age to give a total dose of 8mg/kg body weight. Control and pamidronate-treated mice were assessed for muscle strength by weekly grip strength tests from 5-13 weeks. At 13 weeks of age, serum, bone and muscle tissue was assessed. Mice treated with pamidronate had increased cortical bone volume, architecture and strength with increased resistance to fracture in femurs. While overall long bone growth was not affected by pamidronate, there was significant inhibition of remodeling in metaphyseal trabecular bone with evidence of residual calcified cartilage. There were no effects of pamidronate on osteoclast, osteoblast or osteocyte numbers on trabecular bone, however, dynamic histomorphometry showed 80-90% reduction in bone formation. In vitro assessment of bone marrow derived osteoclasts showed 90% reduction in TRAP-stained multinucleated cells suggesting that pamidronate significantly depleted osteoclast precursors from the bone marrow.

Pamidronate treatment had positive effects on skeletal muscle in the Mdx mice with decreased serum creatine kinase, decreased mRNA encoding brain-type creatine kinase in muscle and evidence of improved muscle histology, however, muscle function measured by grip strength was not altered by pamidronate.

These results suggest that early use of bisphosphonates may have positive effects on cortical bone strength and decrease peripheral bone fractures in patients with DMD and has the potential to improve some aspects of dystrophic muscle pathology.

Tissue-Nonspecific Alkaline Phosphatase Enzyme Deficient Mice Reveal Cellular Mechanisms Leading to Craniosynostosis in Murine Hypophosphatasia. Hwa Kyung Nam¹, Jin Liu¹, Cassandra Campbell¹, Manisha Yadav², Jose Luis Millan², Nan Hatch^{*1}. ¹University of Michigan, USA, ²Sanford Burnham Medical Research Institute, USA

Hypophosphatasia (HPP) is a rare metabolic disorder that occurs due to loss-of function mutations in the gene (Alpl) encoding tissue-nonspecific alkaline phosphatase (TNAP). Alpl^{-/-} mice exhibit many characteristics seen in infantile HPP including long bone, tooth and craniofacial skeletal defects. Approximately 40% of infants affected with HPP develop craniosynostosis but it is unknown how premature cranial bone fusion occurs in this rachitic disorder. To investigate the etiology of HPP-associated craniosynostosis, we assessed pathogenic changes that occur prior to the onset of craniosynostosis in Alpl^{-/-} mice +/- daily postnatal subcutaneous injection with mineral-targeted TNAP. Craniosynostosis, cranial bone volume and density, and craniofacial skeletal shape abnormalities were assessed by histology, digital caliper measurements and micro CT. The influence of TNAP deficiency on cranial bone and suture cell proliferation and differentiation was assessed by immunohistochemistry, and in vitro studies of cells isolated from Alpl^{-/-} and Alpl^{+/+} mice. As expected, treatment with mineral-targeted TNAP prevented the cranial bone hypomineralization seen in Alpl^{-/-} mice. TNAP enzyme replacement also prevented a localized and transient cranial bone hypermineralization seen in untreated Alpl^{-/-} mice prior to the onset of craniosynostosis, and prevented craniosynostosis. Further analysis indicated that TNAP deficiency leads to aberrant osteoblastic gene expression and diminished proliferation in cranial bone cells and tissues. Some but not all of these cellular abnormalities were rescued by treatment with inorganic phosphate (Pi). Together, these results confirm an essential role for TNAP in craniofacial skeletal development and demonstrate the efficacy of TNAP enzyme replacement for preventing craniofacial abnormalities leading to craniosynostosis in murine infantile HPP. Future studies are required to determine if mineralization, differentiation and/or proliferation changes caused by TNAP deficiency cause craniosynostosis, and establish the degree to which TNAP influences other forms of craniosynostosis.

Towards the identification of the genetic defect underlying the osteopetrosis (op/op) rat. Eveline Boudin^{*1}, Hanna Witwicka², Geert Vandeweyer¹, Paul Odgren², Wim Van Hul¹. ¹Department of Medical Genetics, University & University Hospital of Antwerp, Belgium, ²Department of Cell Biology, University of Massachusetts Medical School, USA

The osteopetroses are rare genetic disorders characterized by increased bone mass resulting from a defect in bone resorption by osteoclasts. The group of osteopetroses is genetically, radiologically, and clinically very heterogeneous. So far, mutations in several genes have been identified which have increased the understanding of osteoclast differentiation and function. The osteopetrosis (op/op) rat is a severe osteopetrosis mutation spontaneously developed on a LEW/SsN background. The phenotype is inherited in an autosomal recessive manner and affected mutants show generalized sclerosis, fail to develop bone marrow cavities in the long bones, and the bones have a typical club-shaped appearance due to the impaired resorption. The osteoclasts of the op/op rats are larger, reduced in number, and their activity is greatly impaired, although, they still can form the ruffled borders and clear zones essential for the function of osteoclasts. Linkage studies demonstrated that the responsible gene is localized in a 1.36Mb region on chromosome 10. We previously reported the exclusion by Sanger sequencing of mutations in the coding regions of candidate genes such as Cln7 and Atp6v0c, located in the linked region. To identify the disease causing mutation in the op rat, the complete linked region (rn5, chr10: 13365691-14721326) was sequenced using sequencing-by-synthesis technology (HiSeq, Illumina Inc.). Sample preparation and enrichment of the selected region was performed using the KAPA library preparation kit combined with the NimbleGen SeqCap EZ choice technology. Sequence data of the complete region were generated for DNA from an op/op and two wild type (Lewis and BN/SsN background) rats. Next, the raw data were analyzed using the web-based platform Galaxy. Subsequently, all datasets were compared, and variants homozygous in the op/op rat sample and absent from the wild type samples and from the dbSNP database were selected and annotated using snpEFF. Using this strategy, we identified 77 unknown homozygous variants in the op/op rat sample. None of the variants are located in exonic regions. The majority of the variants, 28, are located in gene introns, while 21 and 9 variants are located respectively upstream or downstream of a gene, and the remaining 19 variants are located in between two genes. The conservation of the identified variants and the effect of the variants on splicing will be investigated in order to identify the disease causing variant.

V-ATPase $\alpha 3$ R740S Mutation Affects Enamel Development in Osteopetrotic Mice. Lisa Johnson^{*1}, Bernhard Ganss¹, Celeste Owen², Grace Bradley¹, Irina Voronov¹. ¹University of Toronto, Canada, ²The Toronto Centre for Phenogenomics, Canada

Osteopetrosis is a disease characterized by sclerotic bone due to deficient osteoclast function. Over 50% of the cases of autosomal recessive osteopetrosis are associated with mutations in the vacuolar H⁺-ATPase (V-ATPase) $\alpha 3$ subunit. This multisubunit proton pump is highly enriched in osteoclasts and is responsible for extracellular acidification necessary for proper bone resorption. Patients with osteopetrosis also develop dental anomalies, such as delayed tooth eruption and enamel defects. Bone marrow transplantation at an early age corrects bone and tooth eruption abnormalities, but does not appear to rescue the enamel defects. We hypothesized that $\alpha 3$ -containing V-ATPases are also expressed in ameloblasts and play an important role in enamel formation. To test this hypothesis we investigated enamel mineralization and spatiotemporal expression of enamel matrix proteins using a mouse model with an $\alpha 3$ mutation. This mutation replaces evolutionary conserved arginine responsible for proton translocation with serine (R740S), resulting in a nonfunctional proton pump. Mice with this mutation have mild osteopetrosis in the heterozygous (+/R740S) and severe disease in the homozygous (R740S/R740S) animals. Histological and μ CT data showed that R740S/R740S mice displayed aberrations in both crown and root development, likely due to bony constraints created by the overabundant sclerotic mandibular bone. Enamel thickness and mineralization were significantly decreased in R740S/R740S mice compared to +/R740S and wild type (+/+) animals as measured by μ CT. Delayed enamel mineralization in R740S/R740S was confirmed by scanning electron microscopy. Immunohistochemistry showed that the expression pattern of secretory stage protein amelogenin was comparable in all three genotypes at postnatal day 5, but displayed heavier cytoplasmic staining in R740S/R740S ameloblasts at a later (day 9) time point, suggesting delayed transition to the maturation stage. The expression of maturation stage proteins amelotin and odontogenic ameloblast-associated protein (ODAM) had lighter and more diffuse staining patterns in R740S/R740S ameloblasts compared to other genotypes, confirming delayed transition to the maturation stage. $\alpha 3$ protein was expressed at low levels in the ameloblasts, with higher expression during the secretory stage. Our results suggest that $\alpha 3$ -containing V-ATPases may play a role in enamel protein secretion, contributing to enamel defects observed in R740S/R740S mice.

Generation of human bone from a subject with osteogenesis imperfecta (OI) using iPSC-induced MSCs. Xiaonan Xin^{*1}, Xi Jiang¹, Liping Wang¹, Li Chen¹, Kyle Shin¹, Mark Kronenberg¹, Nathaniel Dyment¹, Jianping Huang¹, Benjamin Lerner¹, Keiichi Fukuda², Noemi Fusaki², Akihiro Iida², Mamoru Hasegawa², David Rowe¹, Alexander Lichtler¹. ¹University of Connecticut Health Center, USA, ²DNAVEC Corporation, Japan

Previously we reported our EB-EGM protocol for differentiation of hESC or iPSC into MSC-like cells, which form human cartilage and bone in a murine in vivo calvarial defect model. Histological analysis suggested that the implanted cells undergo endochondral-like bone formation, which was further confirmed by RT-PCR demonstrating expression of lineage specific human genes. Here we present the generation of human OI-iPSC and transplantation of the OI-iPSC derived MSC into a calvarial defect of the NSG/Col3.6GFP mouse. The OI iPSC were derived from the subject's fibroblasts harboring a COL1A1 Gly313Ala mutation utilizing Sendai viral vectors. This transplantation protocol resulted in better in vivo skeletogenic potential than iPSC produced with Yamanaka retroviral vectors. The transplanted mice were injected with calcein and tetracycline at 7 and 1 day prior to sacrifice, and the tissue within the defect was harvested at 12 weeks. The tissue formed by OI iPSC derived MSCs showed distinctly different morphology compared with tissue formed by control iPSC. In the control, the majority of the tissue was composed of chondrocytes, and bone was formed around invading blood vessels. In contrast, OI cells only formed bone near the edges of the defects. The bone tissue produced an actively mineralizing matrix that was forming in an appositional manner but without osteoclastic remodeling. It contained a marrow cavity and was separated from the rest of the implants by fibrous tissue. Human specific BSP antibody staining demonstrated accumulation of human bone matrix. Cells resembling hypertrophic cartilage cells were also seen, suggesting that the implanted OI iPSC derived MSCs underwent endochondral bone formation. However, the center of the defects showed no evidence of bone formation; instead, the majority of cells, which were human nuclear antigen positive, contained large vacuoles, with some having a signet ring appearance resembling adipocytes. Further analysis of specific markers will be done to determine whether these cells are adipocytes. The fact that human bone was only found next to the mouse bone at the edges of the defects suggests that the mouse bone may be facilitating production of bone by the human cells. We plan to use laser capture microscopy (LCM) to better understand the tissues formed by the OI iPSC cells and to probe the molecular consequences of the OI mutation on osteogenic differentiation and matrix production.

Serotonin Measured in Platelet Poor Plasma is Normal in OPPG Patients. Myrto Eliades¹, Sara Schwab^{*2}, Christine Simpson³, Karl Insogna³, Mary Pavlovich², Elizabeth Streeten². ¹University of Maryland School of Medicine, Us, ²University of Maryland School of Medicine, USA, ³Yale School of Medicine, USA

Purpose: Osteoporosis-pseudoglioma (OPPG) is a rare autosomal recessive disorder of childhood-onset osteoporosis and congenital blindness due to inactivating mutations of *LRP5*. Conflicting data in mice have been reported on the involvement of duodenal serotonin in the pathogenesis of OPPG. We previously found that serum serotonin was elevated in OPPG. However, platelet leakage of serotonin can cause spuriously high serum serotonin. The aim of this study was to measure serotonin in platelet poor plasma (PPP) and platelet pellet (PP) in OPPG patients compared to unaffected controls.

Methods: Eleven patients with OPPG (aged 15.0 ± 7.0 yrs) and known *LRP5* mutations and 16 unaffected first degree relatives (aged 25.5 ± 17.1 yrs) were recruited from our Old Order Mennonite kindred. This kindred consists of 3 nuclear families, all sharing common ancestors. Fasting blood was collected in tubes containing EDTA and ascorbic acid (5mg), immediately placed on ice and processed within 3 hours. An ELISA and ultrasensitive ELISA were used to measure PP and PPP serotonin respectively. Samples were blinded before being sent for analysis to the Yale Mineral Metabolism laboratory.

Results: The mean PPP serotonin level in subjects with OPPG was not different from that in controls (13.00 ± 6.93 vs. 10.86 ± 6.97 ng/mL; affected vs. control; $p=0.31$). There was no effect of age on PPP serotonin. The mean PP serotonin level was higher in OPPG (543.28 ± 174.67 vs. 403.25 ± 163.65 ng/mL; affected versus control; $p=0.04$). Since PP serotonin tended to decline with age the analysis was repeated using only closely age-matched affected and control subjects (11 affected vs. 9 controls; mean age 15 vs. 12 yrs respectively). In this analysis mean PPP serotonin levels remained the same in the two groups (13.00 ± 6.93 vs. 10.16 ± 6.78 ng/mL; affected vs. control; $p=0.22$), but mean PP serotonin levels were no longer significantly different (543.28 ± 174.67 ng/mL vs. 450.39 ± 155.27 ng/ml; affected vs. control; $p=0.40$).

Conclusions: Contrary to our previous results measuring serum serotonin, we found no significant differences in PPP and PP serotonin levels between 11 individuals with OPPG and 16 unaffected controls. Our results do not support the notion that circulating serotonin levels mediate the low bone mass resulting from loss-of-function mutations in *LRP5* in humans.

Characterization of Bone Phenotypes in Sickle Cell Trait and Sickle Cell Disease Mice. Liping Xiao^{*1}, Biree Andemariam¹, Pam Taxel¹, William T Zempsky², Douglas J Adams¹, Marja Marie Hurley¹. ¹University of Connecticut Health Center, USA, ²Connecticut Children's Medical Center, USA

The molecular mechanisms of bone loss in Sickle cell disease (SCD) have not been fully investigated. Sickle cell trait (SCT) is clinically silent; however, its effect on BMD or fracture risk is unknown. DXA of BMD and BMC was performed on 6 month-old female Control, SCT, and SCD mice. Micro-CT of vertebrae and femurs, and femur mechanical integrity testing (3-point flexure) was performed. Body weight was significantly decreased in SCT and SCD. Total body BMD was significantly decreased by 12% in SCD, and BMC significantly decreased by 20% and 19% in SCT and SCD, respectively. Tibial BMD was significantly decreased by 11% in SCD, and BMC significantly decreased by 12% and 11% in SCT and SCD, respectively. There was a 7% and 17% significant decrease in BMD and 10% and 19% decrease in excised femur BMC in SCT and SCD, respectively. Vertebral BMC of SCT and SCD were significantly decreased by 6 and 13%, respectively. Micro-CT revealed no differences in SCD or SCT femur trabecular bone: however, mid-diaphyseal cortical mass (Table 1) was significantly reduced in SCT and SCD. Cortical thickness was significantly decreased in SCD versus Control. Diaphysis structural stiffness and strength was significantly reduced in SCT and SCD (Table 2). Trabecular and cortical matrix mineralization density of SCD was reduced by 3.5% relative to Control and SCT mice. Histomorphometry (Table 3) of cortical femur showed a significant increase in N.Oc/B.Pm in SCD versus Control. Ir.L.Th, MAR, BFR/BS were significantly decreased in SCD compared with Control and SCT. BFR/BS was lower in SCT compared to Control. Trabecular analysis showed increased OC.S/BS but decreased Ir.L.Th, MAR, BFR/BS in SCD compared with Control.

Quantitative PCR of femur mRNA (Table 4) revealed decreased Runx2, osteocalcin and Dmp1 in SCD vs. Control and SCT. Trap was decreased in SCT vs. Control, and further decreased in SCD. Serum calcium, phosphorus, PTH, 25(OH)VitaminD, CTX-1 were normal. However serum osteocalcin and IGF-1 were decreased in SCD mice compared with Control and SCT. In addition IGF-1 was decreased in SCT mice compared with Control (Table 5).

We conclude that reduced bone mass in SCD and SCT mice carries architectural consequences that are detrimental to the mechanical integrity of femoral diaphysis, and may include deficits in cortical matrix integrity and/or mineral content. Furthermore reduced osteoblast terminal differentiation could contribute to reduced bone formation in SCD mice.

Reduction of p27 expression correlates with somatic *MEN1* gene mutations in sporadic parathyroid adenomas. Filomena Cetani¹, Simona Borsari², Elena Pardi², Federica Saponaro², Liborio Torregrossa³, Fulvio Basolo³, Paolo Miccoli³, Claudio Marcocci². ¹University Hospital of Pisa Endocrine Unit 2, Italy, ²Department of Clinical & Experimental Medicine University of Pisa, Italy, ³Department of Surgical, Medical & Molecular Pathology & Critical Area University of Pisa, Italy

MEN1 is the main gene responsible for tumorigenesis of syndromic and sporadic primary hyperparathyroidism (PHPT). Up to date somatic mutations of the *MEN1* gene (20-35%) represent the main molecular defects of sporadic PHPT. Germline mutations of the Cyclin-Dependent Kinase Inhibitor 1B (*CDKN1B*) gene encoding p27 have been associated with multiple endocrine tumors in rats and humans. Menin, as a component of a Histone Methyltransferase Complex, directly regulates the expression of the *CDKN1B* binding to transcriptional regulatory elements of its promoter. P27 is mainly localized in the nucleus in quiescent cells, where negatively regulates the progression of G1 to S phase of the cell cycle, whereas in proliferating cells a fraction translocate to the cytoplasm where it can be degraded by proteolysis. Loss or reduced nuclear expression of p27 have been frequently detected in various

human malignancies, while *CDKN1B* somatic mutations are rarely involved in tumorigenesis.

We evaluated the expression of p27 protein in a group of 50 sporadic parathyroid adenomas *CDKN1B* mutation-negative and its statistic correlation with *MEN1* gene mutations.

Immunohistochemistry was performed using the Ventana Benchmark immunostaining system. A monoclonal anti-p27 antibody was used to detect p27 expression. Nuclear and cytoplasmic p27 expression was scored as "negative" in case of no staining in any cell, or ≤20-10%, respectively, of positive cells. In addition, *MEN1* gene alterations were studied by automatic sequencing the tumor DNA and performing Loss of Heterozygosity (LOH) analysis at *MEN1* locus. Fifty-four percent (27/50) of the sporadic adenomas had negative p27 nuclear staining. Positive cytoplasmic staining was detected in 12 adenomas (24%). Somatic *MEN1* mutations (associated with LOH in all, but one sample) were identified in 15 of 50 (30%) samples. Twelve of 15 *MEN1* mutation-positive adenomas (80%) had a negative nuclear p27 staining. Moreover, we observed that no *MEN1* mutation was detected in samples with positive p27 cytoplasmic staining.

The occurrence of *MEN1* gene mutations in our cohort is in agreement with the percentage previously reported in the literature in sporadic parathyroid adenomas. Herein we found that *MEN1* mutations significantly segregated in tumors negative for p27 nuclear and cytoplasmic staining, suggesting that menin inactivation may be directly related to the downregulation of p27 expression through the inhibition of *CDKN1B* transcription rates.

Anti-inflammatory role of Vitamin D in IL-1β-mediated inflammatory chemokine, IL-8 synthesis in Osteoarthritis. Aparna Maiti¹, William A Jiranek². ¹Virginia Commonwealth University, USA, ²Virginia Commonwealth University School Medicine, USA

Osteoarthritis (OA), is one of the most common form of arthritis, and the leading cause of chronic disability in the United States. The common risk factors for OA include obesity, previous joint injury, genetics, epigenetics and anatomical factors. Additional factors include gender, race, and nutritional factors, such as vitamin D deficiency. There are various pro-inflammatory mediators found to be increased in OA patients, including interleukin-1β (IL-1β), interleukin-6 (IL-6), interleukin-8 (IL-8), and tumor necrosis factor-α (TNF-α). IL-1β production is markedly increased, and has the capability to induce several pro-inflammatory mediators including IL-8, TNF-α, angiogenic factors, and proteolytic enzymes involved in the recruitment of local hematopoietic cells during OA. These catabolic effects of IL-1β are exerted through the activation of several signaling pathways including the activation of master transcription factor NF-κB, which regulates several genes including IL-8, and TNF-α. Vitamin D has many immunomodulatory actions and deficiency is linked to the development of arthritis although the mechanism is unclear. Severe vitamin D deficiency is also associated with methylation changes in immune cells DNA. We observed that high level of IL-8 induction in low serum vitamin D human synovial tissue samples which suggests that serum vitamin D deficiency may enhance the development of OA. However, whether Histone methylation (H3K9me3), a repressor histone mark of transcription, is also involved in vitamin D-mediated IL-1β activated IL-8 mRNA synthesis regulation remains mostly unknown in OA. In our study, we explored the molecular basis of IL-1β mediated IL-8 regulation and anti-inflammatory role of vitamin D associated with OA progression in humans. Adult human mesenchymal stem cells (hMSCs) have the ability to differentiate into different bone cells lineage. We used hMSCs as our cell model to explore our hypothesis. We found that IL-1β treatment to hMSCs or IL-1β treated human monocytes (U937) conditioned medium enhanced NFκB activation and its several target genes including IL-8, and TNF-α mRNA synthesis in hMSCs. Furthermore, vitamin D pre-treatment with hMSCs inhibits IL-1β-mediated NFκB activation and IL-8 mRNA synthesis. Interestingly, vitamin D pre-treatment followed by IL-1β treatment in hMSCs, dramatically enhanced nuclear bulk histone H3 methylation (H3K9me3), a repressor mark of transcription. Our data suggested that vitamin D is playing an important anti-inflammatory role via inhibition of NFκB and enhancing promoter histone H3 methylation (H3K9me3) for transcription repression of inflammatory mediators such as IL-8 in OA.

Fibroblast growth factor 23 (FGF23) increases cardiac contractility and induces cardiac mechanical alternans which are eliminated by FGFR4 antibody treatment. Matthew Hendrix¹, Chelsea Shapland¹, Chad Touchberry², Alexander Grabner³, Christian Faul³, Michael Wacker¹. ¹University of Missouri-Kansas City School of Medicine, USA, ²University of Memphis, USA, ³University of Miami School of Medicine, USA

FGF23 is released by osteocytes and is an important hormone in bone-kidney crosstalk in the regulation of phosphate. During chronic kidney disease (CKD), as kidney function declines, plasma levels of FGF23 increase significantly in order to maintain phosphate homeostasis. This increase in FGF23 has been correlated with

cardiac pathologies. Recently, we have shown that acute FGF23 increases intracellular calcium in isolated adult primary cardiomyocytes as well as increases cardiac contractility in left ventricular cardiac muscle strips. While FGFR1-4 are expressed in the heart, it is currently unknown which receptor mediates the acute effects of FGF23 on cardiac muscle contractility. Therefore, in this study we utilized adult male CD1 mouse hearts and dissected out left ventricular muscle strips to test the effects of FGF23 on contractility in the presence of an isoform specific FGFR4 blocking antibody (U3 Pharma/Daiichi-Sankyo). In addition, to determine if our results translated to a whole heart preparation, the aortas of isolated hearts were cannulated and we reverse perfused the coronary circulation by a modified Langendorff system. Both muscle strip and whole heart preparations were hung in an oxygenated organ bath containing stimulating electrodes, pacing was set between 1 and 1.5 Hz, and contraction was measured. FGF23 treatment (9000 pg/ml) of paced left ventricular muscle strips increased contractility 1.6 ± 0.1 fold over control contraction ($P < 0.01$; $n = 5$) and pretreatment with anti-FGFR4 eliminated this increase ($P > 0.05$ compared to control; $n = 5$). Interestingly, FGF23 treatment of paced Langendorff perfused hearts caused contraction abnormalities predominantly in the form of mechanical alternans (17 ± 6 alternans/min) followed by transient increases in cardiac contractions (1.4 ± 0.1 fold over control; $P < 0.01$; $n = 4$). Anti-FGFR4 pretreatment of perfused hearts prevented both the FGF23-induction of alternans as well as the change in contraction ($P > 0.05$ compared to control; $n = 4$). These results suggest that FGF23 works via FGFR4 to alter cardiomyocyte calcium levels which affects cardiac contractility and promotes abnormal ventricular rhythms. Previously, it has been shown that pathological hypertrophy induced by chronic FGF23 administration was also mediated by FGFR4 (Faul et al. 2014) and thus the cardiac contractility, calcium homeostasis, and hypertrophy effects may be linked. In conclusion, cardiac FGFR4 is an important target for preventing the cardiac effects of FGF23 on the heart during CKD.

Metabolic Acidosis Stimulates MEPE Expression Regulating Fibroblast Growth Factor 23 in Osteoblasts. Nancy Krieger^{*1}, Min Ho Kim², David Bushinsky². ¹University of Rochester, USA, ²University of Rochester School of Medicine, USA

Serum fibroblast growth factor 23 (FGF23) increases significantly with progressive chronic kidney disease (CKD), leading to reduced renal tubular phosphate (Pi) reabsorption and decreased serum 1,25(OH)₂D₃. Increased FGF23 is associated with increased mortality. FGF23 is synthesized in osteoblasts and osteocytes; however, the primary factors regulating its production are not clear. Patients with CKD have decreased renal net acid excretion leading to metabolic acidosis (MET). During MET, acid is buffered by bone with release of mineral calcium (Ca) and Pi. MET increases intracellular Ca signaling and cyclooxygenase 2 (COX2)-induced prostaglandin production in the osteoblast leading to decreased osteoblastic bone formation and increased osteoclastic bone resorption. We recently found that MET directly stimulates FGF23 in mouse bone and primary osteoblastic cells utilizing the same signaling pathways. To further characterize the regulation of FGF23 by MET we have studied gene expression pathways upstream of FGF23 production in primary cells isolated from neonatal mouse calvariae. Confluent osteoblastic cells were incubated in neutral (NTL, pH=7.44, Pco₂=38 mmHg, [HCO₃]=27 mM) or acid (MET, pH=7.18, Pco₂=37 mmHg, [HCO₃]=13 mM) medium. The major extracellular phosphoglycoprotein, MEPE, has been shown to stimulate FGF23. We observed a significant stimulation of MEPE RNA expression as early as 3h after changing to MET medium compared to NTL (relative expression = 1.47 ± 0.30 , MET vs 0.76 ± 0.12 , NTL, $p < 0.05$). Significant stimulation increased further at 6 and 24h. This early increase in MEPE precedes any significant stimulation of FGF23 RNA expression by MET in the osteoblast which first becomes significant by 6h. No significant changes in PHEX expression were observed in response to MET compared to NTL. Thus, the stimulation of MEPE by MET appears to be an initial step in the regulation of FGF23 by MET in mouse osteoblasts. By better understanding the MET regulation of FGF23 in bone, therapeutic interventions directed toward correction of MET, especially in CKD patients, can be devised and have the potential to not only prevent bone resorption but also lower FGF23 and perhaps decrease mortality.

Ablation of maternal Gnas exon Nesp (Nesp^{m-/p+}) in mice dramatically reduces Gsa expression in brown adipose tissue. Olta Tafaj^{*1}, Harald Juppner². ¹Massachusetts General Hospital, Harvard Medical Sc¹, USA, ²MGH, USA

The *Gnas* locus gives rise to *Gsz* and several splice variants, including 1A, Xlas, Nespas and Nesp. The promoters for 1A, XI, and Nespas are methylated on the maternal allele and transcripts are thus derived exclusively from the paternal allele; the converse is observed for Nesp. The promoter for *Gsz* does not undergo parent-specific methylation. However, in some tissues, like proximal renal tubules (PRT), *Gsz* is derived mainly from the maternal allele, while expression from the paternal allele is silenced through unknown mechanisms. PTH-responsive PRT cells are difficult to isolate, thus precluding their use for mechanistic studies. Brown adipose tissue (BAT), which also shows predominantly maternal *Gsz* expression, can be readily

isolated from mice of different ages. Using RT-qPCR, *Gsz* expression in WT-BAT was maximal at E17.5 and then declined after birth. XI, 1A, and Nesp transcript levels were maximal at E16.5 and showed a pronounced decline by P20. To distinguish between maternal and paternal RT-PCR products, we took advantage of a SNP in exon 11 (G in Sv129; C in BL6). Matings between WT-Sv129 females and WT-BL6 males resulted in offspring that are heterozygous for the SNP thus allowing assessment of the parental contribution by BanII enzyme digestion of the PCR products. Densitometric gel analysis of RT-PCR digests revealed that *Gsz* in BAT is predominantly transcribed from the maternal allele at all developmental time points (E16.5 to P60). To investigate the genomic elements that potentially contribute to *Gsz* allelic silencing, BAT from mice with maternal ablation of *Gnas* exons Nesp/Nespas2-4 (Nesp^{m-/p+}) and XI (XI^{p-/m+}) were studied. At E18.5, BAT from Nesp^{m-/p+} mice, which show decreased methylation at *Gnas* exons 1A, XI, and Nespas, revealed a >3-fold decrease in overall *Gsz* transcript levels. This decrease in *Gsz* expression occurred primarily because of reduced transcription from the maternal allele; surprisingly, however, transcripts appeared to be derived from both parental alleles. Conversely, BAT from mice with ablation of the paternal exon XI (XI^{m+/p-}) revealed on day P2 an $\approx 30\%$ increase in *Gsz* mRNA level that could be attributed to enhanced paternal expression. Taken together, our data indicate that *Gsz* expression in BAT is strongly affected by *Gnas* methylation and that a non-methylated *Gnas* region comprising exon XI and possibly exon 1A may contribute *in cis* to the reduction of paternal *Gsz* expression in BAT and possibly other tissues, such as PRT cells.

Intermittent PTH treatment induces bone anabolism through regulatory T cells. Mingcan Yu^{*1}, Lindsey Walker¹, Jerid Robinson¹, Abdul Malik Tyagi¹, Jau-Yi Li¹, Jonathan Adams¹, Richard DiPaolo², Roberto Pacifici³. ¹Emory University, USA, ²St. Louis University, USA, ³Emory University School of Medicine, USA

Intermittent PTH (iPTH) treatment stimulates bone formation and increases bone mass in mice and humans. iPTH stimulates bone marrow (BM) CD8+ T cells to release Wnt10b, an osteogenic Wnt ligand essential for inducing Wnt signaling in osteoblastic cells and bone formation. In this study we have found that iPTH treatment at 80µg/kg/day for 4 weeks increases the production of Wnt10b by CD8+ T cells by increasing the differentiation of BM naïve CD4+ cells into CD25+Foxp3+ regulatory T cells (Tregs), an effect which results in a >2 fold increase in the number of BM Tregs. iPTH directly targets CD4+ cells and increases their sensitivity to the Treg-inducing factor TGFβ, via a dual effect on notch signaling. iPTH upregulates the Notch ligand Jagged1 in osteoblasts (OBs) and increases the sensitivity of CD4+ cells to Jagged1. The resulting upregulation of Notch-1c leads to recruitment of Smad3 and RBPJ to the Foxp3 promoter to activate Foxp3 transcription. B cells are the most abundant antigen presenting cells in the BM. Tregs down regulate the costimulatory molecules CD80/86 on B cells via their surface receptor CTLA4, thus preventing the activation of CD28 on CD8+ cells. Stimulation of CD8+ cells by iPTH in conditions of blunted CD28 signaling stimulates Wnt10b gene expression. This is because repression of CD28 signaling leads to inhibition of a β-arrestin-phosphodiesterase complex, resulting in up-regulation of cAMP levels in T cells. The Wnt10b promoter contains two essential CREB binding sites and cAMP is a critical inducer of Wnt10b transcription. To demonstrate relevance, Tregs were depleted *in vivo* by either treatment of WT mice with anti CD25 Ab, or by treating DEREK mice with diphtheria toxin (DT). DEREK mice express DT receptor under control of the FoxP3 promoter. Thus, FoxP3+ Tregs are selectively depleted in DEREK mice upon DT administration. In both models *in vivo* depletion of Tregs prevents the capacity of iPTH to expand Tregs, induce Wnt10b production, activate Wnt signaling, stimulate bone formation and increase bone mass. In summary these findings demonstrate a novel effect of PTH on the differentiation of naïve CD4+ cells into Tregs. Expansion of Tregs is a critical, previously unknown mechanism by which iPTH exerts its bone anabolic activity.

PTEN is a novel mediator of the anti-proliferative effects of (1-34) PTH in osteoblastic cells. Andrew Sunters¹, Imelda McGonnell², Robert Fowkes², Gabriel Galea², Lance Lanyon³, Joanna Price^{*4}. ¹Royal Veterinary College, United Kingdom, ²The Royal Veterinary College, United Kingdom, ³Bristol University, United Kingdom, ⁴University of Bristol, United Kingdom

PTH and mechanical loading are both potent osteogenic stimuli, with intermittent PTH being the only drug licensed to treat osteoporosis. In young mice PTH and mechanical loading also act synergistically to increase cortical bone mass. Here we explore the potential mechanisms underlying this interaction, specifically the role of the phosphatidylinositol 3-kinase (PI3K) pathway that is known to be activated by mechanical strain in osteoblasts. Quiescent UMR-106 osteoblastic cells treated with 10-100pM (1-34) PTH displayed a mitogenic response, but no proliferation was

observed with doses exceeding 1nM. Similarly 10-100pM PTH had no effect on exponential proliferation whilst doses exceeding 1nM blocked proliferation. Mechanical strain-induced proliferation following application of 4-point bending to serum depleted UMR106 cells was unaffected by 100pM PTH, but attenuated by 100nM, which also attenuated the expression of the Wnt inhibitor Sost. Western blotting showed that activation of the AKT/GSK-3 beta/beta-catenin axis by strain was unaffected by 100pM, but blocked by 100nM PTH. PTH induced a dose-dependent increase in the expression of the phosphatase MKP-1, maximally increasing between 1 and 100nM, correlating with reduced AKT phosphorylation. AKT phosphorylation increased following treatment with the PKA inhibitor H89, basally or in response to PTH or by PKA activators di-Br ATP or forskolin, suggesting a dependence of MKP-1 induction on protein kinase A. 100nM PTH treatment or ectopic over-expression of MKP-1 correlated with increased expression of the PI3K inhibitor PTEN and subsequent reduction of AKT phosphorylation. 100nM PTH treatment of ROS17/2.8 cells, which lack PTEN, failed to inhibit AKT phosphorylation or proliferation, despite stimulating MKP-1. Transfection of UMR-106 cells with anti-PTEN siRNA attenuated PTH inhibition of AKT phosphorylation and proliferation, highlighting a key role for PTEN in regulating AKT mediated control of proliferation. 100nM PTH inhibited AKT inhibitory phosphorylation of Foxo3a correlating with increased expression of the cell cycle regulator p27, a Foxo3a and PTH target. The observation that PKA-dependent activation of MKP-1 by PTH stimulates PTEN expression, repression of AKT and subsequent Foxo3a mediated transcription of p27 represents a novel mechanism underlying the anti-proliferative effects of PTH, potentially rendering cells insensitive to the proliferative effects of Sost attenuation.

Dietary Fat Independent of Caloric Intake Impairs Cortical Bone Structure via Glucocorticoid Signaling in Osteoblasts and Osteocytes. Sarah Kim^{*1}, Holger Henneicke², Sylvia Gasparini², Markus Seibel³, Hong Zhou². ¹ANZAC Research Institute, Australia, ²Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia, ³Department of Endocrinology & Metabolism, Concord Hospital, The University of Sydney, Australia

High-fat diets adversely affect bone morphology, strength and development while simultaneously increasing systemic glucocorticoid levels. We hypothesized that a mechanistic link exists between high dietary fat content, increased glucocorticoid signaling in osteoblasts and osteocytes and structural bone changes.

We tested this hypothesis in a transgenic (tg) mouse model in which glucocorticoid signaling has been selectively disrupted in osteoblasts and osteocytes via targeted overexpression of the glucocorticoid-inactivating enzyme, 11 β -hydroxysteroid dehydrogenase type 2. Seven-week-old male tg mice and their wild type (WT) littermates (n=12-15/group) were fed *ad libitum* a control diet (13.8kJ/g total energy (TE), 14% TE as fat, 26% TE as protein) or an isocaloric high-fat diet (iHFD; 13.8kJ/g TE, 43% of TE as fat, 26% TE as protein) for 18 weeks. Body weight and food intake were measured weekly and serum corticosterone (CS) levels were quantified after 10 weeks of feeding. At endpoint, body composition was assessed by DXA, and both the tibia and L3-vertebra were analyzed by micro-CT.

As animals were fed an isocaloric diet, changes in body weight, lean mass and fat mass did not differ between groups. Mice fed the iHFD had higher serum CS concentrations than mice on the control diet (iHFD: 365 \pm 24nM CS vs. control: 291 \pm 33nM CS; p=0.07). Serum CS levels in WT and tg mice fed the same diets were similar (control: WT 288 \pm 32nM CS, Tg 295 \pm 56nM CS; iHFD: WT 352 \pm 36nM CS, Tg 378 \pm 33nM). Isocaloric high-fat feeding resulted in significant loss of tibial cortical volume (WT: -14% vs. tg: -1%, p<0.01), cortical thickness (WT: -15% vs. tg: -1%, p<0.05) and area (WT: -14% vs. tg: -1%, p<0.01) in WT but not tg mice when compared to their respective controls. Similarly, WT iHFD mice exhibited loss of tibial trabecular bone mass when compared to WT controls (BV/TV: -23%, p=0.07). This difference was due to a decrease in trabecular number and a corresponding increase in trabecular separation, while trabecular thickness remained unaffected. In iHFD tg mice, tibial trabecular bone was not significantly affected compared to control fed tg mice (BV/TV: -15%, p=0.54). Trabecular bone in the vertebra was unaffected in both WT and tg iHFD mice.

We conclude that high dietary fat intake, independent of overall caloric intake and obesity induces severe loss of cortical bone via glucocorticoid signaling in osteoblasts and osteocytes.

SU0123

Estrogens protect against endocortical bone resorption in both female and male mice; likely via ER α -mediated suppression of SDF1/CXCL12 in uncommitted mesenchymal progenitors. Srividhya Iyer^{*1}, Serra Semahat Ucer², Ha-Neui Kim², Li Han², Aaron Warren², Julie Crawford², Maria Almeida², Stavros Manolagas². ¹Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, ²Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA, USA

Estrogens in women and both androgens and estrogens in men contribute to the maintenance of bone mass. Evidence from mice with conditional deletion of the estrogen (ER) or androgen (AR) receptors has revealed that in cortical, but not cancellous, bone ER α signaling in uncommitted mesenchymal progenitors targeted by Prx1-Cre attenuates endocortical resorption in females. The effects of androgens, on the other hand, do not require AR signaling in any cell type of the mesenchymal lineage, nor do they require ER α signaling downstream of committed osteoblast progenitors targeted by Osx1-Cre, or AR or ER α signaling in the osteoclast lineage. We investigated the possibility that ER α signaling in uncommitted mesenchymal progenitors protects against endocortical resorption in both sexes. We report that estrogens (E2), but not androgens (DHT), prevented the ORX-induced loss of cortical bone mass in C57BL/6 mice; DHT, nonetheless, prevented the loss of cancellous bone. We next performed microarray analysis of FACS preparations of GFP:Osx1-Cre targeted ER α null cells and identical cell preparations from mice with intact ER α . The mRNA for stromal cell-derived factor1 (SDF1) a.k.a CXCL12 – a chemotactic cytokine that is abundantly expressed in Prx1-Cre targeted cells and promotes osteoclast generation – was increased by 3.7-fold. Similarly, the mRNA and secreted protein levels of SDF1 were higher (5- and 100- fold, respectively) in bone marrow cell cultures from female ER α ^{fl/fl}:Prx1-Cre mice as compared to identical cultures from littermate controls. More strikingly, both OVX and ORX increased the levels of SDF1 in the bone marrow plasma; and E2 administration to ORX mice prevented it. Bone marrow macrophages co-cultured with ER α ^{fl/fl}:Prx1-Cre bone marrow stromal cells developed twice as many TRAP+ osteoclasts as compared to similar cultures of ER α ^{fl/fl} cells. Finally, the protein levels of SDF1 in the supernatant of bone marrow cell cultures from wild type C57BL/6 mice was decreased in the presence of E2; and the SDF1 mRNA in the same cells was also decreased by E2, but not DHT. These data suggest that estrogens protect against endocortical resorption in both males and females, at least in part, via ER α -mediated actions (upon aromatization of androgens to estrogens in males) on Prx1-Cre targeted uncommitted mesenchymal progenitors. These actions repress SDF1 production, thereby attenuating osteoclast formation (and perhaps homing) at the endosteal surface.

Female Mice are Resilient to Glucocorticoid-Induced Bone Loss. Sylvia Gasparini^{*1}, Holger Henneicke², Sarah Kim², Lee Thai², Hong Zhou², Markus Seibel³. ¹ANZAC Research Institute, Australia, ²Bone Research Program, ANZAC Research Institute, The University of Sydney, Sydney, NSW, Australia, Australia, ³Department of Endocrinology & Metabolism, Concord Hospital, The University of Sydney, Sydney, NSW, Australia, Australia

Glucocorticoid induced osteoporosis (GIO) is the most common form of secondary osteoporosis (1). However, to date, most mechanistic studies of GIO have been performed in male mice. We compared the effect of exogenous glucocorticoid (GC) administration on bone in male and female mice, while concurrently examining the main cellular target of GCs in the skeleton.

We made use of a transgenic (tg) mouse model in which GC signaling has been selectively disrupted in osteoblasts and osteocytes via targeted overexpression of the glucocorticoid-inactivating enzyme, 11 β -hydroxysteroid dehydrogenase type 2. Eight-week-old male (M) and female (F) wild-type (wt) and tg mice received either placebo (plc) or corticosterone (CS) at a dose of 50 μ g/ml or 75 μ g/ml dissolved in the drinking water for 4 weeks. Body weight and water intake were measured weekly, while body composition as well as bone mineral content (BMC) and density (BMD) were assessed by DXA at baseline and endpoint.

Male and female mice consumed the same amount of water irrespective of treatment (~4ml/mouse/day). The physiological increase in BMC (Fig 1.; M-plc-wt +17%, M-plc-tg +24%, F-plc-wt +23%, F-plc-tg +29%) was dose dependently diminished by CS administration in male wt mice while tg mice increased their BMC despite CS exposure, particularly at a lower CS dose (M-50 μ g-wt +5.6% vs. M-50 μ g-tg +14%, p<0.05 & M-75 μ g-wt +0.4% vs. M-75 μ g-tg +8.8%, p<0.05). Surprisingly BMC in female mice was unaffected by CS treatment even at the higher CS dose (F-50 μ g-wt +17.7% vs. F-50 μ g-tg +24.3%, p=ns & F-75 μ g-wt +18.4% vs. F-75 μ g-tg +22.4%, p=ns). Similar observations were made for BMD, where CS treatment adversely affected wt males while wt females remained resilient to CS (M-50 μ g-wt +6.7% vs. F-50 μ g-wt +10.1%, p=0.06 & M-75 μ g-wt +6.1% vs. F-75 μ g-wt +12.7%, p<0.01).

Disruption of glucocorticoid signalling in the osteoblast partially protects male mice from the deleterious effects of GCs on bone. Interestingly, young female mice are less sensitive than their male littermates to the negative impact of high dose exogenous GCs on bone.

The Adipokines and Estradiol in Relation to Bone Mineral Density and Carotid Atherosclerosis in Postmenopausal Women – The OSTPRE-BBA Study. Miika Värri*¹, Leo Niskanen², Tomi-Pekka Tuomainen³, Risto Honkanen⁴, Heikki Kröger⁵, Marjo Tuppurainen⁶. ¹University of Eastern Finland, Finland, ²Endocrinology, Helsinki University Hospital & University of Helsinki, Finland, ³Institute of Public Health & Clinical Nutrition, University of Eastern Finland, Finland, ⁴Kuopio Musculoskeletal Research Unit (KMRU), Surgery, Institute of Clinical Medicine, University of Eastern Finland, Finland, ⁵Department of Orthopaedics, Traumatology & Hand Surgery, Kuopio University Hospital, Finland, ⁶Department of Obstetrics & Gynaecology, Kuopio University Hospital, Finland

Purpose: Carotid artery calcifications (CAC) and high carotid arteries intima-media thickness (cIMT) are by unknown mechanisms associated with low bone mineral density (BMD) in postmenopausal women. The link between atherosclerotic vascular changes and BMD may be via the adipose tissue, which by secreting adiponectin and leptin and modifying estradiol (E2), may influence these processes. Our aim was to study the relationships of aforementioned factors to bone health (BMD) and carotid atherosclerosis measured with CAC and cIMT. **Methods:** This cross sectional OSTPRE-BBA study (Bone, Brain and Atherosclerosis) is a part of the Kuopio Osteoporosis Risk Factor and Prevention Study (OSTPRE), Finland. The 290 women (mean age 73.6 years, range 69.2 – 79.2) were randomly selected from the OSTPRE cohort in 2009. BMD, total body fat mass (FM) were measured with dual energy x-ray absorptiometry (DXA), cIMT (mm) and CAC (no/yes) were measured with B-type ultrasound. Free estradiol, adiponectin and leptin were measured from serum samples. Correlation, analysis of variance, linear and binary logistic regression were used in analyses between BMD, CAC or cIMT as dependent variable and adipokines or E2 as independent variable. The analyses with BMD were adjusted with total body FM, age, current smoking, and with E2 levels, where appropriate. The analyses with CAC were adjusted with total body FM, age and dietary calcium intake. **Results:** Total body FM was associated with leptin ($r=0.795$, $p<0.001$) and adiponectin ($r=-0.305$, $p<0.001$). E2 levels were associated with leptin ($\hat{O}=0.131$, $p<0.001$), but not with adiponectin (adjusted with FM). There were no significant differences between E2 tertiles and total or femoral neck BMD nor with cIMT and CAC. Serum adiponectin levels were inversely associated with femoral neck ($\hat{O}=-0.142$, $p=0.019$), and total body BMD ($\hat{O}=-0.138$, $p=0.009$), but showed no relationships with CAC. Leptin levels were not associated with BMD. The odd's ratio was 1.6 between CAC and leptin quartiles ($p=0.010$). There were no associations between adipokines and cIMT. **Conclusions:** In conclusion, the loss of the bone mineral and vascular calcification are connected by adipokines secreted by adipose tissue in postmenopausal women. Endogenous E2 levels were not independently associated with BMD or vascular calcifications, but cross-sectional analysis may not reveal the role of E2 in these processes.

1,25-Dihydroxyvitamin D Induces Vitamin D Receptor-Dependent Large-Scale Changes in mRNA Expression in Human Skeletal Muscle Cells. Zachary Ryan¹, Theodore Craig¹, Clifford Folmes², Xuwei Wang³, Ian Lanza⁴, Niccole Schaible⁵, Jeffrey Salisbury⁶, K. Sreekumaran Nair⁴, Andre Terzic², Gary Sieck⁷, Rajiv Kumar*¹. ¹Division of Nephrology & Hypertension, Department of Medicine, USA, ²Division of Cardiovascular Diseases, Department of Medicine, USA, ³Division of Biomedical Statistics & Informatics, Department of Health Sciences Research, USA, ⁴Division of Endocrinology, Department of Medicine, USA, ⁵Mayo Clinic, USA, ⁶Department of Biochemistry & Molecular Biology, USA, ⁷Department of Physiology, Biophysics & Biomedical Engineering, USA

Muscle weakness and myopathy are prominent features of vitamin D deficiency and respond rapidly to therapy with vitamin D3. Treatment with 1-hydroxylated vitamin D analogs reduces falls in humans. The goal of this study was to determine whether 1,25-dihydroxyvitamin D3 (1,25(OH)2D3) alters skeletal muscle function in humans through changes in nuclear gene expression.

Gene expression was assessed using next generation, whole transcriptome sequencing (RNA-seq) following treatment of primary cultures of human skeletal muscle cells with 1,25(OH)2D3, 10-8M or vehicle. Primary cultures of human skeletal muscle cells treated with control siRNA or vitamin D receptor (VDR) anti-sense siRNA prior to treatment with 1,25(OH)2D3 were analyzed by RNA-seq. Human skeletal muscle biopsies and skeletal muscle cells were verified to express the VDR. Over one thousand nine hundred genes were differentially expressed following treatment of VDR-expressing skeletal muscle cells with 1,25(OH)2D3. RNAs encoding proteins involved in 1,25(OH)2D3-metabolism (CYP24A1), muscle relaxation (parvalbumin), cytoskeletal dynamics (IGFN, ARHGAP16), RNA and nucleotide binding (TDRD1), cellular energy metabolism (IGFL3), apoptosis (FAM12) and nucleosome function (HIST1H3J) were significantly up-regulated. The most significantly repressed RNAs encoded calpain 11 (calcium-sensitive cysteine protease), WFDC1 (involved in cellular proliferation) and podocan (involved in cell migration). Eighty three mRNAs encoding mitochondrial proteins were significantly altered by 1,25(OH)2D3. Changes in gene expression are dependent upon cellular VDR expression as only 15 genes are altered following treatment of primary cultures of human skeletal muscle cells treated with a control siRNA compared with the 1947 genes altered when the VDR is silenced by an anti-VDR siRNA. These genes are identical to those altered by 1,25(OH)2D3 in cells expressing normal amounts of the VDR but the changes are quantitatively reduced. We also demonstrated that deletion of the VDR in cells resulted in changes in gene expression that were in the opposite direction of those observed following treatment of VDR expressing cells with 1,25(OH)2D3. In skeletal muscle cells,

1,25(OH)2D3 alters the expression of nuclear mRNAs encoding cellular and mitochondrial proteins that influence energy metabolism, cell proliferation, cytoskeletal dynamics and apoptosis.

1,25-Dihydroxyvitamin D₃ Alleviates Inflammatory Bowel Phenotypes in a Genetic Mouse Model with a High Disease Susceptibility. Savantani Goswami*¹, Shiyan Yu¹, Juan Flores¹, Sylvia Christakos², Nan Gao¹. ¹Department of Biological Sciences, Rutgers University, USA, ²Department of Microbiology, Biochemistry & Molecular Genetics, Rutgers University, USA

The anti-inflammatory function of 1,25-dihydroxyvitamin D₃ (1,25(OH)₂D₃) the hormonally active form of vitamin D, is widely recognized in multiple biological systems, with its protective role against experimental colitis having been established previously. The pathogenesis of chronic inflammatory bowel disease (IBD) attributes to genetic as well as environmental factors. Although various susceptibility loci for Crohn's disease and ulcerative colitis have been identified, their contributions to disease mechanisms remain poorly defined. We show for the first time that genetic ablation specifically in mouse intestinal epithelial cells of a recycling endosome small GTPase, Rab11a, a gene adjacent to a Crohn's disease risk locus, results in increased expression of pro-inflammatory cytokines (e.g., IL-6), enhanced IRF5+ M1 macrophage infiltration into the submucosa, increased crypt cell proliferation, early onset enteritis and IBD phenotypes. Rab11a deficiency was found to alter TLR9 sorting and processing resulting in an inflammatory response. In order to determine whether vitamin D supplementation may be beneficial under conditions of genetic predisposition to IBD, we investigated the effect of 1,25(OH)₂D₃ on the IBD phenotypes in Rab11a intestinal epithelial cell specific knockout mice. 1,25(OH)₂D₃ (50 ng per mouse) was administered by intra-peritoneal injection on day 1 and 3 to Rab11a mutant mice expressing IBD phenotypes. The tissues were analyzed on day 6. 1,25(OH)₂D₃ administration to mutant mice resulted in a significant decrease in intestinal IL-6 mRNA (4 fold ; $p < 0.01$ compared to vehicle treated), decreased expression of NF-κB (p65) in intestine, a reduction of M1 macrophage infiltration, and reduced crypt cell proliferation. Rab11a deficient intestines showed blunted and branched villi with pseudo epithelial layer stratification, whereas 1,25(OH)₂D₃ treatment partially restored the morphology towards normal intestinal villus architecture. These data suggest beneficial effects of vitamin D supplementation in

protecting against disease pathogenesis under conditions of genetic predisposition to IBD.

SU0128

1,25-Dihydroxyvitamin D₃ treatment of mice infected with *M. tuberculosis* results in increased pathogen burden. Kamlesh Bhatt*¹, Sylvia Christakos², Padmini Salgame¹. ¹NJMS-Medicine-Infectious Diseases, Rutgers University, USA, ²Department of Microbiology, Biochemistry & Molecular Genetics, NJMS, Rutgers University, USA

In vitro studies have shown that 1,25-dihydroxyvitamin D₃ (1,25(OH)₂D₃), the hormonally active form of vitamin D, restricts intracellular Mycobacterium tuberculosis (Mtb) replication via induction of the anti-microbial peptide, cathelicidin. In addition to the induction of cathelicidin, 1,25(OH)₂D₃ also inhibits the production of inflammatory cytokines including IFN γ and IL-17. During primary tuberculosis both IFN γ and IL-17 are induced and play a role in the protective immune response. Thus vitamin D can be a double edged sword in tuberculosis. Despite significant evidence showing the negative effect of 1,25(OH)₂D₃ on Mtb growth in vitro, the impact of the aggregate effect of 1,25(OH)₂D₃ in vivo on host resistance against Mtb has remained undetermined. We therefore examined the effect of 1,25(OH)₂D₃ on the outcome of Mtb infection in the mouse model. C57BL/6 mice were treated with 1,25(OH)₂D₃ (1 ng/g bw) or vehicle one day prior to aerosol infection with Mtb (Erdman strain in a whole body inhalation exposure system) and then every other day via subcutaneous injection during the course of the study (4–6 weeks; at least 5 mice/time point and two individual experiments). At 6 weeks post infection 1,25(OH)₂D₃ treated animals had significantly increased bacterial burden as determined by plating serial dilutions of lung homogenates for colony forming units (CFUs) (vehicle treated, 5.3 Log₁₀ CFUs/Lung vs. 1,25(OH)₂D₃ treated, 6.1 Log₁₀ CFUs/Lung p < 0.01). The development of inflammatory lesions in the lungs of the vehicle and 1,25(OH)₂D₃ treated mice was compared histologically. At 6 weeks post infection in the mice receiving 1,25(OH)₂D₃ there was a significant decrease in the B cell rich lymphocytic clusters in the lungs (vehicle; 21 ± 1 vs. 1,25(OH)₂D₃ treated; 11 ± 1 μ m²; p < 0.01). 1,25(OH)₂D₃ treated mice also exhibited increased expression of IL-10 in lymph nodes and lungs (IL-10 production has previously been shown to promote bacterial growth during Mtb infection, in part, due to poor T cell responses). Our findings indicate for the first time using an in vivo model that the immune-modulatory functions of 1,25(OH)₂D₃ interfere with the establishment in the lungs of the appropriate cytokine axis necessary for generating optimal granulomatous response and anti-Mtb immunity and caution that 1,25(OH)₂D₃ treatment may have adverse effects on the host adaptive immune response to Mtb.

Assessment of 24,25-dihydroxyvitamin D as a Marker of Vitamin D Status in Children. Selene Bantz*, Christine Simpson, Jane Zhang, Thomas Carpenter. Yale University School of Medicine, USA

Vitamin D is an important nutrient for skeletal and extraskeletal health. Optimal vitamin D status, reflected by circulating 25-hydroxyvitamin D (25D), is controversial. Most agree that 25D < 20 ng/mL identifies a risk for bone and mineral abnormalities; others suggest that 25D < 40 ng/mL warrants supplementation. 25D is widely accepted as the best measure of vitamin D status, but other derived markers have been proposed. 25D is converted to 1,25(OH)₂D (1,25D) or 24,25(OH)₂D (24,25D). As stores decrease, regulatory mechanisms shift to maximize production of 1,25D with less production of 24,25D.

Employing these homeostatic principles, Kaufmann investigated normal, healthy women with 25D levels < 20 ng/mL. After supplementation with increasing doses of vitamin D, curvilinear increases in serum 25D and 24,25D occurred, with both metabolites reaching plateau values at doses of 4000 IU/day. Marked elevations of the 25D:24,25D ratio occurred as 25D decreased to < 25 ng/mL. Large elevations in this ratio were evident with only modest changes in circulating 25D. The study concluded the 25D:24,25D ratio may serve as a more sensitive marker of vitamin D deficiency than PTH or 25D alone.

We hypothesized this relationship may be evident in children and examined circulating 25D and 24,25D in 364 healthy infants and toddlers, aged 6-36 months. Vitamin D intake was quantified using a 24-hr recall methodology. 24,25D correlated strongly with 25D (R = 0.47; p < 0.00001). Both 24,25D and 25D correlated positively with daily vitamin D intake per body weight (R = 0.18, p < 0.003 and R = 0.36, p < 0.00001, respectively) and total daily vitamin D intake (R = 0.222, p < 0.0002 and R = 0.286, p < 0.00001, respectively). Consistent with Kaufmann's observation, the 25D:24,25D ratio was inversely associated with vitamin D intake (R = -0.117, p < 0.044), but the ratio was a weaker indicator of vitamin D intake than either metabolite alone. Moreover, the 25D:24,25D ratio did not correlate with vitamin D intake corrected for body weight (R = 0.045, p < 0.5).

In our study of young children, the 25D:24,25D ratio did not serve as a more sensitive marker of vitamin D insufficiency than 25D, as was demonstrated in an older female population. This may be due to overall looser regulation of the vitamin hydroxylases in children than in adults. More studies are needed to understand the utility of 24,25D as a biomarker in a variety of populations.

Calcitriol Is Not Required During Fetal Development to Regulate Serum Minerals or Skeletal Development, Although It May Act Through Non-Genomic Pathways to Stimulate Placental Calcium Transport. Kamal Alhani*¹, Yue Ma¹, Beth J. Kirby¹, René St-Arnaud², Christopher Kovacs¹. ¹Memorial University of Newfoundland, Canada, ²McGill University, Canada

Study of two vitamin D receptor ablation models found that *Vdr* null fetuses have normal serum minerals, PTH, and skeletal morphology/mineralization. But in both models placental calcium transport and placental expression of the calcitriol-dependent channel TRPV6 were increased. These results, and prior studies in severely vitamin D deficient rats, suggest that calcitriol is not required during fetal development. However, *Vdr* null fetuses have high calcitriol levels which conceivably acted through non-classical receptors to increase placental calcium transport and TRPV6 expression.

We used *Cyp27b1* null mice, which do not make calcitriol, to study the role of calcitriol during fetal development. *Cyp27b1*^{+/−} mice were mated to generate pregnancies with WT, *Cyp27b1*^{+/−}, and *Cyp27b1* null fetuses. Pregnant dams were given an intracardiac injection of ⁴⁵Ca and ⁵¹Cr-EDTA to measure placental calcium transport. Fetal serum and amniotic fluid were collected; intact fetuses were reduced to ash; ash mineral content was assessed by atomic absorption spectroscopy; tibiae, placentas, and fetal kidneys were harvested.

As compared to their WT littermates, *Cyp27b1* null fetuses had normal serum calcium (2.2 ± 0.2 vs. 2.2 ± 0.1 mM) and phosphorus (4.3 ± 0.3 vs. 3.9 ± 0.2 mM), and amniotic fluid calcium (1.8 ± 0.1 vs. 1.7 ± 0.1 mM) and phosphorus (1.5 ± 0.1 vs. 1.7 ± 0.2 mM). They also had normal tibial lengths, morphology, and mineral deposition. Skeletal ash weight, and calcium and phosphorus content of the ash, were normal. Placental calcium transport at 5 min was 0.94 ± 0.04% in *Cyp27b1* nulls vs. 1.00 ± 0.03 in *Cyp27b1*^{+/−} and 1.05 ± 0.09 in WT (p = NS). qPCR showed loss of *Cyp27b1* expression but no change in renal or placental expression of calcium or phosphorus transporting genes, including TRPV6, calbindin-D-9k, Ca²⁺ATPase, and NaPi2a/b/c.

In summary, loss of calcitriol in *Cyp27b1* null fetuses did not significantly alter any measured parameter of mineral or bone homeostasis, confirming earlier evidence from mice and rats that calcitriol/vitamin D is not required during fetal development. However, whereas placental calcium transport and *Trpv6* expression were increased in *Vdr* null fetuses, in *Cyp27b1* nulls placental calcium transport was non-significantly reduced and *Trpv6* expression was unaltered. These findings may indicate that high levels of calcitriol are able to act through non-genomic receptors to upregulate placental calcium transport and *Trpv6* expression in *Vdr* null fetuses.

Expression of Vitamin D Receptor in Seminal Vesicle of Cholesterol Formula Mice. Dong Won Byun*¹, Tae-Hee Kim², Hae-Hyeog Lee². ¹Soon Chun Hyang University Seoul Hospital, South Korea, ²Department of Obstetrics & Gynecology, Soonchunhyang University Hospital, South Korea

Objective

By VDR stimulation, Vitamin D controls calcium homeostasis and bone health and Genomic function of VDR indicates spermatogenesis that is important for in male reproductive organ. Authors evaluated the VDR expression in seminal vesicle with high cholesterol formula diet rat, because there is no report about relationship or difference in VDR in seminal vesicle between high cholesterol and control.

Methods

Male C57BL/6 mice aged 5 weeks were raised for 13 weeks. After one week of adaptation-period, they were fed different diet on normal AIN-93G diet, or high cholesterol diet containing 2% cholesterol for 12 weeks. The antibodies used were rabbit anti-VDR primary polyclonal.

Result

There was no significant difference in VDR reactivity in seminal vesicle, body weight of rat and weight of seminal vesicle between high cholesterol group and normal control group.

Conclusion

Our data give the no difference in expression of VDR of seminal vesicle rat between high cholesterol formula diet and normal AIN-93G diet. But we confirm the VDR expression in seminal vesicle.

Keywords: Vitamin D receptor, cholesterol, seminal vesicle

MATURE OSTEOBLASTS REGULATE VITAMIN D-MEDIATED BONE RESORPTION DURING GROWTH AND DIETARY CALCIUM/PHOSPHORUS RESTRICTION. Jackson Ryan¹, Michele Milne², Rebecca Sawyer¹, Patrisha Russel³, Kate Barratt⁴, Yolandi Starczak¹, Helen Tsangari¹, Gerald Atkins⁵, Howard Morris¹, Rachel Davey³, Paul Anderson⁶. ¹University of South Australia, Australia, ²University of Melbourne, Australia, ³University of Melbourne, Australia, ⁴University of South Australia, Australia, ⁵University of Adelaide, Australia, ⁶Musculoskeletal Biology Research, University of South Australia, Australia

Active vitamin D (1,25D), bound to the vitamin D receptor (VDR), can directly regulate osteoblast activity modulating bone resorption via induction of RANKL. However, it is somewhat unclear as to which cells of the osteoblast lineage are predominantly responsible for this activity. We have generated mature Osteoblast-VDR Knock Out (mOb-VDRKO) mice using an osteocalcin promoter-Cre to demonstrate the role of VDR-mediated bone resorption in mature osteoblasts during growth and under dietary calcium/phosphorus restriction. 6 week old female mOb-VDRKO mice displayed a pronounced reduction in RANKL mRNA expression, metaphyseal osteoclast surface (OcSur/BS) and serum X-laps. As a consequence, trabecular bone volume (BV/TV%) was increased in the femur (19%, p<0.05) and vertebra (21%, p<0.05) in comparison to littermate controls. The increase in trabecular bone in female mOb-VDRKO persisted at 12w of age but was absent by 26w of age. When 3 week old female mOb-VDRKO mice were subjected to a combined low calcium (0.03%) and phosphorus diet (0.08%) (LowCa/P) for 3 weeks, serum PTH levels and X-laps levels were approximately 2-fold greater than LowCa/P fed control mice, resulting in the abrogation of the bone phenotype to levels comparable to control mice. When the LowCa/P diet was continued until 20 weeks of age, higher serum PTH and X-laps levels persisted in mOb-VDRKO mice, which was associated with deleterious effects on bone including a deranged growth plate, cortical spaying and marked intra-cortical porosity. By comparison, 6 week old female Osteocyte-specific-VDRKO mice (deletion driven by Dmp1-Cre), exhibited no structural differences in femoral trabecular BV/TV%, and unchanged OcSur/BS. However, when 3 week old Oy-VDRKO KO mice were fed the LowCa/P diet for the 3 weeks, periosteal and endosteal circumference measure were reduced by 13% and 16% and when compared to levels in LowCa/P diet fed control mice, suggesting impaired bone remodelling specifically in cortical bone. Collectively, these data suggest that mature osteoblasts play a greater role in VDR-mediated bone resorption than osteocytes in young mice fed a normal diet. However, VDR and mature osteoblasts and osteocytes play a role in regulating bone turnover in response to dietary calcium/phosphorus restriction.

The Vitamin D Receptor Interacts with Peroxisome Proliferator-activated Receptor Gamma and Suppresses Target Gene Expression in Keratinocyte Stem Cells. Vaibhav Saini^{*1}, Francesca Gori², Marie Demay³. ¹MGH, Harvard Medical School, USA, ²Harvard School of Dental Medicine, USA, ³Massachusetts General Hospital, USA

Vitamin D Receptor (VDR) null mice develop hypocalcemia, hyperparathyroidism, osteomalacia, rickets, and alopecia. A calcium and phosphate enriched, lactose supplemented diet prevents all of these abnormalities with the exception of alopecia. Hair follicle morphogenesis is unaffected in VDR null mice; however, they exhibit absence of postmorphogenic hair cycling due to impaired self renewal and lineage progression of keratinocyte stem cells (KSCs), leading to the development of lipid laden dermal cysts.

To identify the molecular pathways dysregulated in the absence of the VDR in KSCs, RNA-Seq analysis was performed on KSCs isolated from 18-day-old VDR null and WT mice. Ingenuity Pathway Analyses identified over 1,900 differentially regulated genes involved in organismal survival, cell death and survival, cell proliferation, organ morphology, and lipid metabolism. Based on the presence of the lipid laden dermal cysts in the VDR null mice we focused on the genes involved in lipid metabolism. A significant increase in peroxisome proliferator-activated receptor gamma (PPARγ), PPARγ coactivator-1 beta (PGC1β), and *Lipoprotein Lipase* (LPL) mRNA expression was observed in the KSCs of VDR null mice compared to those of WT mice. ChIP-Seq analyses of KSCs from WT and VDR null mice identified VDR binding sites in the promoters of *PGC1β*, an established co-activator of PPARγ, and *LPL*, a known downstream target of PPARγ. ChIP analyses of primary murine keratinocytes confirmed VDR recruitment to the promoters of the *PGC1β* and *LPL* genes. Of note, the VDR and PPARγ were recruited to the same regulatory regions of the *LPL* gene, suggesting co-transcriptional regulation of *LPL* by these two nuclear receptors. To address whether the VDR and PPARγ could physically interact, immunoprecipitation analyses were performed. These studies demonstrated that the VDR co-immunoprecipitated PPARγ in transiently transfected COS-7 cells as well as in primary murine keratinocytes.

These data demonstrate that absence of the VDR leads to enhanced expression of PPARγ and its target genes in keratinocyte stem cells. The presence of a physical interaction between the VDR and PPARγ suggests that coordinated regulation of

gene expression by these nuclear receptors is required for normal lineage commitment of KSCs.

Vitamin D and Key Regulators of Bone Turnover during Pregnancy. Bernhard Svejda^{*1}, Astrid Fahrleitner-Pammer². ¹Gynecologist, At, ²Department of Internal Medicine, Medica I University Graz, Austria

Background: In order to develop the fetal skeleton the mineral metabolism of the mother must adapt to meet the fetal calcium demand. Conflicting and few data are available on bone turnover and vitamin D status of pregnant women. The aim of this study was to investigate serum levels of Vitamin D (25-OH Vitamin D), osteoprotegerin (OPG), soluble Receptor Activator of NF-κB Ligand (sRANKL), Dickkopf-related protein 1 (DKK1) during pregnancy in healthy women in order to analyze whether or not these markers change after conception.

Methods: 200 women gave informed consent for additional blood sampling. 178 unselected healthy women were included – pregnant women n=125 first trimester (T1); n=86 second trimester (T2); n=3 third trimester (T3); and n=21 postnatal women within 7-11 weeks postpartum. Blood sampling was performed after an overnight fast between 7 and 10 am in the morning and serum levels of OPG, DKK1 and free sRANKL (Biomedica, Austria) and Vitamin D (Immudiagnostik AG, Germany) were assayed by ELISA.

Results: Median serum OPG levels were significantly higher during pregnancy (Trimenon 1= 4.9, Trimenon 2= 6.75 and T3= 5.25 pmol/l) and postpartum 5.8 pmol/l, compared to 3.8 pmol/l for healthy, non-pregnant women (all except T3 p<0.05). DKK-1 levels were significantly lower during second and third trimester (T1= 27.2, T2= 19.7 and T3= 21.8 pmol/l) (p<0.05), but returned to normal (29.9 pmol/l) post partum = 29.7 pmol/l. Free sRANKL significantly decreased (p<0.05) during pregnancy in all three trimesters (T1= 0.08, T2 & T3= 0.03 pmol/l), but post partum levels were found similar (0.15 pmol/l) to the levels of non-pregnant women. Vitamin D levels significantly decreased (p<0.05) during pregnancy and stayed low post partum (T1= 40.1, T2 = 45.6, T3= 30.3 and postpartum = 34.7 nmol/l) compared to non-pregnant women 58.8 nmol/l.

Conclusions: These preliminary results show significant changes of serum levels of OPG, free sRANKL, DKK-1 and Vitamin D during pregnancy mainly during the first two trimesters. The changes of OPG, sRANKL and DKK1 may play a crucial role in the prevention of maternal bone loss. While maternal vitamin D deficiency may result in several negative outcomes for mother and child indicating an urgent need of an appropriate vitamin D supplementation during pregnancy.

Vitamin D deficiency and CYP27B1 ablation in the mammary epithelium accelerates tumor development in male mice carrying the PYMT oncogene. Jiarong Li^{*1}, René St-Arnaud², Timothy Reinhardt², Richard Kremer⁴. ¹McGill University, Canada, ²Shriners Hospital for Children, Canada, ³Iowa State University, USA, ⁴MUHC, Canada

Breast cancer in men is rare with a lifetime risk of 1 in 1000 compared to 1 in 8 in women. A strong inverse relationship between vitamin D exposure and breast cancer development has been reported in women and vitamin D has been shown to slow breast cancer progression in female mice models. In contrast this relationship has never been investigated in male studies. We previously reported the beneficial effect of vitamin D administration in the pYMT mouse model of breast tumor progression. In this model female mice develop breast cancer rapidly with palpable tumors around 6 weeks rapidly progressing to metastatic carcinoma at around 11 weeks. In contrast the male counterparts develop palpable tumors at around 18-20 weeks and metastatic disease around 30-36 weeks. In order to investigate the mechanistic relationship between vitamin D and breast cancer development in this male model of breast tumor progression, we used two different approaches. First we examined the effect of either a low (25IU/kg) or high (1000 IU/kg) vitamin D diet on tumor progression. Next we ablated CYP27B1, the enzyme responsible for the conversion of 25 hydroxyvitamin D (25OHD) to 1, 25-dihydroxyvitamin D (1, 25(OH)2D, in the mammary epithelium of male pYMT animals using the Cre/LoxP recombination system. Animals fed the low vitamin D diet had very low 25OHD but normal calcium levels and an earlier tumor onset and accelerated tumor growth compared to the high vitamin D diet group (n=4 per group P<0.001). Ablation of CYP27B1 reduced by over 80% 1α hydroxylase expression in the mammary epithelium as shown by confocal microscopy and Western Blot analysis and a similar reduction of 1, 25(OH)2D production in breast tumor extracts. Tumor onset was significantly accelerated with palpable tumors appearance around 14 weeks compared to 20 weeks in control animals (n=39 per group, P<0.001) and accompanied with accelerated tumor growth and of the number and size of lung metastases (P<0.05). Comparative gene array analysis of tumor tissues showed that over 1100 genes were either up or downregulated in CYP27B1 ablated tumors compared to control tumors (FC>2, P<0.05) with the major pathways involving cell death and apoptosis.

In summary our data demonstrate that vitamin D is an important regulator of male breast cancer development in this representative model of human breast cancer

and suggest that human studies are warranted to determine the role of vitamin D in the development male breast cancer.

CDKN1a/p21 suppresses osteogenesis and regenerative bone remodeling in an age-dependent manner. Elizabeth Blaber*¹, Yasaman Shirazi-Fard², Eduardo Almeida². ¹NASA Ames Research Center, USA, ²Space Biosciences Division, NASA Ames Research Center, USA

CDKN1a/p21 has previously been implicated in cell cycle and tissue regeneration arrest. In this study of the CDKN1a/p21 knock out (KO) mouse, we report a novel phenotype for this molecule in bone, leading to accelerated bone remodeling and aging. Because CDKN1a/p21 is elevated in bone subjected to mechanical unloading in microgravity, we investigated its role in bone formation and in the cellular response to alterations in mechanical load.

In juvenile (11-week old) KO mice, we found increased trabecular bone formation in the distal femur, indicated by increased bone volume fraction (BV/TV, 35.8%) and trabecular number (Tb.N, 34.4%), and decreased trabecular spacing (Tb.S, -17.9%). Cortical bone of the femoral midshaft in juvenile KO mice exhibited decreased periosteal perimeter (Ps.Pm, -3.4%) and a trend for decreased cortical thickness (Ct.Th). Additionally, three-point bending of the tibias from KO mice showed significantly decreased bone stiffness (-19.3%).

In adult (18-week old) mice, BV/TV, Tb.N, Tb.S, and mechanical properties showed no significant differences in KO mice compared to WT, but woven bone structure and increased osteoclast numbers were highly indicative of rapid bone remodeling. In addition, cortical bone in adult KO mice showed typical characteristics of aged bone, including, increased cross-sectional tissue area (T.Ar, 15.6%), Ps.Pm (8.8%), cross-sectional bone perimeter (B.Pm, 10.5%), and marrow area (Ma.Ar, 23.9%) with a corresponding decrease in bone area fraction (B.Ar/T.Ar, -9.1%). However, in vitro, mesenchymal stem cells from KO mice exhibited maintenance of differentiation potential indicated by significantly increased proliferation rates and mineralized nodule formation.

KO mice subjected to hindlimb unloading for 14 days revealed greater sensitivity to mechanical unloading resulting in nearly tripled cortical and trabecular bone loss compared to WT mice. However, in vitro, the ability of mesenchymal stem cells from KO mice to differentiate into mature mineral forming osteoblasts was increased, again indicating maintenance of regenerative potential.

In total, these findings indicate an important role for CDKN1a/p21 in regulating bone formation and bone turnover and suggest a potential target for therapeutic intervention in treating bone formation deficits.

Effects of Mechanical Unloading on Skeletal Structure and Properties of Connexin 43 Transgenic Mice. Huiyun Xu*¹, ruofei liu², ruixin yang², zhouqi yang², sumin gu³, jean jiang³, peng shang⁴. ¹Northwestern Polytechnical University, Peoples republic of china, ²Key Laboratory for Space Biosciences & Biotechnology, School of Life Sciences, Northwestern Polytechnical University, China, ³Department of Biochemistry, University of Texas Health Science Center at San Antonio, USA, ⁴Key Laboratory for Space Biosciences & Biotechnology, School of Life Sciences, Northwestern Polytechnical University, USA

As the most abundant connexins in bone cells, connexin43 (Cx43) forms gap junctions and hemichannels, which play critical roles in cell-cell communication in bone tissue. Our previous studies have shown that R76W transgenic mouse model blocks gap junction channel, but promotes hemichannel function specifically in osteocytes. In this study, we aim to understand the function of Cx43 mutant in response to mechanical unloading by subjecting 10-week-old R76W and wildtype C57BL/c mice (WT) to hindlimb suspension (HLS) for four weeks. The bone structure, bone material properties and dynamic bone formation of femur were detected by microCT, three-point bending and bone histomorphometry analysis, respectively. Our results showed that mechanical unloading obviously increased bone loss of WT and R76W mice. But the bone mineral density (BMD), bone volume/tissue volume (BV/TV) and trabecular thickness (Tb.Th) of male-R76W mice significantly decreased more than that of WT mice. In cortical bone, male-R76W mice also showed larger changes after HLS treatment, including smaller BMD, BV/TV, cortical thickness (Ct.Th) and larger marrow cavity. The three-point bending analysis showed that mechanical unloading decreased the material properties of both R76W and WT mice, including elastic module, ultimate load and stiffness. The changes of R76W were all less than that of WT mice, but the difference was not significant. Previous studies have shown that inhibition of gap junction function leads to restraining of sensitivity for mechanical unloading. Our results showed an increase of sensitivity in R76W mice to mechanical unloading. We assumed that difference response may be due to the role

of increased hemichannel function in R76W mice. Further studies will be done with ?130-136 transgenic mouse model, which block both gap junctions and hemichannel function. Then we can compare the response of R76W and ?130-136, to distinguish the role of gap junctions and hemichannels. The results of bone histomorphometry analysis showed that the changes of mineral apposition rate (MAR) and bone formation rate (BFR/BS) decreased more in female-R76W mice compared with that of WT mice. However the alternation of BMD and material properties were not different with WT mice. It is likely that bone absorption also decreased along with the inhibition of bone formation.

Effects of Simulated Microgravity and Hypergravity on the Matrix Mineralization in Osteoblast MC3T3-E1 and Preosteocyte-like Cell MLO-A5. Zhouqi Yang*¹, Fengtao Hao², Dandan Dong², Peng Shang². ¹Northwestern Polytechnical University, Peoples republic of china, ²Key Laboratory for Space Bioscience & Biotechnology, Institute of Special Environmental Biophysics, Faculty of Life Sciences, Northwestern Polytechnical University, China

The normal 1g-earth gravity is vital for maintaining bone homeostasis. Gravity change may result in the destroy of bone balance *in vivo*, such as weightlessness-induced bone loss, however, its cellular mechanism still remains unclear. In this study, a random positioning machine (RPM) and a 2g centrifuge were employed to investigate the long-term effects of simulated microgravity and hypergravity on matrix mineralization in osteoblast MC3T3-E1 and preosteocyte-like cell MLO-A5 via alizarin red S staining. In addition, the calcium consumption in culture medium and total protein level in osteoblasts and preosteocytes exposed to abnormal gravity environments were detected with atomic absorption spectroscopy and BCA assay. After culturing for 21 days with RPM, osteoblast demonstrated a decrease in the mineralized nodules formation. Similarly, a reduction in matrix mineralization was found in preosteocytes after a 9-day exposure to RPM, while shortly increased in day 6. During culturing period with RPM, total protein level was not altered in osteoblasts, but significantly decreased in preosteocytes. The calcium deposits slowed in day 7 and slightly accelerated in day 14 and day 21 in osteoblasts, and a similar tendency was also found in preosteocyte after being subject to a 9-day exposure to RPM. In contrast, Hypergravity (2g) environment had different impacts on osteoblasts and preosteocytes. After 21-day 2g centrifugation, matrix mineralization in MC3T3-E1 cells was distinctly inhibited, calcium consumption was suppressed and total protein level was increased. For preosteocyte MLO-A5 cells, 9-day 2g centrifugation enhanced mineralized nodule formation and calcium consumption in culture medium, but no evident change was found in cellular total protein. From these results, it is concluded that microgravity inhibited the matrix mineralization in both osteoblast and preosteocyte. Hypergravity (2g) has different influences on the mineralization ability for various differentiation stages of osteoblast-like cells.

Elcatonin Prevents Bone Loss due to Skeletal Unloading by Suppressing Bone Resorption with Unloading-Induced High Expression of Calcitonin Receptors in Bone Marrow Cells. Manabu Tsukamoto*¹, Kunitaka Menuki², Teppei Murai², Akihisa Hatakeyama², Shinichiro Takada², Kayoko Furukawa², Akinori Sakai². ¹University of Occupational & Environmental Health, Japan, ²Dept. of orthopaedic surgery, University of occupational & environmental health, Japan

Introduction: Osteoclasts highly express specific receptors of calcitonin, which acts directly on osteoclasts to reduce their motility and activity. There is no evidence of efficiency of elcatonin for prevention of bone loss due to skeletal unloading in mice. The aim of this study is to investigate the effect of elcatonin on bone loss due to unloading. Materials and Methods: C57BL/6J male 7-week-old mice were assigned to four groups with either ground control (GC) or tail suspension (TS) and either administration of elcatonin 20U/kg (EL) or vehicle (veh) three times per week; GCEL, GCveh, TSEL, TSveh. Mice were sacrificed at 1, 4 and 7 days, and blood samples, bilateral femurs and tibias were obtained for analysis. Results: The expression of calcitonin receptor (Calcr) mRNA at 1 day of TSveh and the number of Calcr-positive cells at 4 days of TSveh were significantly increased more than those of GCveh. After 7 days of unloading, the trabecular bone volume of the proximal tibia and trabecular bone mineral density of distal femur measured by pQCT in TSEL were significantly increased more than those in TSveh. The parameter of bone resorption, the osteoclast surface, the osteoclast number and the serum level of TRACP-5b, were significantly decreased in TSEL. On the other hand, the number of preosteoclasts, which was TRACP-positive mononuclear cells, was significantly increased in TSEL. There was no difference of the parameter of bone formation, the bone formation rate, the mineral apposition rate and the serum level of PINP, between TSveh and TSEL. At 4 days of TSEL, the expression of NFATc1, Cathepsin K and ATP6V0D2 mRNA in bone marrow cells were decreased. At 7 days of TSEL, the expression of Sphk1 mRNA in bone marrow cells was increased. Conclusions: Tail-suspension induces high

expression of calcitonin receptors in bone marrow cells of hindlimb and calcitonin prevents unloading-induced bone loss by suppressing bone resorbing activity.

Influence of Mechanical Loading on Alignment of Biological Apatite Crystallites and Lacunar-canalicular System in Rabbits. Muneteru Sasaki¹*, Shinichiro Kuroshima¹, Takayoshi Nakano², Takashi Sawase¹. ¹Nagasaki University, Japan, ²Osaka University, Japan

Introduction

Osteocytes, which reside within bone matrix, are regulator cells that control bone reaction in response to mechanical stimulation. Bone matrix is mainly constituted of collagen and biological apatite. Recently we have indicated that the orientation of biological apatite (BAP) c-axis in bone matrix were associated with mechanical strength of bone. However, relationship between osteocyte network and preferential alignment of BAP c-axis around bone matrix via loaded implants is unclear. The aim of this study was to investigate osteocyte ultrastructural morphology and the alignment of BAP c-axis around loaded implants.

Materials and Methods

Anodized Ti-6Al-4V alloy dental implants were placed in the both sides of proximal tibia metaphysis of each rabbit. Mechanical repetitive loading was randomly applied along the long axis of the implant (50 N, 3 Hz, 1,800 cycles, 2 days/week) for 8 weeks at 12 weeks after implant placement using a custom made loading device (loading group). The implants in remaining side did not received any loading (control group). Tibiae with the implants were dissected, and resin embedded samples were prepared following manufacturer's instructions. Scanning electron microscopy (SEM) and microbeam X-ray diffractometer were used to investigate osteocyte morphology and crystallographic orientation of BAP c-axis, respectively.

Results and Conclusions

The number of osteocytes and cell process in loading group was significantly increased compared with control. Osteocyte dendrite processes in control group evenly aligned, whereas their processes in loading group randomly aligned. Preferential alignment of BAP c-axis in control group was consistent with the longitudinal direction of osteocyte cell bodies, but the consistency was not observed under loaded condition. Our findings suggests that mechanical repetitive loading affected not only the development of lacuno-canalicular system but also the preferential alignment of BAP c-axis.

Mechanical Vibration Promotes Proliferation and Differentiation of Cementoblasts and its regulation of Osteogenesis via ERK1/2 Signaling Pathway. Dawei Liu, Hua Wang*. Marquette University School of Dentistry, USA

Objective: To study the effect of mechanical vibration on the proliferation and differentiation of cementoblastic OCCM.30 cells and its regulation of osteoblastic mineralization. **Methods and Methods:** OCCM.30 cementoblasts were subjected to low-magnitude (0.3 × g) sinusoidal vibrations at various frequencies (0, 30, 60, 90 Hz) for 1 h every day. For signal transduction studies, cells were pre-incubated with U0126 (20mM) or DMSO for 1 h and then subjected to mechanical vibration for 1 h. Conditioned medium (CM) was collected from OCCM.30 cells 1 h after the completion of 1 h of mechanical vibration at various frequencies. Osteoblastic MC3T3-E1 cells were cultured in a mixture 1:1 (v/v) of growth medium and CM for 7 days and 14 days. **Results:** Mechanical vibration enhanced cementoblastic proliferation and differentiation, most significantly at 60 Hz. Application of an ERK1/2 signaling pathway blocker - U0126 partly blocked this vibration-induced up-regulation. After induced with the CM, there was a significant increase in osteoblastic mineralization in the vibration group as the frequency increased, most significantly after 7 days of culture. **Conclusion:** Mechanical vibration induces and promotes the osteogenesis of cementoblasts via the potentiation of ERK1/2, which is able to enhance the osteoblastic mineralization.

A novel β_3 -integrin based mechanosome structure in bone tissue. Pamela Cabahug-Zuckerman¹, Robert Majeska¹, Mia Thi², Dave Spray², Shledon Weinbaum¹, Mitch Schaffer¹. ¹the City College of New York, USA, ²Albert Einstein College of Medicine, USA

Osteocyte (OCY) processes are 10-100X more sensitive to physiological stimuli than OCY bodies [1-4]. In vitro studies of MLO-Y4 cells show activation of cellular Ca^{2+} signaling when <10pN fluid forces are focused at OCY process attachments, and inhibition of the Ca^{2+} response when either $\alpha_5\beta_3$ integrins (β_3) or ATP are blocked [4]. β_3 found along OCY processes in situ don't colocalize with either vinculin [5] or paxillin [6], suggesting β_3 in bone tissue don't form typical focal adhesion complexes and ruling out classical integrin transduction mechanisms. We test the

hypothesis that in situ β_3 -based foci along OCY processes, sites of high membrane strains during mechanical loading [1], associate with ligand-gated and stretch-activated Ca^{2+} channels. Mice femoral bone sections were double immunostained for β_3 and one of candidate channels: CaV3 Ca^{2+} channel [7], P2X₇R purinergic channel, Panx1 hemichannel and Cx43, found in OCY processes [8,9], but not expected to associate with β_3 . Structured Illumination Microscopy was used to acquire images with resolutions of 100nm [10]. Protein distribution and pair colocalization were quantified from single optical planes of foci on OCY processes, from lacuna margins sampled every 0.5 μ m up to 3.5 μ m away, Fig1a. Manders Coefficients were used to assess overlap of β_3 and candidate channel foci. For each protein pair two coefficients were measured: the 1st tested association between a channel as reference and β_3 ; the 2nd, the reverse. Values >0.4 indicate biologically significant colocalizations [11]. ANOVA & M-W U-test were used to compare values. β_3 , CaV3, P2X₇R, Cav3 and Panx1 were concentrated at the most proximal region of OCY processes and then decreased with distance, unlike Cx43 which had the lowest value, Fig1b. At the proximal region <1.5 μ m from the lacuna margin, association between the CaV3, P2X₇R and Panx1 with β_3 foci were >0.4, indicating biologically significant colocalization; likewise, reverse coefficients show β_3 foci association with CaV3, P2X₇R and Panx1 in the same region, Fig2, although to a lower extent, indicating that a fraction of β_3 sites may be associated with other channels or simply be anchors. Here we show that P2X₇R, critical to OCY cell mechanotransduction in vitro, is present on OCY processes in situ. Moreover, this receptor channel strongly colocalizes with β_3 attachment sites. A similar strong association was also found between β_3 foci and T-type calcium channel CaV3 and hemichannel Panx1, but not with Cx43. β_3 attachment foci are sites of high tension in the cell process membrane during mechanical loading [1]. Our studies suggest that foci found on processes consisting of $\alpha_5\beta_3$ integrins, P2X₇R, CaV3 and Panx1 may function as novel integrin-based mechanosome complexes.

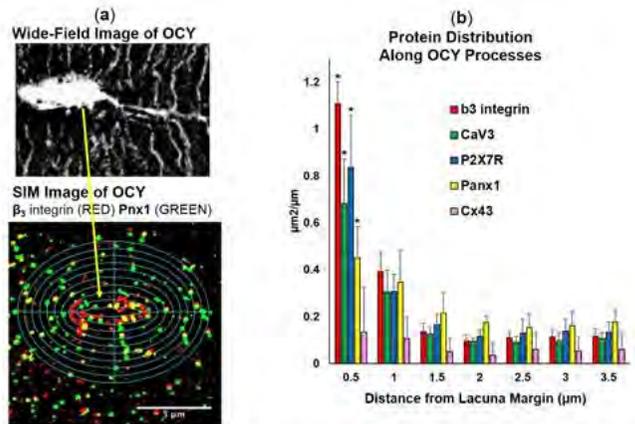

Fig1 (a) Example of a Structured Illumination Microscopy (SIM) image of one optical plane examined, showing the elliptical donut regions of interest in blue, for a β_3 and Panx1 pair; and a Wide-Field image, for comparison. (b) The distribution of all proteins examined along osteocyte processes. * = $p < 0.05$ versus distances $> 0.5 \mu$ m.

Fig1

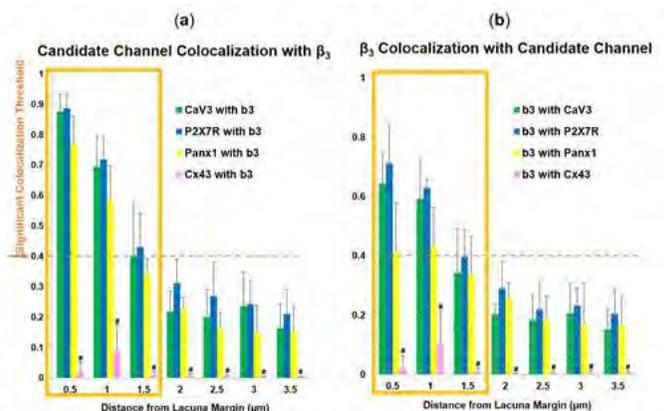

Fig2 Manders Coefficients are shown above, where the 0.4 threshold for biological significance is indicated by the dashed orange line. (a) Colocalization of candidate channels with β_3 , are high at the proximal region of osteocyte processes, within the rectangular orange outline, and also seen (b) in β_3 colocalization with CaV3, P2X₇R and Panx1; not Cx43. # = $p < 0.05$ vs β_3 , CaV3, P2X₇R & Panx1

Pulsed electromagnetic fields (PEMF) enhance osteoblastic differentiation of human bone marrow stromal cells by activation of microRNA21 expression and the TGF- β signaling pathway. Zhiming He*¹, Nagarajan Selvamurugan², Jawed Siddiqui¹, Teruyo Nakatani¹, Erik Waldorff³, Nianli Zhang³, James Ryaby³, Nicola Partridge⁴. ¹New York University, USA, ²SRM University, India, ³Orthofix, Inc., USA, ⁴New York University College of Dentistry, USA

Previously we reported that PEMF stimulates the proliferation, osteoblastic differentiation and mineralization of human bone marrow stromal cells (hBMSCs). Our further studies by Affymetrix microarray analysis suggested the osteogenic effects were through activation of certain signaling pathways and regulation of specific gene expression, notably the TGF- β signaling pathway and microRNA21 (miR21), respectively. In order to verify the role of the TGF- β signaling pathway, we examined phosphorylation of Smad 2/3 proteins, the critical TGF- β intracellular signaling components, in differentiating hBMSCs after PEMF treatment. We found that PEMF causes highly increased phosphorylated Smad2 in human osteoblastic cells in their differentiation phase and lesser but clear activation in their mineralization phase compared to controls. No Smad3 phosphorylation was found in either treatment group. Neutralization with pan-TGF- β antibody blocked the PEMF-induced Smad2 phosphorylation and decreased the stimulatory effect of PEMF on osteoblastic RNAs. MicroRNA21 has been shown to be an osteogenic miRNA and has members of the TGF- β pathway as target genes. RT-qPCR showed miR21 expression is increased by PEMF treatment in differentiating hBMSCs. The significance of miR21 expression was determined by RNA interference with transient transfection of miR21 inhibitor and miR21 mimic. Transient transfection with miR21 inhibitor increased miR21's putative target gene, Smad7, an antagonist of the TGF- β signaling pathway in both control and PEMF-treated hBMSCs. PEMF caused a decrease in expression of Smad7 presumably via stimulation of miR21. Runx2, a bone transcription factor, was increased by PEMF treatment and the miR21 inhibitor prevented the PEMF stimulation of Runx2 expression in differentiating hBMSCs. Increased expression of Runx2 correlated with increased alkaline phosphatase mRNA expression after PEMF treatment and the miR21 mimic further enhanced this effect. It has been shown that Smad7 interacts with Smurf2 (E3 ubiquitin ligase) but it does not interact with Runx2. Thus, based on the results we suggest that PEMF could mediate its effect on bone metabolism by regulating miR21, which leads to a decrease in Smad7 to activate the TGF- β signaling pathway, stimulating Runx2 mRNA expression and stabilizing its protein levels. Therefore, this study identifies that miR21 expression and activation of the TGF- β signaling pathway play important roles in PEMF's effects on hBMSCs.

Role of P₂R-ER Ca²⁺ Signaling Pathway in Medium Intensity Focused Ultrasound induced Ca²⁺ Oscillations in *In-Situ* Osteocytes. Minyi Hu*, Jian Jiao, Daniel Gibbons, Yi-Xian Qin. Stony Brook University, USA

Osteocyte mechanotransduction has gained significant research attention for its clinical potential in related dysfunctional bone remodeling. Elevation of [Ca²⁺]_i has been observed as one of the earliest biochemical events in bone cells under external physical signals. Our lab has recently observed *in-situ* Ca²⁺ oscillations in response to Medium Intensity Focused Ultrasound (MIFU). However, the underlying biochemical mechanisms responsible for such Ca²⁺ signaling is unknown. Thus, the current study aimed to investigate the roles of various Ca²⁺ signaling pathways in MIFU-induced Ca²⁺ oscillations *in-situ*. All animal protocols were approved by SBU's IACUC. Fresh calvarias were obtained from 3mo Black6 mice immediately after euthanasia, and were kept in DMEM w/ 5% FBS and 1% penicillin/streptomycin til ready for incubation in specific Ca²⁺ signaling blockers: 1) Amlodipine (L-type VGCC antagonist; n=4), 2) 18 α -glycyrrhetic acid (18 α -GA, reversible intercellular GJ blocker; n=5), 3) thapsigargin (TG, inhibitor of Ca²⁺-ATPase pump of the ER; n=5), 4) NNC 55-0396 (T-type Ca²⁺ channel inhibitor; n=5), 5) pyridoxalphosphate-6-azophenyl-2',4'-disulfonic acid (PPADS, nonselective P₂R blocker; n=2), 6) ICG-001 (antagonist of Wnt/ β -catenin-TCF-mediated transcription; n=3), and control (n=5). The samples were stained w/ Fluo-8 AM for Ca²⁺ fluorescent label, and subjected to 6W of MIFU stimulation for 30sec. Real-time confocal imaging (40X, 488-nm, 2 frames/sec) was performed to capture the Ca²⁺ signals. To analyze, the fluorescent intensity of each cell body was extracted as a function of time. By normalization to the

baseline, the responsive percentage, number of spikes, normalized spike magnitude, and the initiation time were quantified. Results showed that 6W MIFU-induced Ca²⁺ oscillations were completely abandoned by PPADS ($p < 0.01$ vs. control). TG significantly lowered the number of Ca²⁺ spikes and spike initiation time; NNC 55-0396 also significantly lowered the spike initiation time ($p < 0.05$ vs. control). We concluded that the P₂R-ER pathway played a major role in *in-situ* MIFU-induced Ca²⁺ oscillations. This study provided promising findings on the signaling mechanisms involved in the interactions between acoustic mechanical stress and *in-situ* osteocytic Ca²⁺ oscillations, which provides future exploration of the ultrasound triggered mechanosensing mechanism.

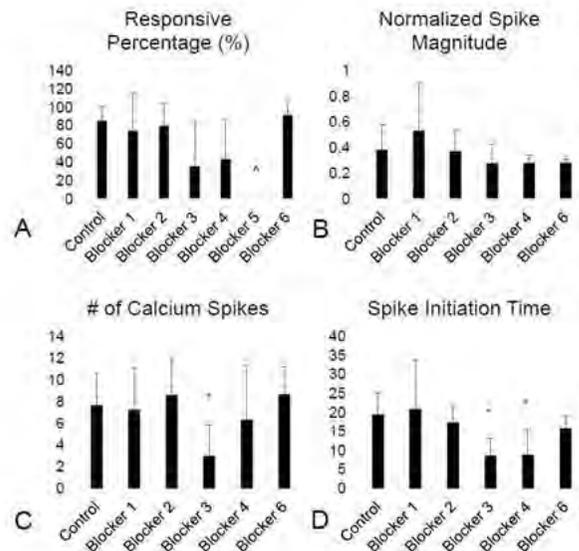

Figure 1. Investigation of the roles of various Ca²⁺ signaling pathways in 6W MIFU-induced Ca²⁺ oscillations. (A) Responsive percentage, (B) normalized spike magnitude, (C) number of spikes, and (D) spike initiation time. Blocker 1 – Amlodipine, Blocker 2 – 18 α -GA, Blocker 3 – TG, Blocker 4 – NNC 55-0396, Blocker 5 – PPADS, Blocker 6 – ICG-001. * $p < 0.01$ vs. control; $p < 0.05$ vs. control.

Effect of mechanical stimulation on the Hedgehog signaling in osteoblast. Matsumoto Kenichi*¹, Tsuyoshi Shimo¹, Naito Kurio², Tatsuo Okui³, Akira Sasaki². ¹Okayama University, Japan, ²Department of Oral & Maxillofacial Surgery, Okayama University Graduate School of Medicine, Dentistry, & Pharmaceutical Sciences, Japan, ³Department of Oral & Maxillofacial Surgery, Okayama University Graduate School of Medicine, Dentistry, & Pharmaceutical Sciences, Okayama, Japan

INTRODUCTION: Previously, we have reported that Sonic Hedgehog (SHH) signaling was activated in osteoblasts at the dynamic remodeling site of a bone fracture. Mechanical stimulation is one of the crucial factor in bone remodeling and speculated the involvement of the primary cilia as a sensor of Hedgehog signaling. In this study, we examined the effect of mechanical stimulation on the Hedgehog signaling and primary cilia. **METHODS:** The right eighth ribs of 8-week-old male ICR mice were fractured, resected, decalcified, and immunofluorescence staining were performed. To evaluate the effects of mechanical stimulation on the osteoblasts, MC3T3-E1 cells were stimulated by low-intensity pulsed ultrasound (LIPUS). Expression of primary cilia was examined by anti-gamma tubulin and anti-acetylated tubulin antibody. **RESULTS:** SHH was expressed in bone marrow cells at the fracture site on day 3 and the number of primary cilia in MC3T3-E1 cells were increased in the osteoblasts. The number and the length of primary cilia were increased by LIPUS stimulation for 24 and 48 hours. LIPUS upregulated the expression of Patched, Gli1 and Gli2 protein and stimulated the differentiation in MC3T3-E1 cells. **CONCLUSION:** Our results suggested that mechanical stimulation mediate the primary cilia and upregulate the osteoblast differentiation through Hedgehog signaling.

Orthodontic Force-Induced Nociception Stimulates Sympathetic Nervous Signaling Centrally, which Accelerates Tooth Movement through Osteoclast Activation. Hisataka Kondo*¹, Mayo Kondo², Ken Miyazawa², Shigemitsu Goto², Akifumi Togari². ¹Aichi-Gakuin University, Japan, ²Aichi Gakuin University, Japan

Orthodontic force changes bone architecture through stimulation of bone remodeling. Recent we reported that experimental tooth movement (ETM) induced osteoclast activation in periodontal ligament through stimulation of the sympathetic nervous system (Kondo et al. Bone. 2013;52(1):39-47). However, it is unknown how orthodontic force stimulates the sympathetic nervous system. ETM changes the distribution of sensory and sympathetic nerve fibers in periodontal ligament, so we compared the effects of sympathectomy and sensory lesion on ETM. Sensory neuron lesion produced by capsaicin (CAP) showed similar results to sympathectomy by 6-hydroxydopamine (6-OHDA), which suppressed tooth movement and the proportion of osteoclast-covered surface on bone (alveolar socket) (Oc.S/BS) in periodontal ligament. CAP treatment also inhibited ETM-induced increase in a sensory neuromarker, calcitonin gene-related peptide (CGRP)-immunoreactive (IR) neurons, and a sympathetic neuromarker, tyrosine hydroxylase (TH)-IR neurons, in periodontal ligament. On the other hand, 6-OHDA treatment did not suppress ETM-induced increase in CGRP-IR neurons, but did suppress TH-IR neurons in periodontal ligament. Furthermore, treatment with β -agonist, isoproterenol (ISO), masked CAP-induced inhibitions of tooth movement and Oc.S/BS. Destruction of ventromedial hypothalamus (VMH) by gold thioglucose (GTG) treatment suppressed the ETM-induced increases of tooth movement, Oc.S/BS and CGRP-IR. These data suggest that ETM activates osteoclasts through the neural loop of the sensory-central-sympathetic nervous system.

Strain Determination in Finite Element Models of the Mouse Forearm under Dynamic Loading. Mark Begonia*, Mark Dallas, Mark L. Johnson, Ganesh Thiagarajan. University of Missouri-Kansas City, USA

Whole bone strain leads to heterogeneous gene expression, which is believed to be linked to strains experienced by individual osteocytes and their lacuna. Bone strain can be predicted with numerical finite element (FE) models, but their accuracy relies on the anatomical and material properties of a specimen. Previously, we measured forearm strains via strain gaging and a non-contact method known as Digital Image Correlation (DIC) to quantify the bone stiffness induced by gage attachment, and we found that DIC values exceeded gage values in the ulna (148%) and radius (221%). In this study, we simulated cyclic axial compression in FE models of 3 different TOPGAL mouse forearms and analyzed strains after including the interosseous membrane (IOM) and mouse-specific material properties. FE strains were then compared to strain gage and DIC values to assess the true strain response. The goal of this research is to apply a multiscale FE modeling scheme where the strain fields observed in these macro FE models are used to find activated osteocytes in micro FE models of the bone.

FE models were created in the Mimics® Innovation Suite and modified in the FEBio Software Suite to incorporate the IOM. The 1st iteration FE models used Young's moduli (E) and densities (ρ) from literature for the ulna (E_u : 20 GPa; ρ_u : 1168 kg/m³) and radius (E_r : 18 GPa; ρ_r : 1172 kg/m³). The 2nd iteration used moduli from 3-point bending (E_u : 19.1-21.9 GPa; E_r : 12.1-15.4 GPa), densities from μ CT (ρ_u : 1052-1077 kg/m³; ρ_r : 1023-1092 kg/m³), and an IOM stiffness from tension tests (15 N/mm). Peak strains were higher in the ulnae (6%) and radii (10.7%) of the 2nd iteration FE models vs. the 1st iteration. Compared to DIC and gage values, Forearm #1 had a peak ulna strain (4185 $\mu\epsilon$) that was closer to the DIC value (3887 $\mu\epsilon$) than gage value (1565 $\mu\epsilon$) while the peak radius strain (1736 $\mu\epsilon$) ranged between the DIC value (2845 $\mu\epsilon$) and gage value (884 $\mu\epsilon$). In Forearm #2, the peak strains in the ulna (2528 $\mu\epsilon$) and radius (1626 $\mu\epsilon$) were both lower than DIC values yet higher than gage values. The variation in peak ulna strains between Forearm #1 and #2 are due to differences in bone geometry and Young's modulus (E_1 : 19.4 GPa; E_2 : 21.9 GPa), and ongoing work on the third mouse specific FE model could elucidate this finding. Ultimately, this study shows that due to the IOM and individualized material properties, our FE models accurately predict bone strains ranging between strain gage and DIC values.

CaMKK2 inhibition enhances bone fracture healing. Uma Sankar*¹, Justin Williams², Mariah Hassert², Jianying Liu², Yinghua Cheng², Alexander Robling², Melissa Kacena², Yong Li². ¹Indiana University Purdue University Indianapolis, USA, ²Indiana University School of Medicine, USA

Fractures associated with osteoporosis and acute trauma result in significant medical costs, loss of productivity and loss of patient quality of life. Prolonged healing time and non-union occur in 5-10% of fractures, contributing to further medical costs and patient morbidity. Established therapies such as bisphosphonates only reduce the risk of fractures by an average of 20% and do not promote efficient bone growth and

fracture healing. Consequently, there are no current pharmacological treatment options available to promote efficient bone fracture healing.

We recently identified Ca²⁺/calmodulin (CaM)-dependent protein kinase kinase 2 (CaMKK2) to have roles in the anabolic and catabolic pathways of bone remodeling. Pharmacological inhibition of CaMKK2 in female mice using its selective cell-permeable inhibitor STO-609 protects from ovariectomy-induced osteoporosis. Moreover, treatment of 32 week old male mice with STO-609 reverses age-associated decline in bone volume and strength. Based on these studies, we hypothesized that targeting CaMKK2 will result in accelerated fracture healing. To test this hypothesis, we generated unilateral mid-shaft fractures will be using the three-point bending method (first described for use in rats by Bonnarens and Einhorn, 1986) in the right femurs of 10-week old anesthetized male mice after first inserting an intramedullary pin (25 gauge needle, approx. 0.5 mm) retrograde through the distal condyle of the femur. Radiographic analyses were performed to confirm the location and quality of the fractures. Fractured animals were divided into three groups: (a) saline only (n=15), (b) STO-609 from day 0 (n=15) and (c) STO-609 from day 7 (n=15). Tri-weekly intraperitoneal (i.p.) injections of saline or STO-609 (10 μ mol/kg) were performed for 6 weeks. Progression of fracture healing was monitored through weekly radiographic examination. Fractured callus and non-fractured contralateral femur diaphysis were analyzed by micro computed tomography, histology, immunohistochemistry and histomorphometry. Preliminary results indicate that treatment with STO-609 results in the formation of a robust callus at the fracture site, as well as a 43% increase in total bone volume, 50% increase in trabecular thickness, 9% increase in trabecular number and a 10% decrease in trabecular separation. These data indicate accelerated healing of femoral fractures following the pharmacological inhibition of CaMKK2.

Effect of intermittent administration of teriparatide (PTH1-34) on BMP induced bone regeneration in a rat critical-sized femoral defect model. Sadaaki Kanayama*, Takashi Kaito, Masafumi Kashii, Takahiro Makino, Tokimitsu Morimoto, Masayuki Furuya, Kazuma Kitaguchi, Yusuke Sakai, Hideki Yoshikawa. Osaka University Graduate School of Medicine, Japan

Introduction

Although clinical bone morphogenetic protein (BMP) therapy is effective, required doses are very high. The uncontrolled release of high concentrations of BMPs can cause inflammation and unintended bone formation. Intermittent administration of PTH1-34 results in osteoblastic proliferation and differentiation, thereby leading to an increase in bone mass. Recently, up-regulation of BMP and Wnt signaling by PTH have been reported. These mechanisms indicate the possibility of synergistic bone regeneration by the co-administration of BMP and PTH. The aim of this study is to elucidate the effect of intermittent administration of PTH1-34 on BMP-induced new bone in a rat critical-sized femoral defect (7mm) model.

Materials and methods

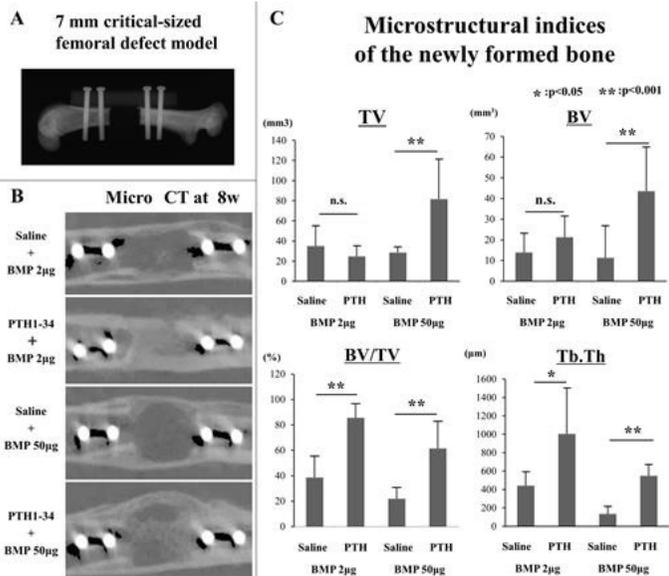

A total of 32 SD rats (10w) were operated (Fig.A) by two different BMP-2 treatments; 1) 2 μ g (low dose), 2) 50 μ g (high dose). Each of the BMP treatments was studied in combination of intermittent PTH1-34(180 μ g/kg/w) or saline injection since 2w before the operation to 8w after operation. Microstructural indices of the newly formed bone and the contralateral femur were evaluated by micro CT (0, 1, 2, 4, 6, 8w). Bony fusion at femoral defects was evaluated using micro CT.

Results

Micro CT demonstrated bone formation since post-op. 2w and bony fusion since post-op. 4w in all groups. Fusion rates at post-op. 8w were not significantly different w/ or w/o PTH (PTH/Saline: BMP; 2 μ g 100%/75%, 50 μ g; 100%/100%). Microstructural indices of the newly formed bone (BV/TV, Tb.Th) were significantly improved by PTH in both BMP low and high dose groups. BV/TV of the contralateral femur was also significantly increased at post-o. 8w (PTH 38.3%; saline 15.7%, $p < 0.001$) (Fig.B,C). Though the TV of newly formed bone in BMP low dose group did not significantly changed by PTH, the TV in BMP high dose group significantly increased by PTH ($p < 0.01$).

Discussion and Conclusions

Intermittent PTH1-34 administration significantly improved the quality of the newly formed bone in this model. However, the remodeling process of the newly formed bone in this model was sluggish or devoid compared to that in our previous rat spinal fusion model. Stress shielding by internal fixation may inhibit the osteocyte-mediated remodeling process where PTH can work through PTH/PTH-related peptide type 1 receptor (PPR). These results suggest that mechanical stress which works through PPR in osteocyte may play a critical role in the remodeling of BMP-induced new bone.

Intermittent PTH1-34 administration improved the quality of the BMP-induced new bone

Effects of Sclerostin Antibody in Attenuation of Cortical Bone Loss in Ovariectomized Rats with Concurrent Mechanical Unloading. Dongye Zhang*¹, Mariana Miranda¹, Minyi Hu¹, Liangjun Lin¹, Xiaodong Li², Hua Zhu Ke³, Yi-Xian Qin¹. ¹Stony Brook University, USA, ²Amgen Inc., USA, ³UCB Pharma, United Kingdom

Osteoporosis is a skeletal disease characterized by low bone mass and microarchitectural deterioration of cortical and trabecular bone with a consequent increase in bone fragility and susceptibility to fracture. Sclerostin antibody (Scl-Ab) increased bone formation and bone mass, and decreased bone resorption in animal models of bone loss due to estrogen deficiency (OVX) or immobilization. The current study was undertaken to examine the effect of Scl-Ab on cortical bone in OVX rats with concurrent hindlimb suspension (HLS). Four-month-old virgin female SD rats were divided into 7 groups (n=11 per group). HLS was performed 2 weeks after sham or OVX; and treatment was initiated at the time of HLS. Scl-Ab (25 mg/kg) or vehicle was injected sc twice per week for 5 weeks. The femoral diaphyses were analyzed with μ CT, four-pt bending and histomorphometry for cortical thickness (Ct.Th), mechanical properties and bone formation parameters. Ct.Th was significantly lower in HLS alone, OVX alone and OVX+HLS groups (-13.7%, -14.2% and -15.4%, respectively) than sham control. Scl-Ab significantly preserved Ct.Th in all three conditions, (Fig.1). Scl-Ab prevented the decrease in stiffness associated with HLS or OVX+HLS. Ultimate load was not significantly lower in HLS, OVX or OVX+HLS as compared with Sham controls, but it was significantly greater in Scl-Ab-treated HLS or OVX rats (Fig.2). Scl-Ab-treated HLS, OVX and HLS+OVX showed significant increases in mineralizing surface (MS/BS) as compared to respective controls at both endosteum (Ec) and periosteum (Ps) sites. Ps. bone formation rate (BFR/BS) was elevated in HLS, OVX and HLS+OVX groups treated with Scl-Ab (721%, 55% and 460%, respectively). Similarly, Ec.BFR/BS increased by 636%, 42% and 312%, respectively, in Scl-Ab-treated groups compared with respective control, indicating the thickening of the cortical bone was associated with dynamic bone formation events at both Ec. and Ps. sites (Fig.3., 4.). In summary, Scl-Ab increased Ps. and Ec. bone formation and prevented cortical bone thinning condition in HLS-, OVX- as well as HLS+OVX rats. The data suggested that sclerostin antibody represents a promising therapeutic approach for bone loss induced by estrogen deficiency with concurrent mechanical unloading.

Femur Midshaft Cortical Thickness

Osteoblastic Monocyte Chemoattractant Protein-1 (MCP-1) Mediates Parathyroid Hormone's Anabolic Actions in Bone: Role of TGF- β Signaling. Jawed Siddiqui¹, Joshua Johnson², Joseph Tamasi³, Nicola Partridge². ¹New York University, USA, ²Department of Basic Science & Craniofacial Biology, New York University College of Dentistry, USA, ³Bristol-Myers Squibb, USA

Parathyroid hormone is now the only osteoanabolic hormone available for treating osteoporosis. The precise mechanisms behind the PTH's anabolic effects are still not completely clarified. Microarrays of bone from rats injected with hPTH-(1-34) daily for 14 days showed that the chemokine, MCP-1, was the most highly stimulated gene. Recently, we have shown that PTH's anabolic effects are abolished in MCP-1^{-/-} mice. In addition, MCP-1 increases multinucleated osteoclasts in culture and MCP-1^{-/-} mice do not recruit osteoclasts after PTH injection, suggesting these cells are implicated in PTH's actions through MCP-1. To identify the cells expressing MCP-1, we performed *in situ* hybridization of MCP-1 mRNA in rat tibiae. Daily hPTH injection to 4 month old male rats showed increased expression of MCP-1 in bone lining osteoblasts and in cells surrounding blood vessels compared to saline-injected animals. To determine the role of MCP-1 in PTH's actions, 4 month old male wild type (WT) and MCP-1^{-/-} mice were injected daily with hPTH (8 μ g/100g/day) or saline for 6 weeks. Immunohistochemistry of tibiae showed very little staining for phosphorylated Smad2 in marrows of MCP-1^{-/-} mice, especially after PTH treatment, whereas pSmad2 staining was enhanced in marrows of WT mice. Similarly, Western blot analyses of bone marrows showed enhanced pSmad2 expression in WT mice after hPTH treatment whereas MCP-1^{-/-} mice showed no PTH-mediated increase in Smad2 phosphorylation. These data show that MCP-1 is necessary for PTH-mediated TGF- β signaling in bone marrow. In addition, mRNA analysis of the distal femurs of hPTH-injected mice showed that PTH induced the expression of ALP, c-fos, CCR2, Coll (α 1) and TGF- β 1 in WT mice but failed to demonstrate such changes in MCP-1^{-/-} mice. Alizarin Red-S staining of bone marrows from these mice, cultured for 21d in osteoblast differentiation medium, showed enhanced mineralized nodule formation from WT mice treated with PTH while marrows from MCP-1^{-/-} mice showed no effect of PTH treatment. Together we conclude that, MCP-1, secreted by cells of the osteoblast lineage in response to PTH stimulation, is necessary for the recruitment of monocytes and pre-osteoclastic cells towards remodeling sites and assists in the formation of mature osteoclasts. Subsequently, latent TGF- β 1 released from bone matrix enhances the recruitment of BMSCs towards the remodeling sites and facilitates osteoblast differentiation and bone formation.

Bisphosphonate treatment differentially affects bone mechanical properties of mice with robust and slender bone. Drew Brown¹, Erin McNerny¹, Jason Organ¹, Chris Newman¹, Karl Jepsen², Matthew Allen¹. ¹Indiana University School of Medicine, USA, ²University of Michigan, USA

Although currently used anti-osteoporosis drugs, such as bisphosphonates, are highly effective in reducing fractures, there are individuals who adversely respond to these drugs and experience atypical femoral fractures (AFFs). The goal of this study was to test the hypothesis that bisphosphonates exert differential effects on bone mechanical properties of animals that have a robust (high total cross-sectional area / bone length) versus a slender (low total cross-sectional area / bone length) bone morphology. Skeletally mature male A/J (slender; n=16) and B6 (robust; n=16) mice were dosed with zoledronic acid (ZOL; 0.08 mg/kg) or vehicle (VEH) at 14 and 18 weeks of age and at 22 weeks of age femora were collected and frozen in saline-soaked PBS. High-resolution microCT scans of the femora were taken to examine trabecular bone morphology of the distal metaphysis region and mid-diaphysis cortical bone geometry. Mechanical properties were assessed using four-point bending to failure. Confirming previous work, VEH-treated animals with robust bones had significantly higher cortical bone mechanical properties and cross-sectional area, and lower tissue mineral density, compared to VEH-treated slender animals. ZOL significantly increased ultimate load (+26% versus +7%) and stiffness (+23% vs no effect) to a greater degree in robust mice compared to slender. Pre-yield displacement tended to be higher in ZOL-treated slender bones (+11%) and lower in robust bones (-14%)

Improving PTH/Raloxifene Combination Osteoporosis Therapy in a Preclinical Model. Joseph Bidwell¹, Yu Shao², Selene Hernandez-Buquer³, Paul Childress⁴, Drew Brown³, Yongzheng He⁵, Marta Alvarez⁶, Feng-chun Yang⁷, Stuart Warden⁸, Matthew Allen³. ¹Indiana University School of Medicine, USA, ²Medical & Molecular Genetics, Indiana University School of Medicine, USA, ³Anatomy & Cell Biology, Indiana University School of Medicine, USA, ⁴Microbiology & Immunology, USA, ⁵Pediatrics Neonatal Basic Research, Indiana University School of Medicine, USA, ⁶Orthopaedic Surgery, Indiana University School of Medicine, USA, ⁷Biochemistry & Molecular Biology, Miller School of Medicine, University of Miami, USA, ⁸Health & Rehabilitation Science, Indiana University School of Medicine, USA

The bone-forming potency of parathyroid hormone (PTH) wanes during osteoporosis therapy. Adding an anti-catabolic with PTH to enhance anabolism has yielded mixed clinical results. Disabling the transcription factor Nmp4 enhanced PTH anabolism in mice likely by increasing the number of bone marrow (BM) osteoprogenitors and BM CD8⁺ T cells. Here we addressed whether various PTH+anti-catabolic therapies are more efficacious in osteoporotic Nmp4^{-/-} mice than wild type (WT). Mice were ovariectomized at 12wks of age. Therapies were initiated at 16wks and included PTH only (30 μ g/kg/day), the bisphosphonates alendronate (ALN) only (1 μ g/kg/day), zoledronate (ZOL) only (80 μ g/kg 1x dose), the selective estrogen receptor modulator (SERM) raloxifene (RAL) only (1mg/kg/day), PTH+ALN, PTH+RAL, PTH+ZOL and a vehicle control comprised of all the carriers. Dual energy X-ray absorptiometry was used to record total bone mineral density (BMD) throughout the experiment. At 24wks of age mice were euthanized and the cancellous and cortical bone of the distal femur and L5 vertebra were analyzed by micro-computed tomography. Fluorescence-activated cell sorting of the BM was used to profile osteoprogenitors and T cells. Expanded cultures of mesenchymal stem/progenitor cells (MSPCs) were established for *in vitro* studies. Statistical analyses used either a series of 2W ANOVAs, 1W ANOVA, or the Kruskal-Wallis ANOVA by ranks. Post hoc tests included the Tukey-Kramer HSD and the Student's t tests. PTH+RAL therapy was the most effective at augmenting PTH mono-therapy in both genotypes and disabling Nmp4 significantly improved response to PTH+RAL but had no effect on the PTH+bisphosphonate treatments. The PTH+RAL-treated Nmp4^{-/-} mice exhibited a significantly larger increase in femoral and L5 BV/TV. This therapy increased the Nmp4^{-/-} but not WT mouse % change total body BMD over PTH mono-therapy. The PTH+RAL treatment further elevated the number of BM Nmp4^{-/-} osteoprogenitors. Raloxifene enhanced mineralization of WT MSPCs but did not further augment the precocious Nmp4^{-/-} MSPC mineralization. PTH+RAL increased the percentage of WT BM CD8⁺ T cells to equal that of the already expanded Nmp4^{-/-} pool. We conclude that Nmp4 suppresses the combined actions of PTH and the SERM raloxifene on osteoprogenitors, osteoblasts, and perhaps CD8⁺ T cells but does not regulate bisphosphonate activity. Nmp4 and its associated pathways may be novel targets for adjuvant anabolic osteoporosis therapy.

Disclosures: Joseph Bidwell, Eli Lilly

while displacement to fracture was significantly reduced in both strains (-15 and -26% for A/J and B6, respectively). After accounting for differences in bone size, there was no significant effect of treatment on ultimate stress or modulus in either strain. Modulus of toughness in ZOL-treated animals was lower in both strains (-16% for A/J and -27% for B6) due in part to divergent effects on pre-yield toughness (+18% in A/J and -23% for B6). These data suggest that bones with slender and robust morphologies are differentially affected by bisphosphonates, with robust bones showing a significantly greater benefit to whole bone stiffness and strength but appearing to be more negatively affected with respect to differences in both pre-yield displacement and post-yield properties. Future work will aim to understand the tissue-level basis for differential responses of these two divergent morphologies through study of remodeling suppression in a model with intracortical remodeling.

Bortezomib inhibits *P. gingivalis* LPS-induced alveolar bone loss in mice. Youngkyun Lee*. Kyungpook National University School of Dentistry, South Korea

Healthy bone is maintained by the coordinated activities of the osteoblast-mediated bone formation and osteoclast-dependent bone resorption. Pathologic conditions such as hormonal imbalance and inflammation cause increased osteoclastogenesis resulting in the osteoporosis, rheumatoid arthritis, and periodontitis. Bortezomib is novel anti-myeloma agent that also has direct beneficial effect on bone formation. However, the role of bortezomib in osteoclastogenesis and underlying mechanisms still remain fully comprehended. In the present study, we show that bortezomib directly inhibited the receptor activator of nuclear factor κ B ligand (RANKL)- and lipopolysaccharide (LPS)-dependent osteoclast differentiation. Interestingly, the bortezomib-mediated inhibition of osteoclastogenesis was transient, since the removal of bortezomib from culture completely restored osteoclast differentiation. Bortezomib impeded the induction and nuclear localization of nuclear factor of activated T-cells, cytoplasmic 1 (NFATc1) and reduced both macrophage colony-stimulating factor (M-CSF)- and RANKL-induced ERK phosphorylation. In a mouse model of periodontitis, bortezomib prevented alveolar bone erosion induced by *P. gingivalis* LPS. These data not only suggest previously unappreciated mechanism by which bortezomib regulates bone resorption, but also propose novel applications of bortezomib beyond its use as an anti-myeloma agent.

Differential effects of OPG, alendronate and a Cathepsin K inhibitor on load adaptation in mice. Nicolas Bonnet¹, Le Duong², Serge Ferrari³. ¹University Geneva Hospital (HUG), Switzerland, ²Merck & Co, USA, ³Service des Maladies Osseuses, Hôpitaux Universitaires, Genève, Switzerland

We previously reported that osteopetrotic Cathepsin K (CatK) knock-out mice have an increased long bone adaptation to mechanical loading, suggesting an interaction between CatK inhibition and biomechanical stimulation. Here we tested whether pharmacological inhibition of CatK improves the long bone response to axial compression and how it compares to other antiresorptives. Adult male mice were treated with the CatK inhibitor L235 (30mg/kg twice a day), alendronate (ALN, 25 μ g/kg/d sc, twice a week), OPG-Fc (4mg/kg sc, twice per week) or PBS (Veh) for 3 weeks. Axial compression (12N, 2Hz, 7min) was applied to the tibia for 1 week after initiating treatment for two weeks (n=5 per group). Bone turnover markers were measured at baseline and sacrifice. BMD, microstructure and cortical strength by 3-points bending of tibia were evaluated at sacrifice.

Compared to the non-loaded site (NL), axial compression increased BMD in all treatments groups (from +19.4% to +22.2%, all p<0.05). However, loading significantly increased cortical bone volume and mineralized perimeter both at the periosteal and endosteal vs those from non-loaded (NL) tibia only in Veh (+4.5%, +43% and +15% vs NL, respectively all p<0.1) and even more prominently in L235 group (+8.5%, +72% and +109% vs NL, respectively, all p<0.05) but not in ALN or OPG-Fc groups. However, OPG-Fc maximally increase bone mass, trabecular and cortical parameters independently of loading, so that trabecular and cortical bone parameters were ultimately similar in OPG-Fc and loaded L235-treated groups. CTX and osteocalcin reflected the differential mechanism of action of the various treatments. Indeed, both markers were decreased by OPG-Fc and to a lesser extent by ALN. In contrast, during the experiment L235 treatment reduced CTX, similar to ALN, but maintained osteocalcin levels as in Veh (+24.8% and +42.8%, respectively).

In this study, while inhibiting bone resorption less than OPG-Fc, the CatK inhibitor maintained bone formation and allowed a better bone adaptation to loading. This also suggests that a certain level of load must be applied to reach the optimal skeletal strength during treatment with a CatK inhibitor. The molecular mechanisms of CatK inhibition in mediating the adaptive response of the skeleton to loading are currently under investigation.

Effect of IL-18 on mechanical loading-induced osteoclastogenesis and bone resorption solely, and in synergy with IL-12. Yumiko Ochi¹*, Hideki Kitaura², Keisuke Kimura², Masahiko Ishida², Haruki Sugisawa², Jafari Saeed², Akiko Kishikawa², Teruko Takano-Yamamoto². ¹Tohoku University, Japan, ²Division of Orthodontics & Dentofacial Orthopedics, Department of Translational Medicine, Tohoku University Graduate School of Dentistry, Japan

In mechanical loading-induced osteoclastogenesis, cellular responses are mediated by interactions between various factors such as cytokines. It has been reported that TNF- α was recognized one of the important factor for osteoclastogenesis. It has also been reported that TNF- α plays an important role in mechanical loading-induced osteoclastogenesis and bone resorption. We previously reported that the proinflammatory cytokine interleukin-18 (IL-18) inhibited TNF- α -mediates osteoclastogenesis *in vitro* and *in vivo*. However, its influence on mechanical loading-induced osteoclastogenesis and bone resorption is still unknown. We established mechanical loading-induced osteoclastogenesis in mice for exploring the mechanism underlying the mechanical loading-induced bone changes. Thus, the purpose of this study was to investigate the effect of IL-18 and combination of IL-18 and IL-12 on orthodontic tooth movement and associated root resorption in mice model. Mouse orthodontic tooth movement model was established, and investigated whether IL-18 inhibits osteoclastogenesis and bone resorption on mechanical loading. The maxillary first molars of male mice were subjected to mesial force by a Ni-Ti coil spring. IL-18 was injected locally adjacent to the first molar every other day. After 12 days of experimental tooth movement, the amounts of orthodontic tooth movement and the number of tartrate-resistant acid phosphatase (TRAP)-positive cells along the loaded alveolar bone and root surface was counted as osteoclasts and odontoclasts, respectively, in histological sections. Orthodontic tooth movement and the number of osteoclasts were significantly decreased in IL-18 treated mice. IL-18 significantly suppressed the mechanical loading-induced odontoclast formation and root resorption. Furthermore, IL-12 and IL-18 synergistically inhibited the mechanical loading-induced osteoclast formation and odontoclast formation. Our results suggested that IL-18 might be a useful adjunct for regulation of the extent of orthodontic tooth movement and control of root resorption.

Effects of alendronate and low-intensity pulsed ultrasound therapies on bone mineral density at cancellous osteotomy sites in the proximal tibia of ovariectomized rats. Chie Sato*, Naohisa Miyakoshi, Yuji Kasukawa, Hayato Kinoshita, Kentaro Ouchi, Masashi Fujii, Tetsuya Kawano, Masazumi Suzuki, Michio Hongo, Yoichi Shimada. Dept. of Orthopedic Surgery, Akita University Graduate School of Medicine, Japan

Purpose We previously reported that alendronate (ALN) increased the bone mineral density (BMD) at cancellous bone osteotomy sites. In contrast, low-intensity pulsed ultrasound (LIPUS) improved cancellous bone healing after osteotomy, but did not affect the BMD. However, the effects of ALN and/or LIPUS on the BMD at cancellous bone osteotomy sites in an osteoporotic animal model remained unclear. Thus, we aimed to evaluate the effects of ALN and/or LIPUS on the BMD at cancellous bone osteotomy sites in ovariectomized (OVX) rats.

Methods Six-month-old female Sprague-Dawley rats underwent OVX or sham surgery, and then underwent osteotomy at the right proximal tibia and tying with non-resorbing thread at seven-month. We created five groups: 1) Sham (n=15), sham operation plus treatment with ALN vehicle and sham LIPUS (SEFHS; Teijin, Japan); 2) OVX-Control (n=11), OVX plus treatment with ALN vehicle and sham LIPUS; 3) OVX-ALN (n=10), OVX plus treatment with ALN (1 μ g/kg/day) and sham LIPUS; 4) OVX-LIPUS (n=12), OVX plus treatment with ALN vehicle and LIPUS (20 min/day); and 5) OVX-Combined (n=11), OVX plus treatment with ALN and LIPUS. BMD was assessed by dual-energy x-ray absorptiometry (Hologic QDR-4500; Hologic, MA, USA) at 20 mm proximal to the cancellous osteotomy site at the right tibia after 2 and 4 weeks of treatment with ALN and/or LIPUS.

Results The BMD in the OVX-Control and OVX-LIPUS groups was not significantly lower than that in the Sham group after 2 weeks. After 4 weeks, the BMD in the OVX-Control and OVX-LIPUS groups was significantly lower (p<0.05, respectively) than that in the Sham group. ALN without LIPUS for 4 weeks, but not 2 weeks, significantly increased the BMD compared with that in the OVX-Control group (p=0.0252). Combined ALN and LIPUS for 4 weeks, but not 2 weeks, significantly increased the BMD compared with that in the OVX-Control group (p<0.01) and OVX-LIPUS group (p<0.01).

Conclusion ALN with or without LIPUS for 4 weeks, but not 2 weeks, recovered the BMD of the proximal tibia after cancellous bone osteotomy in OVX rats. However, there were no significant effects of LIPUS on BMD at the proximal tibia after osteotomy in OVX rats.

SU0159**Effects of Long-Term Odanacatib Treatment on Bone Gene Expression in Ovariectomized Adult Rhesus Monkeys: Differentiation from Alendronate.**

Eric Muise^{1*}, Maureen Pickarski², Alexei Podtelezhnikov¹, Andrey Loboda¹, Yejun Tan¹, Guanghui Hu¹, John Thompson¹, Le Duong¹.
¹Merck & Co., Inc, USA, ²Merck & Co., Inc., USA

Odanacatib (ODN) is a selective and reversible Cathepsin K (CatK) inhibitor, currently in late stage development for postmenopausal osteoporosis. We previously reported efficacy of ODN versus alendronate (ALN) on bone turnover, DXA-based BMD in ovariectomized rhesus monkeys treated for 20 months. The study consisted of 4 groups: VEH (vehicle), L-ODN (2mg/kg), H-ODN (4mg/kg) daily p.o., and ALN (15µg/kg, twice-weekly, s.c.). L-ODN and ALN doses were selected to approximate the clinical exposures of ODN 50-mg and ALN 70-mg once-weekly, respectively. Both doses of ODN and ALN effectively reduced bone resorption markers vs VEH. Conversely, ODN reduced formation markers to a significantly lesser degree than ALN. L-ODN increased lumbar spine and hip BMD to levels similar to ALN, supporting the efficacy of ODN in protection of bone loss. Here, we profiled the RNA from tibial metaphysis and diaphysis of monkeys treated with VEH, L-ODN or ALN using Affymetrix microarrays. The H-ODN group was not included in this study. L-ODN and ALN produced strikingly different effects on known bone-related genes and pathways at the transcriptional level. ALN generally reduced the expression of known osteoblast/bone formation-related genes (N=34), including TGFBR1, SPP1, and PTH1R (-1.3, -1.4, and -1.4 fold change, respectively), while ODN either increased or showed no change. Conversely, ODN treatment resulted in an increase in the expression of osteoclast-related genes (N=45), including genes involved in osteoclast differentiation (NFATC1 (1.7 fold) and TM7SF4 (2.6 fold)) or activity (CTSK, ACP5, CALCR; 1.6, 1.7, and 1.9 fold change, respectively). ALN showed either no change or reduced the expression of these same osteoclastic genes. Interestingly, ODN and ALN also differentially regulated genes participating in osteoclast-osteoblast bidirectional communications, including RANKL, SEMA4D or CTHRC1 (2.6/no change, 1.3/-1.5, and no change/-1.9 fold change for ODN/ALN, respectively). Effects on gene expression levels of these bone resorption- and formation-related genes were confirmed by RT-PCR. The molecular profiling results are consistent with the observed differential mechanisms of these two therapies on bone remodeling in monkeys as previously delineated by histomorphometry. Long-term treatment with ALN decreases bone remodeling while ODN maintains osteoclast-derived signals in mediating subsequent bone formation.

SU0160**Generation and characterization of a humanized cathepsin K mouse model.**

Maureen Pickarski^{1*}, Myung Kyun Shin², Michael Gentile², Le Duong².
¹Merck & Co., Inc., USA, ²Merck & Co., Inc, USA

Odanacatib (ODN), a selective, reversible inhibitor of human cathepsin K (CatK), is in development for treatment of osteoporosis. Human versus rodent CatK exhibit ~86% amino acid similarity and even less around the enzyme active site. Due to interspecies differences, potency of selective human CatK inhibitors is significantly reduced against the rodent enzymes. To take advantage of the range of well characterized disease models in rodent, we attempted to generate a humanized CatK mouse for direct evaluation of human CatK inhibitors. The mouse *ctsk* exon/intron region downstream of the signal peptide (aa.1-14, exon2) to the stop codon (exon8) was replaced with orthologous ~9.5kb human *ctsk* genomic region in C57Bl/6N ES cells. The Neo cassette from targeted ES cells was removed and then injected to establish the humanized *ctsk* mouse line. Wild-type (^{m/m}*ctsk*, WT), heterozygous (^{m/h}*ctsk*) and homozygous (^{h/h}*ctsk*) mice were tested for CatK mRNA levels, bone mineral density (BMD) and resorption marker (CTX). RT-PCR analysis showed only mouse or human CatK mRNA in WT or ^{h/h}*ctsk* tibia, respectively; whereas mRNA from both species was detected in ^{m/h}*ctsk*. DEXA-based BMD of total femur revealed no differences in WT (0.057±0.001 g/cm²), ^{m/h}*ctsk* (0.057±0.001 g/cm²) and ^{h/h}*ctsk* (0.058±0.001 g/cm²). Serum CTx was previously shown to be significantly higher in global CatK^{-/-} vs. WT mice. Here, CTx levels from age-matched WT, ^{h/m}*ctsk* and ^{h/h}*ctsk* animals were comparable, yet lower than that of CatK^{-/-} mice. BMD and CTx results suggested ^{h/h}*ctsk* fully replaced ^{m/m}*ctsk* gene and was sufficiently active to maintain bone mass comparably to WT level. Next, bone marrow derived osteoclasts (OC) from WT, ^{m/h}*ctsk* and ^{h/h}*ctsk* mice were cultured on bovine cortical bone slices; resorption activity was determined by CTx in the media. ^{h/h}*ctsk*-OC vigorously resorbed bone (234nM CTx), compared to OC from ^{h/m}*ctsk* (89nM) or WT (54nM). The different resorptive activities of humanized vs. murine OC are likely due to species differences of CatK in degradation of bovine collagen. Treatment with ODN inhibited ^{h/h}*ctsk*-OC resorption at a potency (IC₅₀~39nM) similar to human OC (IC₅₀~20nM), without displaying significant activity against murine OC (3µM). Taken together, the *in vivo* and *in vitro* assessments of OC resorption activity in ^{h/h}*ctsk* mice demonstrated successful development of a humanized CatK mouse line suitable for further validation by a pharmacological approach in a disease model of bone loss.

SU0161**Herbacetin inhibits osteoclast differentiation through downregulating NFATc1 signaling and suppresses bone loss in LPS-induced mouse model.**

Yunjo Soh^{1*}, Liang Li¹, Mahesh Sapkota¹, Se woong Kim².
¹School of Dentistry, Chonbuk National University, South Korea, ²School of Dentistry, Chonbuk National University, South Korea

A constant balance between osteoclast-induced bone resorption and osteoblast-induced bone formation are a dynamic process for bone remodeling. Inhibition of osteoclast differentiation in a certain extent can play a significant role in treating bone resorption-associated diseases such as osteoporosis. Herbacetin, an active flavonoid belonging to flavonoid, has various biological effects such as antioxidant, antitumor, and anti-inflammatory activities. However, the novel biological activity of Herbacetin in osteoclast differentiation still has not been studied. Therefore, we tried to reveal the effect and mechanism of Herbacetin on osteoclastogenesis in RANKL-treated RAW264.7 cells and LPS-induced mouse model. Herbacetin significantly inhibited the RANKL-induced osteoclast formation and differentiation in a concentration dependent manner. Additionally, the suppressive effect of Herbacetin resulted in the decrease of osteoclast-related genes including RANK, TRAP, cathepsin K, MMP2 and MMP-9. Herbacetin also decreased the expression of c-Fos and NFAT-c1, blocked the activation of JNK, and significantly inhibited the bone resorption activity in pit formation assay. Furthermore, the *in vivo* suppressive effect on bone loss was assessed quantitatively in a LPS-induced mouse model using micro-computational tomography and histochemical analyses. Taken together, this study identifies Herbacetin as a potent inhibitor of osteoclastogenesis and bone resorption and provides evidence for its therapeutic potential to treat diseases involving abnormal bone lysis.

SU0162**Compensatory Mechanisms in Mouse Offspring with Inherently Weak Bones Suggest a Genome-by-Environment Interaction *in utero*.**

Maria Raygorodskaya¹, Arkady Torchinsky², Yankel Gabet², Chen Shochat¹, Eugene Kobylansky², David Karasik^{1*}.
¹Faculty of medicine in the Galilee, Bar Ilan University, Israel, ²Sackler school of Medicine, Tel Aviv University, Israel

Establishment of normal structure and functioning of bones begins early in life. An exposure of embryo to different adverse environmental factors can detrimentally affect offspring's bones later in life. Our purpose was to investigate to what extent the genetic differences between mouse strains translate into variable response to teratogen 5-deoxy-2'-cytidine (5-AZA).

Two inbred strains, C3H/HeJ (C3H, with inherently stronger bones) and C57Bl/6J (C57, with weaker bones), were studied. Females were injected with diluted 5-AZA or saline (control) at day 10 of pregnancy (dpf). Five mice offspring from each strain/sex groups (C3H males and females, C57 males and females) at two ages (3- and 6-month-old) were studied. We compared left femora of treated and untreated mice within each group using micro-CT analysis and calculated the change in bone parameters between 3 and 6-month old and strain-by-environment interactions, using two-way ANOVA. We tested expression of 84 osteogenic genes in limb buds of embryos from each group at age 11 dpf.

At age 3 mo, treated C57 female offspring demonstrated decrease of cortical volumetric bone mineral density (p<0.05). Treated females from both strains demonstrated loss of cortical thickness (p<0.05). Loss of trabecular thickness was observed in treated C3H females (p<0.01). At age 6 mo, treated C3H males demonstrated loss of cortical thickness (p<0.01), had lower trabecular number and higher trabecular separation (p<0.05; Fig.1). Treated C57 males and females demonstrated increase of trabecular thickness (p<0.05; Fig.2). Furthermore, we revealed significant (p<0.05) strain-by-treatment interactions for several measurements, such as change in trabecular thickness in male groups (Fig.3).

Analysis of gene expression revealed 10 genes that differed (at least 2-fold) between control and treated samples. Two of them, *Csf2* and *Tnfa*, were upregulated in treated C57 but downregulated in treated C3H embryos.

Ultimately, this study demonstrates that the exposure to a sub-teratogenic dose of 5-AZA *in-utero* affects bone structure in young adult offspring. In 3-month-old mice, teratogenic exposure caused bone loss in both strains. At the age of 6 mo, bone loss was observed in the strain with strong bones (C3H), while, on the contrary, in the strain with weak bones (C57) there was gain (thickening of bone trabeculae) which might be an evidence of genome-by-environment interaction. Genes such as *Csf2* and *Tnfa* may be involved in this process.

Effects of Activin Receptor Type IIB Fusion Protein (ActRIIB-mFc) on Serum Biomarkers and Bone Remodeling in Osteogenesis Imperfecta Model (*oim/oim*) Mice. Young Jeong¹, Molly Hulbert², Mark Dallas², Yixia Xie², Scott Pearsall³, Sarah Dallas⁴, Charlotte Phillips⁵. ¹University of Missouri, USA, ²University of Missouri Kansas City, USA, ³Accelaron Pharma Inc, USA, ⁴University of Missouri Kansas City, USA, ⁵University of Missouri Columbia, USA

Osteogenesis imperfecta (OI) is a heritable connective tissue disorder characterized by compromised biomechanical properties of type I collagen containing tissues such as bone. The transforming growth factor- β superfamily (TGF- β) comprises diverse cytokines, including TGF- β , activins, bone morphogenic proteins (BMPs), and growth and differentiation factors (GDFs). Activin A is highly expressed in bone cells to regulate osteoblastogenesis and osteoclastogenesis, whereas GDF-8 (myostatin) regulates muscle growth and differentiation. These two cytokines control cellular processes by signaling through activin receptor type IIs. Recent studies have shown improved bone quality and increased muscle mass and force production in mature rodents treated with soluble activin receptor type IIB fusion protein [ActRIIB-Fc(RAP-031), Accelaron Pharma]. We therefore investigated whether RAP-031 would increase bone mass in the osteogenesis imperfecta mouse (*oim/oim*) model. At 2 months of age, bi-weekly injections (10mg/kg) of RAP-031 were given for 8 weeks to *oim/oim* mice and WT littermate controls. Previously, we showed that the overall body weights and hindlimb skeletal muscle weights were increased with RAP-031 treatment regardless of genotype. By μ CT analyses, female WT femora showed increases in several geometric parameters, while *oim/oim* mice femora showed a gain in cortical bone thickness and trabecular BV/TV with RAP-031 treatment. Serum levels of the bone formation biomarker, procollagen type I N-terminal propeptide, were unchanged in Wt and *oim/oim* mice with RAP-031 treatment. In contrast, levels of the bone resorption serum biomarker, C-terminal telopeptide, were increased with RAP-031 treatment in *oim/oim* mice. By histomorphometric analyses, femora from female Wt mice exhibited an increase in periosteal bone formation rate, mineral apposition rate and mineralizing surface with RAP-031 treatment. The *oim/oim* mice exhibited similar trends although they did not reach significance. Our findings suggest that systemic administration of RAP-031 in Wt mice induced gains in both muscle size and cortical and trabecular bone geometry. *Oim/oim* mice exhibited increased muscle mass and increased femoral trabecular bone geometry with RAP-031 treatment, suggesting ActRIIB receptor fusion protein may provide a new therapeutic approach to enhance bone and muscle function in osteogenesis imperfecta.

Interplay between the adaptive immune and bone system in fracture healing: Friend or foe? Claudia Schlundt*¹, Hanna Schell¹, Hans-Dieter Volk², Georg Duda¹, Katharina Schmidt-Bleek¹. ¹Julius Wolff Institute & Center for Musculoskeletal Surgery; Berlin Brandenburg Center for Regenerative Therapies, Charité-Universitätsmedizin Berlin, Germany, ²Institute for Medical Immunology; Berlin Brandenburg Center for Regenerative Therapies, Charité-Universitätsmedizin Berlin, Germany

The bone and the immune system (IS) are interdependent on each other. During bone fracture, homeostasis is disturbed. Bone fracture healing starts with a hematoma formation that is accompanied by an inflammatory reaction. This is an indispensable step for the initiation and regulation of the regenerative healing process. T cells seem to play a key role in regulating the healing process by determining the local cytokine milieu in the fractured area. In our well established mouse osteotomy model, we could already show that a specific depletion of CD8+ T cells leads to a better healing outcome compared to an untreated wild type (WT) group (higher BV/TV). CD4+ CD25+ regulatory T cells (Tregs) are another promising candidate playing a crucial role in bone fracture healing. In studies with sheep, we already observed a higher amount of Tregs in an osteotomy hematoma compared to a soft tissue hematoma. We hypothesize that Tregs have a positive modulating effect on the bone fracture healing process as well as outcome.

To evaluate the impact of Tregs in fracture healing, freshly isolated murine Tregs were adoptively transferred prior to surgery in our mouse osteotomy model (C57BL/6). Animals with different immune competence were compared: SPF (specific pathogen free; less activation of the IS) (Treg+ SPF) and semi sterile housing (activation of the IS) (Treg+). An osteotomy was performed in the left femur after stabilization by an external fixator. By μ CT analysis, the healing outcome was analyzed 21d post-surgery in comparison to an untreated WT group. In the Treg+ animals, half of the mice healed significantly better (BV: $p=0.01$; TV: $p=0.01$) compared to the control mice. However, the other half showed a significantly poorer healing outcome (BV: $p=0.01$; TV: $p=0.01$) in comparison to the WT. In contrast, in the Treg+ SPF mice, all animals had a higher TV ($p=0.065$) as well as BV ($p=0.015$) with regard to the WT group. The consistent healing outcome in the Treg+ SPF mice confirmed our assumption of the partially negative impact of the adaptive IS in fracture healing. Semi sterile housing conditions lead to a higher activation of the IS. The controversial healing outcome in the Treg+ animals clearly shows the impact of the individual immune status of an animal in immunological research approaches. This brings our model closer to the clinical situation and shows the importance of evaluating the individual status of the patient's immune system prior to immunotherapy.

Live imaging of osteoblast-osteoclast coupling in a medaka fish model for osteoporosis. Christoph Winkler*¹, Tingsheng Yu¹, Manish Dasrani¹, Sudha Sundaram¹, Wen Hui Tan¹, Anita Buettner¹, Ann Huvssseune², Paul Eckhard Witten². ¹National University of Singapore, Singapore, ²Ghent University, Belgium

Small laboratory fish, such as zebrafish and medaka, have become powerful vertebrate models for biomedical research and to model human diseases. Bone homeostasis in humans and fish requires the controlled activity of bone forming osteoblasts and bone resorbing osteoclasts. Interfering with the concerted interplay between bone cell types leads to bone diseases, such as osteoporosis. In order to generate an animal model for osteoporosis that is suitable for live imaging and drug screening, we produced transgenic medaka fish that allow the ectopic formation of osteoclasts, as well as conditional ablation of osteoblasts. Using reporter lines, we are able to follow the behaviour of osteoblasts and osteoclasts at various differentiation stages during bone resorption and repair in vivo in living specimen. We show that inducible expression of receptor activator of nuclear factor kappa-B ligand (RANKL) in transgenic medaka fish results in ectopic osteoclast formation, which leads to severe osteoporosis-like phenotypes. Interestingly, the induced osteoporotic lesions stimulate recruitment of osteoblast progenitors that accumulate at the lesion sites and contribute to bone repair. In this medaka model, osteoclast activity can be blocked by treatment with Etidronate and Alendronate, two bisphosphonates commonly used in human osteoporosis therapy. Both drugs efficiently ameliorate induced skeletal defects by blocking bone resorption and permitting bone repair by recruited osteoblast progenitors. We developed protocols to isolate distinct bone cell populations from medaka larvae during bone degeneration and repair by fluorescence activated cell sorting (FACS). Transcriptome sequencing was performed to identify novel molecular pathways implicated in recruitment of osteoblast progenitors to osteoporotic lesion sites. This project is supported by funds from the Singapore Ministry of Education (MOE2013-T2-2-126).

Seasonality in Bone Mineralization of Auditory Ossicles and Long Bones in the Primate *Macaca fuscata*. Makoto Morikawa¹, Porrawee Pomchote², Tadashi Sankai³, Yuzuru Hamada², Koichi Matsuo*¹. ¹Keio University School of Medicine, Japan, ²Primate Research Institute, Kyoto University, Japan, ³National Institute of Biomedical Innovation, Japan

Bones of adult mammals undergo continuous change due to dynamic bone remodeling and secondary mineralization processes. In humans, bone mass decreases with sex hormone levels, while mineralization increases with aging. However, seasonal variations in non-human primate bones are incompletely characterized. To address these activities, we analyzed bones in Japanese macaques (*Macaca fuscata*), primates exhibiting strong seasonality in breeding behavior. We first isolated the largest and smallest bones, femur and auditory ossicles, respectively, from dried specimens of 52 male monkeys that had died over the past 30 years, assuming that specimens reflected bone mass and mineralization status at time of death. We then analyzed bone volume and tissue mineral density (TMD, mg/cm³) using micro-CT. We also measured TMD of distal radii of 14 living macaques, as well as serum testosterone levels of 8 living monkeys in both breeding (autumn/spring) and non-breeding (spring/autumn) seasons. Intriguingly, average rates of change in radial trabecular TMD (Δ TMD, mg/cm³/day) as well as testosterone levels (ng/dl/day), increased to the maximum positive value at the mid-breeding season, and decreased to the maximum negative value at mid-non-breeding season. TMD seasonality was further confirmed by analysis of dried femur and malleus specimens. Such seasonal changes may counteract yearly effects of aging on bone in non-human primates.

The impact of reducing osteal macrophages and their efferocytotic function on bone turnover and bone mass. Benjamin Sinder*¹, Amy Koh¹, Megan Michalski¹, Lorenz Hofbauer², Hernan Roca¹, Laurie McCauley¹. ¹University of Michigan, USA, ²Technische Universität Dresden, Germany

Osteal macrophages are critical cells that support bone mass and bone healing. An important macrophage function is efferocytosis (phagocytosis of apoptotic cells), a process critical for wound healing and associated with the production of anti-inflammatory factors, Wnts, and chemoattractants in non-skeletal tissues. Trabectedin is an anti-cancer treatment approved in Europe for soft-tissue sarcomas that also reduces mononuclear phagocytes and tumor-associated macrophages. The purpose of this study was to use trabectedin to examine the role of osteal macrophages, and their efferocytosis function, on bone. Two trabectedin regimes included short-(1wk) and long-(6wk) term treatments followed by microCT, histology, serum, complete blood counts, bone marrow flow cytometry, RT-PCR, and efferocytosis outcomes. The initial cellular response was assessed in 16wk old male C57/B6 mice administered trabectedin (0.15mg/kg) or vehicle (veh) for 1wk, n=8/group. Flow cytometric analysis of bone marrow confirmed trabectedin altered the macrophage and mononuclear phagocytic populations, with reduced M1 F4/80⁺CD86⁺ (-33%), M2 F4/80⁺CD206⁺ (-19%), and CD68⁺ (-39%) cells. The shift in macrophages by trabectedin corresponded with reduced serum P1NP (-27%), a marker of bone formation, and TRAcP5b (-38%), a marker of bone resorption. The whole bone phenotype was assessed in a separate cohort of mice administered trabectedin (0.15mg/kg, bi-weekly for 6wks) or veh, n=11/group. Trabectedin significantly reduced trabecular BV/TV (-56%) in the tibia, evidenced with reduced trabecular number (-38%). To examine functional changes in efferocytosis with trabectedin, fresh bone marrow cells from mice treated for 1wk were co-cultured with FITC⁺ carboxylated apoptotic-mimicry beads. Trabectedin significantly decreased F4/80⁺ macrophages (-28%) that were engulfing, or attached to, FITC⁺ beads, indicating reduced efferocytotic capability. These data suggest that trabectedin effects on bone are due to reductions in the macrophage population as well as their individual efferocytotic capacity. In conclusion, trabectedin significantly inhibits mononuclear phagocytes and macrophages, decreases efferocytosis, and reduces bone turnover and bone mass.

Active vitamin D possesses beneficial effects on the interaction between muscle and bone. Ippei Kanazawa*¹, Ken-ichiro Tanaka¹, Toru Yamaguchi¹, Shozo Yano¹, Hiroshi Kai², Toshitsugu Sugimoto¹. ¹Shimane University Faculty of Medicine, Japan, ²Kinki University Faculty of Medicine, Japan

Background and aims: Vitamin D deficiency and advanced glycation end products (AGEs) are involved in the pathogenesis of osteoporosis and sarcopenia. However, the effects of vitamin Ds and AGEs on myogenesis and the interaction between muscle and bone remains still unclear. We previously showed that osteoglycin (OGN) is secreted from myoblasts and stimulates osteoblastic differentiation, suggesting that it plays important roles in the interaction between muscle and bone. The aim of this study is thus to examine the effects of vitamin Ds and AGEs on myoblastic

differentiation of C2C12 cells and osteoblastic differentiation through OGN expression. Materials and Methods: Mouse myoblastic C2C12 cells (ATCC) were used. AGE2 and AGE3 were prepared by incubating 50 mg/mL BSA with 0.1 M DL-glyceraldehyde and 0.1 M glycolaldehyde, respectively, at 37 °C for 7 days. After reached cell confluent, C2C12 cells were incubated with or without 1,25D for 2 days. After that, the cells were washed and incubated in DMEM without FBS and 1,25D for 24 hours. Then, the medium was collected. Results: 1,25-dihydroxyvitamin D3 (1,25D) induced the expression of MyoD, myogenin and OGN, and these effects were abolished by vitamin D receptor (VDR) suppression by siRNA in C2C12 cells. Moreover, conditioned medium from 1,25D-pretreated C2C12 cells stimulated the expression of type I collagen and alkaline phosphatase in osteoblastic MC3T3-E1 cells, compared to control medium from 1,25D-untreated C2C12 cells. In contrast, conditioned medium from VDR-suppressed and 1,25D-pretreated C2C12 cells showed no effects. Although AGE2 and AGE3 suppressed the expression of MyoD, myogenin and OGN, 1,25D blunted the AGEs' effects. Conclusion: These findings showed for the first time that active vitamin D plays important roles in myogenesis and muscle-induced osteoblastogenesis through OGN expression. Active vitamin D treatment may rescue the AGEs-induced sarcopenia as well as -suppressed osteoblastic differentiation via OGN expression in myoblasts.

FGF9 is highly expressed in an osteocyte-like "mini-bone" cell line and inhibits C2C12 myogenesis via overexpression of myostatin. Jian Huang*, Jeanha Choi, David Robbles, Seth Evans, Lora McCormick, Sarah Dallas, Marco Brotto. University of Missouri Kansas city, USA

We previously reported that PGE₂ is a secreted factor from osteocytes that significantly accelerates myogenesis and Ca²⁺ release from the sarcoplasmic reticulum of muscle cells. We recently communicated that another osteocyte factor, Wnt3a, also exerts similar effects on myogenesis. After performing a qPCR gene array, we found that FGF9 was upregulated in a cell line, OmGFP66, which differentiates in vitro to form "mini-bone" structures containing embedded osteocytes within mineralized lacunae. FGF9 is strongly expressed in neurons, and has roles in regulating embryonic development, cell proliferation, differentiation, and migration. To investigate the potential effects of FGF9 as a bone to muscle signaling factor, C2C12 myoblasts were treated with 2, 10, and 50ng/ml FGF9 recombinant protein. Myogenesis was monitored by myosin heavy chain and myonuclei staining at day 3 of differentiation. The control Fusion Index was 47.6% ± 2.6 compared to 38.2 ± 4.8 (*p* > 0.05) for the 2ng/ml; 34.6% ± 6.99 for 10ng/ml (*p* < 0.05), and 17.0% ± 2.1 for 50ng/ml *p* < 0.0001 (*n*=3). These results suggest that FGF9 may work as an inhibitory signaling factor from bone to muscle. To study molecular mechanisms underlying the inhibitory effects of FGF9 on C2C12 differentiation, the expression of myogenic markers (*MyoD*, *MyoG*, *MHC* and *Myostatin*) were analyzed by qRT-PCR. No significant changes in *MyoD* expression were found in FGF9 treated groups compared to controls. In the 2ng/ml FGF9 group, there was no significant change in the expression of *MyoG*, *MHC* and *Myostatin*. In the 10ng/ml group there was a significant 29.1% decrease in expression of *MHC*. In the 50ng/ml group, *MHC* expression was decreased significantly by 58%. Also, in 10ng/ml and 50ng/ml FGF9 treated C2C12 cells, *MyoG* expression was decreased significantly by 21.1% and 20.5%, respectively. Interestingly, expression of the myogenic inhibitor *myostatin* was increased significantly in 10ng/ml and 50ng/ml FGF9 treated C2C12 cells by 135.3% and 185.8%, respectively. These results suggest that FGF9 inhibition of C2C12 cell differentiation may be mediated by the overexpression of *myostatin*. These results could potentially imply that bone cells function as major regulators of muscle homeostasis by secreting both stimulatory and inhibitory factors for the fine-tuning of myogenesis. This could have important applications to a range of musculoskeletal pathological conditions, including the twin diseases of aging osteo-sarcopenia.

Acute Marrow Inflammation Induced by Muscle Paralysis Does Not Directly Mediate Rapid Bone Resorption. Brandon Ausk*, Leah Worton, Ronald Kwon, Sundar Srinivasan, Edith Gardiner, Steven Bain, Ted Gross. University of Washington, USA

Transient muscle paralysis induced by a single injection of Botulinum Toxin A (BTxA) precipitates extremely rapid and predominantly focal bone loss in adjacent bones. Acute trabecular bone resorption (beginning within 3 d and completed by 12 d post-paralysis) arises via RANKL mediated osteoclastic resorption. At 3 d post-paralysis, bone marrow gene expression reflects the presence of an inflammatory response with TNF-alpha upregulated 4-fold vs naïve mice. Cell sorting data from proximal tibia bone marrow supports this thesis as acute CD4+ T-cell infiltration occurs within 24 hr of calf paralysis. We therefore hypothesized that inhibition of the marrow inflammatory response would mitigate BTxA induced bone resorption. We tested this thesis by assessing acute bone loss following calf paralysis in three mouse KO models of inflammatory signaling deficiency: 1) TNF-alpha (germ deletion of TNF-alpha), 2) Toll-Like Receptors (MyD88 KO), and 3) T-Cells (TCR δ KO). A fourth group of C57 mice served as WT controls (*n*=6 to 8/grp). All mice received high-resolution μ CT imaging of the proximal tibia metaphysis on d 0, d 5, and d 12.

Outcomes measures included standard trabecular morphology analyses, normalized as percent change from baseline (i.e., d 0) for each mouse to account for any baseline differences in trabecular morphology across mice strains. One-way ANOVAs were performed on d 5 and d 12 datasets to determine the effect of each inflammatory deficiency upon on BTxA induced osteoclastogenesis. Consistent with historical data, muscle paralysis induced significant trabecular degeneration in WT mice by d.5 (39.2 ± 1.8%) with loss reaching (76.8 ± 2.5%) at d 12. When compared to WT controls, the same temporal osteoclastogenic response following muscle paralysis was observed in the TNF-alpha KO (d.5: 30.5 ± 4.6%, *p*>0.59; d.12: 75.7 ± 1.9%, *p*=1.00), MyD88 KO (d.5: 45.6 ± 3.6%; d.12: 77.3 ± 0.8%, both *p*=1.00) and TCR δ KO mice (d.5: 39.8 ± 2.8% on d.5, d.12: 78.9 ± 1.5%, both *p*=1.00). We conclude that interruption of three critical aspects of inflammatory signaling does not alter the rate or extent of osteoclastic trabecular resorption induced by transient muscle paralysis. However, these data do not preclude the possibility that an acute neurogenic inflammatory event could induce osteoclastogenesis upstream of bone marrow inflammation.

Exogenous IGF-1 Fails to Increase Muscle Fiber Cross-Sectional Area After Severe Burns. Lucas Sansevero¹, Amina El Ayadi², Yi-Xian Qin¹, Celeste C Finnerty³, Minyi Hu⁴, Sachin Hegde³, Anesh Prasai⁵, Laura Porro³, Noe Rodriguez⁶, David Herndon³, Gordon Klein^{*7}. ¹Department of Bioengineering, State University of New York at Stony Brook, USA, ²Shriners Hospitals for Children & University of Texas Medical Branch, USA, ³Shriners Hospital for Children & University of Texas Medical Branch, USA, ⁴Department of Bioengineering, State University of New York at Stony Brook, USA, ⁵Shriners Hospitals for Children, Galveston Texas, USA, ⁶Shriners Hospital for Children & University of Texas Medical Branch, USA, ⁷University of Texas Medical Branch, USA

Severe burn injury is associated with muscle wasting and negative nitrogen balance. During disuse muscle atrophy ectopic expression of IGF-1 within the gastrocnemius attenuates the reduction of muscle fiber cross-sectional area, muscle mass and density (Alzghoul et al FASEB J 2004) while overexpression of human IGF-1 in mouse muscle is associated with an increase in muscle mass (Banu et al Calcif Tissue Int 2003). The aim of our study was to determine whether continuous infusion of IGF-1 in rats following severe burn could increase muscle cross-sectional area. To that end we continuously infused IGF-1, 3.8 mg/kg/d via an implanted Alzet minipump in rats following a 60% surface area scald burn under anesthesia and evaluated gastrocnemius cross-sectional area in microns squared following sacrifice at 1 (n=6) or 4 (n=7) weeks post-burn compared to specimens from identically burned rats with no intervention (n=7) and normal ratw undergoing sham burn (n=8 at 1 wk, n=7 at 4 wk). Specimens of muscle were subject to cryosection followed by hematoxylin and eosin staining and analysis of muscle fiber cross-sectional area using Photoshop and Image J. Results indicated that one-way ANOVA failed to demonstrate a significant rise in muscle fiber cross-sectional area with IGF-1 infusion (*p*=0.175), an analysis confirmed by use of unpaired *t* tests. Possible explanations include loss of IGF binding proteins to attach IGF-1 to its receptor in muscle, or to down-regulation of the IGF-1 receptor itself due to the burn injury, or to a dose of IGF-1 that was inadequate for the extent of catabolic injury resulting from the burn.

Investigation for the Protecting Effects and Molecular Mechanisms of Exercise on Glucosamine-induced Insulin Resistance in Ovariectomized Rats. Chung-Hwan Chen^{*1}, Lin Kang², Shih-Tse Chen³, Tsang-Hai Huang⁴. ¹Kaohsiung Medical University Hospital & Kaohsiung Medical University, Taiwan, ²National Cheng Kung University Hospital, Taiwan, ³National Taiwan University Hospital Hsin-Chu Branch, Taiwan, ⁴National Cheng-Kung University, Taiwan

Objective:

Glucosamine (GlcN), which had been reported to cause insulin resistance (IR), is a popular nutritional supplement used to treat osteoarthritis in menopausal women, who are exposed to the risk of type 2 diabetes mellitus (T2DM) and metabolic syndrome due to ovarian hormone deficiency. We previously found female rats do not develop IR upon GlcN treatment except after ovariectomy (OVX) and the underlying mechanisms are relevant to decreasing the expression of glucose transport protein subtype 4 (GLUT4) in skeletal muscle and increasing the size of pancreatic islets. Herein, we used ovariectomized (OVX) rats and add exercise regimen to investigate whether exercise can reverse GlcN-induced IR.

Materials and methods:

The female rats were divided into 5 groups: (1) Sham-operated group (SHAM), (2) SHAM with 750 mg/kg/day GlcN intraperitoneally (i.p.) injected for 14 days, (3) OVX group, (4) OVX with 750 mg/kg/day GlcN i.p. injected for 14 days, (5) OVX with GlcN 750 mg/kg/day intraperitoneally injected for 14 days and then receiving exercise regimen (running program) for 8 weeks. Intraperitoneal glucose tolerance test

(IPGTT) was performed to measure plasma glucose and insulin, and calculate clinical homeostasis model assessment-insulin resistance (HOMA-IR) and glucose-insulin index.

Results and conclusions

Fasting plasma glucose increased in the OVX + GlcN group, and fasting plasma insulin and HOMA-IR were elevated more significantly in this group. After receiving exercise regimen (running program) for 8 weeks, no increase in fasting plasma glucose, insulin, and HOMA-IR were found. In IPGTT, plasma glucose, plasma insulin, HOMA-IR, and glucose-insulin index were significantly elevated only in the OVX with GlcN group after IP glucose injection, implying that IR was induced by GlcN only in female rats without the protection of ovarian hormone. However, the elevated plasma glucose, plasma insulin, HOMA-IR, and glucose-insulin index disappeared after exercise regimen (running program) for 8 weeks, implying the GlcN-induced IR in OVX rats could be reversed by exercise.

The results demonstrate that female rats do not develop IR upon GlcN treatment except after ovariectomy. Those who take GlcN after menopause or bilateral oophorectomy should watch their blood glucose level closely, especially after meals. Exercise had the protecting effect for GlcN-induced IR in female rats and investigation for the underlying mechanisms is ongoing in our present studies.

Vestibular System Is Involved in Changes of Muscle and Bone Induced by Hypergravity in Mice. Naoyuki Kawao*¹, Hironobu Morita², Koji Obata², Yukinori Tamura¹, Katsumi Okumoto³, Hiroshi Kaij¹. ¹Kinki University Faculty of Medicine, Japan, ²Gifu University Graduate School of Medicine, Japan, ³Life Science Research Institute, Kinki University, Japan

Linkage between muscle and bone has recently noted. Gravity change in a space flight concurrently affects muscle and bone with changes in vestibular signals and sympathetic outflow. However, the roles of vestibular signals in the gravity-dependent muscle and bone changes remain unknown. We therefore investigated the involvement of vestibular system in hypergravity-induced muscle and bone changes in mice. Bilateral inner vestibules were surgically lesioned (VL) in male C57/BL6 mice, 6 weeks old. After a recovery period for 14 days, the mice were kept in 1 g or 3 g environment for 4 weeks by using a centrifuge. The tibial muscle and bone mass were analyzed by quantitative computed tomography (QCT) and evaluated by adjusting with body weight, since hypergravity or VL itself significantly reduced body weight. QCT analysis revealed that VL blunted the increases in tibial muscle mass and trabecular bone mass induced by hypergravity, although hypergravity did not affect cortical bone and fat mass. Histological analysis showed that VL antagonized the increase in cross sectional area of muscle fiber induced by hypergravity in soleus, but not in gastrocnemius. Although hypergravity did not affect number of Pax7-positive cells (muscle satellite cells) and mRNA levels of Pax7, atrogene-1 and MuRF1 in soleus, VL suppressed mRNA levels of myogenic genes (MyoD, Myf6 and myogenin) enhanced by hypergravity, suggesting that vestibular system contributes to the hypergravity-induced muscle hypertrophy partly through an enhancement of myogenic differentiation. As for muscle-derived humoral factor affecting bone, VL blunted the increase in the levels of FAM5C and follistatin, a myostatin inhibitor, enhanced by hypergravity in soleus, although hypergravity did not affect the mRNA levels of myostatin, IGF-1, FGF2, TGF- β , osteoglycin and irisin. On the other hand, propranolol, a blocker of beta-adrenergic receptors, antagonized the increases in muscle and bone mass induced by hypergravity, suggesting the involvement of sympathetic tones in the effects of hypergravity on muscle and bone. In conclusion, the present study indicates that gravity change affects muscle and trabecular bone through vestibular signals and the subsequent sympathetic outflow in mice. The control of vestibular system might be important for the management of osteopenia and muscle wasting in space flight and bed rest state.

ZIP4 Silencing Improves Bone Loss in Pancreatic Cancer. Qiang Zhang¹, Xiaotian Sun², Jingxuan Yang³, Hao Ding¹, Catherine Ambros⁴, Xiaohong Bi*⁵, Min Li³. ¹University of Texas Health Science Center, USA, ²University of Oklahoma Health Sciences Center, USA, ³The University of Oklahoma Health Sciences Center, USA, ⁴University of Texas Health Science Center at Houston, USA, ⁵University of Texas Health Science Center at Houston, USA

Pancreatic cancer (PC) patients usually suffer severe nutrition deficiency, muscle wasting, and loss of bone mass. While muscle wasting has been extensively investigated, bone loss and its related molecular mechanism in PC is poorly understood. Effective prevention and treatment of bone loss in these patients can improve their life quality, reduce both direct and indirect medical costs, and enhance the therapeutic efficacy of the primary disease. We have previously found that silencing of a zinc transporter ZIP4 prolongs the survival and reduces the severity of PC-associated cachexia in vivo. However, the role of ZIP4 in the pancreatic cancer-related bone loss remains unknown. In this study we investigated the effect of ZIP4

knockdown on the bone structure, composition and mechanical properties of femurs in an orthotopic xenograft mouse model using microCT and Raman spectroscopic imaging and whole bone testing. Our data showed silencing ZIP4 restored the bone tissue mineral density values to the control group levels which were significantly increased compared to the untreated PC animals. Bone mineral crystallinity significantly decreased and collagen content significantly increased with the treatment of ZIP4 knockdown, indicating the presence of smaller or less crystalline mineral crystallites and elevated new bone formation in the treatment group. Significant differences were observed among groups in elastic and plastic energy, plastic displacement, elastic and plastic toughness, and plastic strain. The improved mechanical properties in the ZIP4 silencing group suggest that the bones from these animals demonstrated higher ductility and could absorb more energy before failure when compared to the untreated PC animals. Western blot showed that RANKL in control PC cells was higher than that in ZIP4 knockdown cells under zinc-deficient environment. Coculture in the medium from ZIP4 knockdown cells increased the average osteoclast count per high-power field and upregulated the RANK and TRAP mRNA levels in differentiated murine macrophages, suggesting that RANK/RANKL pathway may be involved in the ZIP4 mediated bone loss seen in PC patients. These combined results further support that the participation of ZIP4 in the development and progression of pancreatic cancer may be an important event, and also verify its potential significance as a therapeutic target for treating patients with such devastating disease and cancer related disorders.

Clinical Features and HLA-B loci of Japanese Patients with Ankylosing Spondylitis (2nd report). Tsuyoshi Kobashigawa*, Yuki Nanke, Hisashi Yamanaka, Shigeru Kotake. Tokyo Women's Medical University, Japan

Background: The pathogenesis of AS remains to be elucidated. Despite the strong association between HLA-B27 and susceptibility to AS, the exact pathogenic role of HLA-B27 in AS and other spondyloarthropathies has yet to be determined [1].

Objective: To elucidate the clinical features of Japanese AS patients visited our clinic and the relationships between AS and HLA-B loci. Our hypothesis is other HLA-B loci except for B27 related to AS.

Methods: Sixty-three AS patients visited our clinic in 2 years (2007 to 2008). We enrolled 32 AS patients (male: 27, mean age (SD): 37.4 (13.0) year-old) whose HLA were measured. HLA data of the registered donors in the Japanese unrelated bone marrow donor registry [2] were used as a healthy control group data. We analyzed the relationships between AS and HLA using Chi square test.

Results: In the present study, the frequency of patients fulfilled the ESSG [3] criteria was 31 (96.9%) patients and 1 male patient unfulfilled without experience of inflammatory spinal pain (ISP) and synovitis, but he had some histories of alternate buttock pain (ABP), enthesopathy and sacroiliitis. The frequency of symptoms of ESSG criteria were as follows; ISP: 5 patients (15.6%), synovitis: 22 (68.8%), positive family history: 3 (9.4%), psoriasis: 3 (9.4%), IBD: 1 (9.4%), enthesopathy: 12 (37.5%), ABP: 8 (25.0%) and sacroiliitis: 22 (68.8%), and that of definite AS patients fulfilled the modified New York criteria (MNYC) [4] was 21 (65.6%). On the other hand, 11 (34.4%) probable AS with radiographs finding of sacroiliitis were without clinical symptoms. The frequency of MNYC's symptoms were as follows; low back pain: 13 (96.9%), limitation of lumbar spine: 12 (40.6%), chest expansion: 12 (37.5%), and sacroiliitis: 22 (68.8%). Moreover, we detected 14 HLA-B loci: HLA-B27 ($p=2.3 \times 10^{-317}$) was strongly related to development of AS, and HLA-B52 ($p=0.017$) was possibly related to that.

Conclusion: The present findings supported our hypotheses because there was a tendency that HLA-B52, except for B27, showed a relation to AS.

Epiphyseal Bone, Subchondral Bone Plate and Epiphyseal Trabecular Bone in Surgically and Chemically Induced Rat Models of Osteoarthritis. Jukka Morko*, ZhiQi Peng, Jukka Vääräniemi, Katja M Fagerlund, Jukka P Rissanen, Jenni Bernoulli, Jussi M Halleen. Pharmatest Services Ltd, Finland

Several experimental animal models have been developed for human osteoarthritis (OA) and used to study the preclinical efficacy of disease and symptom modifying OA drug candidates. Recently, the histopathology initiative of Osteoarthritis Research Society International (OARSI) has presented recommendations for histological OA assessment. These recommendations focus on articular cartilage, synovium, joint capsule, and growth plate. When studying treatment effects on bone, the histological OA assessment should be completed with the analysis of epiphyseal bone, subchondral bone plate and epiphyseal trabecular bone. In this study, we performed a systemic characterization of these bone compartments together with knee joint discomfort, pain and degenerative changes in four rat OA models. Unilateral OA was induced in knee joints of male Lewis rats at 3 months of age using the following OA models: intra-articular moniodoacetate (MIA, 1 mg), medial meniscal tear and medial collateral ligament transection (MMT+MCLT), anterior cruciate ligament transection and partial medial meniscectomy (ACLT+pMMx), and ACLT. Body

weight, static weight bearing and static secondary mechanical allodynia were followed during the in-life phase of the study. Knee joints were harvested at the end of the in-life phase, and histological OA assessment was performed following the OARSI recommendations and by analyzing the amount of epiphyseal, subchondral and trabecular bone in medial tibial plateau. Knee joint discomfort was observed in operated hind limbs during the first week, and knee joint pain in operated and MIA-injected hind limbs during the first week and at the end of the in-life phase. Knee joint pain was associated with cartilage degeneration down to intermediate layer and mild synovial inflammation in the rat MIA model, with marked cartilage loss down to tidemark, large osteophytes and synovial inflammation in the rat MMT+MCLT and ACLT+pMMx models, and with cartilage loss down to deep layer, osteophytes and mild synovial inflammation in the rat ACLT model. These OA changes were observed together with decreased amount of epiphyseal and/or subchondral bone in the rat MIA and ACLT models and with increased amount of epiphyseal and subchondral bone in the rat MMT+MCLT model. These results can be used to design studies for testing the preclinical efficacy of OA drug candidates on bone in association with articular cartilage, synovium and knee joint discomfort and pain.

HIGH PREVALENCE OF VARIOUS UPPER LIMB MUSCULOSKELETAL DISORDERS IN KOREAN ORCHARDISTS. Sang-Hyon Kim^{*1}, Sang-Il Lee², Sang-Heon Lee³, Young-Il Seo⁴, Jinseok Kim⁵, Jung Soo Song⁶. ¹Div. of Rheumatology, South Korea, ²Division of Rheumatology, Department of Internal Medicine, ²Department of Preventive Medicine, Gyeongsang National University School of Medicine, ³Clinical Research Institute, Gyeongsang National University Hospital, Jinju, Republic of Korea, South Korea, ³Division of Rheumatology, Konkuk University School of Medicine, Seoul, Republic of Korea, South Korea, ⁴Division of Rheumatology, Hallym University Medical Center, Ahnyang, Republic of Korea, South Korea, ⁵Department of Internal Medicine, Jeju National University Hospital, Jeju, Republic of Korea, South Korea, ⁶Division of Rheumatology, Department of Internal Medicine, Chung-Ang University Medical school, Seoul, Republic of Korea, South Korea

Background: Orchardists are expected to show high prevalence of upper limb musculoskeletal disorders (MSDs) due to their heavy works and working postures. However, there are no systematic studies relating upper limb MSDs in Korean orchardists. **Objectives:** To evaluate the prevalence and characteristics of upper limb MSDs among orchardists in rural areas of Korea. **Methods:** The study was carried out from June 2013 to May 2014 in a tertiary medical center. The physical examinations of upper extremities were performed by rheumatologists, orthopedists, and rehabilitation medicine specialists. The plain radiographs of shoulder, elbow, and hand, nerve conduction examination of upper extremities, and MRI of both shoulder were taken. The Disabilities of the Arm, Shoulder, and Hand (DASH) questionnaire was used to assess symptoms and function of upper extremities. **Results:** Five hundred and fifty orchardists were included. Participants comprised of 49.5% female and 50.5% male with mean age of 59.5 ± 8.1 years. The mean farming duration was 31.3 ± 13.2 years. A total of 34 different types of upper limb MSDs were detected. The most frequent disorder was myofascial pain syndrome (80.5%) followed by rotator cuff syndrome (58.9%), hand osteoarthritis (58.0%), carpal tunnel syndrome (42.9%), and lateral epicondylitis (39.5%). Prevalence of any form of MSD was 98.5% and of three and more of MSDs was 77.3%. Participants with longer duration of farming had higher numbers of MSDs. Almost part of pruning and harvesting postures in orchard farming were loaded works for musculoskeletal systems. Total DASH score was relatively high (14.9 ± 14.4). **Conclusions:** Almost orchardists have upper limb MSDs. Our results suggest the need to implement interventions in orchardists to prevent MSDs.

Assessment of Notch Activation Status in Bone Cells in Inflammatory Arthritis using Hes1-GFP Reporter Mice. Wen Sun^{*1}, Hengwei Zhang¹, Xing Li¹, Brendan Boyce¹, Matthew Hilton², Lianping Xing¹. ¹University of Rochester Medical Center, USA, ²Duke University School of Medicine, USA

Notch signaling plays a critical role in maintenance of bone homeostasis in part via HES-mediated suppression of mesenchymal stem cell (MSC) differentiation toward the osteoblast lineage. Notch is activated in MSCs in TNF transgenic (TNF-Tg) mice, a model of chronic inflammatory arthritis, and thus inhibits osteoblast differentiation. However, the distribution of cells with active Notch signaling in bone, bone marrow (BM) and synovium, and changes in expression levels under normal and arthritic conditions have not been reported. Here, we used Hes1-GFP reporter and Hes1-GFP/TNF-Tg mice and found that Hes1-GFP+ cells, including MSCs, hematopoietic and endothelial cells, have a heterogeneous distribution in normal BM. CD45-/GFP+ cells expressed high levels of mesenchymal surface markers and formed CFU-F and CFU-

ALP colonies. Expansion of CFU-F colonies was associated with a rapid increase in Hes1-GFP+ cells and GFP intensity. In Hes1-GFP/TNF-Tg mice with established arthritis, the numbers of Hes1-GFP+ cells, including CD45-/Hes1-GFP+ MSC-enriched cells and CD45+/CD11b+/Hes1-GFP+ myeloid precursors were increased significantly in BM. Hes1-GFP+ cells that were osteocalcin-, some of which expressed the endothelial cell marker CD31, localized mainly near the endosteal surface and small blood vessels. Compared to the moderate increase within the BM, the numbers of GFP+ cells in synovium were markedly increased (fold over Hes1-GFP mice: 1.5±0.4 in BM vs. 13.5±1.7 in synovium). About 70% of synovial GFP+ cells were F4/80+ macrophages, 15% were B220+ B cells, and 5% were CD31+ endothelial cells. Further analysis indicated that most of F4/80+/GFP+ macrophages expressed the M1 macrophage marker iNOS, but not the M2 marker CD206+ (74.8±5.9% M1 vs. 25.2±5.9% M2). Treatment of BM macrophages from Hes1-GFP mice with the M1 inducers, LPS or TNF, promoted GFP+/iNOS+ M1 macrophage formation, while the M2 inducer, IL4, promoted CD206+ M2 macrophage formation, but these cells were GFP-. Thus, the majority of cells with active Notch signaling in the inflamed synovium are M1 macrophages. Currently, we are in the process of treating Hes1-GFP/TNF-Tg mice with Thapsigargin, a Notch inhibitor and M2 macrophage inducer, to determine its effect on joint inflammation, Notch activation and macrophage polarization. Hes1-GFP mice represent a useful tool for assessment of the distribution and activation status of Notch in bone cells using *in vivo*, *ex vivo*, and *in vitro* assays.

Comparative Study between Denosumab and Minodronate with Eldecalcitol as the Treatment after 2-Year Daily Teriparatide in Osteoporosis in Patients with Rheumatoid Arthritis. Yuji Hirano^{*}, Shinya Hirabara, Masaaki Isono. Rheumatology, Toyohashi Municipal Hospital, Japan

Background: Although daily teriparatide (dTPTD) treatment greatly increases bone mineral density (BMD), increase of BMD is not enough after 2-year dTPTD treatment in some patients with osteoporosis (OP). It is known that no treatment after dTPTD treatment results in decrease of BMD. Although effective treatment strategy after 2-year dTPTD treatment is necessary, it is controversial. This prospective study compared minodronate with eldecalcitol (MIN/ELD) and denosumab (DMB) as the treatment after 2-year dTPTD treatment in OP in patients with rheumatoid arthritis (RA-OP).

Methods: Female RA-OP patients treated with MIN/ELD (n=21) or DMB (n=10) after dTPTD were used. Patients' characteristics, change of BMD (lumbar spine and total hip: LSBMD and THBMD) measured by DEXA at every 6 month from the initiation of dTPTD and change of bone turnover markers (BTM) (PINP and TRACP-5b) at every 6 month from the initiation of dTPTD were compared between two groups. DMB (60mg) was injected every 6 month with prescribing of native vitamin D and calcium. MIN (50mg) was administered every 4 weeks and ELD (0.75µg) was administered every day. MIN is a bisphosphonate drug and ELD is activated vitamin D.

Results: Patients' characteristics (MIN/ELD: DMB): Mean age (70.2: 70.8). Body mass index (20.8: 21.3). FRAX (39.6%: 33.8%). PSL use (71.4%: 70.0%). No significant differences in patients' characteristics were observed between two groups. % increase of LSBMD (dTPTD6m/12m/18m/24m/AfterTPTD6m): 7.0/11.7/12.3/12.0/16.8 in MIN/ELD and 10.3/13.7/15.2/16.1/18.4 in DMB. % increase of LSBMD after dTPTD treatment was 4.4% in MIN/ELD and 1.8% in DMB, respectively. No significant differences were observed at all time-points. % increase of THBMD: 1.2/3.1/4.3/5.3/5.9 in MIN/ELD and 1.5/4.4/4.7/4.7/6.5 in DMB. % increase of THBMD after dTPTD treatment was 0.6% in MIN/ELD and 1.1% in DMB, respectively. No significant differences were observed at all time-points. % change of BTM was expressed as the value at the initiation of dTPTD was 100. PINP: 100/413.9/355.7/258.5/219.2/44.5 in MIN/ELD. 100/407.4/380.5/272.8/228.6/56.9 in DMB. TRACP: 100/148.9/157.4/139.8/144.7/51.2 in MIN/ELD. 100/188.0/209.7/178.5/178.6/91.9 in DMB. There were no significant differences in BTM between two groups.

Conclusions: This study shows that short-term efficacy of MIN/ELD equals to that of DMB as the treatment option after 2-year TPTD in RA-OP. Long-term results are necessary in the future.

Effects of Monosodium Urate (MSU) Crystals on MLO-Y4 Cell Viability; Is There a Role for Osteocytes in Bone Erosion in Gout? . Ashika Chhana^{*}, David Musson, Karen Callon, Dorit Naot, Greg Gamble, Jill Cornish, Nicola Dalbeth. University of Auckland, New Zealand

Purpose: Gout is the most common form of inflammatory arthritis. It is characterised by the deposition of monosodium urate (MSU) crystals within joints. MSU crystals are found within subchondral bone. We have previously shown that patients with advanced gout have enhanced osteoclast-mediated bone resorption and impaired osteoblast-mediated bone formation, leading to focal bone erosion. Given that the osteocyte has been shown to be a master regulator of bone

remodelling, the aim of this study was to investigate the effects of MSU crystals on osteocyte-like cell viability.

Methods: MSU crystals were prepared by recrystallization of uric acid. MLO-Y4 osteocyte-like cells were cultured on plastic (2D) or in 3mg/mL type I collagen gels and cultured with 0.01-0.5mg/mL MSU crystals or soluble urate for 24 hours. Cells were then washed and MSU crystals or urate completely removed. Cell viability was assessed 24 hours and 48 hours after the addition of MSU crystals using MTT and alamarBlue assays. BCP, CPPD and aluminium crystals were tested using the same methods. Live-dead staining was also performed 24 and 48 hours after the addition of MSU crystals to cells cultured in collagen gels with MSU crystals for 24 hours.

Results: In 2D cultures, 0.1-0.5mg/mL MSU crystals significantly reduced MLO-Y4 cell viability by ~70% 24 hours after the addition of MSU crystals ($P<0.05$). In collagen gels, higher concentrations of MSU crystals (0.3-0.5mg/mL) reduced MLO-Y4 cell viability by ~30-40% 24 hours after the addition of MSU crystals ($P<0.01$); whereas lower concentrations of MSU crystals (0.01-0.1mg/mL) had no effect ($P>0.05$). However, 48 hours after the addition of MSU crystals, culture with the higher concentrations (0.3-0.5mg/mL) of MSU crystals resulted in a 100% reduction of MLO-Y4 cell viability ($P<0.01$). The inhibitory effect on cell viability was specific to MSU crystals, as soluble urate and other types of crystals did not reduce MLO-Y4 viability. Live-dead staining demonstrated that there was a spatial-dependent effect of MSU crystals on MLO-Y4 cell death. Greater cell death was observed at the top of the gel (closer to the site of crystal deposition) compared to the bottom of the gel (further away from the site of crystal deposition) 48 hours after the addition of MSU crystals for 24 hours. A further 24 hours of culture (72 hours after the addition of MSU crystals) revealed dead cells through all layers of the collagen gel. Conclusion: These results indicate that MSU crystals are toxic to osteocyte-like cells and that direct crystal-cell interactions are not necessarily required to reduce osteocyte viability. The interactions between MSU crystals and osteocytes may contribute to bone erosion in gout.

Crosstalk Between BMSCs and Regulatory T Cells Through A GILZ/Del-1-Dependent Mechanism. Nianlan Yang*, Babak Baban, Carlos Isales, Xing-Ming Shi. Georgia Regents University, USA

Background: Bone marrow mesenchymal stem cells (BMSCs) have potent modulatory effects on T-cells either through direct cell-cell contact or through releasing soluble factors such as indoleamine-2,3-dioxygenase, interleukin-27 and transforming growth factor beta etc. However, studies on the interaction or crosstalk between the bone cells and immune cells in the bone marrow are sparse. We showed previously that glucocorticoid induced leucine zipper (GILZ) inhibits pro-inflammatory cytokine TNF-alpha-induced COX-2 expression and antagonizes TNF-alpha inhibition of osteogenic differentiation. Recently, we found that GILZ can induce the expression of developmental endothelial locus-1 (Del-1), a secreted protein which has been implicated in the regulation of neutrophil recruitment and inflammatory bone loss, in bone tissues. Thus, in this current study, we seek to exploit whether the induction of Del-1 by GILZ in BMSCs is involved in bone and immune system communication. Methods: Bone marrow and peripheral blood cells were collected from GILZ transgenic mice, in which the expression of GILZ is under the control of a 3.6kb type I collagen promoter fragment (Col3.6-GILZ). Lymphocyte profiles were analyzed by using flow cytometry assay. Del-1 expression in bone tissues was determined by real time RT-PCR and histochemistry analysis. Cytokine production was measured using ELISA. Mixed lymphocyte reaction was performed to determine the regulator effect of GILZ on T lymphocytes. Results: Del-1 expression is increased 3-9 fold ($p<0.05$) in the bone tissues of GILZ transgenic mice and this is coupled with significant increase of IL-10 (2.8 \pm 1.7, $p<0.1$) and decrease of IL-6 (0.1 \pm 0.01, $p<0.01$) and IL-12 (0.47 \pm 0.06, $p<0.05$). FACS results showed that the percentages of FOXP3+ and CD25+ cells are increased significantly in both blood (4.44% vs. 11%, $p<0.1$ and 1% vs. 3.5%, $p<0.1$) and bone marrow (1.35% vs. 6.5%, $p<0.05$ and 1.75% vs. 5.25%, $p<0.05$) of the GILZ Tg mice, which is also confirmed by immunohistochemistry study. Mixed lymphocyte reaction show that compared to control BMSCs, GILZ-expressing BMSCs (MSC-GILZ) induce less allogenic lymphocytes to proliferate (4% vs. 16%); however, the induction activity of MSC-GILZ on Treg cells population is 2-fold higher than the control cells. Conclusion: GILZ expressed in BMSCs upregulates Treg cells by inducing Del-1 expression and altering cytokines profile, thus plays a critical role mediating the crosstalk between BMSCs and Tregs in the bone marrow microenvironment. This data, together with our previous findings that overexpression of GILZ in BMSCs antagonizes TNF-alpha-elicited inflammatory responses suggest that GILZ plays important roles in bone-immune cell communication and BMSC immune suppressive functions.

Development and characterization of two polyclonal antibodies directed against human periostin. Philippe Vergnaud¹, Aurélie Pagnon-Minot², Cindy Bertholon³, Yannick Lhoste¹, Emeric Chassaigne¹, Olivier Borel³, Evelyne Ginevts³, Tanja Schubert¹, Philippe Clezardin³, Roland Chapurlat⁴, Jean-Charles Rousseau^{*3}. ¹BioClinicaLab, Lyon, France, ²Novotec, France, ³INSERM UMR 1033, Lyon, France, ⁴INSERM UMR 1033 & Hospices Civils de Lyon, Lyon, France

Purpose: Matricellular protein periostin (PN) is mainly expressed in the periosteum. PN regulates Notch1 signaling, activates lysyl-oxylidase and mediates cancer cell adhesion, survival and invasion in different tissues. The aim of this study was to develop two polyclonal antibodies against the Fas-1 region of human PN and determine their specificity in human serum and bone tissue specimens.

Methods: *In silico* analysis of the total protein sequence of human PN led us to identify two amino acid sequences that are suitable for antibody generation (Patent n° 13/375870) in the second and fourth Fascilin-like domains [ETLEGNTIEIGCDGDSI (Ab-34) and KGFEPGVTNLIKTTQGSK (Ab-12), respectively]. These two peptides were injected in rabbits following a standard protocol of 10 weeks of immunization. Specific polyclonal antibodies Ab12 and Ab34 were purified by immunoaffinity chromatography. We assessed the specificity of these antibodies for PN by immunohistochemistry (IHC) and western blotting (WB) using, respectively, human bone tissue and human sera previously depleted for albumin, IgG and transferrin.

Results: Ab-12 and Ab-34 antibodies did not have the same pattern of recognition of PN. WB analysis of the serum showed that, under non-reducing conditions, Ab-12 recognized two bands, a high molecular weight band around 200 kDa and a second one at 75 kDa. After treatment of the serum with dithiothreitol to reduce disulfide bonds, the 200 and 75kDa bands disappeared and 3 new bands were detected at 70, 50 and 25 kDa. On the other hand, under non-reducing conditions, Ab-34 recognized a single band at 75 kDa in the serum. After dithiothreitol reduction, this band at 75 kDa migrated at a molecular weight of 100 kDa, indicating that the reduction of intradisulfide bonds in PN leads to a more extended conformation of the molecule and makes it run more slowly in the gel. By IHC, Ab-12 stained the cytoplasm of osteoblasts, lining the endosteal surface between cortical bone and the bone marrow, and the cytoplasm of osteoblasts present within the Haversian canals. Ab-34 stained the periosteum and the Haversian canals.

Conclusion: We have generated two polyclonal antibodies against the Fas-like domains of human PN. Our preliminary results suggest that they bind at least two forms of PN molecules in the serum and bone.

A Dynamic Anesthesia System for Long-Term Imaging in the Adult Zebrafish Skeleton. Brenen Wynd*¹, Karuna Patil², Claire Watson³, George Sanders², Ronald Kwon³. ¹Department of Orthopaedics & Sports Medicine, USA, ²Department of Comparative Medicine, University of Washington, USA, ³Department of Orthopaedics & Sports Medicine, University of Washington, USA

Zebrafish (*Danio rerio*) represent a potentially powerful model for bone biomedical research due to their unique optical properties and amenability to *in vivo* imaging strategies. However, to date application of such strategies to study zebrafish bone physiology has been hindered by two challenges: most of the zebrafish skeleton ossifies post-embryonically, and established anesthetic regimens for long-term imaging (i.e., 1-24hrs) in zebrafish embryos are ineffective in adults (with mortality occurring within 20-40 minutes [1]). To overcome this challenge, the goal of the project was to develop an anesthesia system for long-term *in vivo* imaging in the adult zebrafish. For this, we constructed a computer-controlled anesthetic system consisting of a 3D-printed imaging chamber coupled to programmable peristaltic pumps. The pumps intermittently replenished the chamber with anesthetic and fresh water to avoid respiratory arrest (RA). Using 0.0035% benzocaine, we found that statically administering this solution resulted in a mean time to RA of 4.9 \pm 2.9hrs, roughly 3-12 times longer than sedation times previously reported using MS-222/isofluorane cocktails [1]. Next, we examined the potential to use an intermittent dosing regimen (15min of anesthetic water followed by 5min of fresh water) to extend this sedation period. Over an 8hr testing period, we found that dynamic administration successfully maintained the fish between stage 2 and 3 anesthesia while significantly increasing the percent of survival at 8hrs compared to static controls (S: 14%, D:75%, $p<0.05$, Fig 1). As proof of concept, we subjected a single fish to 24hr sedation; the system was able to successfully keep the fish sedated with normal respiratory rates (140-198 breaths/min) for the entire trial period. In summary, we have shown the potential for a dynamic anesthesia protocol utilizing benzocaine to achieve sedation in adult zebrafish for up to 24 hours, a period of time sufficient to observe *de novo* bone formation during fin regeneration [2]. Given the large number of transgenic zebrafish reporter lines and new imaging practices for examination of fluorescence and mineralization [3], this study opens new opportunities to reveal the molecular and cellular events mediating osteogenesis in the adult zebrafish skeleton.

Analysis of Osteoactivin in Reamer-Irrigator-Aspirator (RIA) Wastewater as an Osteogenic Factor for Bone Regeneration. Gregory Sondag¹, Lucas Upperman^{*2}, Douglas Crowder¹, Derek Klaus¹, Ethan Scott³, Eric Miller¹, Favez Safadi¹. ¹NEOMED, USA, ²Northeast Ohio Medical University, USA, ³Rootstown, USA

Non-unions and critical-size bone defects are challenging problems that can be successfully treated with a combination of rigid fixation and autologous bone graft. Historically, harvesting iliac crest bone graft (ICBG) has been the gold standard for massive bone grafting procedures; however, ICBG harvest is limited by the amount of graft available as well as a relatively high complication rate. Recently, the Reamer-Irrigator-Aspirator (RIA) device has become a popular method to obtain large amounts of autologous bone graft, with less donor site morbidity compared to ICBG. The RIA is an intramedullary reaming device capable of retrieving finely morselized cortical cancellous bone in excess of 90 cm³ that has osteogenic properties comparable to ICBG. The aspirated femoral contents are passed through a filter to collect and separate the desired bone graft from the remaining filtrate or wastewater (WW). Traditionally, the WW is discarded; however, recent studies have demonstrated the presence of growth factors and viable cells within WW. In this study we examined the presence of osteogenic factors in the WW and tested their effects on RIA-derived growth factors on mesenchymal stem cell (MSC) differentiation *in vitro* and *in vivo*. We also show the presence of the osteogenic factor osteoactivin (OA) – a downstream mediator of BMP-2 discovered by our lab – in the WW. Our results indicate that OA can be found in greater concentrations in the concentrated WW than in the platelet rich plasma (PRP-control). To demonstrate the multipotency effect of MSCs extracted from the wastewater, we differentiated these cells into the osteogenic and adipogenic lineages confirmed by ALP and Oil Red Staining respectively. In order to determine the effects of WW supplement on MSC proliferation and survival, we added concentrated WW to MSCs over 72 hours. MSC's treated with WW demonstrated 80% increased proliferation and survival rates over untreated controls. Furthermore to assess the osteogenic potential of the WW *in vivo*, 5-mm critical-size defects were made in the calvaria of immunodeficient mice. The defects were either left untreated or packed with a collagen sponge. The sponge was loaded with either PBS, PRP, or WW. Four weeks post-surgery, the calvaria and were harvested and assessed by microCT analysis. WW showed dramatic in bone regeneration compared to controls. These data suggest that WW has an osteogenic potential to stimulate bone regeneration in large bony defects and fracture repair.

Beta-Aminopropionitrile Treatment Effects on MC3T3-E1 Osteoblast Gene Expression and Type I Collagen Production. SILVIA CANELON^{*1}, Joseph Wallace². ¹Purdue University, USA, ²Indiana University-Purdue University at Indianapolis, USA

Type I collagen morphology can be characterized using fibril D-spacing, a metric that is sensitive to differences in collagen structure across tissue types and disease states. D-spacing describes repeating bands of gap and overlap regions of collagen molecules arranged in a quarter-staggered array. This fibrillar structure is stabilized by enzymatic crosslinks initiated by lysyl oxidase (LOX), a step which can be disrupted using beta-aminopropionitrile (BAPN). Murine *in vivo* studies have confirmed effects of BAPN on collagen nanostructure and the objective of this study

was to evaluate the mechanisms of these effects *in vitro* by measuring D-spacing and quantifying gene expression of type I collagen and LOX. Osteoblastic cells were cultured and differentiated in dishes in the presence or absence of 0.25mM BAPN (n=4/group). Cells proliferated in complete α -MEM media for 7 days then differentiated for 7 days using ascorbic acid. Media was removed from the dishes and cells dissociated from the matrix with an EDTA buffer. The matrix was allowed to dry and imaged in air using atomic force microscopy (AFM) in 5 locations/dish. A 2D Fast Fourier transform was performed on 10 fibrils/location to extract D-spacing (50 fibrils/dish, ~200 fibrils/group). The experiment was repeated for qRT-PCR analysis (n=5). Following RNA isolation and RT, qRT-PCR was performed using SYBR Green primers and master mix (coll1a1, coll1a2, LOX, and β -actin as reference) and gene expression levels analyzed using the comparative C_T method. The D-spacing distribution of collagen produced in the presence of BAPN was shifted toward significantly higher D-spacing values, indicating that BAPN affects the morphology of collagen produced *in vitro*, supporting aforementioned *in vivo* experiments. In contrast, no difference in gene expression was found for any target gene in BAPN-treated samples relative to controls suggesting that inhibition of LOX does not upregulate the LOX gene to compensate for the reduction in aldehyde formation, nor does it regulate expression of genes encoding type I collagen. To understand how inhibition of LOX affects collagen stability, Fourier Transform Infrared (FTIR) spectroscopy has been used in a preliminary study to indirectly measure enzymatic crosslinks by determining the area ratio of two bands in the amide I region of type I collagen produced *in vitro*. Studies are underway to fully characterize the impact of BAPN-treatment on this measure of collagen crosslinking.

Characterization of Mineralization-Competent Matrix Vesicles During Odontoblast-supported Mineralization. Sandeep Chaudhary^{*1}, Maria Kuzynski¹, Morgan Goss¹, Callie Mobley¹, Anne Poliard², Odile Kellermann³, Jose-Luis Millan⁴, Dobrawa Napierala⁵. ¹University of Alabama at Birmingham, USA, ²UFR d'Odontologie Université Paris Descartes 1 rue Maurice Arnoux, France, ³INSERM UMR-S 1124, Université René Descartes Paris 5, Centre Universitaire des Saints-Pères, France, ⁴Sanford Children's Health Research Center, Sanford-Burnham, Medical Research Institute, USA, ⁵Oral & Maxillofacial Surgery, Institute of Oral Health Research, School of Dentistry, University of Alabama at Birmingham, USA

The process of mineralization is initiated by membranous vesicles, called matrix vesicles (MVs), which are released by bone, dentin, and cartilage cells into fibrous extracellular matrix (ECM). Mineralization-competent MVs are enriched in tissue-nonspecific alkaline phosphatase (TNAP), PHOSPHO1 phosphatase, and PO₄³⁻ and Ca²⁺ transporters, which facilitate initial hydroxyapatite crystal formation and thus mineralization. The regulation of MVs formation is not yet clear. Here, we investigated the role of cytoskeletal organization and Rho/Rac1/Cdc42 GTP-ases in the biogenesis of mineralization-competent MVs. We used preodontoblast-derived 17IIA11 cell line as a model of MV-initiated mineralization in osteogenic medium containing 10mM sodium phosphate and 50mg/ml ascorbic acid. MVs were analyzed by Nanosight NS300 and Western blot. Remodeling of cytoskeleton components was inhibited by cytochalasin D, nocodazole, forchlorfenuron and dynasore. We determined that osteogenic conditions induce rapid production of MVs. The number of MVs/cell significantly increased by 5 fold within the 12h and 11 fold within 24h of osteogenic differentiation in comparison with untreated cells. This was associated with activation of Rac1 and Cdc42 GTP-ases but not RhoA. MVs release was increased by non-cytotoxic levels of inhibitors of cytoskeletal organization, with the strongest effect of nocodazole, which inhibits polymerization of microtubules. Comparative protein analyses revealed differential distribution of TNAP and PHOSPHO1 isoforms between MVs and cells in osteogenic and non-osteogenic conditions. Furthermore, we determined that molecular markers of MVs released by 17IIA11 cells were different than proteins in exosomes from serum and cancer cell lines. Earlier, we demonstrated that 17A111 cell lines deficient for the Trps1 transcription factor showed impaired MVs production and mineralization. In this study, we observed that Trps1 deficiency results in impaired activation of Rac1 and Cdc42 in osteogenic conditions. Taken together, our results suggest that osteogenic properties of 17IIA11 cell line rely in MVs released by cells and cytoskeletal modelling along with activation of Rac1 and Cdc42 play a role in MVs biogenesis during odontoblast-supported mineralization.

EDA and EDB Containing Fibronectin Stimulate Osteoblast Differentiation by Acting on $\alpha 4\beta 1$ and $\beta 3$ Integrins Respectively. Carla Sens*¹, Katrin Rau¹, Verena Klemis¹, Inaam Nakchbandi². ¹University of Heidelberg & Max-Planck Institute of Biochemistry, Germany, ²Max-Planck Institute of Biochemistry & University of Heidelberg, Germany

Fibronectin is an extracellular matrix protein produced by many cell types. It modulates the behavior of adjacent cells by binding to cell surface receptors called integrins. Several isoforms have been described. In contrast to the circulating Isoform, the EDA isoform contains an extra domain A and the EDB isoform an extra domain B. Deletion of fibronectin in osteoblasts results in decreased bone mineral density. This effect is mediated by diminished osteoblast differentiation that cannot be corrected by the circulating isoform of fibronectin, suggesting a role for EDA and/or EDB in modulating osteoblast differentiation.

We first evaluated the role of EDA. Transient transfection of a construct of EDA in wildtype newborn murine calvarial osteoblasts enhanced osteoblast differentiation (von Kossa staining, alkaline phosphatase and osteocalcin). In contrast, using siRNA directed against EDA suppressed differentiation. Addition of EDA increased pFAK suggesting that integrins mediate the enhanced differentiation. EDA binds to either $\alpha 4\beta 1$, $\alpha 9\beta 1$ or enhance binding to $\alpha 5\beta 1$ integrins. Deletion of $\beta 1$ integrin in osteoblasts prevented EDA-mediated differentiation. Stimulating $\alpha 4$ or $\alpha 9$ by culturing on VCAM enhanced differentiation. In contrast, inhibiting $\alpha 4\beta 1$ diminished pFAK and osteoblast differentiation. Taken together these data suggest that $\alpha 4\beta 1$ integrin mediates osteoblast differentiation. In line with these findings, a peptide called CS1 that activates $\alpha 4\beta 1$ increased total BMD in treated mice. This effect was mediated via racl and enhancement of wnt signaling.

Similar studies were performed for EDB. EDB enhanced differentiation and its silencing using siRNA inhibited differentiation. However, EDB effects are mediated by $\beta 3$ integrin, because the absence of $\beta 3$ prevented EDB effects. Adding echistatin activated $\beta 3$ in osteoblasts and enhanced differentiation. This was mediated by the RGD sequence because transfecting EDB without RGD into osteoblasts prevented stimulation by EDB, even in the presence of $\beta 3$ integrin. Further, knockout of $\beta 3$ in one allele only is associated with a decrease in BMD in 5-week-old $\beta 3^{+/-}$ heterozygote mice, while homozygote loss is not, because $\beta 3$ integrin is critical for osteoclastic resorption.

In summary, EDA activates $\alpha 4\beta 1$ integrin, while EDB in cooperation with RGD activates $\beta 3$ integrin. Both effects result in enhanced osteoblast differentiation. Furthermore, pharmacologic stimulation of $\alpha 4\beta 1$ increases bone formation and density *in vivo*.

Human micro-RNAs miR-29b, miR-30c2 and miR-125b and their target genes are important modulators of bone metabolism. Andreas Kindmark*¹, Navya Laxman², Carl-Johan Rubin³, Hans Mallmin⁴, Olle Nilsson⁴, Elin Grundberg⁵, Tomi Pastinen⁵. ¹Uppsala University Hospital, Sweden, ²Department of Medical Sciences, Uppsala University, Sweden, ³Department of Medical Biochemistry & Microbiology, Uppsala University, Sweden, ⁴Department of Surgical Sciences, Uppsala University, Sweden, ⁵Department of Human Genetics, McGill University & Genome Quebec Innovation Centre, McGill University, Montreal, Quebec, Canada, Canada

Background: MicroRNAs (miRNAs) are important post-transcriptional regulators that have recently introduced an additional level of intricacy to our understanding of gene regulation. We have investigated miRNA-mRNA interactions that may be relevant for bone metabolism by assessing correlations and interindividual variability in miRNA levels and global correlations between miRNA and mRNA levels in a large cohort of primary human osteoblasts (HOBs) obtained during orthopedic surgery in otherwise healthy individuals.

Materials and methods: miRNA levels were assessed by LNA arrays and qPCR. mRNA levels were assessed using Illumina arrays in bone cells from a total of 95 subjects undergoing orthopedic surgery for osteoarthritis. We used an integrated analysis of global miRNA - mRNA correlations, mRNA expression profiling, DE, bioinformatics analysis and functional studies to identify novel target genes for miRNAs with the potential to regulate osteoblast differentiation and extracellular matrix production. We also performed functional studies by overexpression and knockdown of miRNAs

Results: We identified differential expression (DE) of 24 miRNAs, and found 9 miRNAs exhibiting DE between males and females. In functional assays, the differentially expressed miRNAs hsa-miR-29b, hsa-miR-30c2 and hsa-miR-125b were found to target genes highly relevant to bone metabolism, e.g. Collagen, type I, alpha 1 (COL1A1), Osteonectin (SPARC), Runt-related transcription factor 2 (RUNX2), Osteocalcin (BGLAP) and Frizzled-Related Protein (FRZB). Overexpression or knock-down of the miRNAs also affected mineralization. **Conclusion:** hsa-miR-29b, hsa-miR-30c2 and hsa-miR-125b are involved in orchestrating the activities of key regulators of human osteoblast differentiation and extracellular matrix proteins by their convergent action on target genes and pathways to control skeletal gene expression.

Leukotrienes B₄ and C₄ play a role on the osteogenic differentiation by mechanism dependent on their receptors binding. Flávia Oliveira*¹, Amanda Pereira¹, Marília Buzalaf¹, Camila Peres-Buzalaf², Rodrigo Oliveira¹. ¹Bauru Dental School - University of São Paulo, Brazil, ²Universidade Sagrado Coração, Brazil

Leukotrienes (LTs) are lipid mediators derived from arachidonic acid metabolism via 5-lipoxygenase (5-LO) and they are shown to modulate bone remodeling. Although osteoblasts present LT receptors, little is known about their effects on these cells. Therefore, we hypothesized to study the role of exogenous LTB₄ and LTC₄ on proliferation and differentiation of preosteoblast lineage cells. To accomplish this, we have used LTB₄, LTC₄ as well as BLT1 and CysLT1 receptors antagonists on MC3T3-E1 cells. *In vitro* data have demonstrated that LTB₄ at 10⁻¹⁰ M increased cell proliferation while at higher doses (10⁻⁸ and 10⁻⁹ M) decreased it when compared to untreated cells. On day 10, exogenous LTB₄ significantly increased preosteoblast proliferation, regardless the tested dose (p<0.05). Also, the treatment of cells with 10⁻⁷, 10⁻⁸ and 10⁻⁹ M LTC₄ increased the cell density on day 1, compared to control cells. On the other hand, on 7 and 10 days, only lower doses of LTC₄ (10⁻⁸ and 10⁻⁹ M) have enhanced it (p<0.05). Thus, we clearly have shown that LTs alter the proliferation of preosteoblasts in a time- and dose- dependent manners. In addition, the pretreatment of cells with BLT1 or CysLT1 receptor antagonists have impaired the increased LTB₄ and LTC₄-induced proliferation, respectively. Osteoblast differentiation was assessed by alkaline phosphatase (ALP) activity, alizarin red-staining bone nodule formation and type 1 collagen and 5-LO expression in osteogenic medium cultured MC3T3-E1 cells. The data have showed that exogenous LTC₄ or LTB₄ increased the ALP activity on day 7, but decreased on day 14, suggesting that LTs modulate ALP activity in a time-dependent manner. Also, the mineralized bone nodules were increased when cells were treated with LTB₄ or LTC₄, compared to untreated cells (p<0.05). While 5-LO expression was up-modulated in differentiated cells on 7 and 14 days (p<0.05), the expression of type 1 collagen was unaltered by both LTs. We conclude that exogenous LTB₄ and LTC₄ affect osteogenic differentiation, judged by increased proliferation and bone formation markers. Importantly, they act through BLT1 or CysLT1 receptors specific binding, respectively and thus they may serve as a therapeutic target for bone diseases in the future.

MicroRNAs Involved in Bone Metabolism Are Transported into Matrix Vesicles during Bone Formation. Yuko Nakao*¹, Yuichiro Takei², Tomoko Minamizaki², Hirotaaka Yoshioka², Faisal Ahmed¹, Kotaro Tanimoto², Shumpei Niida³, Yui Yoshiko². ¹Hiroshima University Graduate School of Biomedical & Health Sciences, Japan, ²Hiroshima University Institute of Biomedical & Health Sciences, Japan, ³Biobank, National Center of Geriatrics & Gerontology, Japan

MicroRNAs (miRs) coordinate a broad spectrum of biological processes via epigenetic machinery to regulate gene expression, and growing evidence suggests the roles of miRs in bone and its related diseases. Exosomes have been of great interest in recent years, especially in the context of miRs in the vesicles as cell-to-cell signaling molecules. Exosomes are secreted by most cell types from multivesicular endosomes and present in biological fluids, including blood and urine, while matrix vesicles (MVs) are extracellular organelles budding from osteoblasts and resided in the premineralized matrix of bone. MVs play a pivotal role in bone mineralization and contain a number of biological molecules including tissue non-specific alkaline phosphatase, annexins and growth factors involved in osteoblastogenesis. We hypothesized that, as the proper assembly "bone," MVs provide a protective and enriched source of miRs involved in bone formation and resorption. We prepared MVs from the mouse osteoblastic cell line MC3T3-E1 using ultracentrifugation methods. To evaluate miR expression profiling, we performed microarray analysis on MVs (SurePrint Mouse miRNA Microarrays). Of 1,881 mouse miRs listed, 194 were identified in MVs, and 74 shared homology with human counterparts. To further analysis, we chose 10 miRs of interest, based on the concept that target gene(s) of miRs were established or predicted to be involved in bone resorption and formation. We also confirmed these miRs in primary human and rodent osteoblasts and corresponding MVs. Among miRs tested, miR-125b and let-7c were more abundant in MVs, compared with cells. To determine whether miRs in cells versus MVs are involved in matrix mineralization, we treated MC3T3-E1 cells with U0126, an inhibitor MEK1/2, to enhance matrix mineralization. Eighty-one miRs, including miR-125b and let-7c, were significantly down-regulated, while none of miRs identified in MVs were up-regulated.

Mineralization in MC3T3-E1 Osteoblast Cultures: A Comparison with Bone. William Addison¹, Valentin Nelea², Florencia Chicatun², Yung-Ching Chien³, Nicolas Tran-Khanh⁴, Michael Buschmann⁴, Showan Nazhat², Mari Kaartinen², Hojatollah Vali², Mary Tecklenburg⁵, Renny Franceschi⁶, Marc McKee^{*2}. ¹Harvard University, USA, ²McGill University, Canada, ³University of California at San Francisco, USA, ⁴Ecole Polytechnique, Canada, ⁵Central Michigan University, USA, ⁶University of Michigan, USA

MC3T3-E1 osteoblast cell cultures are the most commonly used in vitro model of bone matrix mineralization. Despite the widespread use of this cell line to study biomineralization, there is as yet no systematic characterization of the mineral phase produced in these cultures. Our aim was to provide a comprehensive, multi-technique biophysical characterization of this cell culture mineral, and compare it to mouse bone mineral, to determine the suitability of MC3T3-E1 cultures for biomineralization studies. Energy-dispersive X-ray spectroscopy (EDS), X-ray diffraction (XRD), electron diffraction, Fourier-transform infrared spectroscopy (FTIR), confocal microscopy, and transmission (TEM) and scanning (SEM) electron microscopy were used to characterize the mineral phase of MC3T3-E1 osteoblast cultures and mouse calvarial bone. Elemental compositional analysis by EDS showed calcium and phosphorus, and trace amounts of sodium and magnesium, in both samples. XRD on intact resin-embedded cultures indicated that similar to mouse bone, apatite crystals grew with preferential orientations along the (100), (101) and (111) mineral planes indicative of guided biogenic growth as opposed to dystrophic calcification. XRD of crystals isolated from the cultures revealed that the mineral phase was poorly crystalline hydroxyapatite with 10-20 nm-sized nanocrystallites. Consistent with the XRD observations, electron diffraction patterns indicated that culture mineral had low crystallinity typical of biological apatites. FTIR confirmed apatitic carbonate and phosphate. With all techniques utilized, cell culture mineral and mouse bone mineral were remarkably similar. SEM and TEM showed that the cultures had a dense, fibrillar collagen matrix with small 100-nm collagen fibril-associated mineralization foci which coalesced to form larger mineral aggregates. Confocal imaging showed that some cells had dendritic processes and became embedded within the mineral in an osteocyte-like manner. In conclusion, we have documented the characteristics of the mineral phase of MC3T3-E1 osteoblast cultures, and determined that this mineral is highly similar to that of mouse bone.

Disclosures: Marc McKee, None.

Murine MicroRNA 126-3p is Upregulated by Endothelin-1 Signaling and Mediates some of Its Pro-Mineralization Effects. Michael Johnson^{*1}, Robert D. Blank². ¹University of Wisconsin, USA, ²Medical College of Milwaukee-Endocrinology, USA

Ecel, encoding endothelin converting enzyme 1 (ECE1), is a positional candidate for a pleiotropic quantitative trait locus affecting femoral size, shape, mineralization, and biomechanical performance and is responsible for 40% of the variation in bone biomechanical performance between HCB8 and HCB 23 congenic mice. ECE1 is a membrane bound protease that converts the inert big endothelin¹ (big ET1) to active endothelin-1 (ET1). Previously, we demonstrated that treatment of TMOB osteoblasts with big ET1 increases mineralization and secretion of IGF1 while decreasing secretion of DKK1 and SOST. Big ET1 exposure also caused significant changes in miRNA expression, suggesting interaction of ET1 with multiple signaling pathways. To further test the hypothesis that ET1 signaling is vital for normal bone physiology we pharmacologically inhibited EDNRA and ECE1 in TMOB osteoblasts. Inhibition of either EDNRA (BQ-123) or ECE1 (phosphoramidon) reduced mineralization ($p < 0.001$). Blockade of EDNRA showed the expected decrease in IGF1 ($p < 0.001$) secretion and increase in DKK1 ($p < 0.001$) and SOST ($p < 0.001$) secretion. However, ECE1 blockade decreased IGF1 signaling ($p < 0.001$) but led to an unexpected decrease in SOST and DKK1. To confirm that this result was not due to non-specific protease inhibition by phosphoramidon, we used *Ecel* siRNA to knockdown *Ecel*. We confirmed knockdown by qPCR and saw similar results in mineralization ($p < 0.001$), and decreased secretion of IGF1, and DKK1 and SOST ($p < 0.05$ respectively). We previously demonstrated that big ET1 treatment increased expression of miRNA 126-3p, a miRNA that is predicted to target murine SOST and decrease its expression, during mineralization by 121X. To test the hypothesis that ET1 signaling partially works through miRNA regulation we transfected TMOB cells with the miRNA 126-3p mimic, a miRNA a 126-3p inhibitor, and a negative control in the presence and absence of big ET1. We found that transfection of the mimic in the absence of big ET1 increased mineralization ($p < 0.01$) and decreased secretion of SOST ($p < 0.05$). We found that transfection of the inhibitor decreased mineralization ($p < 0.01$) and increased secretion of SOST ($p < 0.05$). Our data suggest that the finely balanced process of mineralization is critically influenced by ET1 signaling and that part of influence is mediated through control of miRNA 126-3p expression.

Parafibromin, a transcriptional repressor, is required in early development but not in mature osteoblasts, where its loss results in increased bone mass. Casey Droscha^{*}, Diegel Cassandra, Bart Williams, Van Andel Institute, USA

Inactivating mutations that lead to loss of heterozygosity within the HRPT2 gene are directly linked to the development of primary hyperparathyroidism, parathyroid adenomas, and ossifying fibromas of the jaw (HPT-JT). The protein product of the HRPT2 gene, parafibromin, is a core member of the polymerase-associated factors (PAF) complex, and also binds to a plethora of transcriptional and chromatin remodeling complexes such as RNAPII, histone methyltransferases and β -catenin. Several lines of evidence in both yeast and mammalian cells have demonstrated that parafibromin is a requisite link between the PAF complex and the transiting RNAPII complex coordinating chromatin remodeling to establish and maintain active from inactive chromatin. Developmentally, parafibromin expression is required for mesenchymal precursor survival and proliferation as deletion results in embryonic lethality at E11.5. Hrpt2 cKO mutant embryos lack organ development due to extensive apoptosis evaluated by cleaved caspase-3 immunohistochemical staining. Further work in our lab has shown that conditional loss of parafibromin within mature osteoblasts results in significantly increased cortical bone volume and thickness, reducing cortical porosity. Trabecular thickness and spacing was also significantly higher in Hrpt2 cKO femurs. Biomechanically, Hrpt2 cKO femurs exhibited increased stiffness and maximum load assessed via four-point bending analysis. Interestingly, bone histomorphometry of WT and Hrpt2 cKO femurs display a reduction in osteoblast surface. Further investigations into osteoblast/osteoclast populations to contribute to the Hrpt2 cKO bone phenotype are underway. To assess transcriptional changes upon loss of Hrpt2 expression with mature osteoblasts, calvarial osteoblasts, identified by Cre-mediated GFP expression, from wildtype and cKO neonatal pups were isolated via flow cytometry and RNA was isolated and subjected to RNA-sequence analysis. These results aid in our understanding of the role parafibromin plays within transcriptional regulation, terminal differentiation, and bone homeostasis. Taken together, the roles of parafibromin and the PAF complex are numerous and essential within differentiating or proliferating cells, yet expendable within terminal, post-mitotic cells.

Disclosures: Casey Droscha, None.

Contrasting Effects of Parathyroid Hormone on PHOSPHO1 and Alkaline Phosphatase Expression During Osteoblast Mineralization. Dean Houston^{*1}, Katherine Myers¹, Vicky MacRae¹, Jose Luis Millan², Katherine Staines¹, Colin Farquharson¹. ¹The Roslin Institute, The University of Edinburgh, United Kingdom, ²Sanford Burnham Medical Research Institute, USA

Intermittent parathyroid hormone (PTH) is widely used in the treatment of osteoporosis. The anabolic effects of intermittent PTH on bone are attributed to a number of mechanisms including: stimulation of osteoblast differentiation and inhibition of sclerostin. Despite this, there exists a hiatus in the knowledge surrounding the effects of PTH on key phosphatases required for skeletal mineralization. *Phosphol* and *Alpl*, encoding PHOSPHO1 and tissue-nonspecific alkaline phosphatase (TNAP) respectively, are required for bone mineralization and ablation of either leads to hyperosteooidosis with combined ablation completely abolishing the initiation and progression of skeletal mineralization.

This study sought to investigate the effects of bovine (b)PTH 1-34 on the expression of PHOSPHO1 and TNAP. The osteoblast-like cell line MC3T3-E1 (clone 14) displays profound matrix mineralization over a 10-day period with temporal increases in *Phosphol* and *Alpl* expression (150-fold and 60-fold respectively compared to day 0; $p < 0.001$). Treatment of these cells with 50nM bPTH every 2-days caused a reduction in matrix mineralization at day 10 (42%, $p < 0.05$). At day 10, *Phosphol* mRNA was significantly reduced after a 15 min exposure to bPTH (50nM; 80% decrease, $p < 0.001$). This inhibition was more profound after 1 and 6 hour bPTH exposures (96% & 93% decrease respectively, $p < 0.001$) and persisted to 24 hours (48% decrease, $p < 0.05$). A marked reduction in PHOSPHO1 protein was observed after 24 and 48 hour bPTH treatment. In contrast, the expression of *Alpl* increased after 1 (2.8-fold, $p < 0.05$) and 6 hour (3.6-fold, $p < 0.001$) bPTH exposure which was consistent with increased TNAP protein after 24 and 48 hours of bPTH treatment. The response of *Phosphol* and *Alpl* to 24 hours of bPTH exposure was dose dependent (0.05nM-50nM). Indeed, a 50% reduction ($p < 0.001$) in *Phosphol* expression was achieved by the addition of 0.5nM bPTH with comparable changes at the protein level. Induction of TNAP mRNA and protein was achieved with 5nM bPTH. Further analyses revealed that the cAMP activator forskolin was capable of inducing a suppression of *Phosphol* comparable to the effects of bPTH (93% & 96% respectively). Forskolin induced *Alpl* expression (2.4-fold, $p < 0.05$). In summary, bPTH had differential effects on PHOSPHO1 and TNAP expression during *in vitro* osteoblast mineralization. Initial studies implicate the cAMP/PKA signalling pathway as the mechanism of PTH-induced *Phosphol* inhibition and *Alpl* stimulation.

β -adrenergic blockade suppresses pancreatic lipase expression via osteocalcin in obese mice. Kyunghwa Baek*¹, HyoRin Hwang², Jiho Kang², Danbi Park³, Yewon Kwon³, Heesu Lee³, Sunghee Ko³, Jeong-Hwa Baek².

¹Gangneung-Wonju national university, School of dentistry, South Korea, ²Department of Molecular Genetics, School of Dentistry & Dental Research Institute, Seoul National University, South Korea, ³Department of Pharmacology, College of Dentistry & Research Institute of Oral Science, Gangneung-Wonju National University, South Korea

Obesity is known to be associated with increased sympathetic nervous system (SNS) activation. We previously elucidated β -adrenergic blockade attenuates dietary fat absorption and obesity development and such an effect is associated with downregulation of pancreatic lipase (PNLIP) expressions in pancreatic acinar cells. In the present study, we tested whether β -adrenergic blockade downregulates bioactive osteocalcin secretion in osteoblasts, thereby reduces PNLIP expressions in pancreatic acinar cells.

Forty of male 6wk old C57BL/6 mice were assigned into control diet (CON) and a high calorie diet (HIGH) group. In each diet group, mice were treated with vehicle (VEH) or with propranolol, a β -adrenergic antagonist (BB; 0.5 g/L in drinking water) over 12 wks. Over 12 weeks, increase in body weight observed in the HIGHVEH group was mitigated in HIGHBB mice. Increase in fecal fat amount observed in HIGHVEH mice was mitigated in HIGHBB mice. Increase in PNLIP mRNA and protein levels observed in HIGHVEH mice pancreatic tissues was abolished in HIGHBB mice. Expression levels of *Esp* in HIGHVEH mice femur was higher vs. in CONVEH mice, but this increment was attenuated by propranolol in HIGHBB animals. Reduction in serum undercarboxylated osteocalcin (ucOC) level in HIGHVEH mice was mitigated in HIGHBB mice. In MC3T3E1 osteoblasts, upregulated *Esp* expression, followed by downregulated ucOC secretion observed in isoproterenol treated cells, was attenuated by propranolol treatment. In 266-6 cells, mouse pancreatic acinar cell line, PNLIP expression decreased when the cells were treated with ucOC. Luciferase assay showed that ucOC attenuated isoproterenol induced mouse PNLIP promoter activity. G protein-coupled receptor (GPCR6A) was highly expressed in mouse pancreatic tissue and in 266-6 cells. Knockdown of GPCR6A by siRNA suppressed downregulating effect of ucOC on PNLIP expressions, proposing that GPCR6A mediates responses to osteocalcin in pancreatic acinar cells.

In summary, β -adrenergic blockade mitigated body weight increase and dietary fat absorption during high fat diet feeding and attenuated increment in PNLIP expression. In the context of SNS stimulation, β -adrenergic blockade rescued bioactive osteocalcin secretion in osteoblasts, thereby suppressed PNLIP secretion in pancreatic acinar cells. These data suggest an important role for β -adrenergic signaling pathway in bone and pancreas response to excessive energy metabolism.

Homer-1b/c is required for calcium-sensing receptor-mediated signaling in osteoblasts. Mark Rybchyn¹, Tara Brennan-Speranza¹, Arthur Conigrave¹, Rebecca Mason*². ¹Sydney University, Australia, ²University of Sydney, Australia

Homer proteins are known to interact with G-protein coupled receptors such as Group 1 metabotropic glutamate receptors type 1 and type 5 and with calcium-signaling proteins in the brain and some other tissues. In human osteoblasts, we show for the first time that the scaffolding protein Homer-1b/c binds to the calcium sensing receptor (CaSR), in a calcium (Ca^{2+})-dependent manner. RNAi studies showed that Homer-1b/c was required for CaSR expression, whereas CaSR knockdown enhanced Homer-1b/c expression. We also show for the first time, that Homer-1b/c mediates extracellular Ca^{2+} - and CaSR-dependent activation of Akt via the protein kinase mammalian target of Rapamycin complex 2 (mTORC2). RNAi and western blot studies showed that this process results in stimulation of key downstream signaling pathways, such as Akt-dependent canonical Wnt signaling, along with resistance to apoptosis. Homer-1b/c and CaSR are highly expressed in osteosarcoma cells, thereby contributing to a high survival phenotype. Since the CaSR is essential for skeletal development, these new findings reveal Homer-1b/c as a key physiological component of functional and survival pathways in bone-forming cells.

Hydrogen sulfide protects osteoblastic cells against homocysteine-induced oxidative damage: Implications for the treatment of osteoporosis. Neetu Tyagi, Anuradha Kalani*, Suresh Tyagi. University of Louisville, USA

Clinical studies report that children born with severe hyperhomocysteinemia (HHcy), due to deficiency in cystathionine- β -synthase (CBS) gene, resulting in an elevation in plasma homocysteine (Hcy) levels, develop skeletal malformations with

weaker bone. However, pathogenic mechanisms that increase oxidative stress, DNA damage, the triggering of apoptosis and excitotoxicity by homocysteine (Hcy) are unsubstantiated. Interestingly, all these important factors may be involved in the development of osteoporosis. Osteoporosis is a bone disease that leads to an increased risk of fracture. Hydrogen sulfide is a gaseous signaling molecule; produced endogenously in the body has been demonstrated protective in various diseases. However, the effect of H_2S has not been explored in Hcy induced oxidative damage in MC3T3-E1 (osteoblastic) cells. Therefore, the present study was designed to investigate whether H_2S ameliorated Hcy-induced redox stress in MC3T3-E1 cells. The MC3T3-E1 cells were exposed to Hcy treatment in the presence or absence of NaHS (donor of H_2S). Our results demonstrate that Hcy-induced cell toxicity, increased the levels of free radicals which leads to apoptosis. Hcy also increased NADPH-oxidase-4 (NOX-4) expression and mitigated thioredoxin-1 (Trx-1) expression. NaHS increased cell viability and stimulates osteoblast proliferation by enhancing both transcription and activity of alkaline phosphatase in MC3T3-E1 cells that was decreased by Hcy. Additionally, treatment with NaHS stimulated the transcriptional level of osteocalcin. NaHS reversed the reduced superoxide dismutase activity, decreased reactive oxygen species production, and suppressed NADPH oxidase activity in Hcy treated cells. NaHS treatment also produced anti-inflammatory effect of H_2S . Western blotting analysis demonstrated that the protective effects of H_2S were facilitated by ERK1/2 MAPKs. In conclusion, H_2S protects osteoblastic cells against oxidative stress-induced cell injury via an MAPK-dependent mechanism. Our findings suggest that H_2S may have a therapeutic potential for osteoporosis.

RBPJK Deficient Mesenchymal Stem Cell Enhances Osteogenesis by Up-regulation of BMP Signaling. Bo Tian*¹, Junkui Sun¹, Xifu Shang², John Marymont¹, Yufeng Dong³. ¹Department of Orthopedic Surgery, LSUHSC-Shreveport, LA, USA, ²Anhui provincial Hospital, China, ³Louisiana State University, USA

Recently we have demonstrated the importance of RBPJK-dependent Notch signaling in the regulation of mesenchymal stem cell (MSC) differentiation during skeletogenesis both in vivo and in vitro. Here we further performed RBPJK loss-of-function experiments to demonstrate for the first time that RBPJK deficient MSC shows enhanced differentiation and osteogenesis acts via up-regulation of the BMP signaling. It was found that RBPJK highly expressed in fresh isolated human bone marrow MSCs and its expression was progressively down-regulated during spontaneous differentiation and even greater in osteogenic media induced differentiation. Deletion of RBPJK in MSCs not only enhances alkaline phosphatase (ALP) activity and cell spontaneous differentiation, but also significantly accelerates condition media induced osteogenic differentiation by showing enhanced Alizarin red staining, gene expression of Runx2, Osteopontin (OPN), Type I collagen (COL1a1) in culture (Fig. 1). Furthermore, luciferase assays demonstrate that deletion of RBPJK in MSCs significantly enhanced BMP signaling reporter 12XSBE activity. Additionally, phosphor-smad1/5/8 expression was also significantly increased upon removal of RBPJK in MSCs (Fig. 2). Taken together, our results proved that inhibition of Notch signaling in MSCs promotes cell osteogenic differentiation by up-regulation of BMP signaling, and RBPJK deficient MSC maybe a better cell population for cell-based bone tissue engineering. These data provide novel insights into our understanding of the molecular mechanisms underlying Notch regulation of osteogenesis.

Discovery of Long Noncoding RNAs During Osteoblast Differentiation of Pluripotent Mesenchymal Stromal Cells. [Coralee Tye*](#), [Jonathan Gordon](#), [Hai Wu](#), [Janet Stein](#), [Jane Lian](#), [Gary Stein](#). University of Vermont College of Medicine, USA

Long noncoding RNAs (lncRNAs) recently emerged as novel regulators of gene expression. These molecules are critical for lineage commitment, differentiation, development, disease progression and organism viability. lncRNAs have these diverse regulatory roles by facilitating epigenetic mechanisms including chromatin looping, histone post-translational modification, directly regulating mRNA splicing, transcription, protein translation, as well as functioning as microRNA sponges. Thus, lncRNAs have tremendous potential for regulating the “bone” genome. Because there are few studies of lncRNAs in bone tissue, we initiated characterization of lncRNAs in osteoblast lineage cells by global expression analysis. We performed next-generation sequencing (RNA-Seq) on primary mesenchymal stromal cells (MSCs) undergoing osteoblastic differentiation to 4 specific stages of maturation: day0 (proliferation), day7 (commitment), day14 (extracellular matrix deposition) and day21 (mineralization). Results from human MSCs (hMSCs; Adult Mesenchymal Stem Cell Resource, Texas A&M IRM) and mouse bone marrow derived MSCs (mMSCs) were compared and we found 22% of mouse lncRNAs had conserved expression in human, compared to 97% conserved expression of mRNAs. This suggests unique functions for lncRNAs within species, but also demonstrates that mouse models can be used for functional evaluation of a subset of lncRNAs relevant to human disease. We identified 1912 annotated lncRNAs expressed during mMSC differentiation and 5363 lncRNAs in hMSCs. During mMSC differentiation, 198 lncRNAs are differentially expressed (FDR adjusted p-value <0.05). To validate their expression, expression profiles were correlated with ChIP-Seq analysis of epigenetic modifications associated with transcriptional activation, elongation and repression (H3K4me³, H3K27ac, H3K36me³, H3K27me). As with mRNAs, changes in lncRNA expression are reflected at the chromatin level by changes in histone marks. Dynamic changes were observed in a subset of lncRNAs; others were constitutively expressed. Intersection of lncRNAs with enrichment profiles of Runx2 revealed >40% of lncRNAs genomic loci were bound by Runx2. Our comprehensive dataset identifies over a hundred lncRNAs that are dynamically expressed during osteogenesis, many of which are potentially regulated by Runx2. These findings open novel dimensions for exploring lncRNAs in regulating normal bone formation and their deregulated expression in skeletal disorders.

Identification of novel enhancer regions in mesenchymal stromal cells that regulate osteogenic differentiation. [Jonathan Gordon*](#)¹, [Hai Wu](#)², [Coralee Tye](#)², [Joesph Boyd](#)², [Andre van Wijnen](#)³, [Janet Stein](#)², [Gary Stein](#)², [Jane Lian](#)². ¹University of Vermont, USA, ²University of Vermont, Department of Biochemistry, USA, ³Mayo Clinic, Department of Orthopedic Surgery, USA

Adult bone formation requires a highly regulated program of differentiation from a mesenchymal-derived osteoprogenitor to a mature osteocyte. Epigenetic mechanisms control mesenchymal stromal cell (MSC) commitment to a mature osteoblast through facilitating of binding of transcriptional regulators to promoter regions of

genes, however less well understood are inter- and intra-genic regulatory regions that control cell-type-specific gene expression programs. These regulatory elements called enhancers, are bound by transcription factors (TFs) and specific post-translationally modified histones, and play key roles in the control of tissue morphogenesis. To define novel regulatory regions during osteogenesis, pluripotent CD45-/Ter119-/SCA1+/CD29+/Nestin+/CD146+/aSMA+ MSCs were isolated by FACS to obtain a homogenous population of cells that were differentiated to mature osteoblasts (defined by expression of late-stage marker genes (e.g. Ibsp, Dmp1 and Mepe)). We then used ChIP-seq to develop genome-wide enrichment profiles of intergenic genomic regions of occupied by TFs, cofactors, chromatin regulators, and transcription apparatus occupying osteogenic-specific enhancers in MSCs. Supervised pattern discovery was performed using ChromHMM to segment genomic regions into active, quiescent, TF-bound, transcribed and super-enhancer regions. From this analysis, we identified novel enhancers near genes involved in osteogenesis and novel enhancers for bone formation were predicted in intragenic regions of several osteoblast-related genes. Several novel enhancers were identified within the HoxA cluster (chr6: 52,151,599-52,268,229), as well as intragenic enhancers in the osteoblast regulators Znf521 (chr18: 52,151,599-52,268,229), Runx2 (chr17:44,603,989-44,814,627) and Sp7 (chr15:102,357,177-102,366,271). In addition we identified new regulatory regions proximal to VISTA-defined enhancers near the Fgfr1 gene, previously identified to regulate bone formation. Ongoing functional evaluation of these regions will provide new information on the regulation of osteoblast gene function and MSC commitment.

In conclusion, we have defined novel regulatory regions, denoted by histone modifications and transcription factor binding sites that function as enhancers critical for osteogenic differentiation. This comprehensive epigenetic signature of lineage commitment and osteoblast differentiation is clinically relevant to pathogenic conditions involving bone loss and repair.

Inhibition of c-src activity in primary bone marrow cells mimics the decreased expression of the osteoblast phenotype seen in tumor cells. [Ashley Dinkel*](#), [Joseph Tarr](#), [Dana Branch](#), [Joshua Luster](#), [Thomas Owen](#). Ramapo College of New Jersey, USA

Deletion of the c-src gene results in decreased osteoclast and increased osteoblast activity resulting in osteopetrosis. PP2 is a commonly used c-src inhibitor and PP3 is a structurally similar inactive compound. Previous work showed that PP2 treatment of primary rat calvarial osteoblasts (ROB) increases their differentiation as demonstrated by increased mineralized nodule formation. We tested PP2 and PP3 on ROS 17/2.8 osteosarcoma cells in order to further investigate the mechanisms through which c-src inhibition drives differentiation. C-src inhibition by PP2 beginning at plating decreased alkaline phosphatase (AP) activity at days 4 and 8 as compared to cells treated with PP3, in contrast to the ROB cells. In order to address whether this unexpected observation was due to the tumor-derived nature of ROS cells, rat bone marrow cells (BMC) were chosen as a second osteoblastic differentiation system. BMCs were treated with PP2 or PP3 by a single application or by continuous treatment. For single applications, cells were treated with PP2 or PP3 at plating or with the first or second media change (days 3 or 7). Continuous treatment involved adding PP2 or PP3 beginning at plating or at the first or second media change and continuing until harvest. BMCs were fixed on day 25 and stained for AP activity and mineralized nodules. BMC differentiation was quantitated by image analysis for both AP positive and mineralized nodule area. Our results in BMCs mirrored those found in the ROS cells, not those found in the primary rat calvarial cells; the application of PP2 resulted in less differentiation. Addition of a single dose of PP2 at plating resulted in a 50-70% decrease in AP positive and mineralized nodule area, whereas addition of a single dose of PP2 at days 3 or 7 had no effect as compared to PP3-treated cells. With continuous treatment, a similar decrease was seen when cells were dosed beginning at plating or day 3, however, if dosing was initiated at day 7, a smaller decrease of ~25% was seen in AP activity. These data suggest that c-src is involved in the commitment of bone marrow stem cells to becoming osteoblasts as well as in their initial differentiation. ROS 17/2.8 cells are thought to represent early stage osteoblasts potentially equivalent to the BMCs several days after attachment. In contrast, the increased differentiation seen in ROB cells following PP2 treatment may be due to the calvarial osteoblasts' different developmental origin.

Neuropeptide-Receptor expression during Osteoblastic Differentiation of Mouse iPS cells. [Tetsuya Goto*](#). Kagoshima University Graduate School of Medical & Dental Sciences, Japan

Recent evidence suggests that both sensory and autonomic nerves affect bone metabolism; however, it has been unclear how neuropeptides are associated with the differentiation of pluripotent stem cells into osteoblastic cells. To evaluate the putative effects of neuropeptides during the differentiation of mouse induced pluripotent stem (iPS) cells into calcified tissue-forming osteoblastic cells, we investigated the expression patterns of neuropeptide receptors at each differentiation stage; iPS, Embryoid body, early osteoblast, and late osteoblast stages. Mouse iPS cells were seeded onto feeder cells and then transferred to low-attachment culture dishes to form

embryoid bodies. Embryoid bodies were cultured for 4 weeks in osteoblastic differentiation medium. The expression of α 1-adrenergic receptor (AR), α 2-AR, β 2-AR, neuropeptide Y1 receptor (NPY1-R), neuropeptide Y2 receptor (NPY2-R), calcitonin gene-related protein receptor (CGRP-R), and neurokinin 1-R (NK1-R) was assessed by reverse transcription-polymerase chain reaction (RT-PCR) and real-time PCR. Among these neuropeptide receptors, CGRP-R and β 2-AR were expressed at all stages of cell differentiation, including the iPS cell stage, with peak expression occurring at the early osteoblast-differentiation stage. Another sensory nervous system receptor, NK1-R, was expressed mainly in the late osteoblast-differentiation stage. Furthermore, CGRP-R mRNA showed an additional small peak corresponding to embryoid bodies cultured for 3 days, suggesting that embryoid bodies may be affected by serum CGRP. These data suggest that the sensory nervous system receptor CGRP-R and the autonomic nervous system receptor β 2-AR may be involved in the differentiation of iPS cells into the osteoblastic lineage. It follows from these findings that CGRP and β 2-AR may regulate cell differentiation in the iPS and embryoid body stages, and that each neuropeptide has an optimal period of influences during the osteoblast-differentiation process.

Pin1-mediated modification prolongs the nuclear retention of β -catenin in wnt3a-induced osteoblast differentiation. Hea-rim SHIN¹, Taegyung Lee¹, Han-sol BAE¹, Rabia ISLAM¹, Won-joon YOON¹, Young-dan CHO², Bong-su KIM¹, Kyung-mi WOO¹, Hyun-mo RYOO¹. ¹Seoul National University, South Korea, ²Seoul National University, South Korea

The canonical Wnt signaling pathway plays an important role in osteoblast differentiation and cancer development. β -catenin nuclear localization is a crucial step in the pathway as it functions as a transcription factor with LEF/TCF. Pin1 plays a key role in the post-phosphorylational conformational change of β -catenin by cis/trans isomerization and Pin1 is known as a regulator of turnover and subcellular localization of β -catenin in cancer. However, the association of Pin1 in Wnt-induced osteoblast differentiation is poorly understood and the detailed molecular mechanism that promotes β -catenin nuclear localization has yet to be revealed. Therefore, we investigated whether Pin1 functions in bone formation by regulating β -catenin. Proximal tibial osteoblasts of Pin1 knock-out (KO) mice showed a reduction in β -catenin levels, and Pin1 controls Wnt-induced TOP Flash activity in Pin1 WT/KO mouse embryonic fibroblast (MEF) cells. Pin1 knockdown repressed Wnt3a-induced osteoblast differentiation and bone marker gene expression in MC3T3E1 cells. In contrast, overexpression of Pin1 enhanced osteoblast differentiation stimulated by Wnt3a administration. In addition, the transcriptional synergy of Wnt3a with Pin1 was observed in TOP Flash and alkaline phosphatase gene promoter activity. In this study, we demonstrate that Pin1 binds to β -catenin in the nucleus and Pin1 activity increases the nuclear retention of β -catenin, while it does not stimulate translocation of β -catenin into the nucleus. Isomerized β -catenin did not bind to nuclear adenomatous polyposis coli (APC), a tumor suppressor and nuclear β -catenin chaperone, which consequently increases retention of β -catenin in the nucleus. These results provide great insight into the importance of Pin1 in β -catenin-mediated osteogenesis and tumorigenesis.

A murine model of acute and chronic long bone segmental defect repair. David Rowe^{*}, Liping Wang, Jianping Huang. University of Connecticut Health Center, USA

The functional repair of a critical-size long bone segmental defect implies the reconstitution of the cortical bone and the ability of the animal to ambulate free of orthopedic support. Here we report a model in both the tibia and femur of mice that are immune tolerate to all cell sources and carry a Col3.6GFPtpz reporter to mark host derived bone cells. In either long bone, a 3.5 mm defect is created and supported by either a rigid or compliant fixation device. Each device is designed to be removed or released in the living animal to test the functionality of the repair. The test material can be either cells or scaffold and can be introduced at the time of surgery, or 4-6 weeks after the initial surgery when end-capping of the bone has developed. In the chronic non-union model, a second surgery is performed in which the ends of the bones are freshened followed by introduction of the test cells or scaffold. Primary BMSCs derived from a mouse carrying a Col3.6GFPcyan reporter were plated in MEM/5% O2 and expanded for 5-6 days without passage. Approximately 1x10⁶ cells were added to a commercial collagen scaffold (Healos) placed within the defect space. The mice are followed by serial digital X-rays and the support structure are removed when the cortical bone has developed (5-6 weeks). The animals are injected with alizarine complexone 1 day prior to sacrifice, which is usually 4-6 weeks after the supports are removed.

The histology demonstrates that the regenerated bone comes almost exclusively from the donor cells. Within the defect space, the bone lining cells carry the Col3.6GFPcyan reporter, are AP positive and actively depositing a mineralization label. Host osteogenic activity is limited to the site where the support structures were applied. A striking feature is the distribution of the osteoclastic activity. In the compliant repair, osteoclasts are located on the periosteal surface and resemble the inward movement of the outer cortical shell of a fracture. In a rigid fixation, the

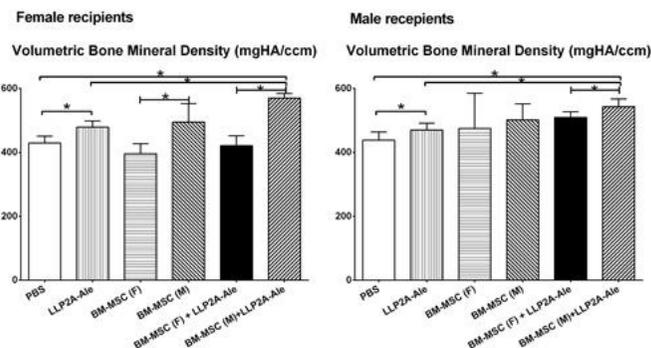

osteoclasts are restricted to the marrow and endocortical surface. Despite the regeneration of the cortex, the matrix still contains regions of unresorbed proteins and the endochondral->periosteal conversion to lamellar bone remains incomplete. We believe that this model will be an informative and relatively low cost platform for characterizing intrinsic donor cells capacity and host environmental factors that contribute to a successful repair outcome.

Bone targeted delivery of mesenchymal stem cells for fracture healing and sex difference. Wei Yao^{*1}, Evan Lay², Hongliang Zhang², Haiyan Chen², Nancy Lane². ¹University of California, Davis Medical Center, USA, ²Center for Musculoskeletal Health, Internal Medicine, University of California at Davis Medical Center, USA

Introduction. Traumatic fractures can require hospitalization, surgery, frequent physician visits, and lost time from work. Exogenous mesenchymal stem cells (MSCs) transplantations have been tested in animal models and human fractures. Whether these transplanted MSCs would directly home to fracture sites and participate in the healing process, or indirectly influence the healing process via paracrine mechanisms are under investigations. We have developed a bone-seeking compound, LLP2A-Alendronate (LLP2A-Ale) that selectively targets the integrin α 4 β 1, and increases exogenous MSCs homing to bone. The purpose of this study was to determine if treatment with the LLP2A-Ale or combination of LLP2A-Ale and MSCs would accelerate healing in a closed fracture model and if the effects would differ by sex. **Methods.** The right femurs from were fractured in 2-month-old osterix-mCherry (Ox-mCherry) reporter mice of both sexes. The mice were subsequently treated with placebo (PL), LLP2A-Ale (500 μ g/kg, IM), bone marrow derived MSCs (BM+ MSCs) obtained from either Col1-2.3kb-GFP or the wild-type Ox-mCherry mice from both sexes (BM-MSC (F) & BM-MSC (M), 5 x 10⁵, IM), alone or in combination with LLP2A-Ale. The study endpoints included exogenous MSC bone engraftment assessed at days 7, 14 and 21 post-fracture and callus volumetric mineralization (BMD) assessed at day 21 and 42. **Results.** Initially, LLP2A-Ale increased homing of exogenous MSCs to the fracture callus, located at the periosteum, incorporated into callus and contributed to the endochondral bone formation. At day 42, LLP2A-Ale significantly increased callus BMD compared to PL in both sexes ($p < 0.05$). Treatment with only BM-MSCs derived from males ([M-MSCs (M)]) induced greater callus BMD than BM-MSCs (F). LLP2A-Ale + BM-MSCs (M) had a greater increase in callus BMD both females and males treatment groups compared to either treatment alone (Figure).

Effects of combination melatonin, strontium citrate, vitamin D3 and vitamin K2 on osteoblast and osteoclast differentiation grown as co-cultures. Sifat Maria^{*1}, Larry Enderby², Holly Lassila¹, Christine O'Neil¹, Mark Swanson³, Paula Witt-Enderby⁴. ¹Duquesne University, USA, ²Enderby Healthcare/Legal Consulting, LLC, USA, ³Private practice, Heart Preventions, LLC, USA, ⁴Duquesne University, School of Pharmacy, USA

A translational research study, *Melatonin-micronutrients Osteopenia Treatment Study (MOTS)*, was designed to assess the efficacy of combination natural bone tropic agents: melatonin, strontium citrate, vitamin D₃ and vitamin K₂ (MSDK) on bone health and quality of life in post-menopausal osteopenic women. As part of this study, mechanisms underlying MSDK's effects on bone-forming osteoblasts and bone-resorbing osteoclasts was evaluated using a unique co-culture system containing human bone marrow stem cells (hMSCs) and human peripheral blood monocytes (hPBMCs). Using a novel *in vitro* treatment paradigm that closely mimics the *in vivo* condition, hMSCs/hPBMCs were co-cultured either by seeding hPBMCs directly on top of differentiating hMSCs (layered co-culture) or separately using transwell

(transwell co-culture). Co-cultures were exposed to vehicle, each component (M, S, D or K) alone or combination (MSDK) in either osteogenic (Os+) or growth medium (Os-) for 21 days. Effects of M, S, D and K either alone or in combination on osteoblast and osteoclast differentiation and activity were measured by alizarin red or TRAP staining, respectively. In transwell co-culture, combination MSDK enhanced osteoblast differentiation and mineralization to the greatest extent (30-fold) vs. Os-/V. Layered co-culture study demonstrated similar patterns of osteoblast induction (50-fold vs Os-/V). Interestingly, osteoblast induction occurred at a greater extent in all Os+ treated culture vs Os-/V, suggesting that cell-to-cell contact was important for modulating osteoblast differentiation. In both cases, M and S alone showed a significant increase in osteoblast mineralization suggesting the possible contribution of these two agents in bone formation by MSDK treatment. Parallel assessment of the treatment's effect on osteoclast differentiation showed that combination MSDK inhibited osteoclast differentiation to the greatest extent vs Os-/V cells even though exposure to M, S or K alone also inhibited osteoclast differentiation. Measurement of the ratio of RANKL; an osteoclast inducer and OPG; a RANKL decoy receptor in transwell co-culture further revealed the potential underlying root of MSDK's effect, which involved induction of membrane bound OPG: RANKL ratio by MSDK treatment as a result of both increasing membrane bound OPG level and decreasing membrane bound RANKL level.

SU0208

Ethanol Exposure Increases FoxO Activation in Cultured Primary Rat Mesenchymal Stem Cells. Philip Roper*. Loyola University, USA

The process of fracture healing is complex, and poor or incomplete healing remains a significant health problem. During normal healing, resident mesenchymal stem cells (MSCs) at the fracture site differentiate into osteoblasts and chondrocytes, which are the necessary cell types for callus formation. MSC differentiation relies on canonical Wnt signaling activation of the transcription factor β -catenin within MSCs. β -catenin drives the expression of pro-osteogenic and pro-chondrogenic genes. Alcohol abuse is a major factor associated with increased incidence of poor or delayed healing. Although it is unknown how alcohol actuates perturbed fracture healing, a contributing factor could be alcohol's ability to induce oxidative stress. The family of FoxO transcription factors are activated by oxidative stress, and FoxOs are known to inhibit Wnt signaling by competing for β -catenin, a necessary FoxO cofactor. We have previously shown that FoxO expression, as well as markers of activation, are increased in the fracture callus of alcohol-treated animals exhibiting delays in fracture healing. Also, these alcohol-induced fracture repair deficiencies were attenuated by antioxidant therapy. Therefore, we hypothesize that ethanol exposure inhibits proper MSC differentiation by increasing oxidative stress and FoxO activation within MSCs, which will inhibit Wnt/ β -catenin signaling. To test this, we have cultured primary rat MSCs, and exposed them to either media alone, 50mM ethanol, or 50uM hydrogen peroxide, as a positive control of oxidative stress, for 24 hours. Exposure to either ethanol or hydrogen peroxide in culture increased intracellular oxidative stress by measuring DNA damage. This coincided with an increase in FoxO nuclear localization, by western blotting, and association with β -catenin, as measured by co-immunoprecipitation. We also found ethanol was able to increase FoxO activity, as measured by DNA binding, using a DNA-binding assay. This study shows that alcohol, by increasing oxidative stress, shifts intracellular MSC signaling away from Wnt/ β -catenin signaling and towards FoxO signaling, potentially perturbing the overall MSC differentiation capability. This highlights a potential mechanism behind alcohol-induced impaired healing, thereby elucidating potential methods of intervention while bolstering our overall understanding of fracture healing.

GATA4 Regulates Mesenchymal Stem Cell Differentiation. Aysha Khalid*¹, Miriam Guemes², Gustavo Miranda-Carboni³, Susan Miranda³.
¹University of Tennessee, USA, ²UCLA, USA, ³UTHSC, USA

GATA4 is a zinc-finger transcription factor that is essential in various tissues, such as heart, kidneys, intestine and more recent studies showed that it also has a role in osteoblasts and it is essential for bone mineralization. Total *Gata4* knockout mice or conditional knockout mice, both exhibit embryonic lethality, which suggests that *Gata4* not only is important for bone development but also for mice survival. However, it is not known if GATA4 plays a role in mesenchymal stem cells (MSC) commitment to osteoblasts. MSCs are multipotent cells that can give rise to a range of different lineages, including osteoblasts and adipocytes. This study investigates the expression and function of GATA4 in MSCs, adipocytes and osteoblasts. qPCR analysis of the cDNA of pericytes, bone marrow MSCs, and primary calvarial cells differentiated for 14 days in osteogenic media demonstrated a significant decrease in *Gata4* expression levels as compared to undifferentiated cells. This suggests that GATA4 regulates bone mineralization early in the differentiation process. Cell proliferation rates were also reduced in primary calvarial cells infected with lentivirus expressing shRNA directed to *Gata4* (shGATA4) as compared to GFP (shGFP), as determined by WST-1 assay. Bone marrow stromal cells differentiated for 14 days showed reduced fat accumulation and mineralization, as visualized by Oil red O and

Alizarin Red staining, respectively. This indicates that the knockouts have less bone and less fat which indirectly suggests a cellular defect in MSCs. This defect was confirmed *in vivo* by performing immunohistochemistry on GATA4 knockout and wildtype femurs. The knockouts showed fewer nestin positive stem cells as compared to wildtypes. Together this data suggest that *Gata4* knockouts have fewer and slower proliferating MSCs, which in turn leads to reduced bone mineral density in *GATA4* knockout bones, as compared to wildtype bones.

Localized SOX9 Expression Delineates Regions of Cartilage and Bone Formation in a Tissue-Engineered Construct. Pieter-Jan Stiers*, Nick van Gastel, Riet Van Looveren, Sophie Torrekens, Geert Carmeliet. Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium

Bone tissue engineering is a promising therapy for non-healing bone defects and generally consists of a scaffold, skeletal progenitor cells and/or growth factors. To improve clinical outcome, a better understanding of the behavior of implanted cells, especially during the early stages, is required.

We have previously shown that ectopic implantation of FGF2-pretreated mouse periosteum-derived cells (mPDC^{FGF2}) embedded in a collagen gel resulted in manifest bone formation via endochondral ossification, whereas non-treated mPDC (mPDC^{control}) did not. We now investigated the behavior and fate of the implanted cells as well as the host response during the early phases using intravital imaging together with histology.

One day after implantation numerous mPDC^{FGF2}, but not control cells, were SOX9-positive, whereas SOX9 expression was decreased in mPDC^{FGF2} prior to implantation. Apoptosis, proliferation and migration were hardly detected in both conditions. After 3 days, the organization of the mPDC^{FGF2} implant was completely changed: mPDC in the outer layers were highly proliferative but mostly SOX9 negative, whereas in the center most mPDC expressed SOX9, showed limited proliferation but differentiated to collagen 2-positive chondrocytes. These changes were not observed with mPDC^{control}, although a comparable angiogenic host response was noticed. At day 7, only mPDC^{FGF2} implants had increased in size and contained hypertrophic chondrocytes, although blood vessel invasion at the periphery of the implant was present in both conditions. Close to blood vessels mPDC^{FGF2} differentiated to osteoblasts, analyzed using Col1-dsRed mPDC. The number of donor osteoblasts increased over the following days, especially at sites of invasion into the cartilage, concomitant with the appearance of small numbers of host cells. At day 14, mainly donor cells were found lining the bone trabeculae that had formed, while after 21 days both donor- and host-derived osteoblasts were observed.

Our results show that early after implantation, mPDC with bone-forming potential do not elicit an increased angiogenic response but diverge into distinct populations that form cartilage and bone, both of which derive from a common SOX9-positive progenitor. These insights can help in the development of new, more robust therapies for non-healing bone defects.

Single CD271 marker identifies mesenchymal stem cells from human dental pulp with high osteogenic potential. Christine Hong*, Ruth Alvarez, Hyelim Lee, Cun-yu Wang. UCLA School of Dentistry, USA

Mesenchymal stem cells (MSCs) are a promising tool in regenerative medicine due to their capacity to differentiate into multiple lineages. In addition to MSCs isolated from bone marrow (BMSCs), adult MSCs are isolated from craniofacial tissues including dental pulp tissues (DP) using various stem cell surface markers. However, there has been a lack of consensus on a set of surface makers that are reproducibly effective at isolating putative multipotent dental mesenchymal stem cells (DMSCs). In this study, we used different combinations of surface markers (CD51/CD140a, CD271, and STRO-1/CD146) to isolate homogeneous populations of DMSCs from heterogeneous dental pulp cells (DPCs) obtained from DP and compared their capacity to undergo multilineage differentiation. Fluorescence-Activated Cell Sorting (FACS) revealed that 27.3% of DPCs were CD51+/CD140a+, 10.6% were CD271+, and 0.3% were STRO-1+/CD146+. Under osteogenic conditions, all three subsets of isolated DMSCs exhibited differentiation capacity into osteogenic lineages. Among these isolated subsets of DMSCs, CD271+ DMSCs demonstrated the greatest osteogenic potential. While all three combinations of surface markers in this study successfully isolated DMSCs from DPCs, single CD271 marker presents the most effective stem cell surface marker for identification of DMSCs with high osteogenic potential. Isolated CD271+ DMSCs could potentially be utilized for future clinical applications in dentistry and regenerative medicine.

Analysis of contribution of marrow stromal cells and bone marrow macrophages to mechanical loading-induced osteoclastogenesis and bone resorption. Hideki Kitaura¹, Keisuke Kimura², Masahiko Ishida², Yumiko Ochi², Haruki Sugisawa², Jafari Saeed², Akiko Kishikawa², Teruko Takano-Yamamoto². ¹Tohoku University, Japan, ²Division of Orthodontics & Dentofacial Orthopedics, Department of Translational Medicine, Tohoku University Graduate School of Dentistry, Japan

Mechanical stress such as orthodontic tooth movement induces osteoclastogenesis *in vivo*. It has been reported that TNF- α plays an important role in mechanical loading-induced osteoclastogenesis and bone resorption. *In vitro* studies suggested three cell types, marrow stromal cells, macrophages and T-cells, participate in TNF- α -induced osteoclastogenesis. Our purpose is to determine the *in vivo* contribution of each above mentioned cell types, as direct or indirect TNF- α target cell type to mechanical loading-induced osteoclastogenesis. We established mechanical stress-induced osteoclastogenesis model in mice using orthodontic tooth movement in which an Ni-Ti coil spring was inserted between the upper incisors and the upper first molar. Using TNF receptor 1- and 2-deficient mice (KO), we showed that orthodontic tooth movement and mechanical loading-induced osteoclastogenesis was mediated by TNF- α . We applied orthodontic tooth movement to chimeric mice which wild type mice (WT) marrow was transplanted into lethally irradiated WT (WT>WT), WT marrow was transplanted into lethally irradiated KO (WT>KO), KO marrow was transplanted into lethally irradiated WT (KO>WT) and KO marrow was transplanted into lethally irradiated KO (KO>KO). In those mice, T cells were blocked by anti-CD4 and anti-CD8 antibodies. After 12 days of experimental tooth movement, the amounts of orthodontic tooth movement were measured and the number of tartrate-resistant acid phosphatase (TRAP)-positive cells along the loaded alveolar bone and root surface were counted as osteoclasts and odontoclasts, respectively, in histological sections. The amount of orthodontic tooth movement, the number of osteoclasts and odontoclasts in WT>KO and KO>KO were significantly lower than that in WT>WT and KO>WT mice. These findings suggested that stromal cells were more contributed than bone marrow macrophage in mechanical loading-induced osteoclastogenesis.

Bone Active Nitrogen-containing Bisphosphonates with a Near Infrared Fluorescent Label for Potential Use in Arthritis Models. Shuting Sun¹, Frank Ebetino¹, Kim Nguven², Boris Kashemirov², Charles McKenna², Mark Lundy¹, Xiaodong Hou³, Zhenqiang Yao³, Brendan Boyce³. ¹BioVinc LLC, USA, ²University of Southern California, USA, ³University of Rochester, USA

Rheumatoid arthritis (RA) is characterized by synovial inflammation and articular cartilage and bone erosion. Although there is no cure for RA, disease modifying anti-rheumatic drugs, including anti-TNF agents, significantly improve the clinical course of RA. However, it is still difficult to detect early erosion. A noninvasive tool for diagnosis of erosions and evaluation of the response to therapies is therefore an unmet need. Bisphosphonates (BPs) including risedronate (RIS) and zoledronate (ZOL) have high affinity for bone, particularly at active turnover sites. Thus, BPs could be ideal carriers to deliver imaging probes to sites of bone erosion in RA patients. Near infrared (NIR)-BP conjugates may be used to noninvasively identify bone erosions because of higher penetration depth and attenuation of light scattering. Interestingly, the 5,6-carboxyfluorescein (FAM)-conjugated BPs (FAM-RIS and FAM-ZOL) retain anti-prenylation/antiresorptive activity in J774 macrophages and in osteoclasts, but, no significant anti-prenylation activity is observed with the NIR-BP conjugates based on Alexa fluor 647 (AF647), Cy5 and IRDye 800CW. To expand the utility of these NIR agents, we have prepared a series of AF647-RIS conjugates in order to reduce fluorophore interference on cellular activity. Linker lengths were extended between the AF647 fluorescent label and the pyridyl moiety to increase the distance of the fluorescent component from the BP binding site. To determine if these AF-BP structural modifications improved the osteoclast (OC) inhibitory activity, we tested them *in vitro* using mouse bone marrow cells. We found that while the control probe AF647-RIS had little effect on OC numbers (221+/-37, 241+/-21 and 230+/-36 for 0.1, 1 and 10 μ M AF647-RIS), two linker extensions significantly decreased OC numbers: 218+/-24, 208+/-21 and 19+/-5 for 0.1, 1 and 10 μ M AF647-RIS-v1 (a 3 carbon extension), and 205+/-22, 221+/-19 and 43+/-10 for 0.1, 1 and 10 μ M AF647-RIS-v2 (a 15-atom poly(ethylene glycol) linker), compared to vehicle (239+/-17) and RIS (214+/-37, 220+/-28 and 143+/-21 for 0.1, 1 and 10 μ M). These data suggest that increasing the linker chain length of an AF647-BP conjugate can dramatically increase its inhibitory effects. Thus, while the pharmacologically inactive AF647-RIS may be a useful tool to detect bone erosion in RA, longer linked antiresorptive conjugates (AF647-RIS-V1/V2) may be used to study the location and therapeutic effect of N-BPs.

C-C chemokine receptor 5, a co-receptor of HIV, -mediated signalregulates bone resorption via locomotion of osteoclasts. Ji-Won Lee¹, Akiyoshi Hoshino², Takashi Saitou³, Kazuki Inoue⁴, Shunsuke Uehara⁵, Yasuhiro Kobayashi⁶, Satoshi Ueha⁷, Kouji Matsushima⁷, Masako Ito⁸, Akira Yamaguchi⁹, Yuuki Imai¹⁰, Tadahiro Iimura¹¹. ¹Division of Bio-Imaging, Protea-Science Center (PROS), Ehime University, Japan, ²Department of Pathology, Nagoya University Graduate School of Medicine, Japan, ³Translational Research Center & Artificial Joint Integrated Center, Ehime University, Japan, ⁴Department of Biological Resources, Integrated Center for Sciences, Ehime University, Japan, ⁵Department of Biochemistry, Matsumoto Dental University, Japan, ⁶Institute for Oral Science, Matsumoto Dental University, Japan, ⁷Department of Molecular Preventive Medicine, Graduate School of Medicine, The University of Tokyo, Japan, ⁸Medical Work-Life-Balance Center, Nagasaki University Hospital, Japan, ⁹Department of Pathology, Nagoya University Graduate School of Medicine, Nagoya, Japan, Japan, ¹⁰Division of Integrative Pathophysiology, Proteo-Science Center, Graduate School of Medicine, Japan, ¹¹Division of Bio-Imaging, Proteo-Science Center (PROS), Ehime University, Japan

The lifespan of patients who have HIV infection has increased significantly with global HIV epidemic treatment in last few decades, and simultaneously low bone mass has emerged as a significant comorbidity. C-C chemokine receptor 5 (CCR5) is a co-receptor of macrophage-tropic viruses including HIV. Epidemiological and pathological findings have reported that functional changes in CCR5 correlate with HIV transmission and bone destruction diseases. However, physiological roles of CCR5 in bone metabolism have not been well documented. Live imaging and super-resolution microscopy analyses revealed that *Ccr5*-deficient osteoclasts showed larger in size and disorganized motility, cytoskeletal rearrangement and cell-attachment machineries including integrins, thus leading decreased bone resorption activity. Our further molecular and cellular analyses suggested that CCR5-mediated signal was associated with c-Src and small GTPase activation that was required for proper osteoclasts function. *Ccr5*-deficient mice had significantly increased number and size of osteoclasts, although they did not show significant difference in BMD compared to their wild-type littermates. Interestingly, *Ccr5*-deficient mice were less susceptible to RANKL-induced bone loss, suggesting functional impairment of osteoclasts. Moreover, blockades of human CCR5 by anti-hCCR5 neutralizing antibody obviously inhibited human osteoclastogenesis in dose-dependent manner, without affect to osteoblast differentiation. These data unveil unique and essential roles of CCR5 in bone metabolism and bone destruction diseases, and have implications concerning bone physiopathology for the HIV therapy targeting CCR5.

G Protein-Coupled Receptor 120 Signaling Negatively Regulates Osteoclast Differentiation, Survival, and Function. Hyun Ju Kim¹, Hye-Jin Yoon², Bo Kyung Kim², Sook Jin Seong², Shin-Yoon Kim², Young-Ran Yoon². ¹Kyungpook National University Hospital, South Korea, ²Kyungpook National University, South Korea

G protein-coupled receptor 120 (GPR120) plays an important role in the regulation of inflammation and lipid metabolism. In this study, we investigated the role of GPR120 in osteoclast development and found that GPR120 regulates osteoclast differentiation, survival and function. We observed that GPR120 was highly expressed in osteoclasts compared to their precursors, bone marrow-derived macrophages (BMMs). Activation of GPR120 by its ligand GW9508 suppressed receptor activator of NF- κ B ligand (RANKL)-induced osteoclast differentiation and the expression of nuclear factor of activated T cells c1 (NFATc1), a key modulator of osteoclastogenesis. GPR120 activation inhibited the RANKL-stimulated phosphorylation of I κ B α and JNK without affecting p38. In addition to osteoclast differentiation, GPR120 activation increased the apoptosis of mature osteoclasts by inducing caspase-3 and Bim expression. Activation of GPR120 also interfered with cell spreading and actin cytoskeletal organization mediated by M-CSF but not by RANKL. Coincident with the impaired cytoskeletal organization, GPR120 activation blocked osteoclast bone resorbing activity. Furthermore, knockdown of GPR120 using small hairpin RNA abrogated all these inhibitory effects on osteoclast differentiation, survival, and function. Together, our findings identify GPR120 as a negative modulator of osteoclast development that may be an attractive therapeutic target for bone-destructive diseases.

Inhibition of CysLTR1 Suppresses RANKL-induced Osteoclast Formation and Bone Loss in vivo. Ju-Hee Kang*¹, Mijung Yim². ¹Sookmyung Women's University, South Korea, ²Sookmyung women's university, South Korea

Leukotrienes are inflammatory lipid mediators derived from arachidonic acid through the involvement of the 5-lipoxygenase (5-LO) pathway. They are divided into two groups, LTB4 and Cysteinyl leukotrienes (CysLTs), namely LTC4, LTD4, LTE4. Especially, LTC4 is formed by LTC4 synthase (LTC4S), and it converted to LTD4, and further into LTE4. CysLTs are well known for a cause of many diseases such as asthma, allergic rhinitis, coronary artery, and immune disorder by binding on 2 types of receptor (CysLTR1 or CysLTR2). It has been implicated as a promising drug target to treat various inflammatory diseases. Since little is known about the role of CysLTR1 on osteoclastogenesis, we investigated its functions and intracellular signaling pathways in osteoclast differentiation using CysLTR1 antagonist. In this study, we showed that CysLTR1 antagonist suppressed RANKL-induced osteoclast formation at late (day2-4) stage without cytotoxicity. Real-time PCR analysis revealed that the mRNA levels of osteoclastogenic markers were decreased by CysLTR1 antagonist. In addition, CysLTR1 antagonist reduced RANKL-induced pit formation on dentin slices. Inhibition of CysLTR1 was attributable to reduction in the expression of NFATc1, an essential transcription factor for osteoclast differentiation. It is also associated with impaired activation of multiple signaling events downstream of RANK, including ERK, Akt, CREB, PLC β 2 phosphorylation and I κ B degradation. Ectopic overexpression of a constitutively active form of NFATc1 partly rescued the anti-osteoclastogenic effect of CysLTR1 antagonist. The knockdown of LTC4S in BMMs also resulted in a significant reduction in RANKL-induced osteoclast formation, accompanied by decreased expression of NFATc1. Finally, we evaluated the effect of CysLTR1 antagonist using LPS-calvaria mouse model and ovariectomy mouse model in vivo. CysLTR1 antagonist decreased lipopolysaccharide (LPS)-induced osteoclast formation in vivo. Furthermore, inhibition of CysLTR1 reduced ovariectomy (OVX)-induced bone loss. Our findings suggest that the CysLTR1 can be a therapeutic target for the treatment of bone resorption diseases.

Inhibitory effects of KP-A159, a thiazolopyridine derivative, on osteoclast differentiation, function, and inflammatory bone loss via suppression of RANKL-induced MAP kinase signaling pathway. Hye Jung Ihn*¹, Taeho Lee², Sang-Hyun Kim¹, Hong-In Shin³, Yong Chul Bae⁴, Eui Kyun Park⁵. ¹Department of Pharmacology, School of Medicine, Kyungpook National University, South Korea, ²College of Pharmacy, Research Institute of Pharmaceutical Sciences, Kyungpook National University, South Korea, ³Department of Oral Pathology & Regenerative Medicine, School of Dentistry, IHBR, Kyungpook National University, South Korea, ⁴Department of Oral Anatomy, School of Dentistry, Kyungpook National University, South Korea, ⁵Kyungpook National University, South Korea

Abnormally elevated formation and activation of osteoclasts are primary causes for a majority of skeletal diseases. In this study, we found that KP-A159, a thiazolopyridine derivative, inhibited osteoclast differentiation and function in vitro, and inflammatory bone loss in vivo. KP-A159 did not cause a cytotoxic response in bone marrow macrophages (BMMs), but significantly inhibited the formation of multinucleated tartrate-resistant acid phosphatase (TRAP)-positive osteoclasts induced by macrophage colony-stimulating factor (M-CSF) and receptor activator of nuclear factor- κ B ligand (RANKL). KP-A159 also dramatically inhibited the expression of marker genes related to osteoclast differentiation, including TRAP (Acp5), cathepsin K (Ctsk), dendritic cell-specific transmembrane protein (Dcstamp), matrix metalloproteinase 9 (Mmp9), and nuclear factor of activated T-cells, cytoplasmic 1 (Nfatc1). Moreover, actin ring and resorption pit formation were inhibited by KP-A159. Analysis of the signaling pathway involved showed that KP-A159 inhibited RANKL-induced activation of extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and mitogen-activated protein kinase kinase1/2 (MEK1/2). In a mouse inflammatory bone loss model, KP-A159 significantly rescued lipopolysaccharide (LPS)-induced bone loss by suppressing osteoclast numbers. Therefore, KP-A159 targets osteoclasts, and may be a potential candidate compound for prevention and/or treatment of inflammatory bone loss.

Phosphorylation of the Actin Bundling Protein L-Plastin Regulates the Early Phase of Sealing Ring Formation. Meenakshi Chellaiah*¹, Tao Ma. University of Maryland, Dental School, USA

Background: L-plastin (LPL), also known as fimbrin is a cytoskeleton-associated protein or Plastin-2. This was initially detected in leukocytes, and subsequently in cancer cells derived from solid tumors. LPL consists of phosphorylation sites at serine 5 and serine 7 at the amino-terminal region (NT) and two actin binding domains (ABDs). LPL phosphorylation on Ser 5 and/or 7 increases LPL's F-actin binding and bundling capacity. In addition, LPL stabilizes actin filaments and protects them from depolymerization. The process of sealing ring formation in osteoclasts (OCs) requires major actin filament reorganization; indeed bundling and stability of actin filaments is a fundamental step in sealing ring formation allowing OCs to tightly adhere to the bone surface. Our previous studies presented compelling evidence demonstrating that LPL, in the presence of TNF- α or RANKL, plays a key role in the formation of nascent sealing zones (NSZs) which are precursor zones for mature and fully functional sealing rings. Here, our aim is to identify by structure function analysis, the elements of LPL that are critical to NSZs formation.

Methods: OCs were transduced with TAT-fused full-length (FL) - or elements of LPL in the presence of TNF- α and native bone particles (100 μ m size) for 3-5h to determine their effects on LPL phosphorylation, NSZs formation, and actin content. OCs treated for 12-18h were used to determine mature sealing ring formation and bone resorption level. Vector protein and/or non-specific (NS) TAT-fused HSV-TK proteins were used as controls

Results: Transduction of TAT-fused FL- LPL not only increases the number of NSZs but also increased mature sealing rings, actin content and bone resorption in OCs plated on dentine slices in the presence of TNF- α . OCs transduced with the amino-terminal LPL fragment containing Ser5 and 7 aa demonstrated the following: a) reduced endogenous LPL phosphorylation; b) a significant decrease in the number of NSZs and mature sealing rings in a time-dependent manner; c) punctate podosome-like structures on dentine; d) a decrease in actin content; e) reduced capacity of bone resorption in vitro. There was no change with the LPL peptide containing ABDs alone.

Conclusions: Structure-function analyses with NT-LPL fragments demonstrated that phosphorylation of LPL at Ser5 and 7 regulates the formation of NSZs. Cooperativity between serine phosphorylation and actin-binding to ABDs is required for actin bundling process mediated by LPL. We suggest that inhibiting LPL phosphorylation will attenuate mature sealing ring formation and bone resorption. Therefore, LPL may be a potential therapeutic target for OC mediated bone loss (Supported by NIH-NIAMS 5 R01 AR066044-02).

Regulation of tartrate-resistant acid phosphatase in osteoclasts by tetraspanin CD82. Alexis Bergsma*¹, Cindy Miranti. Van Andel Institute, USA

The tetraspanin CD82 is a metastasis suppressor protein known to be involved in cell adhesion and regulation of tyrosine kinases, integrins, proteases, and Src. However, the normal function of CD82 in development and homeostasis remains elusive. To address this gap in knowledge, our lab generated CD82^{-/-} mice, which are healthy and fertile. Recently, CD82 was identified as being upregulated 9.4-fold during osteoclast differentiation when plated on bone (Crotti, T.N., et al., J Cell Physiol, 2011.). To determine if loss of CD82 impacts bone homeostasis, I evaluated bone parameters in WT and CD82^{-/-} mice using microCT. My preliminary data show that CD82^{-/-} mice have increased bone mineral density, suggesting a possible defect in osteoclasts. In ex-vivo differentiation assays of osteoclasts isolated from CD82^{-/-} mice, the multinucleated osteoclasts displayed a significant reduction in TRAP (tartrate-resistant acid phosphatase) activity. TRAP is a metalloenzyme in osteoclasts that assists in the process of bone resorption. Activation of TRAP requires proteolytic cleavage by the protease Cathepsin K. Because tetraspanins can regulate proteases, I hypothesize that CD82 expression is required for normal differentiation of osteoclasts into fully functional, TRAP-positive cells, and that CD82 is important for Cathepsin K activation of TRAP. Preliminary immunoblotting experiments from the ex vivo differentiated osteoclasts demonstrated that both Cathepsin K and active TRAP protein are decreased in CD82^{-/-} osteoclasts. These observations validate that CD82 is important for osteoclast differentiation and suggest that CD82 is either working to assist in complex assembly of Cathepsin K and TRAP or in their processing into functional proteins. To address this, I am currently working to delineate the localization and processing of Cathepsin K and TRAP between the ER, endosome, and lysosome by confocal microscopy.

Role of the iRhom2/TACE/TNF α pathway in the pathogenesis of haemophilic arthropathy. Coline Haxaire^{*1}, Narine Hakobyan², Jane Salmon¹, Carl Blobel¹. ¹Hospital for Special Surgery, USA, ²Rush University, USA

A major manifestation of Hemophilia A, an X-linked bleeding disorder, is hemophilic arthropathy (HA), a debilitating degenerative joint disease that is caused by intraarticular bleeding. HA typically begins with haemophilic synovitis (HS), a hypertrophy of synoviocytes with inflammation of the synovium and a neovascular response, followed by joint erosion and ultimately arthropathy with cartilage destruction and erosion of the underlying bone. HS has features in common with inflammatory arthritides such as Rheumatoid arthritis (RA). The pro-inflammatory cytokine tumor necrosis factor α (TNF α) is a major target for treatment of RA. TNF α is synthesized as a membrane-anchored precursor that is released by the TNF α convertase (TACE, also referred to as ADAM17). We have recently uncovered a crucial role for TACE and its regulator, iRhom2, in the pathogenesis of inflammatory arthritis in mice. Since RA is caused, at least in part, by inappropriate release of TNF α , we hypothesize that iRhom2/TACE/TNF α also have a pivotal role in promoting HA.

Here, we show that treatment of macrophages with blood *in vitro* activated TNF α shedding, but not from macrophages lacking iRhom2. We then studied the role of TNF α in HA/HS *in vivo* using *Fviii*-deficient mice (*Fviii*^{-/-} mice), using a joint puncture model. *Fviii*^{-/-} developed a severe hemarthrosis one day after knee puncture, and had a synovial invasion with an increase in neovascularisation in the joint space and cortical thickening of the bone two weeks after the puncture. μ CT analysis showed a significant decrease in trabecular bone volume (BV/TV; -74%), number of trabeculae (Tb.N; -41%) and a significant increase in trabecular separation (Tb.Sp; +52%) in the punctured knee compared to the contralateral control. Inactivation of TNF α in *Fviii*^{-/-} mice significantly reduced the osteopenia in the HA/HS model, with improved bone trabecular parameters compared to *Fviii*^{-/-} mice (BV/TV; -57%, Tb.N; -18%; Tb.Sp; +23%). TRAP staining demonstrated that the bone loss in *Fviii*^{-/-} mice was mainly caused by a significant local increase in osteoclast number and osteoclast surface per bone surface compared to *Fviii*^{-/-}Tnf α ^{-/-} mice. Taken together, these preliminary results support the hypothesis that the iRhom2/ADAM17/TNF α signaling pathway contributes to osteopenia observed in HA/HS patients. Further studies are in progress to analyze whether or not this pathway also has role in synovitis and cartilage destruction in HA/HS.

Tensin 3 activates Dock5 to drive podosome organization in osteoclasts and efficient bone resorption. Anne Blangy^{*1}, Heiani Touaitahuata², Nabila Mansouri², Anne Morel². ¹CNRS Montpellier University, France, France, ²CNRS Montpellier University, France

Osteoclasts resorb the bone matrix through a specific adhesion structure called the sealing zone, which is based on a belt of podosome. Whereas the architecture of individual podosomes is getting well understood, a lot remains to be uncovered regarding the molecular mechanisms driving podosome organization into super-structures such as the osteoclast podosome belt. We showed that Dock5, an exchange factor for the small GTPase Rac, is essential for podosome organization in osteoclasts and then for bone resorption *in vitro* and *in vivo* (Vives et al, JBM, 2011; Touaitahuata et al., Dev Biol 2014). We also demonstrated that systemic administration of a small chemical compound inhibitor of Dock5 protects the mice against pathological bone loss while preserving bone formation (Vives, Cres et al., Nature Communications, 2015).

To understand how Dock5 signaling pathways control podosome belt formation, we performed proteomic analyses and identified Tensin 3 as a partner of Dock5 in osteoclasts. As that of Dock5, the expression of Tensin 3 increases during osteoclast differentiation. Confocal and 3D-SIM super-resolution microscopy revealed that Dock5 and Tensin 3 are not associated with individual podosomes. By contrast, they colocalize in the podosome cloud region when these assemble into a belt. Suppression of Tensin 3 in osteoclasts destabilizes podosome organization and severely impairs bone resorption. At the molecular level, we found that binding to Tensin 3 to Dock5 increases its exchange activity towards Rac.

Our results identify Tensin 3 as a novel regulator of osteoclast bone resorbing activity. They further suggest that binding of Dock5 to Tensin 3 allows efficient activation of Rac to ensure the assembly of podosomes into a belt, the basal architecture of the bone resorbing apparatus of osteoclasts.

Bach1 nuclear export attenuates osteoclastogenesis and osteoclast activation via inhibition of intracellular ROS signaling. Hiroyuki Kanzaki^{*1}, Shinohara Fumiaki², Masazumi Matsuzawa³, Yoshiki Nakamura³. ¹Tsurumi University School of Dental Medicine, Japan, ²Tohoku University Graduate School of Dentistry, Oral Microbiology, Japan, ³Department of orthodontics, School of Dental Medicine, Tsurumi University, Japan

Objectives: It was reported that reactive oxygen species (ROS) play a role in osteoclast differentiation as intra-cellular signaling molecule. Previously we reported that transcriptional factor nuclear factor E2-related factor 2 (Nrf2) negatively regulate osteoclastogenesis via anti-oxidative enzyme expression and thereby ROS scavenging. However, it is still remain unknown Bach1, the competitor for Nrf2 in transcriptional regulation of anti-oxidative enzymes can be therapeutic target for bone destructive disease. We hypothesized that Bach1 nuclear export activates Nrf2-dependent anti-oxidative enzyme expression, diminish intracellular ROS signaling, and thereby attenuates osteoclastogenesis. Methods: Mouse monocyte cell-line RAW264.7 were stimulated with sRANKL with or without the induction of Bach1 nuclear export by sodium ferrous citrate (SFC) and 5-Aminolevulinic acid (ALA). Localization of Bach1 was examined with immuno-cyto staining. Expressions of Nrf2, Bach1, and anti-oxidative enzymes such as heme oxygenase 1, were examined by realtime PCR and western blot. Intracellular ROS signaling was examined by flowcytometry using fluorescent ROS probe. sRANKL-dependent osteoclastogenesis were observed, and marker genes for osteoclast differentiation were examined by realtime PCR. Results: SFC and ALA treatment resulted in the Bach1 nuclear export, and induced Nrf2 nuclear import. Bach1 nuclear export increased anti-oxidative stress enzyme expression. Furthermore, Also bach1 nuclear export diminished RANKL-mediated intracellular ROS signaling. Finally, RANKL-mediated osteoclastogenesis was inhibited by bach1 nuclear export. Conclusion: Bach1 nuclear export activates Nrf2-dependent anti-oxidative enzyme expression, and thereby attenuates osteoclastogenesis. Bach1 nuclear export could be therapeutic target for bone destructive disease.

Bone Parameters Are Unchanged by Activation or Deletion of TGF- β Signaling in Mature Osteoclasts. Jenna Regan^{*}, Sutha K. John, Maria Niewolna, Yun She, Khalid S. Mohammad, Theresa A. Guise. Indiana University School of Medicine, USA

Calcified bone matrix is the most abundant source of transforming growth factor beta (TGF- β) in the body. TGF- β that is released and activated during osteoclast-mediated bone resorption can act locally to influence bone remodeling or enter the circulation to exert systemic effects. In the setting of cancer bone metastasis, high TGF- β levels induced by increased osteolysis play a key role in the feed-forward cycle of tumor progression in bone. In addition to its activity on tumor cells, TGF- β in the microenvironment may also signal directly to bone cells to modulate their differentiation and activity. TGF- β has been shown to increase osteoclast differentiation, but whether TGF- β signals directly to mature osteoclasts to modulate their activity or survival, and thus impact bone mass *in vivo*, is not known. To test the importance of TGF- β signaling in mature osteoclasts, we targeted the pathway using transgenic cathepsin K (CatK)-cre mice to either delete TGF β R2 (CatK-cre; T β R2 flox/flox) or induce the expression of constitutively active TGF β R1-T204D (CatK-cre; T β R1-T204D). We monitored the bone phenotype of both male and female mice (N = 11 per group) *in vivo* using micro-computed tomography and dual-energy X-ray absorptiometry at regular intervals from 6 weeks to 6 months of age. Neither deletion nor activation of canonical TGF- β signaling in mature CatK-positive osteoclasts had any profound effect on trabecular or cortical bone parameters or bone mineral density *in vivo*. Likewise, *ex vivo* analyses, including bone marrow cell differentiation assays, failed to indicate any differences between control mice and those with altered TGF- β signaling in mature osteoclasts. Therefore, we conclude that any direct effects of TGF- β signaling in the osteoclast lineage likely occur earlier during the differentiation process and that normal bone homeostasis may not rely on TGF- β signaling in mature osteoclasts.

Sialylated Glycans of MMP-9 Mark Bone Resorption Lacunae. Yukiko Kuroda*¹, Atsushi Kuno², Hisashi Narimatsu³, Koichi Matsuo⁴.
¹Laboratory of Cell & Tissue Biology, Keio University School of Medicine, Japan, ²Research Center for Medical Glycoscience (RCMG), National Institute of Advanced Industrial Science & Technology (AIST), Japan, ³Research Center for Medical Glycoscience (RCMG), National Institute of Advanced Industrial Science & Technology (AIST), Japan, ⁴Laboratory of Cell & Tissue Biology, Keio University School of Medicine, Japan

Wheat germ agglutinin (WGA) is a plant lectin that selectively binds to bone resorption pits formed by osteoclasts on dentine or bone slices (Selander et al., 1994). However, WGA-binding proteins are broadly distributed *in vivo*, and the identities of WGA target glycoproteins on pits/lacunae are unknown. We hypothesized that mature osteoclasts, but not preosteoclasts, produce WGA-binding glycoproteins that stick to the surface of resorption pits. Using a lectin microarray, we searched for lectins with carbohydrate specificity narrower than WGA that differentially recognized mature osteoclast-derived and preosteoclast-derived glycoproteins. Among 45 lectins tested, we identified *Maackia amurensis* hemagglutinin (MAH), which binds to sialylated O-linked carbohydrate chains. MAH stained bone resorption pits formed *in vitro* and specifically bound osteoclasts and blood vessels in the mouse tibial metaphysis. We then affinity purified MAH target glycoproteins from culture media of mature osteoclasts using biotinylated MAH and streptavidin-immobilized magnetic beads. A major MAH-binding protein of 90 kD was further analyzed by MALDI-TOF mass spectrometry and identified as matrix metalloproteinase 9 (MMP-9, also known as gelatinase B). Double-staining of mouse tibial sections with MAH and anti-MMP-9 antibodies revealed overlapping immunostaining in most osteoclasts, suggesting that osteoclast-derived MMP-9 is a MAH target glycoprotein *in vivo*. Interestingly, while MMP-9 signals were distributed along the transverse septum at the chondro-osseous junction, MAH-signals were not. These results suggest that sialylated MMP-9 exists in osteoclastic resorption lacunae, while non-sialylated MMP-9 is present in chondroclastic resorption lacunae at the transverse septum, potentially accounting for differential regulation of bone filling at these lacunae.

Zinc-induced effects on osteoclastogenesis involves activation of HCN channels via changes in membrane potential. Takuya Notomi*¹, Miyuki Kuno², Akiko Hiyama³, Kiyoshi Ohura³, Masaki Noda⁴, Timothy Skerry⁵.
¹Department of Pharmacology, Osaka Dental University, Japan, ²Osaka City University, Japan, ³Osaka Dental University, Japan, ⁴Tokyo Medical & Dental University, Japan, ⁵University of Sheffield, United Kingdom

Zinc is a trace element in the mammalian body, and increasing evidence shows its critical role in bone development and osteoclastogenesis. The relationships between zinc and voltage-gated ion channels have been reported; however, the effects of zinc on membrane potential and the related ion channels remain unknown. In this study, we found that zinc-induced hyperpolarization in RAW264.7 cells (RAW) was promoted by inhibition of hyperpolarization-activated cyclic nucleotide modulated channels (HCNs). In electrophysiological experiments with RAW-derived osteoclasts, HCNs were functional and generated hyperpolarization-activated inward currents (I_h) with properties similar to the I_h recorded in excitable cells such as neurons and cardiomyocytes. Quantitative PCR of HCN subunits HCN1 and HCN4 in RAW cells and bone marrow-derived osteoclasts showed detectable levels of HCN1 mRNA and HCN4 expression was the highest of all four subunits. HCN4 knockdown decreased osteoclastic I_h and promoted osteoclastogenesis in the presence of zinc, but not in the absence of zinc. To determine the effect of membrane hyperpolarization on osteoclastogenesis, we developed a light-controllable membrane potential system in RAW cells by stably expressing the light-driven outward proton pump, Archaeorhodopsin3 (Arch). Arch activation by yellow-green light hyperpolarizes the cell membrane by -11 ± 1.5 mV upon the onset of light stimulation and returned to pre-stimulus potential after termination of the stimulus. Light-induced hyperpolarization accelerated osteoclast differentiation in the presence of RANKL. Thus, HCN activation reduced the hyperpolarization-related promotion of osteoclast differentiation in the presence of zinc. This study revealed the novel role of HCN and membrane potential in non-excitable osteoclasts. Light-induced hyperpolarization may facilitate investigations of changes in membrane potential generated by ligands and chemicals in the search for novel drug candidates to treat bone disorders.

Human scaphoid non-unions exhibit increased TNF-α and osteoclast activity compared to adjacent cancellous bone. Björn Behr*¹, Marcus Lehnhardt², Christoph Wallner³, Stephanie Abraham², Jessica Schira².
¹Ruhr-University of Bochum, Germany, ²Ruhr-University Bochum, Germany, ³Ruhr-University Bochum, Germany

Scaphoid bones have a high prevalence for non-union. Even with adequate treatment, bone regeneration may not occur in certain instances. Although this condition is well described, the molecular pathology of scaphoid non-unions is still poorly defined.

The purpose of the study was an intraindividual gene expression comparison of osteogenic, inflammatory and angiogenic growth and transcription factors between human scaphoid non-unions and adjacent autologous cancellous bone from the distal radius. In addition, histology and immunohistochemical stainings were performed to verify qRT-PCR data.

Gene expression analysis revealed a significant upregulation of TNF-α, RANKL, ALP, CYCLIN D1, MMP-13, OPG, NFATc1, TGF-β and WNT5A in scaphoid non-unions. Interestingly, TNF-α was highly upregulated in all non-union samples (mean: 24 fold increase). Moreover, RANKL, a marker for osteoclastogenesis was increased by 19 fold in non-unions. TRAP staining confirmed this observation. Other inflammatory markers such as IL-1β or IFN-γ were not detectable in both tissues. With respect to genes related to osteogenesis, alkaline phosphatase was significantly upregulated in scaphoid non-unions. No differences were detectable for other osteogenic genes such as RUNX-2 or BMP-2. Importantly, we did not detect differences in angiogenesis between scaphoid non-unions and control in both gene expression and immunohistochemistry.

Summarized, our data indicate chronic inflammation and increased osteoclast activity in scaphoid non-unions. Moreover, scaphoid non-unions still have a partial osteogenic and angiogenic potential which obviously does not lead to sufficient bone healing. These data increase our understanding for the reduced bone regeneration capacity present in scaphoid non-unions and may translate into identification of new therapeutic targets in order to avoid secondary damages and prevent occurrence of non-unions to scaphoid bones.

Titanium Particles and Mechanical Instability of Implants Induce Osteoclast Differentiation Through Indistinguishable Inflammatory Pathways. Mehdi Amirhosseini*¹, Göran Andersson², Per Aspenberg³, Anna Fahlgren⁴.
¹Faculty of Health Sciences, Linköping University, Linköping, Sweden, ²Division of Pathology, Department of Laboratory Medicine, Karolinska University Hospital, Sweden, ³Division of Orthopedics, Department of Clinical & Experimental Medicine, Faculty of Health Sciences, Linköping University, Sweden, ⁴Division of Cell Biology, Department of Clinical & Experimental Medicine, Faculty of Health Sciences, Linköping University, Sweden

Peri-prosthetic bone loss can be due to an inflammatory response to wear debris particles, but clinical (Anthony et al 1990) and experimental (Fahlgren et al 2010) data support additional role of mechanical factors in osteoclast differentiation of periprosthetic loosening. In an established animal model for aseptic loosening (Skripitz et al 2000), mechanical instability differed quantitatively in mRNA expression of inflammatory cytokines compared to titanium particles (Nilsson et al 2012). Therefore, we tested the hypothesis that mechanical instability and titanium particles induce osteoclast differentiation via different pathways, using microarray analysis. Male SD rats with a validated implant for aseptic loosening were exposed either to mechanical instability or titanium particles. The bone tissue underneath the implant was harvested after 0 hrs (control), 3, 48 and 120 hrs for RNA extraction and microarray analysis with RaGene-2:1st Affymetrix array (n=3-4/group). Top 1000 genes that reached the cut-off levels of 1.5 fold-change with a FDR-adjusted p-value below 0.05 were used for pathway analysis using Ingenuity Pathway Analysis software. Compared to controls, both treatments regulated about 300 genes at 3 hrs, 1900 genes at 48 hrs and 900 genes at 120 hrs. Of all the genes regulated significantly, there were no significant differences when mechanical instability was compared with titanium particles at any time point. Pathway analysis showed that mechanical instability and titanium particles shared similar canonical pathways for acute phase response signaling, IL-6 signaling and MIF regulation of innate immunity at 3 and 48 hrs. iNOS signaling and Wnt/β-catenin signaling pathway were shared at 48 hrs and leukocyte extravasation signaling pathway at 120 hrs. Macrophage- and osteoclastogenesis-associated genes showed similar patterns of change. However, a higher RANKL/OPG ratio with titanium particles than with mechanical instability was detected at 48 hrs, suggesting a more rapid osteoclastogenic response induced by particles (Table 1). These data suggest that despite some differences in biologic responses driven by wear debris particles and mechanical loading, the main processes leading to osteoclastogenesis are regulated through similar pathways. However, although key genes showed similar changes in our data, differences in the genes responsible for triggering the inflammatory processes might hide in the cloud of statistical uncertainty.

A RANKL-binding peptide W9 inhibits human osteoclast differentiation and stimulates human osteoblast differentiation. Midori Nakamura¹, Yuko Nakamichi¹, Teruhito Yamashita¹, Yuriko Furuya², Hisataka Yasuda², Nobuyuki Udagawa³. ¹Department of Biochemistry, Institute for Oral Science, Matsumoto Dental University, Japan, ²Nagahama Institute for Biochemical Science, Biochemical Production & Development Center, Oriental Yeast Co., Ltd., Japan, ³Matsumoto Dental University, Japan

A RANKL-binding peptide WP9QY (W9) is known to inhibit mouse osteoclastogenesis. In addition, W9 showed an anabolic effect on cortical bone in mice in vivo. W9 bound RANKL and differentiated osteoblasts with production of autocrine factors like BMP. In this experiment, we examined the effects of W9 on differentiation of osteoblasts, osteoclasts and dendritic cells in human culture system. Osteoclasts and dendritic cells are derived from common progenitors, such as bone marrow-derived macrophages. W9 strongly inhibited multinucleated osteoclast formation in human peripheral blood mononuclear cell cultures in the presence of RANKL and M-CSF for 14 days as well as strikingly stimulated alkaline phosphatase (ALP)-positive osteoblast differentiation in human bone marrow stromal cells for 12 days. In contrast, W9 have no effect on dendritic cell differentiation in human peripheral blood mononuclear cell cultures in the presence of GM-CSF and IL-4 for 10 days. These experimental results indicate that W9 inhibited human osteoclast formation but not dendritic cell differentiation and directly stimulated osteoblast differentiation via RANKL signaling-mediated autocrine factors. Our findings suggest that the reverse signal from RANK on osteoclasts to RANKL on osteoblasts, and the forward signal from RANKL to RANK, could play an important role in the coupling between bone-formation and bone resorption.

Effect of FTY720 on osteoclast formation in rats with periodontitis. Dong-Eun Lee¹, Eun-Jung Bak^{2*}, Ji-Hye Kim¹, Gye-Hyeong Woo³, Yun-Jung Yoo¹. ¹Yonsei University Dental college, South Korea, ²Yonsei University Health System, South Korea, ³Department of Clinical Science, Semyung University, South Korea

Osteoclast precursors (OPs) re-migrate from the bone surface into blood vessels through sphingosine-1-phosphate receptor 1 (S1PR1) expression. T cells also express S1PR1, mediating their migration from the lymph nodes into blood vessels. OP and T cell migration is one of the sequential steps related to osteoclast formation. To characterize the role of S1PR1 in osteoclast formation induced by periodontitis, we investigated effect of S1PR1-binding molecule FTY720 (FTY) on the number of OPs and T cells in periodontal tissue and peripheral blood of rats with ligature-induced periodontitis. Rats were divided into four groups: control (C), FTY (F), periodontitis (P), and periodontitis + FTY (PF) groups. Ligatures were placed around the first molars in the left and right mandibles. The rats were intraperitoneally injected with vehicle or 3 mg/kg FTY daily until they were sacrificed. The number of osteoclasts

and cluster of differentiation (CD)11b, CD3, and receptor activator of NF- κ B ligand (RANKL)-positive cells in first molar furcation were counted by tartrate-resistant acid phosphatase (TRAP) or immunohistochemistry staining. The number of CD11b-positive and CD3-positive cells in peripheral blood was estimated by flow cytometry. The number of osteoclasts in P group was higher than C, PF, and F groups and CD11b, CD3, and RANKL-positive cells were also higher in P group than other groups in furcation. While CD11b-positive cells in furcation of PF group were lower than the P group, they were higher in peripheral blood. Dissimilar to CD11b-positive cells, CD3-positive cells in the PF group were lower in peripheral blood as well as furcation than the P group. RANKL-positive cells in furcation of the PF group were also lower than P group. These results indicate that FTY may facilitate re-migration of OPs from the alveolar bone surface into blood vessels, blocking T cell migration from the lymph nodes into blood vessels and subsequently reducing osteoclast formation induced by periodontitis. This suggests that S1PR1-S1P binding may play a role in osteoclast formation of periodontitis by modulating OP and T cell migration.

Mef2C Targets Energy Metabolism Genes in Bone. Aimy Sebastian¹, Deepa K. Murugesu², Sarah Hatsell³, Aris N. Economides³, Gabriela G. Loots⁴. ¹University of California, Merced, USA, ²Lawrence Livermore National Laboratories, USA, ³Regeneron Pharmaceuticals, USA, ⁴Lawrence Livermore National Laboratories; University of California, Merced, USA

Mef2C is a member of the myocyte enhancer factor-2 (MEF2) family of transcription factors which plays a pivotal role in myogenesis. We have previously shown that Mef2C regulates *Sost* expression and *Mef2C^{CKO};Coll1-Cre* mice have high bone mass (HBM). Recently, we found that Mef2C is expressed in osteoclasts and *Ctsk-Cre* mediated deletion of Mef2C also results in HBM. To understand the mechanisms by which Mef2C regulates bone metabolism we isolated RNA from femurs of *Mef2C^{CKO};Coll1-Cre* and *Mef2C^{CKO};Ctsk-Cre* mice and profiled gene expression using RNA-seq. We found 164 genes up- and 977 genes down-regulated in *Mef2C^{CKO};Coll1-Cre* mice compared to controls while 269 genes were up- and 1292 were down-regulated in *Mef2C^{CKO};Ctsk-Cre* mice. *Sost* was 2.46 fold reduced in *Mef2C^{CKO};Coll1-Cre* mice while *Mef2C^{CKO};Ctsk-Cre* femurs had unaltered levels of *Sost* mRNA. Several bone metabolism related genes such as *Ibsp*, *Mgp* and *Bglap* were down-regulated in *Mef2C^{CKO};Coll1-Cre* mice but were unchanged in *Mef2C^{CKO};Ctsk-Cre* mice, suggesting that osteoblast function is molecularly unaltered in *Mef2C^{CKO};Ctsk-Cre* mice. We found 208 energy metabolism genes [regulators of glycolysis; TCA cycle; oxidative phosphorylation; fatty acid metabolism] down-regulated in *Mef2C^{CKO};Ctsk-Cre* mice, including PGC1 α and PGC1 β , two transcriptional co-activators that have been previously shown to regulate mitochondrial biogenesis and energy metabolism. To identify direct transcriptional targets of Mef2C we mapped publicly available Mef2C ChIP-seq data to the nearest genes and found that 43/208 energy metabolism genes including PGC1 β harbor Mef2C binding sites. Analysis of the energy metabolism gene promoters with HOMER motif finding software identified estrogen-related receptors (ERRs) as the most enriched transcription factors with binding sites in 161/208 promoters. We also found that ERR α and ERR γ are significantly down-regulated in *Mef2C^{CKO};Ctsk-Cre*. It has previously been shown that ERR α coordinates with PGC1 β to regulate mitochondrial function in osteoclasts and both ERR α and PGC1 β gene deletions cause osteoclast defects. Our findings suggest that Mef2C regulates a large number of energy metabolism genes in bone which may have a direct effect on osteoclast and osteoblast function. Further studies will elucidate whether the energy metabolism genes are direct transcriptional targets of Mef2C or whether Mef2C indirectly regulates these genes by modulating the expression of other factors such as PGC1 β or ERR α .

Microgravity Induction of TRAIL in Preosteoclast Cells Enhances Osteoclastogenesis. Yuvaraj Sambandam¹, Kelsey Baird¹, Maxwell Stroebel¹, William Ries², Sakamuri Reddy². ¹Medical University of South Carolina, USA, ²MUSC, USA

Evidence indicates that astronauts experience significant bone loss in space. We previously showed that simulated microgravity (μ Xg) using the NASA developed rotary cell culture system (RCCS) enhanced bone resorbing osteoclast differentiation. However, the mechanism by which μ Xg increases osteoclast formation is unclear. RANK/RANKL signaling pathway is critical for osteoclast differentiation/activity. Tumor necrosis factor-related apoptosis inducing ligand (TRAIL) has been shown to increase osteoclastogenesis. We hypothesize that TRAIL may play an important role in μ Xg enhanced osteoclast differentiation. In the present study, we identified by RT profiler PCR array screening that μ Xg induces high levels (10-fold) of TRAIL expression in mouse bone marrow derived preosteoclast cells compared to ground based (Xg) cultures. Western blot analysis of total cell lysates obtained from μ Xg subjected preosteoclast cells further demonstrated increased (5-fold) levels of TRAIL protein expression. Also, real-time PCR analysis showed a significant increase (12-fold) in TRAIL mRNA expression in these cells. We further identified that μ Xg elevated TRAF-6 protein and mRNA expression in preosteoclast cells. Also, tartrate

resistant acid phosphatase (TRAP) expression levels were increased in these cells without RANKL stimulation. We further identified that addition of TRAIL to RAW 264.7 cells cultured in the presence of RANKL and MCSF potentiated osteoclast differentiation. Interestingly, neutralizing antibody against TRAIL significantly reduced μ Xg induced osteoclast formation. These results indicate that TRAIL signaling plays an important role in the μ Xg increased osteoclast differentiation. Therefore, inhibition of TRAIL expression could be an effective countermeasure for μ Xg induced bone loss.

Morinda citrifolia (Noni) inhibits inflammation-induced osteoclastogenesis. Jeong-Hwa Baek^{*1}, Kanitsak Boonantanasarn², Hanna Gu², Gwan-Shik Kim². ¹Seoul National University, School of Dentistry, South Korea, ²Seoul National University School of Dentistry, South Korea

The primary indigenous use of the Noni plant (*Morinda citrifolia*) is to apply the leaf as a traditional topical treatment for bone fractures or dislocation to promote bone remodeling and reduce inflammation. However, the experimental study of Noni leaves, which have been supported the traditional use is still limited. In this study, we examined the inhibitory effect of Noni on osteoclastogenesis and its molecular mechanisms. Noni ethanol extract was prepared. Osteoclastogenesis was induced by treating RAW264.7 murine monocyte cells with lipopolysaccharide (LPS), TNF- α , or RANKL. In the concentration range that did not show cytotoxicity, Noni significantly decreased the expression levels of osteoclastogenesis-related transcription factors (NFATc1, c-Fos, Fra1, and Fra2) and osteoclast differentiation marker genes (integrin B3, SRC, cathepsinK, and TRAP), and reduced tartrate resistant acid phosphatase activity in all osteoclastogenesis models used in this study. Noni also inhibited expression levels of LPS-induced inflammatory cytokines (IL-6, TNF- α , IL-1 β) and COX2/PGE2 in both RAW264.7 and MC3T3E1 cells. In addition, Noni significantly down-regulated LPS and TNF- α -induced RANKL expression in MC3T3E1 cells. In defining signaling pathways, Noni was shown to significantly suppress LPS-mediated activation of NF- κ B activation and ERK phosphorylation with moderate inhibitory effect on p38, but not on JNK. In conclusion, we demonstrated that Noni leaf has *in vitro* inhibitory effects on inflammatory responses and osteoclast differentiation, suggesting the therapeutic potential of Noni leaf for prevention and treatment of inflammatory bone loss.

PU.1 and HDAC7 Interact to Regulate Osteoclast Differentiation. Nick Blixt^{*1}, Rajaram Gopalakrishnan², Eric D. Jensen², Kim Manskv¹. ¹University of Minnesota, USA, ²Contributing Author, USA

Osteoporosis is a widespread disease caused by increased bone resorption relative to bone formation, resulting in reduced bone density and higher incidence of fractures. Elucidating molecular mechanisms that regulate osteoclast differentiation and activation will lead to improved therapies for osteoporosis and other bone-related diseases caused by increased osteoclastic activity. Our lab has previously shown by both *in vitro* and *in vivo* experiments that Histone Deacetylase 7 (HDAC7) is an inhibitor of osteoclast differentiation through repression of the activity of the MTF transcription factor. MTF binds DNA and functionally interacts with another transcription factor, PU.1, to regulate osteoclast genes. To further characterize the molecular mechanism behind HDAC7's repression of osteoclast differentiation, we asked whether HDAC7 interacts with PU.1. By co-immunoprecipitation, we demonstrated that HDAC7 and PU.1 could physically interact. Reporter assays showed that HDAC7 repressed PU.1's transcriptional activity. We have mapped the amino acids in HDAC7 and PU.1 necessary for their interaction and for HDAC7's repression of PU.1-activated gene expression. Currently we are determining if HDAC7's deacetylase activity is required for HDAC7 to repress PU.1 and seeking to identify osteoclast promoters at which PU.1 and HDAC7 are found together. Based on our data, we conclude that HDAC7 is a potent negative regulator of osteoclast differentiation, acting by repressing both PU.1 and MTF to prevent transcription of osteoclast genes necessary for differentiation and survival.

Disclosures: Nick Blixt, None.

Signaling interactions of myeloid DC precursors on osteoclastogenesis and bone remodeling: an alternative insight. Yen-Chun Grace Liu¹, Andy Yen-Tung Teng^{*2}. ¹Koahsiung Medical University, Taiwan, ²Center for Osteoimmunology & Biotechnology Research, College of Dental Medicine, Kaohsiung Medical University & KMU-Hospital, Taiwan

Background: Dendritic cells (DC) are immune effectors, involved in T-cell immunity where DC/T-cell interactions play a central role in normal & inflammatory conditions, associated with disorders such as rheumatoid arthritis, osteoporosis & periodontitis. Besides being professional antigen presenting cells, DC share common

precursors with osteoclast (OC). Inflammation-associated bone loss is a poorly understood osteo-immune interactions, whose frequency & activity of OC are elevated in response to various stimuli, including osteotropic cytokines & growth factors. Methods: We have developed a working model, where immature myeloid DC subsets (CD11c⁺ MHC-II^{low} CD11b⁺ F4/80⁺ CD31⁻ Ly-6C⁺ CT-R⁻ Cath-K⁻) act as OC precursor in response to RANKL plus stimuli on activation signals (Infect Immun. 2009). Herein, the signal interactions between mDCp/T-cells (e.g., Treg & Th17 cells) and osteotropic cytokines (i.e., IL-17, TGF- β , etc.) that modulate the innate-vs.-adaptive immunity for osteoclastogenesis were investigated using established *in-vitro*/*in-vivo* models. Results: Our data showed that: i) neutralization of TGF- β activity by Mab (or si-RNA) abolished mDDOC development in co-cultures (p<0.03) & *in-vivo* adoptive transfers (p<0.02), based on TRAP & resorptive-pit assays; ii) transfection of SOCS3 or TGF β -R2 lentiviral vectors containing sh-RNA into CD11c⁺ mDCp resulted in a significant inhibition of osteoclastogenesis & bone resorption *in-vitro* & adoptive transfer *in-vivo* (p<0.05); iii) added TGF- β signaling was able to rescuing the reduced TRAP vs. bone resorption upon using TRAF6-KO CD11c⁺ mDCp/T-cells *in-vitro* & *in-vivo* (p<0.05); iv) addition of Foxp3⁺ CD4⁺Treg cells in co-cultures resulted in strongly reduced TRAP expression on osteoclastogenesis vs. bone resorption *in-vitro*, and in calvarias of NOD/SCID mice (p<0.05); whereas, such effects were significantly reversed by IL-17 administered (p<0.05). Summary: The results suggest that: i) immature mCD11c⁺DcP and CD4⁺T-cell interactions is intriguing, which may serve as a unique model to study the links between immunity and inflammation-associated osteoclastogenesis on bone remodeling; ii) TGF- β II & IL-17 (Th17 cells) can interactively signal with RANKL via TRAF6 or unclear novel pathway in mDCp & OCp to modulate osteoclastogenesis, where such alternative signals may be promiscuous, depending on which vital environmental factors interplay for activity at the osteo-immune interface for disease pathogenesis.

Blocking P2X7 receptor prevents the bystander osteocyte RANKL signaling normally triggered by osteocyte apoptosis at microdamage sites. Wing-Yee Cheung^{*1}, Mitchell Schaffler¹, Robert Majeska¹, David Spray², Eliana Scemes². ¹City College of New York, USA, ²Albert Einstein School of Medicine, USA

Osteocyte apoptosis around bone microdamage sites is required to trigger osteoclastogenesis and intracortical remodeling (Cardoso et al., JBMR 2009). Dying osteocytes trigger viable neighboring (bystander) osteocytes to upregulate osteoclastogenic cytokines like RANKL, but how this occurs is unknown. During apoptosis, activated caspase-3 has been shown to open Pannexin 1 (Panx1) membrane hemichannels, releasing a bolus of ATP (Chekeni et al, 2010 Nature). This ATP release is a major 'find-me' signal to bystander cells to call for recruitment of phagocytic cells. We previously showed that osteocytes in Panx1-deficient mice undergo apoptosis as expected in response to microdamage (Mdx); however, the bystander osteocytes do not upregulate RANKL (Cheung et al, 2014 ORS Trans. #0034). These data prompt the hypothesis that bolus ATP released may be an essential signal through which apoptotic osteocytes trigger their intact neighbors to produce RANKL. In the current studies, we tested whether pharmacologically blocking the P2X7 receptor – a major target for ATP signaling – would suppress Mdx-induced RANKL expression in osteocytes. Under IACUC approval, C57Bl/6 mice (14 week old, n=5 each group) were treated with the P2X7R antagonist brilliant blue G (BBG, 50 mg/kg) or PBS vehicle daily for 3 days. Mdx was induced in right ulnae on Day 0 by *in vivo* fatigue loading, after which mice were allowed unrestricted cage activity. On day 3, mice were sacrificed and tissues were processed for IHC analysis. Sections were reacted with antibodies against cleaved caspase-3 (casp3) or RANKL to detect apoptotic osteocytes and osteoclastogenic signaling, respectively. % Casp3⁺ and % RANKL⁺ osteocytes were measured in damaged (Mdx) and non-damaged (non-Mdx) bone regions within the ulnar cortex. BBG treatment did not alter osteocyte apoptosis in Mdx regions. However, BBG completely blocked increases in RANKL⁺ osteocytes in Mdx zones (P<0.05). BBG had no effect on osteocyte Casp-3 or RANKL expression in non-damaged cortical bone regions. These results show that purinergic signaling via P2X7 receptors is an essential component for triggering RANKL upregulation in bystander osteocytes at microdamage sites, thus suggesting a key role of ATP in the activation and targeting of bone resorption.

SU0237

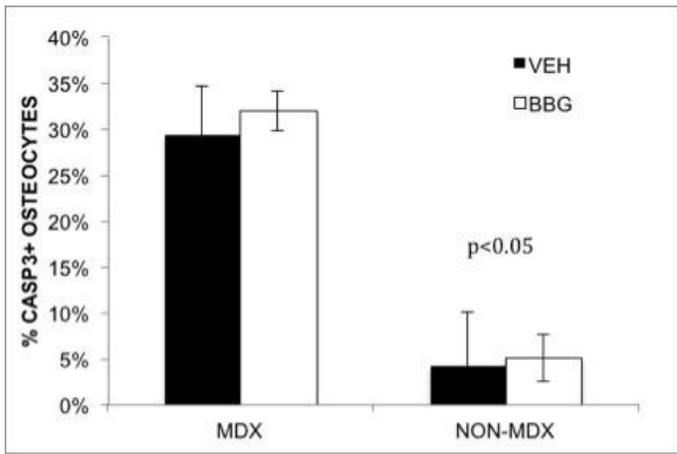

Ex Vivo Preservation of Phenotypic State of Primary Osteocytes via Microbeads-Guided Microfluidic Perfusion Culture. Qiaoling Sun^{*1}, Yexin Gu¹, Wenting Zhang¹, Leah Dziopa², Jenny Zilberberg², Woo Lee¹.
¹Stevens Institute of Technology, USA, ²Research Department, Hackensack University Medical Center, USA

Introduction: Considerable challenges exist for in vitro studies of osteocytes because: (1) current cell lines do not sufficiently represent the phenotypic state of mature osteocytes and (2) primary cells differentiate to osteoblasts upon isolation from bone. In this study, we used a 3D perfusion culture approach to: (1) reconstruct the 3D cellular network of primary murine osteocytes by biomimetic assembly with microbeads and (2) preserve ex vivo the phenotypic state of the osteocytes.

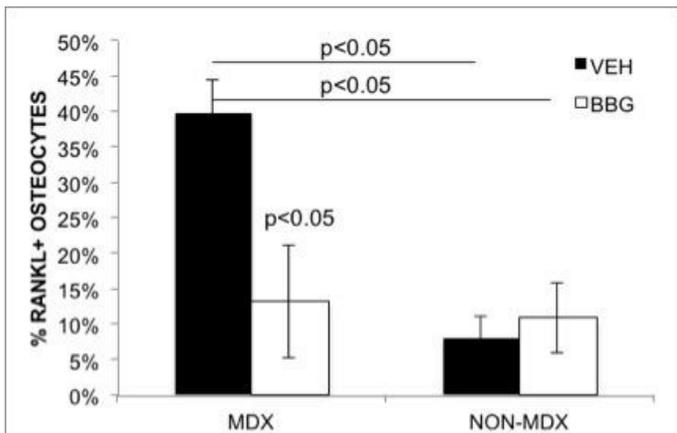

Methods: Primary osteocytes were isolated from long bones of 20-weeks old B10.BR mice by collagenase digestion. For 3D reconstruction with a sufficient number of viable cells, we used cells proliferated from a small population of healthy osteocytes migrated out of digested bone chips. The cells and microbeads (biphasic calcium phosphate) were mixed at a 1:1 ratio and injected into microfluidic chambers to form 3D tissues (Fig. 1a) and cultured for 21 days. The effects of culture time on the viability, differentiation, and proliferation of 3D-reconstructed cells.

Results and Discussion: Mechanically integrated 3D tissues could be produced after 14 days of culture (Fig. 1b). Cells were well distributed in the interstitial spaces between microbeads, and did not proliferate due to the physical confinement within the interstitial sites (Figs. 1c and 1d). The entrapped cells were able to form a 3D cellular network by extending their processes through openings between the microbeads. Because cells began osteoblastic differentiation prior to 3D culture, SOST gene expression was not initially detected, but became significant after 14 days (Fig. 1e). In contrast, SOST expression remained undetectable in 2D culture. FGF23 gene expression was initially detected in both 2D and 3D (Fig. 1f). FGF23 gene expression was significantly increased in 3D after 14 days, but remained at a similar level in 2D.

Conclusions: The results show that the 3D approach was effective in: (1) distributing and entrapping cells within the interstitial spaces between the microbeads, (2) inhibiting proliferation of the entrapped cells, and (3) maintaining cell-to-cell distance to be 20-25 μ m as observed in murine bones. Although cells began osteoblastic differentiation prior to 3D culture, they were able to restore osteocyte gene expressions during 3D culture. The 3D approach is expected to provide a new means of studying the biology of 3D-networked osteocytes and developing bone disease models.

Evidence for the novel role of Dynamin in regulating osteocyte dendrite elongation, and genes critical for bone remodeling. Pierre Eleniste^{*}. Indiana University School of Dentistry, USA

Osteocytes orchestrate bone remodeling by regulating the activity of osteoblasts (OB) and osteoclasts (OC). Osteocytes contain membrane extensions known as dendrites, which allow cell-to-cell coupling with osteocytes, OBs and OCs. However, the mechanisms for dendrite elongation are uncertain. The Dynamin GTPase is involved in various cellular activities, such as endocytosis and actin remodeling. Previously, we demonstrated that Dynamin regulates OB migration and differentiation, as well as OC bone resorbing activity. In the current study, we examined the role of dynamin in osteocyte dendrite elongation and function. MLO-Y4 osteocytic cells were treated with increasing concentrations of dynasore, a chemical inhibitor of Dynamin, for 1-3 days. The cells were imaged and dendrite length quantified. Dynasore-treated MLO-Y4 cells exhibited a significant increase in dendrite length of 162% (day 2) and 171% (day 3) compared to controls. Moreover, dynasore-treated cells exhibited an increase in filamentous actin, suggesting dynamin may be involved in actin remodeling. To examine the role of dynamin on osteocyte gene expression, long-bones were collagenase digested to remove OBs and then treated with dynasore for 3 days, followed by QPCR analysis. Dynasore-treated long bones exhibited a significant >20-fold increase in mRNA expression of Wnt3a, which is known to promote OB differentiation. In addition, dynasore-treated long-bones and MLO-Y4 cells exhibited a 6-fold increase in OPG mRNA levels, suggesting dynamin may regulate osteocyte-mediated OC differentiation. OPG expression is regulated by β -catenin/Tcf4 pathway. Our studies also demonstrate that dynamin regulates β -catenin and GSK-3 β levels and dynamin forms a protein complex with nuclear β -catenin, suggesting it may regulate OPG gene transcription. Together, these studies suggest a novel role for Dynamin in regulating osteocyte dendrite elongation as well as signaling to OCs and OBs to control bone remodeling.

Disclosures: Pierre Eleniste, None.

Approximately 60% of the osteocytes in the bone chips were alive at day 7. Osteocytes in bone chips did express mRNA for the osteocyte markers sclerostin, FGF23, DMP1, and MEPE, and the cytokines IL-1 β , IL-6, and TNF α at day 0 and 7. Osteocytes in bone chips were positive for sclerostin immuno-staining. RA-serum, IL-1 β , TNF α , and the combination of IL-1 β , TNF α , and IL-6 enhanced IL-1 β gene expression (3.3 to 80-fold). RA-serum, IL-8, CCL20, IL-1 β , IL-6, TNF α , and the combination of IL-1 β , TNF α , and IL-6 enhanced TNF α gene expression (2 to 3.5-fold). CCL20, IL-17, IL-1 β , TNF α , and the combination of IL-1 β , TNF α , and IL-6 enhanced IL-6 expression (3 to 87-fold). IL-8, CCL20, IL-1 β , TNF α , and the combination of IL-1 β , TNF α , and IL-6 enhanced IL-8 expression (5 to 233-fold). IL-8, CCL20, IL-1 β , TNF α , and the combination of IL-1 β , TNF α , and IL-6 enhanced FGF23 gene expression (2.3 to 3.9-fold). RA-serum, IL-1 β , and the combination of IL-1 β , TNF α , and IL-6 enhanced SOST gene expression (2.5 to 8.5-fold). RA-serum enhanced DKK1 expression (2-fold).

Active RA-serum, individual exogenous recombinant cytokines, chemokines, and a combination of cytokines modulated gene expression of cytokines, phosphate homeostasis-related signaling molecules, and Wnt inhibitors in human osteocytes cultured in their native matrix. These results suggests that osteocytes could be a new target in the prevention of bone loss in inflammatory diseases.

Bone remodeling is disturbed in rheumatoid arthritis (RA), leading to bone loss, possibly as a result of elevated levels of circulating inflammatory cytokines. Osteocyte signaling plays a vital role in bone mass regulation by orchestrating bone formation and/or bone resorption, but the effect of inflammatory cytokines on osteocyte signaling remains to be elucidated. Therefore we aimed to investigate the effect of RA-serum or exogenous recombinant inflammatory cytokines and chemokines on human osteocyte signaling molecule production.

Human trabecular bone chips were denuded by collagenase-2 treatment for 2 h. Then bone chips, containing osteocytes embedded in their native matrix, were cultured \pm 10% active RA-serum, or \pm 10 ng/ml recombinant IL-1 β , IL-6, IL-17, or TNF α , 200 pg/ml IL-8, 500 pg/ml CCL20, or a combination of IL-1 β , TNF α , and IL-6 for 7 days. Live-dead staining was performed to assess cell viability. Gene expression of cytokines and osteocyte signaling proteins was analyzed by qPCR. Immunostaining was performed for sclerostin.

SU0240

Osteocyte response to mechanical loading is reduced upon exposure to cobalt and chromium ions. Karan Shah*, Peter Orton, Mark Wilkinson, Alison Gartland. The University of Sheffield, United Kingdom

Elevated levels of cobalt (Co) and chromium (Cr) in patients following metal-on-metal hip replacements and modular total hip arthroplasty directly affect osteoclast and osteoblast cell viability and function *in-vitro*¹, with implications for patient bone health. In this study, we provide evidence that Co and Cr compound these direct effects by altering osteocytes' regulation of bone remodelling following mechanical stimuli.

Fluid shear-stress induced changes in intracellular Ca²⁺ were observed in real-time in murine osteocyte cell-line (MLO-Y4) following 30 minute or 24 hours exposure to 50µg/L or 500µg/L combinations of Co²⁺ and Cr³⁺. Time-lapse fluorescence images were analysed using ImageJ and the data expressed relative to control as area under the curve (AUC) and peak intensity. The effect of fluid shear-stress on osteocyte gene expression (RANKL, Dkk-1, CX43 and Gp38) in absence and presence of metal ions was assessed using real time RT-PCR.

Following 30 minute and 24 hour exposure to Co and Cr, a reduction in cellular response (AUC) to mechanical stimuli was observed for 50µg/L (p<0.0001) and 500µg/L (p<0.0001) compared to untreated controls. A reduction in peak response was also observed for both 50µg/L (p<0.0001) and 500µg/L (p<0.0001) at both time-points. MLO-Y4 cells robustly expressed all the genes with the rank order of expression Cx43>Gp38>RANKL>Dkk-1. Application of fluid shear-stress upregulated Gp38 and RANKL expression and reduced Dkk-1 expression. Cells exposed to Co and Cr prior to loading had a blunted increase in Gp38 and RANKL expression following fluid shear-stress, with the effect being dose-dependent, whilst the reduction in Dkk-1 expression was unaffected. CX43 gene expression was unaffected by either loading alone or loading following Co and Cr treatment.

The data suggests that Co and Cr at concentrations observed in patient serum and hip aspirate following hip replacement may impair osteocyte response to mechanical stimuli and reduce the intensity of their response. Alterations in osteocyte-mediated regulation of bone remodelling in response to mechanical loading by metal ions will have significant detrimental effects on bone health.

RANKL Expressed by Osteocytes is Required for the Increase in Bone Marrow B lymphocytes and Bone Loss Caused by Estrogen Deficiency. Yuko Fujiwara*¹, Marilina Piemontese¹, Jinhu Xiong¹, Yu Liu¹, Priscilla Baltz¹, Stavros Manolagas¹, Charles O'Brien². ¹University of Arkansas for Medical Sciences & Central Arkansas Veterans Healthcare System, USA, ²Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Cancellous bone loss caused by estrogen deficiency requires RANKL produced by B lymphocytes and is mimicked by estrogen-receptor alpha deletion from osteoclast precursors. These studies demonstrate that estrogen controls cancellous bone resorption via diverse mechanisms. Under physiological conditions, RANKL produced by osteocytes is essential for osteoclast formation in remodeling cancellous bone. Here we examined whether RANKL produced by osteocytes is also required for the bone loss caused by estrogen deficiency. Mice lacking RANKL in osteocytes, hereafter referred as conditional knockout (KO) mice, were generated by crossing mice harboring a RANKL conditional allele with Dmp1-Cre transgenic mice, which causes Cre-mediated recombination in mature osteoblasts and osteocytes. Ovariectomy and sham operations were performed on 6-month-old conditional KO mice and control littermates and tissues were harvested 6 weeks later. Uterine weight was decreased by ovariectomy in both control and conditional KO mice. As expected, ovariectomy caused bone loss in the spine of control mice as measured by DXA but this did not occur in conditional KO mice. Micro-CT analysis revealed that ovariectomy caused loss of vertebral cancellous bone and femoral cortical bone in control mice but these changes were prevented in conditional KO mice. Consistent with previous studies, ovariectomy increased the number of B lymphocytes in the bone marrow. However, this change was also abrogated in the conditional KO mice. In a separate experiment, estrogen receptor alpha was deleted from the entire B cell lineage using the CD19-Cre driver strain. However, this maneuver did not alter B cell number in intact mice and had no effect on the increase in B cell number caused by ovariectomy. Taken together, these results demonstrate that RANKL expressed by osteocytes is required for the cancellous and cortical bone loss, as well as the increase in B cell number, caused by estrogen deficiency. Moreover, they suggest that estrogen control of B cell number is indirect via osteocytes and that the increase in bone marrow B cell number may be a necessary component of the cascade of events that lead to cancellous bone loss during estrogen deficiency.

Isolating osteocytes from human trabecular bone. Matthew Prideaux*, Christine Schutz, David Findlay, Lucian Solomon, Gerald Atkins. University of Adelaide, Australia

While several murine osteocyte-like cell lines are available and techniques for isolating osteocytes from mouse bone have been described, few models exist for studying human osteocytes *in vitro*. We have developed a method for isolating osteocytes from bone taken from patients undergoing knee arthroplasty. Trabecular bone was dissected and washed to remove marrow and subjected to sequential digestions in collagenase/EDTA. Cells were harvested after each digest, plated on collagen coated wells and cultured over a 5 day time course. Osteocyte gene expression was analysed by RT-PCR and cell morphology examined by phalloidin staining. Cells harvested from digests 1 and 2 expressed low levels of the osteocyte markers *SOST* and *DMP1*, with increased levels observed in digests 3 and 4. The highest levels of these markers were observed in digests 5 and 6, with a 20-fold increase in *DMP1* and a 9-fold increase in *SOST* mRNA compared to digest 1. *FGF23* mRNA expression was absent in the early digests but was observed from digest 3 onwards, increasing up to 150-fold in expression in digest 6. The osteocyte markers *PHEX* and *MEPE* were also expressed in the isolated cells and were increased in the later digests. The cells isolated in digests 1 and 2 displayed a mixed morphology, with osteoblast-like cells and some dendritic osteocyte-like cells after 5 days of culture. Digests 3-6 contained many highly dendritic cells, which were initially observed after 2 days of culture and increased in number and dendricity after 5 days. Treatment of isolated cells from digests 3-6 with PTH or 1,25(OH)₂vitaminD₃ for 24 hours resulted in the downregulation of *SOST* and upregulation of *FGF23* mRNA levels, respectively, similar to osteocytes *in vivo*. In conclusion, we have developed a reproducible method of isolating osteocytes from human bone. Such cells will be invaluable for furthering osteocyte research.

Sclerostin expression in osteocytes of alveolar bone in streptozotocin-induced diabetic rats with ligature-induced periodontitis. Ji-Hye Kim^{*1}, Dong-Eun Lee², Eun-Jung Bak², Yun-Jung Yoo². ¹College of Dentistry, South Korea, ²Yonsei University Dental college, South Korea

Osteocytic sclerostin inhibits bone formation and its expression is stimulated by tumor necrosis factor (TNF)- α . We investigated sclerostin and TNF- α expression in diabetic rats with periodontitis. Rats were divided into control (C), periodontitis (P), and diabetes + periodontitis (DP) groups. After induction of diabetes by streptozotocin, periodontitis was induced by ligature. At day 0 (control) and at days 3 and 20 after induction of periodontitis, alveolar bone, osteoclasts, osteoid, and TNF- α and sclerostin expression were evaluated. The cementoalveolar junction-alveolar bone crest distance of the DP group was longer than that of the P group at day 20 after induction of periodontitis, but the number of osteoclasts was not different. Osteoid area decreased in both the P and DP groups by day 3, but while sustained osteoid suppression was observed in the DP group at day 20, osteoid formation was increased in the P group. The number of sclerostin-positive osteocytes increased in both groups at day 3, but, the increased number of sclerostin-positive osteocytes was maintained only in the DP group through day 20. The number of TNF- α positive cells increased more in the DP group than in the P group. Enhanced alveolar bone loss, suppressed bone formation, and prevalent TNF- α expression were characteristic of the DP group compared to the P group. Suppressed bone formation in the DP was observed simultaneously with increased sclerostin and TNF- α expression. These results suggest that up-regulated osteocytic sclerostin expression in periodontitis with diabetes may play a role in suppressed bone formation.

Bidirectional Notch Signaling Activated by Interactions Between Multiple Myeloma Cells and Osteocytes Drives Tumor Cell Proliferation and Osteoclast Recruitment. Jesus Delgado-Calle^{*}, Judith Anderson, Meloney D. Cregor, Khalid S. Mohammad, Lilian I. Plotkin, Teresita Bellido, G. David Roodman. Indiana University School of Medicine, USA

Multiple Myeloma (MM) is characterized by growth of monoclonal plasma cells in the bone marrow, increased bone resorption, concomitant reduced bone formation, and increased osteocyte apoptosis. The role in MM of matrix-embedded osteocytes, which comprise more than 95% of bone cells and are major regulators of osteoclast and osteoblast activity, is unclear. We investigated the mechanism(s) that trigger osteocyte apoptosis and its significance for MM cell growth and associated bone disease. We found that apoptosis of murine osteocytic MLO-A5 cells is induced by interactions with MM cells lines of murine and human origin as well as with primary CD138+ plasma cells from MM patients, and is blocked by the caspase3 inhibitor DEVD. In addition, apoptosis measured at 8h-24h is abolished by the Notch inhibitor GSIXX, whereas apoptosis measured at 48h is only fully inhibited with a combination of GSIXX and a neutralizing anti-TNF α antibody. These findings demonstrate that osteocyte apoptosis induced by MM is triggered by Notch activation and sustained by MM-derived TNF α . Further, interactions with MM cells increased osteocytic RANKL expression (3-fold) and increase the recruitment of osteoclast precursors by 50% compared to osteocytes cultured alone. These effects were inhibited by blocking osteocyte apoptosis with DEVD or by the combination of GSIXX and anti-TNF α . CD138+ cells from MM patients also increased osteocytic RANKL expression. Further, the percentage of apoptotic and RANKL-positive osteocytes increased by 100% and 53%, respectively, in tumor bearing bones of a mouse model of human MM. Importantly, interactions with osteocytes reciprocally activated Notch signaling in MM cells and in CD138+ cells from patients. Osteocytic cells increased MM cell proliferation by 50% and cyclinD1 expression by 8-fold, and these effects were blocked in a time- and dose-dependent manner by GSIXX. Moreover, osteocytes upregulated Notch receptor 1-4 in MM cells by 4-8-fold. This altered Notch receptor repertoire could impact tumor growth that is dependent on autocrine and paracrine Notch signaling. Thus, bidirectional Notch signaling between MM cells and osteocytes stimulates MM cell proliferation and induces osteocyte apoptosis, which enhances the osteoclastogenic potential of osteocytes. This study emphasizes the ability of osteocytes to impact the MM niche within the bone marrow and supports development of novel approaches to treat MM bone disease by targeting osteocytes.

Mechanisms of Palmitate-Induced Lipotoxicity in Osteocytes. Krishanthi Gunaratnam^{*1}, Christopher Vidal¹, Gustavo Duque². ¹Musculoskeletal Ageing Research Program, Sydney Medical School Nepean, The University of Sydney, Australia, ²Musculoskeletal Ageing Research Program, University of Sydney, Australia

BACKGROUND: Although apoptosis and autophagy play an important role in the regulation of bone metabolism, the mechanisms triggering these two processes in osteocytes (Ocy) remain poorly understood. We have previously demonstrated that

osteoblasts lose their function and undergo autophagy and apoptosis after exposure to palmitic acid (PA), which is the most prevalent fatty acid within the human bone marrow. Here we hypothesized that, as in osteoblasts, PA has a lipotoxic effect on Ocy affecting their function and survival

METHODS: Wild type MLO-Y4 osteocytic cells derived from murine long bones were plated on 0.01% collagen type I-coated plates and cultured in α -MEM in the presence of either PA (250 and 500mM) or vehicle for 48 hrs. Cell viability was measured using MTS-Formazan. Apoptosis was identified by TUNEL and Annexin V assays. Autophagy was quantified using western blotting for LC3 II and flow cytometry analysis of punctate formation using lysoTracker red fluorescence. Finally, changes in Ocy-secreted proteins (sclerostin [Sost], Dickkopf-related protein 1 [Dkk1] and receptor activator of nuclear factor kappa-B ligand [RANKL]) were determined by western blot.

RESULTS: Treatment with PA induced significantly higher levels of cell death (~40%, $p < 0.001$) in a time- and dose-dependent manner. PA induced high levels of apoptosis in MLO-Y4 cells (~35%, $p < 0.001$), with PA-treated cells showing a significantly higher percentage of cytoplasmic area occupied by cytochrome C after 48h of treatment ($p < 0.001$). In addition, we found a dose-dependent failure in autophagy in PA-treated Ocy ($p < 0.01$). Finally, PA treatment induced higher levels of Sost, Dkk1 and RANKL expression in a dose-dependent manner.

CONCLUSION: In summary, we have identified a previously unknown effect of PA on Ocy, which not only corresponds to lipotoxicity but also could explain the high levels of apoptosis and failure in autophagy observed in aged and osteoporotic bone. In addition, PA had an effect on Ocy-secreted factors, which could have a significant effect on bone metabolism *in vivo* that deserves further exploration. In conclusion, the regulation of fatty acid secretion and the inhibition of lipopoptosis would protect Ocy against fat and could become a potential therapeutic target for osteoporosis in the future.

Association between plasma sphingosine 1-phosphate levels and incident fractures in postmenopausal women: A 3-year follow-up observation study. Seung Hun Lee^{*1}, Sung Jin Bae², Hyeonmok Kim³, Seong Hee Ahn³, Beom-Jun Kim³, Jae Suk Chang⁴, Jung-Min Koh³. ¹Asan Medical Center, University of Ulsan College of Medicine, South Korea, ²Health Screening & Promotion Center, Asan Medical Center, University of Ulsan College of Medicine, South Korea, ³Division of Endocrinology & Metabolism, Asan Medical Center, University of Ulsan College of Medicine, South Korea, ⁴Department of Orthopedic Surgery, Asan Medical Center, University of Ulsan College of Medicine, South Korea

Sphingosine 1-phosphate (S1P) has been recognized as a significant regulator of bone metabolism. Recently we found that higher plasma S1P levels were associated with lower bone mineral density (BMD), higher bone resorption marker, and higher risk of prevalent vertebral fracture in postmenopausal women. The objective of the study was to investigate the possibility of S1P as a biomarker for incident fracture risk and insufficient response to bisphosphonate therapy. A total 263 postmenopausal women participated in this 3-year longitudinal study conducted in a clinical unit in Korea. Postmenopausal women were untreated (n = 79) and treated with bisphosphonate, hormone-treated, or selective estrogen receptor modulator (n = 184) with a mean 3.5 years follow-up. Vertebral fracture and non-vertebral fractures were assessed at both baseline and follow-up visits. BMD and bone turnover markers were measured at both baseline and follow-up visits. Plasma S1P levels were obtained from all subjects at the baseline visits. Prevalent fractures were identified in 57 of 263 (21.7%) in this study. Higher plasma S1P levels were significantly associated with higher rate of prevalent fracture after adjustment for femur neck (FN) BMD and potential confounders [Odds ratio (OR): 2.13, 95% confidence interval (CI): 1.08 - 4.22]. A total of 9 (3.4%) incident fractures occurred during the follow-up periods. The fracture-event rate was 95.1 per 10,000 person-years. Subjects with incident fracture had higher plasma S1P levels (mean: 5.87 $\mu\text{mol/L}$, 95%CI: 3.82 - 8.94 $\mu\text{mol/L}$) compared with those without incident fracture (mean: 3.63 $\mu\text{mol/L}$, 95%CI: 3.36 - 3.94 $\mu\text{mol/L}$) even after adjusted for prevalent fracture, FN BMD, anti-osteoporotic medication, annualized changes in FN BMD, and potential confounders ($P = 0.034$). Incident fracture more frequently occurred in the highest plasma S1P tertile group than in the lower two tertile groups [hazard ratio (HR): 5.12, 95% CI: 1.02 - 34.48]. Even after adjustments with confounders including baseline FN BMD, prevalent fracture, anti-osteoporotic medication, annualized changes in FN BMD, and potential confounders, incident fracture more frequently occurred in the highest S1P tertile group (HR: 7.30, 95% CI: 1.05 - 75.75). The OR for insufficient response to bisphosphonate therapy in the highest S1P tertile was 5.03 (95% CI: 1.03 - 24.47), compared with those in the lower two tertile groups. These findings suggest that plasma S1P may be a potential biomarker for the risk of osteoporotic fracture and insufficient response to bisphosphonate therapy in postmenopausal women.

Profiling C3-Epi-25-Hydroxyvitamin D₃ concentrations in paediatric populations as determined by LC-MS/MS. Jonathan Tang^{*1}, Holly Nicholls², Milka Budnik-Zawilska², Paul Brookes³, John Dutton², Isabelle Picc², Christopher Washbourne², William Fraser². ¹University of East Anglia, Norwich, UK, United Kingdom, ²University of East Anglia, United Kingdom, ³Norfolk & Norwich University Hospitals, United Kingdom

Background: The C-3 Epimer of 25 Hydroxyvitamin D₃ (3-epi-25OHD₃) is produced in the liver by the epimerisation pathway of 25-hydroxy vitamin D₃. It differs from 25OHD₃ in configuration of the hydroxyl group at the third carbon (C-3) position. Despite the fact that little is known regarding its clinical significance, higher concentrations 3-epi-25OHD₃ have been reported in paediatric populations than in adults, and that concentration decreases with age.

Objective: This study profiled the concentrations of 3-epi-25OHD₃ in samples from patients of age 0-12 years. A LC-MS/MS technique was developed to resolve and quantify 3-epi-25OHD₃ from 25OHD₃. Commercially available NIST (SRM972a) traceable 3-epi-25OHD commercial standards were used to ensure assay accuracy.

Method: Serum was precipitated with zinc sulphate and acetonitrile containing [³H]-3-epi-25OHD₃ as internal standard. The extract was chromatographed using a 2.6µm 100 x 2.1mm I.D. solid core pentafluorophenyl bonded phase column. Mass detection and quantification were performed by positive electrospray ionization with MS/MS in multiple reaction monitoring mode.

Results: The method was able to fully resolved 3-Epi-25OHD₃ from 25OHD₃. The intra-assay and inter-assay CVs were the epimer were within 8% across the analytical range. In our sample cohort with 25OHD₃ ranged between 7.4 – 185 nmol/L, mean 73 nmol/L. C3-epi-25OHD₃ was detected in 89.7% of samples, mean 3.8 nmol/L ranged between 0.8 - 50.8 nmol/L. Relative percentage of 3-epi-25OHD₃ to 25OHD₃ was averaged at 12%. **Conclusion:** We observed a two fold increase in average concentration of 3-epi-25OHD₃ in paediatric population compare to our previous study on adult population (poster SA0004, ASBMR 2014) and higher concentration was found in neonates than in older children. Our findings showed the level of 3-epi-25OHD₃ in infant contributed to the overestimation of 25OHD₃ that could potentially result in misinterpretation of total vitamin D status. Measurement of 3-epi-25OHD₃ should be included clinical investigations and epidemiological studies of paediatric and infant populations.

Surgery Alters Laboratory Results: Implications for Fracture Liaison Services. Neil Binkley^{*1}, Gretta Borchardt², Ellen Fidler², Jessie Libber², Diane Krueger², Paul Iglar², Joan Lappe³, John Heiner⁴, Richard Illgen⁴, Matthew Squire⁴, Douglas Coursin⁵, Kirk Hogan⁵. ¹University of Wisconsin, Madison, USA, ²University of Wisconsin, USA, ³Creighton University, USA, ⁴University of Wisconsin Department of Orthopedics, USA, ⁵University of Wisconsin Department of Anesthesiology, USA

Background: Fracture liaison services (FLS) are advocated internationally to improve osteoporosis care. As secondary causes of osteoporosis are common, FLS programs often perform laboratory testing. Indeed, a proposed Joint Commission quality measure will require fragility fracture patients to have specified lab tests “ordered or performed” prior to hospital discharge. We hypothesize that lab tests obtained immediately after surgery, e.g., post hip fracture repair, do not accurately indicate an individual’s baseline status.

Methods: Individuals having elective hip total arthroplasty were studied as a surrogate for hip fracture patients. In this ongoing study, 26 adults; 18 women/8 men (mean age 65.0 [8.0] range 53 to 82 years) had blood obtained ~2 wks before surgery, the morning of surgery before anesthesia, at post-op day 1 (POD#1) and at a 6 wk follow-up visit. Hemoglobin (Hgb), serum 25(OH)D, creatinine, calcium, albumin (Alb) and alkaline phosphatase (ALP) were measured at all timepoints.

Results: Of 26 subjects having surgery; 19 had regional, 4 general and 3 combined anesthesia. Mean (SD) estimated blood loss and IV fluid administration during surgery and in the recovery room were 298 (142) mL and 1757 (652) mL respectively. Pre-operative lab results were stable from 2 wks pre-op to day of surgery. Serum calcium, creatinine, ALP, 25(OH)D, Alb and Hgb declined by 11-27% (p < 0.0001) at POD#1 (Table). Calcium, albumin, 25(OH)D and Hgb declined in 100% of subjects. Lab values returned to normal in the 10 subjects with data available at 6 weeks.

Conclusion: Laboratory tests proposed for FLS quality metrics are uniformly and significantly reduced after elective total hip arthroplasty. Similar decrements after fragility fracture surgery are likely. Accordingly, lab test results immediately following surgery do not ascertain a patient’s baseline status; this may lead to incorrect diagnoses/interventions and inappropriately consumes limited healthcare resources. Evaluation for secondary causes of osteoporosis should not be performed immediately post-operatively but rather should be done at a subsequent follow-up visit.

Table 1: Laboratory values (n = 26)

| Timepoint | Analyte | Hgb (g/dL) | Calcium (mg/dL) | Creatinine (mg/dL) | ALP U/L | Alb (mg/dL) | 25(OH)D (ng/mL) |
|----------------|---------|------------|-----------------|--------------------|-------------|-------------|-----------------|
| 2 weeks pre-op | | 13.7 (1.2) | 9.5 (0.4) | 0.84 (0.16) | 80.5 (19.2) | 4.1 (0.3) | 34.9 (15.3) |
| Day of surgery | | 13.5 (1.3) | 9.2 (0.5) | 0.86 (0.17) | 79.4 (19.3) | 3.8 (0.3) | 34.9 (14.7) |
| POD#1 | | 10.8 (1.2) | 8.3 (0.3) | 0.76 (0.16) | 55.7 (14.0) | 3.0 (0.2) | 27.0 (12.3) |

Characteristics of mandibular cortical layer between osteoporotic and normal patients : 3D volumetric analysis with CBCT. Jin-Sun Jeong^{*1}, Yumie Rhee², Jisun Huh³, Kyeong-Mee Park⁴, Yu Gu⁵, Kee-Deog Kim⁴, Wonse Park³. ¹Department of Advanced General Dentistry, Yonsei University College of Dentistry, South Korea, ²Department of Internal Medicine, Endocrine Research Institute, Yonsei University College of Medicine, South Korea, ³Department of Advanced General Dentistry, Yonsei University College of Dentistry, South Korea, ⁴Department of Advanced General Dentistry, College of Dentistry, Yonsei University, South Korea, ⁵Department of Conservative Dentistry, Seoul National University, South Korea

Background: Early detection of osteoporosis is very important for patient’s prognosis. Panoramic radiography is common diagnostic aids not only for general dental evaluation but also for the detection of osteoporosis using inferior cortical layer. However, it is 2D measurement of 3D structure so the errors between inter and intra observer is a problem. Recently, dental cone beam computed tomography (CBCT) is widely used in dental clinic to get 3D skeletal structure of jaw bones with low radiation dose. In this study, we tried to find regional characteristics of mandibular cortical bone with 3D volumetric analysis using CBCT.

Methodology: 20 osteoporotic and normal female patients were included this study. Five parameters using CBCT for RCT (Ramus Cortical bone Thickness), ACT (Angular cortical bone thickness), AI (Antegonial index), and MCW (mandibular cortical width) of mandible were measured using a ROI (region of interest) tool of CTan program at both grayscale 80-120 and 120-200. The t-test was used to determine significance. (P < .05)

Results: Significant differences were found in RCT and ACT through grayscale 120-200 and ACT and AI through grayscale 80-120 from the CBCT images between the patients with and without osteoporosis.

Conclusions: Cortical bone analysis of mandible with CBCT might be effective for early detection of osteoporosis, but site specific evaluation is mandatory.

Examining the Calcaneus Using HRpQCT: Method Reproducibility and Regional Trabecular Variation. Louis Metcalf^{*1}, John Rochester², Nicolas Vilayphiou³, Margaret Paggiosi², Eugene McCloskey². ¹University of Sheffield, United Kingdom, ²University of Sheffield, United Kingdom, ³SCANCO Medical AG, Switzerland

High resolution peripheral quantitative computer tomography (HR-pQCT) assesses volumetric bone density (vBMD) and microstructure at distal sites in the radius and tibia. The calcaneus is equally accessible, has a thinner cortex, is rich in trabecular bone and calcaneal measurements (e.g. quantitative ultrasound) can assess fracture risk. We wished to develop a technique for HR-pQCT scanning of the calcaneus.

The calcanei of 21 cadaveric leg/foot specimens (tibia present=15, tibia absent=6) were each scanned twice in situ, with repositioning, using the XtremeCT (SCANCO Medical AG). All specimens were scanned at an integration time of 100ms and a subset (n=11) also at 200ms. Scans were obtained in the transverse plane centred on the midpoint of the calcaneus (Figure) between the Achilles tendon attachment and flexor digitorum brevis attachment (defined as the height of the calcaneus). This central region was divided into 3 equal 110-slice sections (inferior, middle and superior) and underwent a standard evaluation analysis using a 12.25 x 12.25 x 9.02mm volume of interest (excluding cortical bone). Parameters included vBMD, trabecular number (Tb.N), trabecular spacing (Tb.Sp) and trabecular thickness (Tb.Th).

The mean repositioning error for height measurements was 2.50% but was lower in specimens with the tibia present (0.51% [95% CI: 0.21%, 0.80%]) rather than the foot alone (5.83% [95% CI: 0.74%, 10.92%]). All of the measured parameters showed good reproducibility between scans (R²>0.867, p<0.001). The vBMD and Tb.Th was significantly higher in the superior section compared to the middle and inferior sections (Table), with no significant differences between the latter sections. Increasing the scan integration time from 100ms to 200ms led to an apparent decrease in Tb.N

(-19%, p=0.013) and an increase in Tb.Sp (+34%, p=0.033), with no effect on vBMD or Tb.Th.

Reproducibility has been demonstrated for measurements of density and trabecular morphology in cadaveric calcanei using HR-pQCT. Future studies will compare our findings with micro-CT and examine reproducibility in vivo. Examining specific regions of the calcaneus may prove useful in assessing response to treatment and mechanical loading, as well as fracture risk prediction.

Microindentation Assessed Bone Material Strength Is Associated with Cortical Porosity and Subcutaneous Fat in Older Women. Daniel Sundh^{1*}, Robert Rudäng², Michail Zoulakis², Anna Darelid², Mattias Lorentzon². ¹Institute of Medicine, Sahlgrenska Academy, Sweden, ²GERIATRIC MEDICINE, INSTITUTE OF MEDICINE, Sweden

Microindentation is a novel method to measure actual bone material strength (BMS) in vivo in humans. The association between cortical microstructure and BMS in vivo has not previously been reported.

The aim of this study was to investigate if BMS was associated with cortical bone geometry and microstructure in a population based cohort of 211 women (78.3 ± 1.1 years (mean ± SD)). Bone parameters were measured at the radius and tibia with a High Resolution pQCT (XtremeCT, Scanco Medical). Images were obtained using the manufacturer's recommended standard program (ultradistal site) and at an additional measuring site, at 14% of the bone length. BMS was assessed by four operators using the Osteoprobe® (Active Life Scientific) device, and calculated as the mean of at least 11 valid reference point indentations performed at the midtibia of the non-dominant leg. The coefficient of variation for the method was 3.2%, calculated by duplicate measurements performed on 30 study subjects.

BMS was not associated with age or height, but an inverse association was found for body weight (r=-0.14, p=0.04) and BMS differed by operator (Anova p<0.01). BMS, adjusted for body weight and operator, was correlated to cortical porosity, cortical volumetric BMD and cortical area at the proximal tibial section but not with bone parameters at any other bone site (Table 1). A negative correlation was seen between operator adjusted BMS and total body fat (r=-0.18, p=0.01) but not with total body lean mass (r=-0.10, p=0.15). BMS was associated with DXA-derived fat mass (r=-0.18, p=0.01) rather than lean mass (r=-0.13, p=0.07) at the measured leg. The strongest association between BMS and adipose tissue (r=-0.31, p<0.001) was observed for subcutaneous (s.c) fat (measured using the HR-pQCT images). S.c. fat

was also associated with cortical porosity (r=0.21, p<0.01) and cortical vBMD (r=0.20, p<0.01) at the proximal tibial site.

In a population-based sample of older women, low BMS was associated with reduced cortical vBMD and high porosity, but the associations were apparent only at CT-measurements performed in close proximity to the indentation site, indicating that BMS does not reflect cortical bone microstructure in general. Furthermore, s.c. fat near the indentation site was most strongly associated with BMS and also with cortical porosity and density, indicating a possible adverse effect of adipose tissue on bone material properties and bone microstructure.

Table 1. Correlations between adjusted BMS and bone parameters

| | Tibia | Tibia | Radius | Radius |
|---------------------------------|--------------|---------------------|--------------|--------------|
| | ultradistal* | proximal* | ultradistal* | proximal* |
| Cortical porosity | -0.02 (0.77) | -0.14 (0.04) | -0.02 (0.85) | 0.02 (0.83) |
| Cortical volumetric BMD | 0.10 (0.16) | 0.17 (0.02) | 0.04 (0.65) | 0.004 (0.96) |
| Cortical area | 0.10 (0.16) | 0.16 (0.03) | 0.11 (0.17) | 0.12 (0.11) |
| Trabecular bone volume fraction | 0.12 (0.08) | 0.03 (0.67) | 0.08 (0.29) | 0.04 (0.60) |

Results presented as correlation factors together with a p-value within the parenthesis.

p-value < 0.05 was regarded significant and illustrated in bold numbers.

BMS was adjusted for operator and weight.

The Canadian Multicentre Osteoporosis Bone Quality Study (CaMos BQS): Baseline Comparison of HR-pQCT and pQCT and Fracture Associations.

Andy Kin On Wong^{1*}, Claudie Berger², George Ioannidis³, Karen Beattie³, Christopher Gordon³, Laura Pickard³, Alexandra Papaioannou⁴, David Goltzman², Jerilynn Prior⁵, Heather Macdonald², Maureen Ashe⁵, Leigh Gabel⁵, Danmei Liu⁶, Steve Boyd⁷, Lauren Burt⁷, Michelle Kan⁷, Kyle Nishiyama⁸, Saija Kontulainen⁹, Andrew Frank-Wilson⁹, Chantal Kawalilak⁹, Wojciech Olszynski⁹, K. Shawn Davison¹⁰, Lora Giangregorio¹¹, Robert Josse¹², Eva Szabo¹³, Marta Erlandson⁹, Tassos Anastassiades¹⁴, Norma MacIntyre³, Angela M. Cheung¹³, Jonathan D. Adachi³. ¹University Health Network, Ca, ²McGill university, Canada, ³McMaster University, Canada, ⁴Hamilton Health Sciences, Canada, ⁵UBC, Canada, ⁶CHHM, Canada, ⁷University of Calgary, Canada, ⁸Columbia University, USA, ⁹University of Saskatchewan, Canada, ¹⁰University of Victoria, Canada, ¹¹University of Waterloo, Canada, ¹²St. Michael's Hospital, Canada, ¹³UHN, Canada, ¹⁴Queens University, Canada

Objectives: 1) to validate pQCT bone measures against HR-pQCT; 2) to compare pQCT and HR-pQCT bone measures in their association with fractures. Study design: cross-sectional analyses of a population-based cohort study. Inclusion: Women 60-85 within 6 CaMos centres were approached (N=1066). pQCT: A 2.3 ± 0.5mm thick slice was prescribed at 4% distal radius and tibia (200 µm in-plane resolution). HR-pQCT: 110 slices were acquired at the ultradistal radius and tibia (82 µm isotropic). Image processing: Bone from pQCT slices was segmented using region-growing (OsteoQ, ISS). Bone from HR-pQCT images was segmented using a dual-threshold algorithm (ScanCo). Clinical data: Fractures (low trauma, all trauma, and ever fracture) in the last 15 years were obtained from CaMos. Data analyses: Linear regression analysis determined slopes and intercepts regressing HR-pQCT on pQCT bone measures. Binary logistic regression models examined the association between bone measures from each modality and fractures. Odds ratios were reported with 95% confidence intervals. Analyses were performed for each modality separately. Alternatively, bone measures from pQCT were pooled with HR-pQCT measures after cross-calibration. All models adjusted for age and BMI. Results: In 644 women (mean age: 72 ± 7 years and BMI: 27.68 ± 5.33 kg/m²), linear regression analyses showed significant associations between all pQCT-derived bone parameters and corresponding outcomes on HR-pQCT (R²=0.122-0.908). Bone volume fraction (BTVF) from pQCT images explained the largest variance (R²=0.908) in HR-pQCT images. A larger number of pQCT and HR-pQCT bone parameters associated with fractures by including those who have ever had a fracture as compared to all or low trauma (ORs ranged: 1.28-1.92). At both anatomical sites, HR-pQCT yielded a larger number of parameters that associated with fractures than pQCT. When cross-calibrated pQCT parameters were pooled with HR-pQCT data (Table 1), effect sizes remained similar to that prior to pooling. Smaller fracture numbers for all and low trauma fractures precluded the observation of significant findings. However, by pooling cross-calibrated data, Ct.Th at the radius (2.76(1.16,6.57)) and Tb.Th at the tibia (2.23(1.07,4.63)) were associated with low trauma fractures. Conclusions: Pooling HR-pQCT and cross-calibrated pQCT data yielded stronger associations with fractures. Study centres with poor access to HR-pQCT technology could use pQCT as a valid alternative.

Table I. Comparison of significant associations with fractures (ever) observed at the tibia versus the radius based on pooled sample of HR-pQCT and cross-calibrated pQCT bone parameters.

Cortical and Trabecular Bone Analysis of Hip Fracture Patients using 3D-DXA. Alexis Bague¹, Luis Del Rio Barquero², Silvia Di Gregorio², Yves Martelli³, Miguel A. González Ballester⁴, Ludovic Humbert*³. ¹SIMBioSys – Simulation, Imaging & Modelling for Biomedical Systems, Universitat Pompeu Fabra, Spain, ²CETIR Grup Medic, Spain, ³Galgo Medical, Spain, ⁴SIMBioSys – Simulation, Imaging & Modelling for Biomedical Systems, Universitat Pompeu Fabra - ICREA, Spain

The purpose of this study is to analyze the cortical and trabecular bone of hip fracture patients and controls using 3D-DXA.

A retrospective study was carried out to collect 128 DXA scans of post-menopausal Caucasian women (CETIR Grup Medic, Barcelona), including 64 patients with a hip fracture event occurring between one and 6 years from baseline and 64 age-matched controls without any osteoporotic fracture during at least a 6 years follow-up. None of the patients had osteoporotic fracture at baseline. 3D-DXA was used to obtain patient-specific models from the baseline DXA projections. The 3D-DXA technology provides a three dimensional analysis of the femoral shape and bone density distribution from a single Dual energy X-ray Absorptiometry (DXA) scan, allowing for a separate assessment of cortical and trabecular bone. The algorithm performs the registration of a 3D appearance model incorporating statistical information about the femoral shape and density onto the 2D DXA image. From the resulting patient-specific models, the volumetric BMD (vBMD), BMC, volume (for trabecular and cortical regions) and cortical thickness distribution can be automatically quantified. The clinical parameters were compared over both groups using the Student's t-test.

No statistically significant differences were found between the average age, weight, height and BMI of both groups. Fracture group femurs were bigger than controls (p = 0.007), and had a lower vBMD in both cortical (p = 0.001) and trabecular (p < 0.001) compartments. The average cortical thickness was also lower for fracture group (1.49 mm) than for controls (1.63 mm, p < 0.001).

By providing a detailed analysis of cortical and trabecular bone in 3D using DXA modality, 3D-DXA could potentially improve the management of osteoporosis in clinical routine.

Dynamically Filtered Control of X-ray Flux Maintains Precision and Accuracy Over Wide Tissue Thicknesses in the Norland DXA System. Pat Cunniff¹, Joe Joyce¹, Jing Mei Wang², Tom Sanchez*³. ¹Bone Health Division, Norland at Swissray, USA, ²Bone Health Division, Norland at Swissray, China, ³Norland at Swissray, USA

As in any x-ray assessment, precision and accuracy of measured tissue content can suffer with varying tissue thicknesses as the study is compromised by beam hardening or detector saturation or starvation. The current study examined the performance of a dynamically filtered Norland DXA system evaluating known materials under widely ranging tissue thickness.

A Norland XR-46 fitted with dynamic filtration and calibrated over a 77-step range to adjust for varying thicknesses of material was used to evaluate a known bone mineral content in tissue ranging between 5cm and 30cm of thickness. Evaluations carried out 25 studies of the known bone material in six thickness level starting at 5cm and advancing in 5cm increments to 30cm. Studies were done at seven scan speeds ranging from 65mm/s to 260mm/s. Studies were evaluated for precision of bone mineral density, lean content and fat content and for accuracy in measured bone mineral density in all scan sets.

Independent of scan speed, the Norland XR-46 studies indicate consistent repeatability (2%) and accuracy (2%) in bone density assessments for studies going up to 25cm in thickness. The table below indicates repeatability as a %CV and accuracy as a ratio of measured bone density to true bone density at evaluated scan speeds and tissue thicknesses.

| | 5cm | 10cm | 15cm | 20cm | 25cm | 30cm |
|---------|-----------|-----------|-----------|-----------|-----------|-----------|
| 65mm/s | 0.3/100.6 | 0.3/99.4 | 0.2/100.8 | 0.6/101.2 | 0.4/102.7 | 0.7/105.7 |
| 97mm/s | 0.4/100.5 | 0.5/99.2 | 0.5/101.0 | 0.6/101.2 | 0.7/103.2 | 0.7/104.5 |
| 130mm/s | 0.4/100.6 | 0.3/99.0 | 0.6/100.8 | 0.5/101.4 | 0.9/103.5 | 0.9/102.4 |
| 162mm/s | 0.5/100.7 | 0.6/100.2 | 0.8/100.8 | 0.7/102.3 | 0.9/104.0 | 0.7/104.5 |
| 195mm/s | 0.5/101.0 | 0.8/100.5 | 0.6/100.6 | 0.8/102.0 | 0.8/103.7 | 1.3/104.0 |
| 227mm/s | 0.5/101.0 | 0.7/100.5 | 0.7/101.2 | 0.7/102.6 | 0.9/103.8 | 1.2/104.2 |
| 260mm/s | 0.5/101.0 | 0.8/100.7 | 0.7/100.6 | 0.9/102.1 | 1.1/103.6 | 1.3/103.8 |

Evaluating the repeatability of lean or fat content over the various tissue thicknesses and scan speeds indicates results are generally within 2.0% of the average measured results.

In conclusion, these studies of a well defined bone phantom demonstrate that when fitted with dynamic filtration the Norland scanner is able to deliver results with good precision and accuracy in studies with tissue thickness up to 30cm thick.

Reliability and validity of lower extremity computed tomography as a screening tool for osteoporosis. Ki Hyuk Sung*¹, Soon-Sun Kwon², Seung Jun Mun¹, Seung Yeol Lee³. ¹Myongji Hospital, South Korea, ²National University Bundang Hospital, South Korea, ³Ewha Womans University Mokdong Hospital, South Korea

Introduction: This study aimed to evaluate the reliability and validity of CT as a screening tool for osteoporosis and to estimate the correlation between central BMD and peripheral bone attenuation using lower extremity CT. Methods: In total, 292 patients who underwent a lower extremity, lumbar spine, or abdomen and pelvic CT scan within a 3-month interval of a dual-energy X-ray absorptiometry (DEXA) examination were included. Following reliability testing, bone attenuation of the L1, L2, L3, L4, femoral head, femoral neck, greater trochanter, distal femur, proximal tibia, distal tibia, and talus was measured by placing a circular region of interest on the central part of each bony region on a coronal CT image. Partial correlation was used to assess the correlation between CT and DEXA after adjusting for age and body mass index. Results: In terms of reliability, all bone attenuation measurements, except the femoral neck, showed good to excellent interobserver reliability (intraclass correlation coefficients, 0.691–0.941). In terms of validity, bone attenuation of the L1 to L4, femoral neck, and greater trochanter on CT showed significant correlations with BMD of each area on DEXA (correlation coefficients, 0.399–0.613). Bone attenuation of the distal tibia and talus on CT showed significant correlations with BMD of all parts on DEXA (correlation coefficients, 0.493–0.581 for distal tibia, 0.396–0.579 for talus). Conclusion: Lower extremity CT is a useful screening tool for osteoporosis, and peripheral bone attenuation on lower extremity CT adequately reflects central BMD on DEXA.

Stochastic Predictors from DXA Scans of Human Lumbar Vertebrae Are Correlated with Microarchitecture Parameters of Trabecular Bone. Neil Dong*¹, Rajeshwar Pinninti¹, Amy Twinnereim², Timothy Lowe¹, David Di Paolo¹, Mukul Shirvaikar¹. ¹The University of Texas at Tyler, USA, ²UT Health Northeast, USA

The purpose of this study was to provide a novel stochastic assessment of inhomogeneous distribution of bone mineral density (BMD) from the Dual-energy X-ray Absorptiometry (DXA) scans of human lumbar vertebrae and identify the stochastic predictors that were correlated with the microarchitecture parameters of trabecular bone.

Eighteen human lumbar vertebrae with intact posterior elements from cadaveric spines were scanned in the posterior-anterior projection using a Hologic densitometer (Fig.1a). The BMD map of human vertebrae was obtained from the raw data of DXA scans by directly operating on the transmission measurements of low- and high-energy X-ray beams (Fig.1b). Stochastic predictors, including correlation length, sill variance, and nugget variance, were calculated by fitting a theoretical model onto the experimental variogram of the BMD map (Fig.1c), rather than grayscale images, from DXA scans. The theoretical model represented a comprehensive view, rather than an initial trend, of the experimental variogram. In addition, microarchitecture parameters of trabecular bone in the vertebral body were measured from the 3D images of human vertebrae (Fig.1d) acquired using a Micro-CT scanner.

Significant correlations were observed between stochastic predictors and microarchitecture parameters (Fig.2). The sill variance, to some extent, representing the standard deviation of the BMD map, had significant positive correlations with bone volume fraction ($r=0.621, p=0.006$), trabecular thickness ($r=0.484, p=0.042$), trabecular number ($r=0.611, p=0.007$) and connectivity density ($r=0.515, p=0.029$). The sill variance was also negatively correlated with bone surface to volume ratio ($r=-0.473, p=0.048$) and trabecular separation ($r=-0.614, p=0.007$).

This study demonstrates that the stochastic assessment of the inhomogeneous distribution of bone mineral density from DXA scans of human lumbar vertebrae can reveal microarchitecture information of trabecular bone. In addition, the sill variance observed in this study may represent the point-to-point variations of bone mineral density due to local bone remodeling. A previous study indicated that the standard deviation of vertebral regional bone mineral density values was a good predictor of fracture load. Therefore, stochastic predictors from routine clinical DXA scans of human lumbar spine may have the potential to become an economical and effective tool for providing bone fragility information complementary to BMD.

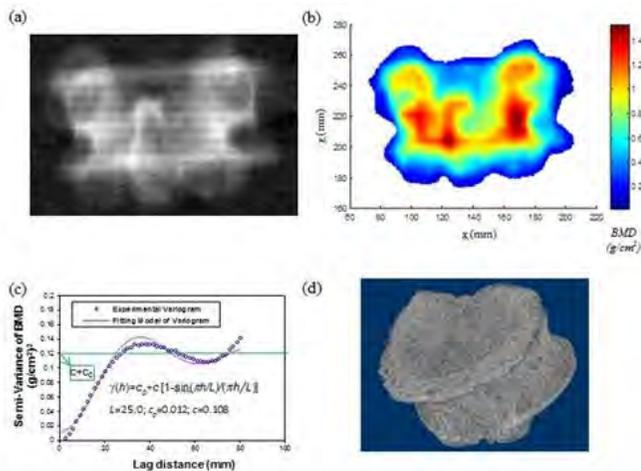

Figure 1. Calculation of stochastic predictors from the BMD map of human vertebrae. (a) A DXA image of human vertebrae in the posterior-anterior projection from a Hologic densitometer; (b) A typical BMD map obtained from the raw data of DXA scans of human vertebrae; (c) A hole-effect fitting model of the experimental variogram of the BMD map. The stochastic predictors, correlation length (L), sill variance (c) and nugget variance (c_0), were extracted from the hole-effect model; and (d) Three-dimensional Micro-CT image of the vertebral body.

A New System for Ultrasonic Assessment of the Calcaneus. Emily Stein¹, Fernando Rosete¹, Mariana Bucovsky¹, Gangming Luo², Jonathan Kaufman*², Alfred Rosenbaum³, Elizabeth Shane¹, Robert Sifferl⁴. ¹Columbia University College of Physicians & Surgeons, USA, ²CyberLogic, Inc., USA, ³Computerized Scanning Associates, USA, ⁴The Mount Sinai School of Medicine, USA

The objective of this study was to evaluate a new clinical ultrasound device (*QRT 250*, CyberLogic, Inc., NY, USA, Fig. 1) in terms of its ability to estimate bone mineral density (BMD) at the calcaneus, as well as to investigate its short-term precision. The device (Fig. 1) rests on the floor and permits real-time evaluation of the calcaneal BMD. The *QRT 250* employs a novel heel positioning system that relies on an individual's foot size to locate a specific region-of-interest (ROI) in the calcaneus. The device measures in thru-transmission net time delay (NTD) and mean time duration (MTD) parameters. NTD is defined as the difference between the transit time of an ultrasound pulse through overlying soft-tissues and calcaneus, and the transit time through soft tissue only of equal overall distance. MTD is a measure of the time duration of an initial temporal cycle of the received waveform. A linear regression of the product of $NTD \cdot MTD$ is used to provide an estimate of calcaneal BMD that would be measured by DXA. A clinical IRB-approved study was carried out in which 67 adults (age range 21-83, 55% female) were measured at the calcaneus using ultrasound and DXA (Lunar GE PIXI, Madison, WI). In addition, ten (10) subjects were each ultrasonically measured five (5) times with full foot repositioning, and the short term precision was evaluated. BMD_{DXA} ranged from a low of 0.45 g/cm^2 to a high of 0.92 g/cm^2 . A linear regression showed that $BMD_{US} = 0.48 \cdot [NTD \cdot MTD] + 0.071$ and that the linear correlation between BMD_{DXA} and BMD_{US} was 0.92 ($P < 0.0001$, Fig. 2). We found that calcaneal ultrasound measurements yield results that are very closely associated with those from DXA. These results are consistent with previous computer simulation and *in vitro* studies, in terms of the ability to ultrasonically estimate calcaneal bone mass. In the short-term precision study, we found a mean percent precision of 1.21%. This is similar to the short-term reproducibility of DXA scanners. In conclusion, although x-ray methods can estimate BMD, osteoporosis remains one of the world's most undiagnosed diseases. This research should enable significant expansion of the identification of bone loss as occurs in osteoporosis using an inexpensive radiation-free ultrasonic device that can serve as a proxy for BMD_{DXA} at the calcaneus.

SU0257

Age dependent sensitivity and specificity of osteoporosis diagnostics at primary healthcare with Bindex. Janne Karjalainen^{*1}, Ossi Riekkinen², John Schousboe³, Heikki Kröger⁴. ¹Bone Index Finland Ltd., Finland, ²Bone Index Finland Ltd, Finland, ³Park Nicollet Institute, USA, ⁴Kuopio University Hospital, Finland

Objectives

An ultrasound based device (Bindex[®]) has been recently introduced to address the challenges in osteoporosis diagnostics at primary care (1). Bindex measures cortical thickness and determines parameter called density index (DI). Thresholds for DI in osteoporosis assessment have been determined in Finnish Caucasian population (n= 448) along the International Society of Clinical Densitometry (ISCD) guidelines (2). In this study, the sensitivity and specificity in different age groups was assessed.

Materials and Methods

A total of 1316 Caucasian females participated the study (age 68.0 ± 9.5 years). Subjects were measured with dual energy x-ray absorptiometry (DXA) to determine bone mineral density (BMD) at proximal femur. Further, the cortical thickness was measured at three locations (distal radius, distal and proximal tibia) with Bindex[®]. Subjects were diagnosed with OP when T-score at femoral neck or total proximal femur was below -2.5 (NHANES III reference database). A subgroup of 865 subjects was formed in which the subjects with T-score -2.1 - -2.9 were removed due to the precision error in T-score values and uncertainty of osteoporosis/healthy status (3). In this subgroup, OP was diagnosed when T-score was below -2.9. The subjects were healthy when T-score was over -2.1. Density index was calculated either by using measurement at one location (DI₁, proximal tibia) or all three locations (DI₃).

Results

The sensitivity of density index showed increasing trend with increasing age and specificity a decreasing trend with increasing age (Table 1 and Table 2). Within the total population of 1316 the negative predictive values ranged from 93.2% to 94.7% with DI₃ and from 91.3% to 92.5% with DI₁ in different age decades.

Conclusions

The trends observed in the sensitivity and specificity of DI for osteoporosis in different age groups suggests that the thresholds values should be adjusted with age. However, the high negative predictive value in all age groups shows very efficient discrimination of healthy individuals and highlights the potential of the technique as a first line screening tool.

Association of Body Habitus to Bone Density and Mass in Adults. John Shepherd¹, Bennett Ng², Alka Kanaya², Kathy Mulligan², Louise Marquino², Bo Fan². ¹University of California, San Francisco, USA, ²UCSF, USA

There is a need to identify men and women at high fracture risk. The current worldwide paradigm of quantifying fracture risk using DXA is woefully underutilized for reasons of cost, x-ray exposure, and accessibility. The FRAX risk model can be used without a BMD assessment but with lower sensitivity. We explore a new low-cost, radiation-free, and highly accessible technology, 3-dimensional whole body optical scanning, to estimate BMD and BMC measures.

Methods: We had a target to recruit healthy ambulatory adult volunteers stratified by sex, and tertiles of age and BMI. Each participant received a whole body DXA using a Hologic Discovery/W and a 3-D optical whole body scan using a Fit3D system. The Fit3D creates 470 anthropomorphic measures (lengths, circumferences, diameters.) To control for covariance, we derived the principal components (PCA) of body shape. We estimated whole body BMD and BMC as well as subregional spine BMD and BMC using step forward linear regression from demographic (DEMO) measures alone (height, weight, age, sex, $1/\text{height}^2$, and BMI), PCA components alone, and DEMO+PCA measures.

Results: To date, 29 individuals (13 men) have been recruited with an average age of 40 +/- 14 years, and BMI of 27.0 +/- 5.6 g/cm². Only 14 PCA modes were required to explain 95% of the variance in body shape. Using DEMO alone, we found correlations of $r^2 = 0.76$ and 0.34 for whole body BMC and subregional spine BMC respectively. Using PCA alone, the r^2 values were substantially higher at $r^2 = 0.88$ and 0.41 for the same measures. Combining DEMO and PCA did not improve the r^2 values beyond PCA alone. Similar results were seen for BMD values: DEMO alone $r^2 = 0.52$ and 0.1 for whole body and spine; PCA alone $r^2 = 0.67$ and 0.33 respectively.

Conclusions: We conclude that whole body and regional measures of bone, but especially whole body BMC, can be well estimated from whole body 3D optical scans. Future studies are needed with populations at risk of osteoporosis with comparisons to hip and spine BMD measures from dedicated scans.

Clinical efficacy of a simplified hip structure analysis method for the prediction of incident hip fracture events. Ben Khoo¹, Joshua Lewis², Keenan Brown³, Richard Prince². ¹Western Australian Health Department, Australia, ²University of Western Australia, Australia, ³Mindways Software, Inc, USA

Non-invasive two dimensional Dual Energy X-ray (DXA) imaging of the proximal femur to produce an areal bone density (aBMD) is a clinically useful predictor of future fracture risk. Recently a four measurements assumption free algorithm, derived from the currently used eight HSA variables, has been used to capture population variation in bone structure at the narrow femoral neck (NN), trochanter (TR) and shaft (S). These parameters include two previously used variables, the localised areal bone mineral density (aBMD) and sub-periosteal width (W) applying to the 0.5 cm wide box at the three sites and two new variables, the standard deviation of a normalised mineral-mass projection profile distribution (s), and the displacement between centre-of-mineral-mass and geometric centre-of-mineral-mass of the projection profile (d). Using a cohort study of 1159 women mean age 75 at baseline who sustained 140 hip fractures over 15 years we determined whether these measures significantly improved 15-year hip fracture prediction compared to the current approach utilising age and total hip BMD. There were strong correlations between the variables. To describe the most parsimonious model for hip fracture risk prediction the 12 base measures (4 from each site), total hip BMD and age were evaluated in stepwise logistic regression models. The final model included TR_s, total

hip BMD and age and provided improved utility for hip fracture prediction compared to total hip BMD and age alone (C-statistic 0.73 and 0.69 respectively, $P = 0.007$, net reclassification improvement 0.166, $P < 0.001$). Many attempts have been made to improve on the predictive ability of aBMD which integrates bone mass and bone area. The addition of one HSA derived variable TR_s which describes the distribution of mass within the scanned area of the trochanter, substantially improved the prediction of 15-year hip fracture probability in elderly women.

Comparison of MRI Measures versus DXA Hip Structural Analysis Narrow Neck Geometric Indices in a Limited Sample of Adolescent Females. Jodi Dowthwaite¹, Tomas Cervinka², Paula Rosenbaum³, Tamara Scerpella⁴. ¹SUNY Upstate Medical University; Syracuse University, USA, ²Tampere University of Technology, Finland, ³SUNY Upstate Medical University, USA, ⁴University of Wisconsin, USA

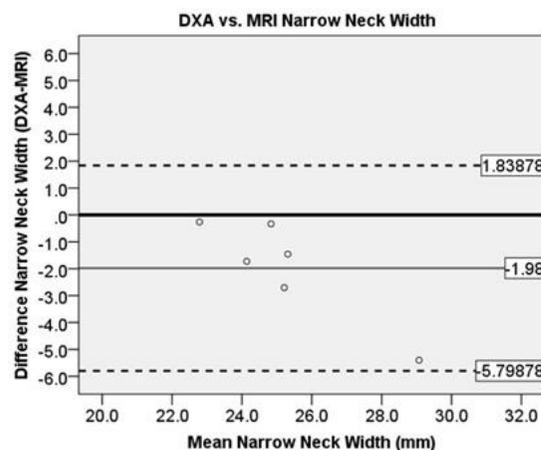

Purpose: Hip structural analysis (HSA) derives proximal femur bone geometric and strength indices from postero-anterior dual energy X-ray absorptiometry (DXA) scans, generating limited radiation exposure. Magnetic resonance imaging (MRI) provides an opportunity to evaluate correlation between 3-dimensional indices of bone geometry and 2-dimensional DXA output, without additional X-ray exposure. In the current analysis, we compared DXA HSA results against output from proximal femur MRI scans in a pilot sample of adolescent females.

Methods: In 6 female subjects, informed assent with parental consent (or informed consent) was obtained for postero-anterior DXA scans (Hologic Discovery A; Waltham, MA) and MRI scans (3.0 T Siemens Magnetom Tim Trio; Malvern, PA) of the left proximal femur. The longest inter-scan interval was 5 weeks. DXA hip positioning was used for both scans. MRI scans used a region-specific coil. MRI images were segmented manually. Anthropometrics were performed. Semi-annual records were used to calculate annual mean weight-bearing organized activity participation. MRI and DXA HSA Narrow Neck assessments of periosteal width, mean cortical thickness, mean endosteal diameter and section modulus were evaluated. Pearson correlations evaluated effect sizes for inter-method associations. Bland-Altman plots evaluated inter-method agreement.

Results: Subject chronological age ranged from 11.1 to 23.6 years (mean 16.0, sd 4.2), and biological age relative to menarche ranged from -0.8 years to 9.2 years (mean 2.9, sd 4.1). Anthropometric means were as follows: height 161.6 cm (sd 7.4); weight 54.0kg (sd 9.7); body mass index 20.5 kg/m² (sd 2.4). Prior year organized weight-bearing physical activity ranged from 1.6 to 18.3 hours per week (mean 8.3, sd 6.0).

Narrow Neck bone index correlations were as follows: mean cortical thickness $r = 0.62$ ($p = 0.15$); endosteal diameter $r = 0.66$ ($p = 0.18$), superior-inferior periosteal width $r = 0.90$ ($p = 0.01$) and section modulus $r = 0.42$ ($p = 0.40$). A Bland-Altman plot indicates underestimation of Narrow Neck periosteal width using HSA that increases with increasing bone width.

Conclusions: Although small available sample size limited statistical significance of results, Pearson r effect sizes for correlations were moderate (> 0.3) to large (> 0.5) for all outcomes, but inter-method agreement was variable. These pilot analyses indicate that HSA geometric and bone strength index parameters should be validated in growing children.

Guided wave-based ultrasound biomarkers of cortical bone discriminate fractured from non-fractured post-menopausal women. Quentin Vallet^{1*}, Jean-Gabriel Minonzio¹, Nicolas Bochud¹, Adrien Etchet², Karine Briot², Sami Kolta², Christian Roux², Pascal Laugier³. ¹Sorbonne Universités, UPMC Univ Paris 06, CNRS, INSERM, Laboratoire d'Imagerie Biomédicale, France, ²INSERM, U 1153, Rheumatology Department, Cochin Hospital, Paris Descartes University, France, ³Université Pierre et Marie Curie-Paris 6, France

Structural decay of bone is not fully assessed by current X-ray methods, and there is an unmet need in identifying women at risk of fracture who should receive a treatment. The last decade has seen the emergence of ultrasound (US) axial transmission (AT) techniques to assess cortical bone. Recent AT techniques exploit the multimode waveguide response of long bones such as the radius. Guided wave (GW)-based approaches would be expected to provide estimates of bone strength-related factors, such as cortical thickness and porosity, which cannot easily be captured by X-ray densitometry techniques. The objective of this cross sectional study was to evaluate if a new GW-based prototype device can discriminate between fractured and non-fractured postmenopausal women. One hundred and nineteen postmenopausal women were included, among whom 78 were non fractured (NF, mean age 61 ± 8 years), and 41 with a non-traumatic fractures (F, mean age 71 ± 10 years). Measurements were performed at the distal radius using a prototype device (Azalée, Paris, France) consisting of 1-MHz multi-transmitter multi-receiver probe. In addition to the fundamental wave (FW) velocity, the cortical thickness (C.Th) and a cortical porosity index (C.PI) were estimated by fitting a homogenized free plate model to the experimental frequency-dependent wavenumbers measured in the 0.5-1.5 MHz frequency bandwidth. The total femur areal bone mineral density (BMD) was obtained using DXA at the proximal femur. The measured characteristics in both groups were as follows: BMD 0.82 ± 0.11 g.cm² T-score=-1.47 ± 0.83 (NF), 0.72 ± 0.12 g.cm² T-score=-2.17 ± 0.79 (F); FW 1681 ± 56 m/s, (NF) 1646 ± 50 m/s (F); C.PI, 10 ± 4%, (NF) 12 ± 3% (F). Discrimination of fractures with ultrasound variables (except for the C.Th) and with BMD was statistically significant (p < 0.05) (US: odds ratios [ORs] = 1.8–2.1, area under the ROC curve [AUCs] 65–68%; BMD: OR = 2.5, AUC 73%). However, after adjustments on age, the differences were no more significant (p>0.05), as expected due to the large difference in age of the two groups. A weak but significant correlation was found between BMD and FW (R=0.26, p<0.005) and BMD and C.PI (R=0.19, p<0.05). In multiple logistic regression analysis, several combinations of US variables and BMD (C.PI and BMD; FW and BMD) were found to be discriminant with AUC of 76%, which improved the AUC by 3% in comparison with BMD alone. These preliminary results suggest that ultrasound GW-based technologies have the potential to yield cortical bone biomarkers to predict fracture risk in postmenopausal women. The study will be completed in the next future by the inclusion of a larger population. This work received financial support from the Fondation pour la Recherche Médicale (FRM DBS201311228444) and was supported in part by a research grant from investigator-initiated studies program of Merck Sharp & Dohme Corp. Inter-Operator Precision and Monitoring Time Intervals for Bone Strength and BMD as Measured from CT Scans — A Comparison of Phantom and Phantomless Calibrations. David Lee^{1*}, Paul Hoffmann¹, Kwang Lee¹, David Kopperdahl¹, Tony Keaveny². ¹O.N. Diagnostics, USA, ²University of California Berkeley, USA

Clinical computed tomography (CT) scans can be analyzed to measure BMD, and, when coupled with finite element analysis, bone strength. The use of a phantomless calibration scheme can expand the availability of CT by not requiring an external calibration phantom. However, precision must be maintained, and the monitoring time interval should be as good as with DXA, the clinical standard. Addressing these issues, we sought to compare the precision and the monitoring time interval of CT-based estimates of BMD and strength in the hip and spine, measured with phantom versus phantomless calibration. VirtuOst (O.N. Diagnostics, Berkeley CA) was used for all analyses, and utilized measurements of blood, fat and air for phantomless calibration. We analyzed CT scans of 56 women (mean age ± SD 62 ± 17 years) and 44 men (59 ± 16 years), acquired on 27 CT scanners. Each scan was processed by two analysts and was calibrated using both calibration techniques. Inter-operator precision was calculated as the percent coefficient of variation. Monitoring time interval for an individual patient was calculated as 2.77 times the clinical precision divided by the annual rate of change. Since repeated CT scans were unavailable, clinical precision was calculated as 0.5% points worse than interoperator precision [1]; annual rates of changes were estimated for a 70-year old Caucasian woman using data from population studies. We found that interoperator precision ranged from 0.49–0.69% across all measured CT parameters, and was similar for phantom and phantomless calibration (Table). The lowest monitoring time intervals occurred for femoral strength at the hip (1.4 years) and trabecular BMD at the spine (1.5 years). Monitoring time interval for vertebral trabecular BMD and vertebral strength were similar to each other, and appreciably shorter than for total spine areal BMD based on the reported precision for DXA [2]. The monitoring time interval for femoral strength was also shorter than for areal BMD, whether measured by CT or DXA. Because the precision was similar for strength and areal BMD, these lower monitoring time intervals were due primarily to the larger annual changes for strength compared to areal BMD. We conclude that, using VirtuOst, precision for CT-based BMD and bone strength were similar for both phantom and phantomless calibration and the monitoring time interval was shorter than for DXA.

Investigating the effects of motion streaks on the association between pQCT-derived leg muscle density and fractures in older adults. Adrian Chan^{*}, Jonathan D. Adachi, Alexandra Papaioannou, Laura Pickard, Andy Kin On Wong. McMaster University, Canada

Objectives: 1) to assess the degree of difference in pQCT-derived leg muscle density computed with versus without motion streaks, and 2) to determine how motion streaks affect the relationship between leg muscle density and fractures, and how they are related to fractures.

Method: Women 60-85 years of age from the Canadian Multicentre Osteoporosis Bone Quality Study participated in this cross-sectional analysis of the population-based cohort. Trans-axial leg scans at 66% of the tibial length were obtained using pQCT and motion was graded on a scale of 1-5 according to motion streak severity. Muscle and motion streak areas were segmented using a semi-automated method (sliceOmatic) incorporating a watershed algorithm with manual refinements. The same scans were analyzed by an automated threshold-based algorithm (Stratec) (Figure 1). Bland-Altman analyses and Student's paired *t*-tests determined the degree of difference in muscle densities before versus after removing motion streaks from

both segmentation methods. The same tests were used to find the degree of difference of motion-corrected muscle densities and motion surface areas computed via sliceOmatic versus Stratec. A binary logistic regression ascertained how motion streak removal or adjustment as a covariate affects the relationship between leg muscle density and fractures for both methods.

Results: The majority (84.5%) of the 439 visually graded scans did not warrant repetition due to the minor presence of motion (<grade 3). Out of 95 women examined (age: 74.12 ± 6.94 years, BMI: 27.85 ± 4.92 kg/m², 47.37% ≥ 1 prior fracture, 28.26% ≥ 1 prior fall), significant differences were found for motion-corrected muscle density for sliceOmatic versus Stratec (p<0.01), motion streak area for both methods (p<0.001), and adjusted versus unadjusted muscle density for sliceOmatic (p=0.001). Motion-adjusted muscle density values were similar between sliceOmatic and Stratec, though sliceOmatic yielded lower values. There were slightly larger associations between motion streak-adjusted leg muscle density and fractures after controlling for age, BMI, and falls compared to unadjusted muscle density (Table I).

Conclusions: Using a semi-automated algorithm to remove motion streaks from pQCT leg scans exhibited a statistically significant decrease in computed muscle density. This change resulted in a larger association between motion streak-adjusted muscle density and fractures after controlling for age, BMI, and falls.

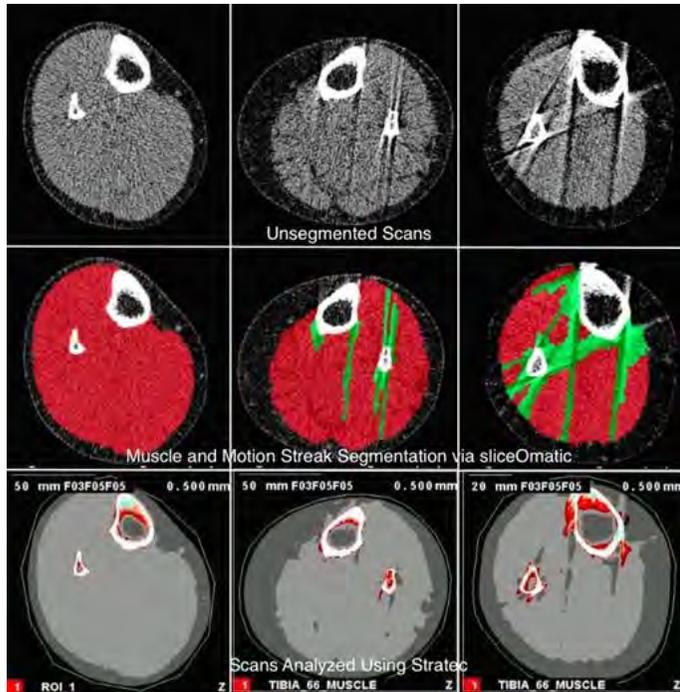

Figure 1: pQCT Leg Scan Segmentations

| Independent Variable | Odds Ratio Adjusted for Age, BMI (95% CI) | Odds Ratio Adjusted for Age, BMI, Falls (95% CI) |
|---|---|--|
| Motion-corrected Muscle Density (sliceOmatic) | 1.226 (1.066 – 1.409) | 1.230 (1.066 – 1.418) |
| Uncorrected Muscle Density (sliceOmatic) | 1.196 (1.051 – 1.361) | 1.190 (1.044 – 1.356) |
| Motion-adjusted Muscle Density (Stratec) | 1.175 (1.006 – 1.373) | 1.167 (0.996 – 1.367) |
| Unadjusted Muscle Density (Stratec) | 1.106 (0.993 – 1.233) | 1.108 (0.996 – 1.234) |

Searching for side to side difference within the same vertebral body - The preliminary QCT study of trabecular bone density in intact lumbar vertebra of elderly patients with back pain. Wojciech Glinkowski¹, Jerzy Narloch^{*2}. ¹Medical University of Warsaw, Poland, ²Chair & Department of Orthopaedics & Traumatology of Locomotor System, Center of Excellence "TeleOrto", Medical University of Warsaw, Poland, Poland

Searching for side to side difference within the same vertebral body - The preliminary QCT study of trabecular bone density in intact lumbar vertebra of elderly patients with back pain

Introduction

Adult scoliosis in elderly group may show up with the vertebral bodies lateral deformities. The research hypothesis concerns in the question whether an intact vertebral bodies may present differences of mineral density trabecular bone from side to side of the same vertebra.

Methods

In a group of 17 female patients (mean, 68.35 ± 3.4 years) with back pain, but no history of osteoporotic fracture 45 intact vertebra were analyzed. Patients average height was 160,4 cm; and weight 65,71 kg. Nine mm-thick ROI's were selected for finding differences between left and right side of the vertebral body. Patients underwent CT scan due to the history of low back pain after minor trauma. The BMD protocol and phantom for each CT examination of the lumbar spine. The data were used for analysis of vertebral bone mineral density using QCTPro Software (Mindways Software Inc., Austin, TX).

Results

Twenty seven percent of vertebrae revealed a substantial difference between left and right sides of the vertebral bodies. The differences in BMD reached approximately 20 mg/cm³. The overall vertebral body density was 72,16 mg/cm³. The density in the right trabecular bone of vertebra was 74,54 but left side was 71,36 72,16 mg/cm³. The average t-score value was -3,73 SD, and z-score was -0,77 SD.

The average difference of side to side comparison of examined vertebra was approximately 10 mg/cm³. All patients met densitometric, QCT criteria of osteoporosis. No case of vertebral compression fracture was detected.

Conclusions

It is expected that approximate difference of 20 mg/cm³ may produce the side to side deformity and produce consequent scoliosis. This preliminary study may show the path for further investigation.

TBS reflects trabecular microarchitecture in premenopausal women and similarly aged men with low traumatic fractures. Christian Muschitz^{*1}, Roland Kocijan², Judith Haschka², Dieter Pahr³, Alexandra Kaider⁴, Didier Hans⁵, Astrid Fahrleitner-Pammer⁶, Heinrich Resch². ¹St. Vincent's Hospital, Austria, ²St. Vincent Hospital Vienna - Medical Department II, Austria, ³Institute of Lightweight Design & Structural Biomechanics, Vienna University of Technology, Austria, ⁴Center for Medical Statistics, Informatics & Intelligent Systems, Medical University of Vienna, Austria, ⁵Center of Bone Diseases, Lausanne University Hospital, Switzerland, ⁶Department of Internal Medicine, Division of Endocrinology & Metabolism, Medical University of Graz, Austria

Purpose: Transiliac bone biopsies are still considered to be the gold standard for the analysis of bone microstructure, but limited to specialized centers. The benefit of Trabecular Bone Score (TBS) in addition to areal bone mineral density (aBMD) for fracture risk assessment has been documented in cross-sectional and prospective studies. The aim of this study was to test if TBS may be useful as a surrogate to histomorphometric trabecular parameters of transiliac bone biopsies. Methods: Transiliac bone biopsies from 80 female patients (median age 39.9 years - interquartile range, IQR 34.7; 44.3) and 43 male patients (median age 42.7 years - IQR 38.9; 49.0) with low traumatic fractures and without any comorbidities known to affect bone metabolism were included. Bone volume fraction (BV/TV), trabecular thickness (Tb.Th), trabecular number (Tb.N), trabecular separation (Tb.Sp), structural model index (SMI) as well as serum bone turnover markers (BTMs) sclerostin, intact N-terminal type 1 procollagen propeptide (PINP) and cross-linked C-telopeptide (CTX) were investigated. Results: Median SMI, Tb.Th and sclerostin levels (45.5 vs 33.4 pmol/L, p< 0.0001) were higher in males. Multiple regression models including gender, aBMD and BTMs revealed TBS as an independent discriminative variable with adjusted R² values of 69.1% for SMI, 79.5% for Tb.N, 68.4% for Tb.Sp, and 83.3% for BV/TV. In univariate regression models BTMs showed statistically significant findings, but in the multiple models only PINP and CTX were significant for Tb.N. Conclusions: TBS is a feasible non-invasive surrogate technique for the assessment of cancellous bone microarchitecture and should be implemented as an additional tool for the estimation of trabecular bone properties.

The Fracturing Phenotype: What Can We Learn from Examining Cross-sectional Geometry with pQCT? Timo Rantalainen¹, Daniel Belavý², Rachel Duckham^{*2}, Tilo Blenk³, Franziska Luhn³, Rainer Rawer⁴, Johannes Willnecker⁴, Gabriele Armbrecht³, Dieter Felsenberg³. ¹Centre for Physical Activity & Nutrition Research, Deakin University, Finland, ²Centre for Physical Activity & Nutrition Research, School of Exercise & Nutrition Sciences, Deakin University, 221 Burwood Highway, Burwood, Victoria, 3125, Australia, Australia, ³Centre for Muscle & Bone Research, Charité Universitätsmedizin Berlin, Hindenburgdamm 30, 12203 Berlin, Germany., Germany, ⁴Stratec Medizintechnik GmbH, Durlacher Str. 35, 75172 Pforzheim, Germany, Germany

Over 50% of fracture cases in women are non-osteoporotic, and are not treated preventatively. Therefore exploring supplementary fracture risk screening methods is prudent. Although evidence suggests that some fractures unrelated to aBMD are possibly due to the deterioration in bone size, structure, and strength, it remains scarcely explored whether a bone phenotype susceptible to fragility fractures exists. Therefore, from a data set of 535 postmenopausal women aged 60 to 94 years, 29 individuals who had suffered a low-energy fracture within the last 10 years (age = 72 (SD 7) years, height = 160 (4) cm, weight = 69.6 (9.6)) were identified and matched for age, height weight and total FN t-score with randomly selected non-fracture individuals. Data from DXA (femoral neck, FN) and pQCT scans (at 38% tibia length and 60% radius length, density and material distribution analysed with BoneJ) along with grip strength, low-intensity fracture history, a history of bisphosphonate use, physical activity, falls within the last year, age at menopause, and timed up and go performance were available. MANOVA indicated no difference between the fracture and matched non-fracture groups (P=0.36) for age, height, weight, FN t-score, age at menopause, bisphosphonate use, falls within the last year, physical activity, grip strength, or up and go time. Whole bone pQCT analysis (total and cortical area, medullary area [Me.Ar], cortical volumetric bone mineral density [Ct.Dn], strength indices) showed 14% larger tibia Me.Ar, and 4.8% lower radius Ct.Dn for the fracture compared to the non-fracture group (P<0.039). Radii, and vBMD distribution analysis showed 6.5%, and 9.9% wider tibia and radius endocortical radii (P<0.043) for the fracture group compared to the non-fracture group, respectively (FIG 1). In further exploration of fracture sites it was observed that the upper limb fracture cases (N = 13) did not differ from other fracture cases while lower limb fracture cases (N = 6) had lower FN t-score, and larger tibial Me.Ar than other fracture cases. In conclusion, the fracture group differed from the matched non-fracture group only based on pQCT-measured bone characteristics. Specifically, enlarged medullary cavity was observed in the fracture history group compared to the non-fracture history group (FIG 1). This indicates that a fragility fracture phenotype may be characterised by an enlarged marrow cavity.

Quantitative proteomics and integrative network analysis identified novel genes and pathways related to osteoporosis. YONG ZENG^{*1}, Lan Zhang¹, Wei Zhu¹, Chao Xu¹, Hao He¹, Yu Zhou¹, Qing Tian¹, Ji-Gang Zhang¹, Fei-Yan Deng², Yao-Zhong Liu¹, Hong-Wen Deng¹. ¹Tulane University, USA, ²Hunan Normal University, China

Osteoporosis is characterized by low bone mineral density (BMD), and can be attributed to excessive bone resorption by osteoclasts. Migration of circulating monocytes from blood to bone is fundamental for subsequent osteoclast differentiation and bone resorption. Osteoimmunology studies suggested a close and complex interaction between immune system and bone metabolism. Identification of those genes and pathways related to osteoclast differentiation and BMD will contribute to a better understanding of the pathophysiological mechanisms of osteoporosis. In this study, we applied the LC-nano-ESI-MSE for quantitative proteomic profiling in 33 female Caucasians with discordant BMD levels, with 16 high vs. 17 low BMD subjects. Comparison of protein expression in high vs. low BMD subjects showed that ITGA2B (p=0.0063) and GSN (p=0.019) were up-regulated in the high BMD group. Additionally, our protein-RNA integrative analysis showed that RHOA (p=0.00062) differentially expressed between high vs. low BMD groups. Network analysis based on multiple tools revealed two pathways: "Regulation of actin cytoskeleton" (p=1.13E-5, FDR=3.34E-4) and "Leukocyte transendothelial migration" (p=2.76E-4, FDR=4.71E-3) that are functionally relevant to osteoporosis. Consistently, ITGA2B, GSN and RHOA played crucial roles in these two pathways respectively. All together, our study strongly supported the contribution of the genes ITGA2B, GSN and RHOA and two pathways to osteoporosis risk.

The Effect of Chronic Hyponatremia on Bone Mineral Loss Evaluated by Retrospective National Danish Patient Data. Christian Kruse^{*1}, Pia Eiken², Joseph G. Verbalis³, Peter Vestergaard⁴. ¹Aalborg University, Dk, ²Department of Cardiology, Nephrology & Endocrinology, Nordsjællands Hospital Hilleroed, Hilleroed, Denmark, Denmark, ³Division on Endocrinology & Metabolism at Georgetown University, USA, ⁴Department of Endocrinology, Denmark

CONTEXT: Hyponatremia is associated with increased risk of osteoporosis in retrospective data. The effect of chronic hyponatremia has been studied sparsely. OBJECTIVE: Evaluating the effect of different severities of chronic hyponatremia on bone mineral content (BMC) and bone mineral density (BMD) loss through serial dual-energy X-ray absorptiometry (DXA) scans. DESIGN: Retrospective cohort study. SETTING: Two regional Danish databases of biochemical and hip and lumbar spine DXA scan data. National Danish patient diagnosis and prescription reimbursement databases. PATIENTS: All patients having undergone serial DXA scans at Aarhus and Aalborg University Hospitals between 2004 and 2011. INTERVENTIONS: Stratification into "normonatremia" ([Na+] = [137.00-147.00] mmol/L), "mild hyponatremia" ([Na+] = [130.00-137.00] mmol/L) and moderate hyponatremia ([Na+] = [120.00-130.00] mmol/L) based on mean and confidence interval (CI) values between the first and last DXA scan. MAIN OUTCOME MEASURE: Baseline, follow-up and delta values for BMC and BMD between groups. Adjustment for comorbidity and medication use. RESULTS: Hip and lumbar spine groups had 884 and 1,069 patients with "normonatremia", 58 and 58 patients with "mild hyponatremia", and 3 and 3 patients with "moderate hyponatremia". Mild hyponatremia was associated with lower BMC and BMD in nearly all regions of the hip, and with worse losses in the trochanteric, femoral neck and total hip regions. Mild hyponatremia had limited effect on the lumbar spine. CONCLUSIONS: Chronic mild hyponatremia seems to greatly affect bone in the hip, while the effect is limited in the lumbar spine. We suggest prospective studies to further examine the association.

Time to Osteoporosis and Incidence of Major Osteoporotic Fracture in Older Men: the MrOS Study. Margaret Gourlay^{*1}, Robert Overman¹, Jason Fine¹, Guillaume Filteau¹, Peggy Cawthon², John Schousboe³, Eric Orwoll⁴, Timothy Wilt⁵, Tuan Nguyen⁶, Nancy Lane⁷, Pawel Szulc⁸, Brent Taylor⁵, Thuy-Tien Dam⁹, Carrie Nielson⁴, Jane Cauley¹⁰, Elizabeth Barrett-Connor¹¹, Howard Fink⁵, Jodi Lapidus⁴, Deborah Kado¹¹, Susan Diem³, Kristine Ensrud⁵. ¹University of North Carolina, USA, ²Research Institute, California Pacific Medical Center, USA, ³University of Minnesota, USA, ⁴Oregon Health & Science University, USA, ⁵University of Minnesota, Minneapolis VA Health Care System, USA, ⁶Garvan Institute of Medical Research, Australia, ⁷University of California, Davis, USA, ⁸University of Lyon, France, ⁹Columbia University, USA, ¹⁰University of Pittsburgh, USA, ¹¹University of California, San Diego, USA

Rationale: No standard of care exists for osteoporosis screening in older men. To guide bone mineral density (BMD) testing interval recommendations, we estimated the time to incident osteoporosis and fracture incidence according to baseline BMD in older men participating in MrOS.

Methods: We conducted a competing risk analysis of 5415 community-dwelling men aged 65 years and older who were without a history of hip or clinical vertebral fracture or antifracture treatment and had up to 8.7 years of concurrent BMD (2 to 5 DXA measurements) and fracture follow-up. We estimated the time for 10% of men with higher baseline BMD (T-scores >-1.50 at the femoral neck, total hip and lumbar spine calculated using young white female norms; n=4203), moderate osteopenia (lowest T-score -1.50 to -1.99; n=680) or advanced osteopenia (lowest T-score -2.00 to -2.49; n=352) to develop osteoporosis by World Health Organization diagnostic criteria (lowest T-score ≤-2.50). Parametric cumulative incidence curves for the time to osteoporosis were estimated from log logistic cumulative incidence models for interval censored data, adjusting for race, baseline age and body mass index. Initiation of antifracture treatment, incident hip or clinical vertebral fracture and death were competing risks. Incident major osteoporotic fractures between the baseline visit and end of follow-up were tabulated.

Results: Only nine men (0.2% of 4203) with higher BMD at baseline developed osteoporosis during follow-up; their time to osteoporosis could not be estimated due to the very small number of endpoint events. The adjusted time for 10% to develop osteoporosis was 8.5 years for those with moderate osteopenia and 2.7 years for those with advanced osteopenia (table). Most men who sustained a major osteoporotic fracture had T-scores >-2.50; in fact, 29% of the hip and clinical vertebral fractures occurred in men with normal BMD at baseline.

Conclusions: These results indicate that older men with baseline BMD T-scores >-1.50 have a very low likelihood of developing osteoporosis in the subsequent 8

years, and suggest that repeat BMD measurements may not be warranted in this group. In contrast, BMD testing intervals as short as 2.5 years may be considered for men with advanced osteopenia. Many men without osteoporosis will experience major osteoporotic fractures, suggesting that risk factors other than BMD must be addressed to prevent fractures in older men.

| Baseline T-score range | Incident osteoporosis by WHO criteria, ³ N (%) | Time interval for 10% of participants to develop osteoporosis, ² years (95% CI) | |
|------------------------------------|---|--|-------------------|
| | | Unadjusted | Adjusted |
| Higher BMD >-1.50 | 9/4203 (0.21) | | |
| Moderate osteopenia -1.50 to -1.99 | 35/680 (5.15) | 8.57 (6.67-10.99) | 8.51 (6.67-10.86) |
| Advanced osteopenia -2.00 to -2.49 | 73/352 (20.74) | 2.59 (2.03-3.30) | 2.68 (2.12-3.40) |

³ osteoporosis defined as lowest T-score \leq -2.50 at femoral neck, total hip or lumbar spine, calculated using BMD norms for young white women

² time estimates adjusted for race and mean-centered age and BMI

Does DNA Methylation Underpin the Social Gradient of Osteoporotic Fracture? A Conceptual Model. [Sharon Brennan-Olsen](#)^{*1}, [Richard Page](#)¹, [Michael Berk](#)¹, [Jose Riancho](#)², [William Leslie](#)³, [Karen Saban](#)⁴, [Julie Pasco](#)¹, [Shae Quirk](#)¹, [Natalie Hyde](#)¹, [Sarah Hosking](#)¹, [Lana Williams](#)¹.

Purpose: Although a social gradient for osteoporosis is documented, the underlying mechanisms for that gradient remain unknown. To advance our understanding of the aetiology and pathogenesis of osteoporosis, there are now large-scale efforts to identify genes associated with fracture risk via genome-wide association studies of bone mineral density. We propose a conceptual model based upon Saban et al's (1) allostatic load theory model, to suggest how DNA methylation (DNAm) may underpin the social gradient in osteoporosis and fracture. We hypothesise that socioeconomic position (SEP) is associated with sensitisation of immune signalling pathways mediated by epigenetic modification that leads to an enhanced state of immune reactivity and oxidative stress and thus places socially disadvantaged individuals at greater risk of osteoporotic fracture.

Methods/Results: Based on a review of the literature, we present a conceptual model (Figure) in which social disadvantage and stress during all stages of life engender a proinflammatory epigenetic signature, leading to a heightened inflammatory state that increases risk for osteoporotic fracture in disadvantaged groups. Despite a paucity of data, the available studies suggest that plasticity in molecular responses in stress response pathways that may be related to the influence of SEP on the epigenetic pathway. Given that the epigenetic signature is influenced by many environmental factors across the lifespan, the epigenome appears to function as a vital conduit that transduces exposures into phenotypic expression and disease risk.

Conclusions: DNAm is a dynamic modulator of gene expression with considerable relevance to the field of osteoporosis. Elucidating the extent to which this epigenetic mechanism mediates the psycho-social environment and risk of osteoporotic fracture may yield novel entry points for intervention that can be used to reduce individual and population-wide risks for osteoporotic fracture. Specifically, an epigenetic evidence-base may enhance the importance of lifestyle modification and stress reduction programs, and help to reduce health inequities across social groups.

Prospective study of kyphosis and lower extremity function in women and men: The Framingham Study. [Amanda Lorbergs](#)^{*1}, [Yanhua Zhou](#)², [Ching-An Meng](#)³, [Brochin Elana](#)³, [Douglas P. Kiel](#)⁴, [L. Adrienne Cupples](#)², [Joanne Murabito](#)², [Dennis E. Anderson](#)⁵, [Brett Allaire](#)⁵, [Mary B. Bouxsein](#)⁶, [Thomas G. Travison](#)⁷, [Elizabeth J. Samelson](#)⁷.
¹Institute for Aging Research, Hebrew SeniorLife & Harvard Medical School, USA, ²School of Public Health, Boston University, USA, ³Institute for Aging Research, Hebrew SeniorLife, USA, ⁴Institute for Aging Research, Hebrew SeniorLife & Harvard Medical School, USA, ⁵Beth Israel Deaconess Medical Center, USA, ⁶Beth Israel Deaconess Medical Center, Harvard Medical School, USA, ⁷Institute for Aging Research, Hebrew SeniorLife & Harvard Medical School, USA

Background: Increased thoracic kyphosis is a spinal disfigurement manifested as a hunched posture. In older women, greater kyphosis is associated with mobility deficits, yet the effect on risk of poor mobility in men is not known.

Objective: We conducted a prospective study to determine the contribution of baseline kyphosis angle (KA) on performance-based measures of physical function at 6y follow-up in a community-based population of women and men.

Methods: Participants included 808 cohort members (447 women, 361 men) with mean age 64y (range, 50-85y) of the Framingham Offspring Study. Baseline (2002-2005) lateral CT images were used to measure kyphosis (T4-T12 Cobb angle, degrees), where greater KA indicates greater forward curvature. At 6y follow-up, participants performed 5 chair stands without using arms and a fast 4m walk. We used linear models to estimate mean chair stand time (s) and gait speed (m/s) at follow-up by sex-specific quartiles of baseline KA. We conducted stratified analysis to evaluate whether the contribution of greater KA to performance measures differed by age (<65, ≥65y).

Results: Mean (SD) baseline KA, chair stand time, and gait speed were 33(9)°, 5.9(1.5) s, and 1.6(0.3) m/s for women and 30(9)°, 6.0(1.5) s, and 1.8(0.4) m/s for men, respectively. Women with greater KA at baseline took longer to perform 5 chair stands (Table; trend, $p=0.009$) and had slower gait speed (trend, $p=0.038$) at follow-up. After adjusting for baseline age, height, weight, and smoking, the association between greater KA and longer chair stand time remained significant (trend, $p=0.024$), whereas the association with gait speed was no longer significant (trend, $p=0.52$). In men, greater KA at baseline was not associated with poor physical function at follow-up. Finally, the results were similar in age <65 and ≥65y (not shown).

Conclusion: Women with greater kyphosis performed chair stands more slowly at 6y follow-up (0.3s slower per 10° increase in KA). Sit-to-stand transitions require a high rate of knee extensor torque development; thus, greater kyphosis may be associated with reduced muscle power. Functional limitations are observed at older ages in men than women. The relatively young age of older adults in our sample may have limited the ability of our study to detect associations in men. Alternatively, accentuated forward curvature may pose greater challenges for women during rapid shifting of the center of mass due to weaker lower extremity muscles.

SU0273

Both High and Low serum Serotonin levels Predicts Incident Non-vertebral Fractures. Dan Mellstrom^{*1}, Ewa Waern², Catharina Lewerin³, Östen Ljunggren⁴, Claes Ohlsson⁵, Daniel Sundh⁶, Mattias Lorentzon⁵, Magnus Karlsson⁷, Steven Cummings⁸, Helena Johansson⁹, Henrik Zetterberg¹⁰, Ulf Lerner⁵. ¹Sahlgrenska University Hospital, Sweden, ²Department of Geriatrics, University of Gothenburg, Sweden, ³Section of Hematology & coagulation, department of internal medicine & clinical nutrition, institute of medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, ⁴Department of Medical Sciences, University of Uppsala, Sweden, Sweden, ⁵Centre for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, ⁶Geriatric Medicine, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, ⁷Clinical & Molecular Osteoporosis Research Unit, Department of Clinical Sciences, Lund University, & department of Orthopedics, Skåne University Hospital, Sweden, ⁸San Francisco Coordinating Center, California Pacific Medical Center Research Institute, USA, ⁹Geriatric Medicine, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, Centre for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, ¹⁰Department of Psychiatry & Neurochemistry, University of Gothenburg, Sweden

Experimental studies indicate that Lrp5 regulates serotonin synthesis in the gut and through this regulate bone formation. A study of women showed that serum serotonin was inversely related to bone density (BMD). The aim of this study was to examine the predictive value of serum serotonin for incident fractures. Elderly men in the Gothenburg part of the Swedish MrOS study (n=1010) (aged 69-81 years) had baseline analysis by Elisa of serum serotonin. 248 incident fractures, of which 61 hip fractures, were observed in radiographic registers up to 10 years from baseline. The probability of incident fracture was determined by Cox proportional hazards models. Serum serotonin levels were associated with hand grip strength (r=0.11, p<0.002) and inversely with hip total BMD (r=-0.08, p<0.01) but not with lumbar spine BMD. Serotonin levels were inversely associated to body mass index (BMI; r=-0.09, p<0.01). Smokers had higher and men with serotonin reuptake inhibitors (SSRI) and falls during the last year had lower serotonin levels (p<0.01). Serotonin levels were not associated to incident fractures in linear models. However, analyzing all fractures there was a u-shaped relationship between fracture risk and quintiles of serotonin. The Hazard ratio (HR 95% CI) for all fractures when comparing quintile 1 to quintiles 2-4 (referent group) was 1.54 (1.14-2.16) and quintile 5 vs. referent group 1.64 (1.20-2.23). The HR for hip fracture was for quintile 1 vs. referent group 1.74 (0.89-3.41) and for quintile 5 vs. referent group 2.95 (1.67-5.20). The HR for non-vertebral fractures was for quintile 1 vs. referent group 1.67 (1.19-2.36) and for quintile 5 vs. referent group 1.70 (1.22-2.38). Serotonin levels did not predict risk for vertebral fracture. Multivariable models adjusting for age, BMI, hip BMD, falls, SSRI and smoking had small impact on the models. HR for hip fracture for quintile 5 vs. referent group in a multivariable model was 2.62 (1.45-4.74). Serum serotonin levels were also associated with plasma osteocalcin (r=0.08, p<0.01) and inversely with serum leptin (r=-0.15, p<0.001). The HR for falls during the last year in quintile 1 of serotonin vs. referent group was 1.79 (1.18-2.71) and in quintile 5 vs. referent group 0.84 (0.51-1.38) adjusted for age, BMI, hip BMD, SSRI and smoking. We conclude that both low and high circulating serotonin predicts non vertebral fractures indicating a relation between cortical bone and serotonin.

Elevated Fasting Triglyceride Levels Are Associated With Risk of Subsequent Fracture in Midlife Women: Study of Women's Health Across the Nation (SWAN). Po-Yin Chang^{*1}, Jennifer S. Lee², Ellen B. Gold³, Wesley Johnson⁴, Carrie Karvonen-Gutierrez⁵, Kristine Ruppert⁶, Elizabeth A. Jackson⁷, Jane A. Cauley⁶. ¹Stanford University, USA, ²Stanford University School of Medicine, USA, ³Department of Public Health Sciences, University of California, Davis, USA, ⁴Department of Statistics, University of California, Irvine, USA, ⁵Department of Epidemiology, University of Michigan School of Public Health, USA, ⁶Department of Epidemiology, University of Pittsburgh School of Public Health, USA, ⁷Division of Cardiovascular Medicine University of Michigan Health Systems, USA

Background: Cardiovascular disease increases risk of osteoporotic fracture. The mechanism is unclear; unfavorable lipid levels could be related. Mice with hyperlipidemia had inhibited osteoblast differentiation, reduced bone mineralization and stimulated osteoclast activity. Atherosclerosis of arteries supplying bone may lead to bone ischemia. We tested the hypothesis that elevated lipid levels were associated with subsequent fracture in midlife women.

Associations of spinal inclination and vertebral deformities with difficulties in activities of daily living. Yasuyo Abe^{*}, Kiyoshi Aovagi. Nagasaki University, Japan

Vertebral deformities are the most frequent form of osteoporotic fractures, which lead to difficulties in activities of daily living (ADLs) and worsening of quality of life. We have previously reported that vertebral deformities are associated with spinal kyphotic change, and forward spinal inclination is associated with impairment in various physical functioning measurements. In this study, we explored associations of spinal inclination and vertebral deformities with selected ADLs among 109 Japanese women ages 40 year and over. Spinal posture was assessed as inclination to a perpendicular line by using computer-assisted device (SpinalmouseU). Greater inclination value means forward inclination of the spine. Lateral spine radiographs were obtained and radiographic vertebral deformities were assessed by quantitative morphometry. A self-administered questionnaire was used to survey participants about low back pain and difficulty in performing selected ADLs. Mean age of the participants was 66.2 years and median value of spinal inclination was 3 degrees. Of the participants, 14.7% had at least one vertebral deformity and 38.5% reported back pain. Number of vertebral deformities had significant positive correlation with spinal inclination (r=0.25). Univariate analysis showed that difficulties in bending- and spine-extended- and walking-related ADLs were associated with older age, greater spinal inclination, and higher prevalence of vertebral deformities. Multiple logistic regression analysis showed that increase in spinal inclination was associated with difficulties in walking related ADLs: "walking 100m on a level surface", "climbing 10 steps", and "walking down 10 steps." On the other hand, vertebral deformities were associated with difficulties in bending- and spine-extended-related ADLs: "bending over or picking up a lightweight object", "lifting a 5 kg object from the floor", and "reaching an object above your head." Back pain was associated with difficulties in walking related ADLs: "climbing 10 steps", and "walking down 10 steps." In conclusion, forward inclination of the spine was associated with walking-related ADLs, part of which might be mediated by back pain, while vertebral deformities were associated with bending- or spine-extension-related ADLs. Associated factors for difficulty might differ in different ADLs.

Disclosures: Yasuyo Abe, None.

Method: From SWAN, 2413 midlife women ages 42-53 years (50% White, 28% Black, 12% Japanese, and 10% Chinese) were at baseline either premenopausal (54%) or early perimenopausal (46%) and had bone mineral density (BMD) measured by DXA. Self-reported fractures (at skeletal sites other than skull or digits) at each near-annual visit from visits 2 to 12 were counted as incident fractures. Fasting blood lipid panel, high-sensitivity C-reactive protein (CRP) and endogenous sex hormones were measured at baseline. We estimated hazard ratios (HR) and 95% confidence intervals (CI) in discrete-time Cox models, adjusting for age, race/ethnicity, study site, menopausal status, body mass index (BMI), fracture history, and smoking (model 1), and also for baseline lumbar spine BMD, diabetes, hormone use, estradiol, sex hormone binding globulin, and CRP (full model).

Results: Median (interquartile range, IQR) levels for baseline triglycerides (TG), total cholesterol, HDL-C, and LDL-C were 89 (67-129) mg/dL, 192 (171-215) mg/dL, 55 (46-65) mg/dL, and 114 (94-135) mg/dL, respectively. At visit 12, retention was 65% (1576 of 2413) and 266 women ever reported fractures. Every 50 mg/dL increase in TG level was associated with an HR of 1.11 (95% CI: 1.05-1.17, model 1) for fractures; per 25mg/dL increase in TG level, HR 1.05 (95% CI: 1.03-1.08). Associations remained in the full model, with HRs of 1.09 (95% CI: 1.03-1.16) per 50 mg/dL change and 1.05 (95% CI: 1.02-1.08) per 25 mg/dL change. Notably, an HR of 1.24 (95% CI: 1.06-1.44) was observed for every 50 mg/dL increase in TG level in Black women (*P* for interaction = 0.057). Women who had a TG/HDL-C ratio ≥ 3 (vs TG/HDL-C < 3) also had an increased hazard for fractures (HR 1.14, 95% CI: 1.03-1.26, full model). Other lipids were not associated.

Conclusion: Pre- and early peri-menopausal women, particularly Black women, with elevated fasting triglycerides had an increased risk of fracture after multivariable adjustment. Further understanding of this relation is warranted.

Fractures from Same-Level Falls in the Workplace: A Descriptive Study of Workers' Compensation Claims in Ontario, Canada. Chamila Adhithetty¹, Dorcas Beaton², Sheilah Hogg-Johnson³, Susan Jaglal¹. ¹University of Toronto, Canada, ²St. Michael's Hospital, Canada, ³Institute for Work & Health, Canada

Background/Purpose: Same-level falls (falls from standing height or less, e.g. slips, trips) account for a significant portion of workplace injuries, and fractures are one of the most disabling outcomes. In 2012 fractures accounted for about 15% of workplace same-level fall injuries in the US, and same-level falls was the leading cause of work-related fractures. Further evidence is required to determine where efforts should be targeted to prevent fractures from same-level falls. The objective of this study was to use Ontario workers' compensation claims data to describe fractures from same-level falls at work in terms of i) the proportion of total claims and ii) worker, employment and circumstance characteristics (demographics; industry; when, where and how fractures occurred).

Methods: Using a descriptive quantitative analysis, this study examined allowed lost-time (LTA) workers' compensation claims from 2002-2011 for workers aged 20-80 years. The analyses focused on LTA claims coded as "fracture" resulting from "fall on same level", but comparisons were also made with non-fracture injuries from same-level falls (e.g. sprains, strains).

Results: There were 828,704 LTA claims over the 10 year period, and 12.4% (n=103,167) were for same-level falls among workers 20-80 years old. The data indicated that 15.3% of LTA claims for fall on same level resulted in fracture (n=15,800). The overall age and gender distribution for fractures indicated that older females (50-80 years) had sustained the greatest proportion of fractures (37.0%) followed by older males (27.7%), younger males (20-49 years) (20.3%) and younger females (14.9%). Fracture and non-fracture claims appeared to affect different regions of the body, with the most common specific fracture sites being wrist and ankle. There were similar proportions of fracture and non-fracture injuries among workers in different industries. The highest proportions of injuries were found among people employed in Services (25.6% of fractures) and Schedule 2 (government and related entities) (21.4% of fractures) industries. Various patterns emerged in the proportions of fractures when industries were analyzed in terms of age and gender differences. Fracture and non-fracture claims were both most prevalent in the winter and during the morning.

Conclusion: These findings will inform efforts to prevent fractures from same-level falls such as interventions directed toward particular industries and/or worker demographics.

High incidence of typical osteoporotic fractures following an atypical femoral fracture. Emmanuel Biver¹, Marie Claude Audet¹, René Rizzoli¹, Raphael Meier², Robin Peter³, Serge Ferrari¹. ¹Division of Bone Diseases, Geneva University Hospitals & Faculty of Medicine, Switzerland, ²Division of Visceral & Transplant Surgery, Geneva University Hospitals & Faculty of Medicine, Switzerland, ³Division of Orthopedic Surgery, Geneva University Hospitals & Faculty of Medicine, Switzerland

Atypical femoral fractures (AFF) are well recognized stress or insufficiency fractures frequently associated with long-term anti-resorptive therapies. Clinical management of patients who sustained an AFF, despite the context of bone fragility, generally includes cessation of bisphosphonates or denosumab treatment. Fracture outcome and fractures incidence following AFF remains however unknown. We previously reported 39 cases of AFF based on retrospective analysis of radiographs and medical records between 2000 and 2010 in Geneva University Hospitals (1). From 2010 to March 2015, all incident AFF were prospectively recorded, in addition to patients follow-up, to complete an observational study of subjects who sustained an AFF between 2000 and 2015. Sixty five subjects (94% women, age 74 ± 9yrs) sustained a subtrochanteric or diaphyseal femoral stress fracture between 2000 and March 2015, including 62 (95%) meeting the ASBMR Task Force 2013 criteria, and 3 sub-prosthetic fractures with morphological characteristics of AFF. Fifty five subjects (85%) had received bisphosphonate or denosumab, whilst 9 (14%) had no exposure to these drugs (one undetermined). Sixty three AFF (97%) were complete and 2 (3%) were incomplete fractures. One subject sustained bilateral complete fractures at once, and 2 subjects had concomitant fragility fractures (humerus and ankle). Nineteen (29%) had concomitant contralateral incomplete fracture on X-ray, needing prophylactic nail for 10 (53%) of them. Longitudinal follow up after AFF was obtained for 50 subjects (77%, range 3 months-12 years). Delayed fracture healing or non-union was observed in 11 patients (22%). Eight (16%) developed a contralateral AFF, including 6 complete AFF. Eighteen (36%) sustained at least one non atypical fragility fracture after AFF (incidence 123/1000 patients-years). Ten subjects (20%) died during the follow-up period. In this observational study of 65 cases of AFF (85% in subjects under antiresorptive drugs), the high incidence of osteoporotic fractures following AFF supports the concept of bone fragility in these patients. These data, in addition to frequent delayed fracture healing, highlight the interest to consider alternative treatments such as bone anabolic agents after AFF. Ref: (1) Meier RP et al. Increasing occurrence of atypical femoral fractures associated with bisphosphonate use. Arch Intern Med. 2012 Jun 25;172(12):930-6.

High Serum SHBG Predicts Incident Vertebral Fractures in Elderly Men. Liesbeth Vandenput¹, Dan Mellström², Östen Ljunggren³, Andreas Kindmark³, Helena Johansson⁴, Mattias Lorentzon⁵, Jason Leung⁶, Inga Redlund-Johnell⁷, Björn Rosengren⁷, Magnus Karlsson⁷, Timothy Kwok⁶, Claes Ohlsson⁴. ¹University of Gothenburg, Sweden, ²Center for Bone & Arthritis Research & Geriatric Medicine at the Sahlgrenska Academy, University of Gothenburg, Sweden, ³Department of Medical Sciences, University of Uppsala, Sweden, ⁴Centre for Bone & Arthritis Research at the Sahlgrenska Academy, University of Gothenburg, Sweden, ⁵Centre for Bone & Arthritis Research & Geriatric Medicine at the Sahlgrenska Academy, University of Gothenburg, Sweden, ⁶Jockey Club Centre for Osteoporosis Care & Control, The Chinese University of Hong Kong, Hong Kong, ⁷Clinical & Molecular Osteoporosis Research Unit, Lund University, & Department of Orthopaedics, Skåne University Hospital, Sweden

Previous prospective cohort studies have shown that serum sex steroid levels associate with non-vertebral fracture risk in men. The predictive value of sex hormones for vertebral fracture risk is, however, less studied.

Elderly men (aged ≥ 65 yrs) from Sweden and Hong Kong participating in the MrOS study had baseline estradiol (E2) and testosterone (T) analyzed by GC-MS and sex hormone-binding globulin (SHBG) by IRMA. Incident clinical vertebral fractures (n=242 cases) were evaluated in as many as 4,324 men during an average follow-up of 9.1 yrs (MrOS Sweden, n=2,847/n=221 cases; MrOS Hong Kong, n=1477/n=21 cases). In a subsample of these men (n=2,256), spine X-rays were obtained at baseline and after an average follow-up of 4.3 yrs to identify incident radiographic vertebral fractures (n=157 cases) (MrOS Sweden, n=1108/n=91 cases; MrOS Hong Kong, n=1148/n=66 cases). The likelihood of incident clinical and radiographic vertebral fractures was estimated by Cox proportional hazards models and logistic regression models, respectively. Discrimination was determined using C-statistics while net reclassification improvement (NRI) was used for reclassification analyses.

Neither serum E2 (HR per SD increase (95% CI): 0.93 (0.80-1.08), p=0.34) nor T (1.05 (0.91-1.21), p=0.51) predicted incident clinical vertebral fractures in age-adjusted models in the combined data set. High serum SHBG, however, associated with increased clinical vertebral fracture risk (1.24 (1.12-1.37), p<0.0001). This association remained significant after further adjustment for FRAX[®] without BMD (1.26 (1.14-1.39), p<0.0001) and FRAX[®] with BMD (1.25 (1.13-1.38), p<0.0001). SHBG slightly

improved clinical vertebral fracture risk classification (AUC) from a model adjusted for age ($p < 0.05$) when examined in MrOS Sweden. When evaluated with the more sensitive NRI, SHBG significantly improved clinical vertebral fracture reclassification models adjusted for age (20%, $p < 0.01$), for FRAX[®] without BMD (19%, $p < 0.01$) and for FRAX[®] with BMD (18%, $p < 0.05$). Similar as for the incident clinical vertebral fractures, neither E2 nor T predicted fracture risk in age-adjusted models in the subsample with incident radiographic vertebral fractures available. Again, high SHBG associated with increased radiographic vertebral fracture risk (combined data set; OR per SD increase (95% CI): 1.22 (1.05-1.43), $p < 0.05$). This association also remained significant after adjustment for FRAX[®] without BMD (1.24 (1.06-1.44), $p < 0.01$) and FRAX[®] with BMD (1.23 (1.05-1.43), $p = 0.01$).

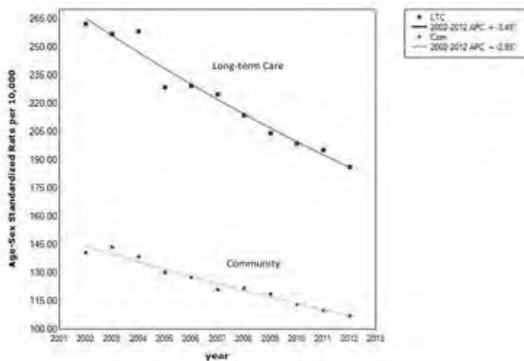

In conclusion, high SHBG predicts incident clinical and radiographic vertebral fractures in elderly men and adds information beyond FRAX[®] with BMD for vertebral fracture risk prediction. The mechanism by which SHBG affects vertebral fracture risk warrants further investigation.

Hip Fracture Rates in Long-term Care Residents Declining Faster than in the Community. Alexandra Papaioannou¹, Courtney Kennedy¹, George Ioannidis¹, Ruth Croxford², Cathy Cameron³, Sara Mursleen¹, Jonathan Adachi¹, Susan Jaglal³. ¹McMaster University, Canada, ²Institute for Clinical Evaluative Sciences, Canada, ³University of Toronto, Canada

Background: Reported hip fracture rates are stable or declining in the last two decades both in Canada and internationally. Fracture incidence trends in institutionalized versus community-dwelling seniors have not been considered, yet long-term care (LTC) cohorts are older, frailer, and at increased risk for falls and fractures. **Purpose:** To compare temporal trends in incident hip fracture rates for LTC versus community-dwelling residents. **Methods:** A retrospective cohort was defined using population-level health administrative data for all individuals aged 65 years and older living in Ontario, Canada between 2002 and 2012. The LTC cohort was defined based on records indicating an LTC admission or a physician visit or prescription filled while residing in LTC. In Ontario, approximately 620 LTC facilities (nursing homes) are funded by the provincial health ministry and provide residential care for older adults who need access to 24-hour nursing, supervision, or higher levels of personal care assistance. Fractures were identified (ICD-10-CA diagnosis codes) from emergency department, inpatient records, and physician claims. To compare overall incidence rates among different years and cohorts, rates were age-sex standardized using the 2002 population of LTC residents as the standard population. Join point regression analyses (Joinpoint Regression Program, Version 4.1.1.5) were used to examine temporal trends in osteoporotic fracture rates. **Results:** Hip fracture rates declined for both LTC and community cohorts during the years 2002-2012 (figure). Rates decreased faster among individuals living in LTC than in the community ($p < 0.05$ for difference in slopes). The annual percent change in hip fracture rates was -3.49 (95% CI: -3.97, -3.01) in LTC and -2.93 (95% CI: -3.28, -2.57) in the community. There was no evidence that the trend changed during the study period for either LTC or the community during (i.e. indicating constant slopes). Although women had higher overall hip fracture rates, there was a similar rate of decline for men and women during the study years. **Conclusions:** Between 2002 and 2012, hip fracture rates in Ontario, Canada decreased more rapidly in LTC versus community-dwelling residents. Initiatives to decrease falls and improve osteoporosis and fracture care have been ongoing by LTC providers and the government-funded Ontario Osteoporosis Strategy which may, in part, have contributed to the decline in hip fracture rates.

Hypertension as a Risk Factor for Fractures: a Systematic and Meta-analysis of Observational Studies. Raghad Alharthy¹, Debra A. Butt², Jeevitha Sriganthan³, George Tomlinson², Angela M. Cheung⁴. ¹University Health Network, Canada, ²University of Toronto Departments of Family & Community Medicine & Medicine, Canada, ³University Health Network Osteoporosis Program, Canada, ⁴University Health Network Osteoporosis Program; University of Toronto Departments of Family & Community Medicine & Medicine, Canada

Background: Two of the most prevalent co-morbidities in the elderly population are hypertension and osteoporosis. Complications from these two conditions account for significant morbidity, mortality and health-care costs. There are no systematic reviews/meta-analyses published to date that examine the association of hypertension as a risk factor for osteoporotic fractures in the elderly.

Methods: We searched Medline, EMBASE, Cochrane, CINAHL and Web of Science from inception to March 11, 2015 without language restriction for all studies assessing the effect of hypertension on fracture risk. We also reviewed the reference lists of qualifying articles and reviews. Two independent reviewers extracted the data and assessed study quality. Using a random-effects model weighted by inverse variance of the effect size, we determined the pooled adjusted and unadjusted risk ratios (RR) and their 95% CIs. Statistical heterogeneity was tested using the I² statistic. Publication bias was assessed using funnel plots comparing standard error and effect size.

Results: Of the 885 citations identified by the search strategy, 6 studies met the inclusion criteria and 2 additional studies were retrieved from the reference lists of included articles. Eight observational studies with a total of 549,181 participants (52% female, average age 66.4 years old) were included in the systematic review: 6 of these had summary estimates adjusted for covariates such as age, sex, BMD, history of falls and use of antihypertensives. Studies evaluated one of three primary outcomes: hip (4 studies), vertebral (4 studies), or any fracture (3 studies). Elderly with hypertension had a significant increase in fracture risk (RR 1.39, 95% CI 1.22-1.58, $p < 0.001$) (See figure). Pooling unadjusted risk ratios from 7 studies resulted in a similar pooled estimate but with wider confidence intervals and greater heterogeneity. These results are not sensitive to the quality of the studies [good and fair studies (RR 1.40, 95% CI 1.13-1.73) versus poor studies (RR 1.37, 95% CI 1.20-1.56)].

Conclusion: This systematic review and meta-analysis of observational studies suggests that having a diagnosis of hypertension may increase the risk of fragility fractures in the elderly by 39%. Further work is needed to examine whether these findings are due to hypertension itself or the effects of the drugs that treat it.

Identification of bone and fall-related patient phenotypes based on hierarchical cluster analysis in patients with a recent fracture. Lisanne Vranken¹, Joop van den Bergh², Piet Geusens³, Caroline Wyers², Robert van der Velde². ¹Maastricht University Medical Centre & VieCuri Medical Centre, NL, ²VieCuri Medical Center, Venlo, The Netherlands, Netherlands, ³Maastricht University Medical Center, Maastricht, The Netherlands, Netherlands

Purpose

Bone mineral density (BMD), bone-related risk factors and fall-related risk factors are independently related to fracture risk. In patients over 50 years of age with a recent fracture, these risk factors are overlapping, heterogeneous, and found in multiple combinations. We evaluated the prevalence of bone and fall-related risk factors in patients visiting the Fracture Liaison Service (FLS) to identify clusters of fracture patients based on bone and fall-related risk factors.

Methods

A retrospective chart review was performed in consecutive patients with a recent fracture visiting the FLS for fracture risk evaluation between January 2009 and June

2011. Cluster analyses were performed using SPSS (version 21.0) to identify clusters of patients.

Results

Out of 3057 patients aged 50-90 years, 1111 consecutive patients, who were willing and able to be evaluated at the FLS, were included (71% women, mean age 65 ± 10 years), 8% presented with a hip, 29% with a major, 57% with a minor and 6% with a finger or toe fracture. Osteoporosis was diagnosed in 29%, osteopenia in 48% and 23% had a normal BMD. A fall in the past year was reported by 25% of patients. At least one bone-related risk factor was present in 90%, and at least one fall-related risk factor was present in 82% of patients. Based on 35 risk factors and using hierarchical cluster analysis a Pearson correlations, 3 variables (BMD, falls past year and ≥5 fall risks) were identified that were representative for each cluster. Based on these 3 variables, the program built five patient phenotypes. The frequency of past fractures was significantly different between the clusters. It was highest in elderly patients (mean 72 ± 11 years) with ≥5 fall risks and in 44% osteoporosis (45%), younger patients (mean 64 ± 9 years) with falls during last year and in 29% osteoporosis (41%) or with osteoporosis (42%). Patients with osteopenia and <5 fall risks or normal BMD with <5 fall risks had less past fractures (25-28%, p<.001 between all clusters).

Conclusion

Detailed evaluation of bone and fall-related risks using cluster analyses in patients at the FLS helps to identify patient phenotypes with different bone and fall characteristics. These clusters were associated with a significant difference in the history of fractures. These results indicate the potential value to use cluster analyses in identifying patients at the FLS at risk of further fractures based on a combination of bone and fall-related risk factors.

Incidence, Skeletal Site of, and Risk Factors for Clinical Fractures in Older Men by Baseline BMD Category. Howard Fink*¹, Terri Blackwell², Brent Taylor³, Eric Orwoll⁴, Kristine Ensrud⁵. ¹GRECC, Minneapolis VA Medical Center, USA, ²California Pacific Medical Center, USA, ³Center for Chronic Disease Outcomes Research, VA Healthcare System, USA, ⁴Oregon Health Sciences University, USA, ⁵Center for Chronic Disease Outcomes Research, VA Health Care System, USA

Older men with osteoporotic BMD are at high fracture risk. However, most men with fractures are not osteoporotic, and characteristics of older men with higher BMD who fracture are uncertain. Therefore, we used data from MrOS, a prospective study in men >=65 yr, to examine whether rates, sites, and risk factors for incident clinical fractures differ in older men by BMD category. Baseline BMD of total hip, femoral neck, and lumbar spine, and a young female reference database were used to categorize 5984 men as normal (T-score >=-1 all sites), low bone mass (-2.5 > T < -1 all sites), or osteoporotic (T < -2.5 any site). Baseline participant characteristics were ascertained by questionnaire and clinic exam. Self-reported incident fractures were collected every 4 months and centrally confirmed by radiology reports. Participant characteristics with age-adjusted associations with incident clinical fracture (p<0.05) were selected for assessment of age-adjusted associations with major osteoporotic fracture (hip, wrist, proximal humerus, or clinical spine; MOF) in analyses stratified by BMD category. We used a test of interaction to evaluate whether association of risk factors with incident MOF differed by BMD category. 54% of men had normal BMD, 40% had low bone mass, and 5% had osteoporosis. Over 10.5 +/- 3.6 yr of follow-up, 9% of men (532) had a MOF. Age-adjusted MOF incidence was 4.4, 11.4, and 26.2 per 1000 person-yr in men with normal BMD, low bone mass, and osteoporosis, respectively (p-trend <0.001). Among men with a MOF, 28% had normal baseline BMD, 56% had low bone mass, and 17% were osteoporotic. Among men with clinical fractures, the percent with a MOF was 34%, 52%, and 68% in those with normal BMD, low bone mass, and osteoporosis, respectively. Age-adjusted associations of risk factors for MOF appeared similar between men with normal BMD, low bone mass, and osteoporosis (Table). In summary, the rate of MOF was 6-fold higher in older men with osteoporosis compared to those with normal BMD. However, >80% of men with MOF were not osteoporotic, and clinical fracture sites were only half as likely to be MOF in men with normal BMD vs. those with osteoporosis. The strength of age-adjusted associations of individual risk factors with MOF appeared similar between men regardless of BMD category. These results suggest that intervention strategies to address modifiable non-BMD risk factors may be essential to reduce the population burden of fractures in older men.

Table. Association of participant characteristics with risk of incident MOF as a function of baseline BMD category

| | Risk for incident clinical fx, HR (95%CI) | | | P for interaction |
|---|---|----------------------|--------------------|-------------------|
| | Normal BMD (3251) | Low Bone Mass (2419) | Osteoporotic (314) | |
| Age (SD) | 1.7 (1.4-2.0) | 1.7 (1.5-1.9) | 1.6 (1.3-2.0) | 0.92 |
| Race, nonwhite | 0.7 (0.4-1.4) | 0.6 (0.4-1.1) | 0.5 (0.2-1.1) | 0.75 |
| BMI (SD) | 1.0 (0.8-1.1) | 0.9 (0.8-1.0) | 0.9 (0.7-1.1) | 0.69 |
| Height change from age 25 (SD) | 1.1 (1.0-1.3) | 1.2 (1.1-1.4) | 1.4 (1.1-1.7) | 0.22 |
| Smoking pk-yr (SD) | 1.1 (0.9-1.3) | 1.2 (1.1-1.3) | 1.1 (0.9-1.4) | 0.76 |
| Walk daily for exercise | 0.9 (0.6-1.2) | 0.9 (0.7-1.1) | 1.0 (0.7-1.6) | 0.86 |
| Moderate or strenuous exercise, sometimes/often | 0.7 (0.5-1.1) | 0.7 (0.5-0.9) | 1.1 (0.6-1.8) | 0.55 |
| Fell past 12 mo | 1.5 (1.0-2.1) | 1.4 (1.1-1.9) | 1.6 (1.0-2.4) | 0.91 |
| Fracture after age 50 | 1.6 (1.4-1.8) | 1.7 (1.3-2.1) | 1.8 (1.2-2.8) | 0.86 |
| Parental fracture | 1.2 (0.8-1.7) | 1.3 (0.9-1.7) | 1.1 (0.6-2.0) | 0.84 |
| Comorbidity score* | 1.4 (1.2-1.7) | 1.4 (1.3-1.6) | 1.3 (1.0-1.6) | 0.60 |
| Self-reported health, G-EX | 0.8 (0.4-1.0) | 0.7 (0.5-1.0) | 1.2 (0.7-2.1) | 0.51 |
| IADL impairment, any | 1.5 (1.1-2.2) | 1.7 (1.3-2.2) | 2.1 (1.4-3.4) | 0.36 |
| CNS-active meds use† | 1.6 (1.0-2.4) | 1.6 (1.1-2.1) | 1.3 (0.7-2.2) | 0.99 |
| Anti-ulcer med use‡ | 1.7 (1.1-2.5) | 1.5 (1.1-2.0) | 1.4 (0.8-2.4) | 0.82 |
| Trails B, total time (SD) | 1.1 (0.9-1.3) | 1.3 (1.1-1.4) | 1.1 (0.9-1.4) | 0.38 |
| Grip strength, mean both hands (SD) | 1.3 (1.1-1.5) | 1.3 (1.1-1.4) | 1.2 (0.9-1.5) | 0.97 |
| Walk speed, m/s (SD) | 1.1 (0.9-1.3) | 1.3 (1.1-1.4) | 1.3 (1.0-1.7) | 0.32 |
| Use arms to stand | 2.2 (1.0-4.8) | 2.7 (1.7-4.5) | 1.7 (0.7-3.9) | 0.70 |

*Co-morbidity score is the number of 8 self-reported physician-diagnosed conditions: COPD, heart attack, stroke, CHF, surgical removal of stomach or intestine, Parkinson's, rheumatoid arthritis, diabetes.

†CNS-active medications defined as urinary antispasmodics, Alzheimer's medications, benzodiazepines, tricyclic antidepressants, trazodone, SSRI, anticonvulsants, or opioids.

‡Anti-ulcer medications defined as a proton-pump inhibitor or H2 blocker.

Loss in Health Related Quality of Life Following Low-Trauma Fractures in Frail Elderly. Jean-Eric Tarride¹, Robert B. Hopkins¹, Louis Bessette², Natasha Burke¹, Jacques Brown², William D Leslie³, Suzanne Morin⁴, Alexandra Papaioannou¹, Louisa Pericleous⁵, Jonathan D. (Rick) Adachi*¹. ¹McMaster University, Canada, ²Laval University, Canada, ³University of Manitoba, Canada, ⁴McGill University, Canada, ⁵Amgen Canada Inc., Canada

Purpose: To estimate the change in health related quality of life (HRQoL) following low trauma fractures using healthcare administrative data from Ontario, Canada.

Methods: HRQoL was estimated using the Health Utility Index (HUI) with the InterRai Minimum Data Set (MDS), a mandatory questionnaire for long term care (LTC) and home care in Ontario (population 14 million). The HUI, a validated HRQoL instrument, allows the calculation of health utility where 0 represents death and 1 the best imaginable health state. For reference, the HUI utility value for Canadians aged 80-84 years is 0.61 and the minimal clinically important difference is 0.03. The MDS was linked to Ontario acute care databases for years 2007-2011 to identify low trauma fractures using ICD-10-CA codes. As the MDS is administered every quarter, changes in HRQoL were estimated over 2 intervals: prior to and 1 month post-fracture, and prior to and 3 years post-fracture. Regressions were used to identify the predictors of the differences in HRQoL over time (e.g. age, sex, fracture type, comorbidities).

Results: 23,382 unique patients with low-trauma fractures were identified with pre-and post- HRQoL assessments; of which 5,057 fractures had at least 3 years of follow-up (39% were hip fractures). The mean age was 83 (SD 10) years, 81% were women, 35% resided in LTC prior to fracture, and 53% had a heart/circulation comorbidity and 43% had a neurological disorder. HRQoL decreased significantly from 0.491 (SD 0.188) pre-fracture to 0.334 (SD 0.166) 1 month post-fracture (p<0.001). Although HRQoL then increased over time, the mean utility value 3 years post-fracture was 0.406 (SD 0.182), a clinically significant reduction from pre-fracture (p<0.001). Similar temporal patterns were seen for all types of fractures (Figure). Regression analyses indicated that older age, living in a LTC facility compared to receiving assistive care at home, having a hip versus other fractures and living with neurological disorders were associated with additional decrements in utility. For example, the difference between baseline and 3-year utility values was statistically greater for individuals with a neurological condition (-0.126) compared to those without (-0.075) (p<0.001).

Conclusion: Among individuals living with non-acute institutional care, fractures have a significant impact on HRQoL up to 3 years following fracture. Although improvement is seen over time, HRQoL never returns to pre-fracture levels.

SU0284

Mortality risk associated with fractures, The 45 and Up study, a population based cohort study of 238,673 Australians. Weiwien Chen^{*1}, Lyn March², Fiona Blyth³, Judy Simpson⁴, Jacqueline Center⁵. ¹Garvan Institute, Australia, ²Kolling Institute of Medical Research, University of Sydney, Australia, ³Sax Institute, University of Sydney, Australia, ⁴University of Sydney, Australia, ⁵Garvan Institute of Medical Research, University of New South Wales, Australia

Background: Mortality post fractures is well accepted for hip and vertebral fractures. However there is less data available for non-hip, non-vertebral fractures. The 45 and Up study is a population based cohort study of community dwelling women and men in the state of New South Wales (NSW), Australia.

Objectives: To examine mortality risk in men and women following all fractures.

Methods: Baseline questionnaire data from the 45 and Up Study were linked to the Emergency Department Data Collection (EDDC), Admitted Patient Data Collection (APDC-including all hospital admissions, procedures and diagnoses within NSW), Registry of Births, Deaths and Marriages (RBDM) and Pharmaceutical Benefits Scheme (PBS-medication dataset). Fractures were identified from the EDDC and APDC using the ICD 9, 10, SNOMED and procedure codes. Death data was obtained from the RBDM dataset. Participants were followed from recruitment (2006-2008) till either death or 31 December 2013. Cox proportional hazards models were used to calculate mortality hazard ratios (HR) between participants who fractured and those who did not.

Results: 113499 men and 125174 women were included for analysis. The mean age of the cohort was 62.6 years (SD: 11.1) in women and 5.6 years (SD: 1.2) in men. The mean length of follow-up was 5.7 years (SD: 1.0) in women and 5.6 years (SD: 1.2) in men. Women had 8414 fractures and men had 5216 fractures. There were 5604 deaths in women and 10017 deaths in men. In the whole cohort, absolute mortality rate was higher in men (15.7/1000 person years) compared to women (7.9/1000 person years). Having a fracture increased mortality by approximately two-fold in both men (33.9/1000 person years) and women (18.6/1000 person years). However this differed for different fracture types as demonstrated by age and Charlson comorbidity index adjusted HRs in the table below. HRs were increased following proximal site but not distal site fractures (see Table). In general, relative risk of mortality was higher in the younger participants.

Conclusion: In a large sample of community dwelling men and women, proximal but not distal fractures were associated with an increased mortality risk after adjustment for Charlson comorbidity index. The cause of this increased mortality needs to be explored.

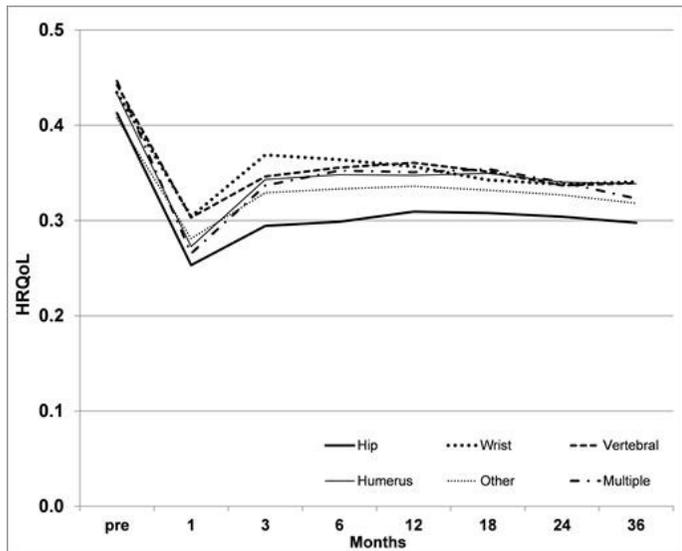

Table: Age and Charlson comorbidity index adjusted hazard ratios

| Fracture | Women | | Men | |
|-----------------------|---------------------|--------------------|---------------------|--------------------|
| | Number of fractures | HR (95% CI) | Number of fractures | HR (95% CI) |
| Proximal sites | | | | |
| • Pelvis | 373 | 2.33 (1.83, 2.97)* | 253 | 3.17 (2.47, 4.06)* |
| • Hip | 1110 | 2.48 (2.16, 2.85)* | 848 | 3.26 (2.86, 3.71)* |
| • Femur | 191 | 2.08 (1.46, 2.97)* | 167 | 2.85 (1.72, 3.49)* |
| • Humerus | 711 | 1.90 (1.46, 2.47)* | 307 | 2.01 (1.52, 2.68)* |
| • Vertebral | 415 | 2.84 (2.20, 3.66)* | 443 | 2.95 (2.38, 3.66)* |

Low level of thoracic bone mineral density and low doses of glucocorticoid use are risk factors for clinical fractures in patients with rheumatoid arthritis: fourth-year results of the TOMORROW study. Tatsuya Koike^{*1}, Kenji Mamoto², Tadashi Okano³, Yuko Sugioka⁴, Masahiro Tada⁵, Kentaro Inui⁶. ¹Search Institute for Bone & Arthritis Disease (SINBAD), Japan, ²Department of Orthopaedic Surgery, Osaka City University Medical School, Japan, ³Department of Orthopedic Surgery, Osaka City University Medical School, Japan, ⁴Center for Senile Degenerative Disorders, Osaka City University Medical School, Japan, ⁵Department of Orthopedic Surgery, Osaka City General Hospital, Japan, ⁶Department of Rheumatology, Osaka City University Medical School, Japan

[Objectives]

Patients with rheumatoid arthritis (RA) who have muscle weakness and stiff or painful joints might be at increased risk of fall and fracture. The present study prospectively determined the incidence of fracture and risk factors in patients with RA who participated in the TOMORROW study (UMIN000003876) that began in 2010.

[Methods]

We evaluated anthropometric parameters, bone mineral density, disease activity and the incidence of clinical fractures for a period of 4 years in 202 patients with RA (mean age, 58.6 years; medication with biological agents, 54.9%) and 202 age- and sex-matched healthy volunteers (Controls; mean age, 57.4 years). The study successful execution rate for 4 years was 91.3 % in RA group and 93.2% in Control group, respectively.

[Results]

The incidence of clinical fractures did not differ significantly between patients with RA (n = 30, 14.9%) and Controls (n = 21, 10.4%) within the 4-year period (p=0.23). Furthermore, there was no difference among the sites of fractures between two groups. After adjusting for risk factors for fractures, including age, sex, smoking and body mass index, logistic regression analysis revealed previous vertebral fracture, past history of clinical fracture and low bone mineral density (BMD) at thoracic vertebrae as the parameters significantly associated with incidence of fractures (odds ratio [OR], 2.60; 95% confidence interval [CI], 1.36-4.98; p = 0.004, OR, 2.03; 95%CI, 1.11-3.71, p=0.022, OR, 3.35; 95%CI, 1.66-6.76, p=0.001, respectively) in whole group. Although the use of glucocorticoid (GC) was also a significant risk factor for fractures (OR, 2.59; 95%CI, 1.31-5.12, p=0.006), being RA was not a risk factor for fracture throughout subjects. Among patients with RA, low BMD at thoracic vertebrae was the most prominent risk factor for fracture (OR, 6.29; 95%CI, 2.29-17.2, p<0.001). Additionally, the use of GC at the entry (2010) (OR, 2.80; 95%CI, 1.23-6.40, p=0.014) was a significant risk factor for fracture in RA patients. Surprisingly, the use of GC more than an average of only 2 mg/day for four years increased OR for fracture in patients with RA (OR, 4.61; 95%CT, 1.87-11.34, p<0.001).

[Conclusion]

Incidence of clinical fractures did not differ significantly between patients with RA and Controls during a 4-year period. Low levels of BMD at thoracic vertebrae and low doses of GC appear significantly associated with an increased frequency of fractures among patients with RA.

Rest-activity patterns and their relation to falls and fractures in older men: The Osteoporotic Fractures in Men (MrOS) Study. Peggy Cawthon^{*1}, Terri Blackwell², Greg Tranah², Douglas Bauer³, Eric Orwoll⁴, Dan Evans², Jane Cauley⁵, Sonia Ancoli-Israel⁶, Katie Stone², Steven Cummings². ¹San Francisco Coordinating Center, USA, ²California Pacific Medical Center Research Institute, USA, ³University of California, San Francisco, USA, ⁴Oregon Health & Science University, USA, ⁵University of Pittsburgh, USA, ⁶University of California, San Diego, USA

Rest-activity levels follow a diurnal pattern in humans, and deficits in these patterns have been associated with increased risk of mortality and cardiovascular disease in older adults. The relation between rest-activity patterns and risk of falls and fractures has not been evaluated. MrOS is a prospective cohort study of 5,994 ambulatory men free of bilateral hip replacements, aged =65 years at enrollment in 2000-2. Using data from a follow-up visit of a subset of the MrOS cohort (2002-3, N for analysis: 3,001), we determined rest-activity patterns. We fit the extended cosine model to activity count values from wrist-worn actigraphy data initially collected to measure sleep characteristics over 4.8*0.8 24-hr periods (SleepWatch-O; Ambulatory Monitoring, Inc., Ardsley, NY). We determined amplitude, mesor, acrophase, and the pseudo-F statistic (Table 1). Following the visit, men reported falls and fractures via mailed questionnaires every four months. Recurrent fallers were classified as men with =2 falls in the year after the visit (versus men with 0-1 fall). Fractures were centrally adjudicated by physician review of radiology reports. Rest-activity components were evaluated as continuous variables with associations reported per SD increase or decrease in models adjusted for potential confounders (footnote, Table 2). Logistic regression was used to estimate the likelihood of recurrent falls; proportional hazards models were used to estimate the risk of non-spine fractures. In the year after the visit, 417 men (14.0%) had =2 falls. Later acrophase (indicating later phase shift of activity) and lower pseudo F-statistic values (indicating greater disorganization of activity), but not mesor or amplitude, were associated with a greater likelihood of falls. In 8.0 years (SD: 3.0) after the visit, 488 men (16.3%) had at least one non-spine fracture. None of the rest-activity patterns were associated with risk of non-spine fractures. No consistent associations were observed between rest-activity patterns and fractures analyzed by anatomical location (that is, spine, hip, wrist, upper arm, ankle/foot/toe). Minimally adjusted models were similar for all outcomes. In summary, later timing of activity and disorganization of activity patterns were independently associated with risk of falls in older men, but this did not translate into higher fracture risk. Future research should evaluate whether interventions that alter circadian patterns affect fall risk.

Table 1. Circadian patterns assessed in MrOS

| Rest-activity component | Definition |
|--|---|
| Amplitude (counts per minute) | Difference between peak & nadir in activity; higher values indicate greater difference in activity |
| Mesor (counts per minute) | Mean level of activity; higher values indicate greater activity |
| Pseudo F-statistic (unit less measure) | Measure of how well the activity fits the extended cosine model; higher values indicate better fit/less disorganization |
| Acrophase (time of day) | Time of day when peak activity (used in amplitude) occurs. Earlier/later indicates phase shift. |

Table 1. Circadian Patterns assessed in MrOS

Table 2. Rest-activity patterns and falls and fractures in older men

| Rest-activity component (SD unit) | Likelihood of recurrent falls (OR per SD, 95% CI)* | Risk of non-spine fractures (HR per SD, 95% CI)* |
|--|--|--|
| Amplitude (-1090 counts/min) | 1.11 (0.95, 1.31) | 1.00 (0.88, 1.12) |
| Mesor (-502 counts/min) | 1.02 (0.88, 1.19) | 0.99 (0.88, 1.12) |
| Pseudo F-statistic (- 512.9) | 1.23 (1.04, 1.46) | 1.04 (0.91, 1.19) |
| Acrophase (1 hour, 12 min) | 1.18 (1.06, 1.32) | 0.99 (0.90, 1.08) |

*adjusted for age, clinic site, race, body mass index, any medical condition (diabetes mellitus, coronary heart disease, hypertension, stroke), smoking, alcohol use, caffeine use, depression, use of benzodiazepines, use of prescription sleep medications, presence of an IADL, walking speed, activity count and nocturia. Fracture models additionally adjusted for femoral neck BMD.

Short Term Functional Outcomes in Elderly Patients Sustaining Fragility Hip Fractures. Jordan Villa^{*1}, Joseph Koresse², Joaquin Moya¹, Arianna Gianakos³, Joseph Lane¹. ¹Hospital for Special Surgery, USA, ²Weill Cornell Medical College, USA, ³Hospital for Special Surgery, USA

Introduction: Hip fracture (HF) is one of the most common fractures in the elderly population with in-hospital mortality ranging from 3% to 9% and higher mortality at 6 months with increase in immobility after the fracture. Guidelines for management after HF surgery recommend first walk within 48 hours. Early ambulation (EA) reduces the negative effects of immobilization, improves functional recovery and is associated with an increased number of discharges directly home. Delay of getting a patient out of bed after this period is associated with poor function at 2 months. Although HF outcomes in elderly women have been established there has been little investigation about short term outcomes in males. We hypothesize that male sex is a predictor of worse short term functional outcome. The aim of this study was to evaluate the difference in time to standing and ambulation in men vs women and other factors associated with short term functional outcomes following HF surgery. **Methods:** A total of 443 patients older than 50 years with fragility HF admitted to the New York Presbyterian Hospital from 2013 to 2014 were included in this retrospective study. Information was collected from medical records. Cox proportional hazards modeling was used to compare time to stand and time to walk between sexes. **Results:** After adjustment for epidemiologic and operative care variables, there was no evidence of an association between sex and time to stand or time to walk ($P = 0.277$ and 0.681). The strongest predictors of a delayed time to stand were dementia and depression ($P = 0.010$ and 0.042). The strongest predictors of a delayed time until first walking were higher ASA, anemia, and higher age ($P=0.002$, 0.016 , and 0.038 , respectively). **Discussion:** The results show that gender is not a variable that can predict short term functional outcomes after surgical stabilization of HF. Results are different from previous studies that report no significant influence of either cognitive impairment or high comorbidity in EA. Although the time to surgery and the type of anesthesia were associated with 30 days outcomes, there has been no association with time to standing or ambulation 5 days after the surgery. **Conclusion:** There is no association between gender and time to stand or time to walk after surgical stabilization of a HF. Instead dementia, depression, ASA, anemia and age predict a longer time to stand and walk in the post-operative course.

A Clinical Definition of Fragility Fracture. Claudia Beaudoin^{*1}, Sonia Jean², Louis Bessette³, Louis-Georges Ste-Marie⁴, Jacques P. Brown³. ¹CHU de Quebec Research Centre, Canada, ²Institut national de santé publique du Québec, Canada, ³CHU de Québec Research Centre, Canada, ⁴Université de Montréal, Canada

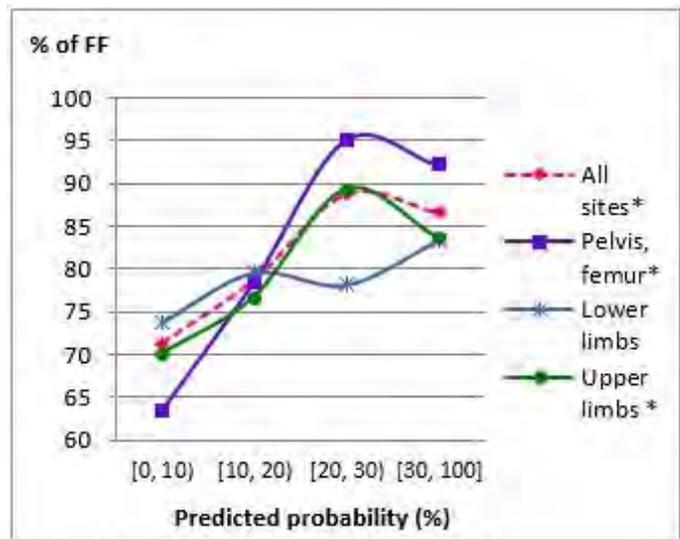

Background: Fractures at a given skeletal site are traditionally considered osteoporotic when fracture risk at this site increases with decreasing BMD and increasing age. **Objective:** The aim of this study was to assess if a simple clinical definition of fragility fracture (FF) based on circumstances of fracture satisfies the classical criteria defining an osteoporotic fracture and correlates with the FRAX risk

of major osteoporotic fracture (MOF). Methods: Women aged 50 and older who suffered a peripheral fracture were recruited in the ROCQ programme. Fractures were classified as FF based on the following definition: occurring spontaneously, from a fall from standing height, sitting, lying, missing 3 or fewer steps, coughing, sneezing or from a movement outside of the normal range of motion. All other fractures were classified as traumatic fractures. Six to eight months following fracture, women completed a questionnaire detailing personal and clinical characteristics. Femoral neck BMD (FN-BMD) were collected for participants who had a BMD measurement within 2 years of the fracture event. BMD data was imputed for about 50% of women who did not have a FN-BMD result available. The FRAX 10-year risk of MOF was calculated with and without BMD. Only fractures that happened before the programme were considered to estimate the risk. Mantel-Haenszel Chi-Square tests for trend were performed to determine whether the proportion of FFs increases significantly with age and FRAX risk and decreases significantly with increasing FN-BMD t-score, both globally and by fracture sites. Results: A total of 2712 women were included in the analyses and provided data on 294 fracture events at the hip or femur, 838 at the lower limbs and 1597 at the upper limbs. Overall, 77% of the fractures were FFs and the proportion of FF increased significantly with age (Fig. 1) and FRAX without and with BMD risk (Fig. 2) at all sites except lower limbs. The proportion of FF decreased significantly with increasing FN-BMD t-score at all sites except lower limbs (Fig. 3). Conclusion: We have shown that a simple clinical definition of FF based on the cause and circumstances of fracture satisfies the classical criteria defining an osteoporotic fracture and correlates with the FRAX predicted risk. These findings provide support to the validity of our definition of FF. A subsequent analysis assessing the ability of the proposed definition to predict a future fracture is planned.

Are Fragility Fractures Associated With Frailty Prior to Fracture? Healthcare Utilisation In Older Women Prior to Fracture Compared With Those Without Subsequent Fracture. Kerrie Sanders¹, Jenny Watts², Lucy Busija¹, Amanda Stuart², David Scott³, Geoff Nicholson¹. ¹Australian Catholic University, Australia, ²Deakin University, Australia, ³Monash University, Australia

To examine the association between frailty and risk of fracture in older women we investigated total healthcare utilisation for one year prior to longitudinal fracture ascertainment in women aged at least 70 years at recruitment. Australia provides universal health coverage through Medicare for all health services except public hospitals. Medicines are subsidized by pharm benefits scheme PBS). Free public hospital care is widely accessible.

Women at higher risk of falls and fracture were recruited. Participants' total PBS scripts and health service use for the year prior to fracture ascertainment, was obtained from Medicare/PBS. These data stratified by age and subsequent fracture (yes/no) were used to calculate the average number of services and scripts per participant in each group. The regional public hospital provided patient level data on all hospital services used. Binominal regression was used to analyse hospital service use.

Healthcare use, scripts and hospital data were obtained from 590 consented women who were then contacted monthly for fracture ascertainment for the next 3 years. All fractures were radiologically confirmed. 68 women sustained fracture(s) and 512 did not.

The average health service and script use for women with and without subsequent fracture was 15.7 vs 18.9 items and 34.4 vs 39.6 scripts, respectively (table). Although the study was only powered to detect a 30% difference in hospital services, the data adjusted for age and self-reported prior fracture (since 50 y.o) suggests number of hospital services was not predictive of subsequent fracture (odds ratio; 95%CI: 1.14; 0.60, 2.17; p=0.7).

The findings suggest older women who fracture are not less healthy prior to the fracture event.

Healthcare services expressed per person per annum*

| Age group (years) | Subsequent fracture Medicare | No fracture Medicare | Subsequent fracture PBS | No fracture PBS |
|-------------------|------------------------------|----------------------|-------------------------|-----------------|
| 70-74 | 10.6 | 15.5 | 29.0 | 32.4 |
| 75-79 | 20.5 | 20.9 | 33.0 | 41.5 |
| 80+ | 14.4 | 21.1 | 41.3 | 47.6 |

*p values not reported as variance not calculated as data were de-identified.

Differences In Pain Experience Between Women With And Without Vertebral Fractures: Novel Independent Descriptors Identified. Emma Clark*, Rachael Goberman-Hill, Tim Peters, University of Bristol, United Kingdom

Background: Osteoporotic vertebral fractures (VFs) are present in approximately 12% of the postmenopausal population, but less than a third come to clinical attention. One reason for this is lack of clear clinical triggers for referral for radiographs, including a lack of evidence about which characteristics of back pain may indicate presence of VF. **Aim:** To investigate whether the quality or type of back pain in people with VFs is different to those with back pain but no VFs, and if so to develop a simple back pain questionnaire for discrimination. **Methods:** A case-control study was undertaken. Digital radiological archives were used to identify a population of potential participants who had a thoracic radiograph for back pain. Inclusion criteria were >60 years, female and thoracic spinal radiograph performed in the previous 3 months. 683 potential participants were approached, and all who agreed to take part self-completed a questionnaire assembled from domains and scales taken from questionnaires previously validated in UK populations including the McGill Pain Questionnaire and the Keele STarT back pain score as well as demographics. Cases were defined at the end of the study as those with a VF identified from spinal radiographs by the PI using the ABQ method. Chi-squared tests were used to assess univariable associations and logistic regression to identify independent predictors of VFs. Receiver Operating Characteristic (ROC) curves were used to evaluate the ability of the combined independent predictors to differentiate between women with and without VFs via Area Under Curve (AUC). **Results:** 64 cases and 135 controls completed questionnaires. Those with VFs were older (77.9 years vs 73.2, $P < 0.001$), more likely to have previously fractured a bone (70.8% vs 42.5%, $P = 0.001$) and more likely to have taken steroids (27.7% vs 10.4%, $P = 0.007$). History of previous fracture, reduced walking distance, poor vision, pain described as crushing, pain not described as taut and pain not spreading down legs were independent predictors of VFs. ROC analysis showed the AUC was 0.81 for these questions. **Conclusion:** We identify novel predictors of VFs in older women based on descriptions of back pain. These could be combined to produce a simple questionnaire that has the potential to discriminate between women who are likely to have a VF and should therefore have diagnostic spinal radiographs, and women who have degenerative spinal disease instead.

ROC curve to evaluate the ability of the combined independent predictors to differentiate between women with and without VFs

Muscle Mass Predicts Incident Fracture in Postmenopausal Women: The OFELY Study. Elisabeth Sornay-Rendu¹, Francois Duboeuf², Stéphanie Boutroy², Roland Chapurlat^{*2}, ¹INSERM UMR1033, Université de Lyon, France, ²INSERM UMR1033 & Université de Lyon, France

The relationships between body composition and bone mineral density are well established but the independent contribution of body composition to the risk of fracture (Fx) has rarely been evaluated prospectively. The aim of this study was to prospectively investigate the prediction of fragility Fx by fat, lean and muscle mass in postmenopausal women. We measured body composition at the 9th annual follow-up of the OFELY study in 595 postmenopausal women, mean age 66.8 yrs. Whole body DXA (HologicÜ, QDR4500) exams were analyzed using the APEX version 4.0.2 to get visceral (VFAT) and subcutaneous fat mass (SFAT) in an abdominal region of interest along with measurement of total body fat mass (FM), lean mass (LM),

appendicular skeletal muscle mass (ASM) and Femoral Neck BMD (FNBM). The LM (LMI) and ASM indexes (ASMI) were obtained by dividing by height squared. During a median [IQR] 13.1 [1.9] yrs of follow-up, 138 women sustained a first incident fragility Fx, including 85 women with a major osteoporotic Fx (MOP Fx: hip, clinical spine, shoulder or wrist). After adjustment for age, women who sustained Fx had lower BMI (-4%, $p = 0.01$), VFAT (-4%, $p = 0.07$), SFAT (-6%, $p = 0.06$), LMI (-6%, $p = 0.002$) and ASMI (-3%, $p = 0.003$), compared with women without Fx ($n = 457$). The differences were more pronounced for women who sustained MOP Fx ($p < 0.01$ for all). After adjustment for age, prevalent Fx, physical activity, incident falls (during the whole follow-up in women without Fx and until the first incident Fx in fractured women) and FNBM, each SD increase of baseline values of LMI and ASMI were associated with significant decreased fracture risk with adjusted hazard ratios [HR(95%CI)] of 0.76(0.61-0.95) and 0.76(0.62-0.94), $p < 0.02$. Those associations remained significant after adding body weight in the multivariate model ($p = 0.02$). For all Fx, FM, VFAT and SFAT were not independently associated with fracture risk in the multivariate model with or without adding body weight. For MOP Fx, FM, VFAT and SFAT, were associated with fracture risk in the multivariate model without ($p < 0.05$), but not with body weight in the model. We conclude that both visceral and subcutaneous fat mass are associated with fracture risk but not independently of BMD and body weight. In contrast, lean mass and appendicular muscle mass indexes predict the risk of fracture in postmenopausal women independently of BMD and clinical risk factors.

Nonsteroidal Anti-Inflammatory Drug Prescriptions are Associated with Increased Stress Fracture Risk in U.S. Army Soldiers. Julie Hughes*¹, Craig McKinnon¹, Lakmini Bulathsinghala², Katelyn Guerriere¹, Mary Bouxsein³, Joseph Kardouni¹, Ronald Matheny, Jr.¹, ¹US Army Research Institute of Environmental Medicine, USA, ²DoD-VA Extremity Trauma & Amputation Center of Excellence, USA, ³Endocrine Unit, Massachusetts General Hospital, Center for Advanced Orthopedic Studies, Beth Israel Deaconess Medical Center, Department of Orthopaedic Surgery, Harvard Medical School, USA

Use of nonsteroidal anti-inflammatory drugs (NSAIDs) is widespread in the U.S. Army and in civilian populations. NSAIDs inhibit prostaglandin synthesis, which is necessary for adaptive bone formation in response to mechanical loading. Further, animal models have shown that adaptive bone formation inhibits development of stress fracture. Whether NSAID use increases risk of stress fractures is not known. Therefore, the purpose of this study was to determine the stress fracture risk among U.S. Army soldiers prescribed NSAIDs. A retrospective cohort study was conducted using data from the Total Army Injury and Health Outcomes Database from 2002 to 2011. We identified soldiers who had stress fractures at the lower extremity and pelvis ($n = 55,162$; 3.1% of male soldiers, 9.1% of female soldiers). Soldiers prescribed NSAIDs between 180 and 21 days prior to injury ($n = 31,463$) were compared with four randomly selected controls from the population at risk ($n = 1,261,297$) after matching on date of stress fracture diagnosis. Conditional logistic regression was used to calculate the odds ratios (OR) for stress fracture. In the unadjusted model, soldiers prescribed NSAIDs were twice as likely to suffer a stress fracture compared to controls (OR = 1.98 [95% CI 1.94-2.02]). A model adjusting for age, race, ethnicity, and length of military service yielded an OR of 2.87 (2.80-2.94) for NSAID use. To account for potential sex-based differences in stress fracture risk with NSAID prescription, a sex-stratified adjusted analysis was performed, yielding an OR of 2.79 (2.68-2.91) for females and 2.84 (2.76-2.92) for males. This retrospective study showed that in both men and women, NSAID prescriptions are associated with a nearly 3-fold increased risk of stress fracture in soldiers.

The views expressed in this abstract are those of the authors and do not reflect the official policy of the Department of Army, Department of Defense, or the U.S. Government.

Osteoporosis markers and atherosclerosis: higher bone density is associated with greater carotid intima-media thickness in middle-aged women. Monika Frvz*¹, Kevin Deere², Debbie A Lawlor³, William D Fraser⁴, L-L Benfield¹, Jon H Tobias², Celia Gregson⁵, ¹School of Social & Community Medicine, University of Bristol, United Kingdom, ²Musculoskeletal Research Unit, School of Clinical Sciences, University of Bristol, United Kingdom, ³MRC Integrative Epidemiology Unit at the University of Bristol, United Kingdom, ⁴Faculty of Medicine & Health Sciences, University of East Anglia, United Kingdom, ⁵University of Bristol, United Kingdom

Aims

Osteoporosis and cardiovascular disease (CVD) are common age-related diseases which have frequently been found to be associated. We aimed to explore the relationship between osteoporosis markers and preclinical atherosclerosis measured

by carotid intima-media thickness (cIMT) in mid-aged, predominantly pre-menopausal women.

Methods

Data from 2933 mothers from the Avon Longitudinal Study of Parents and Children were used. Total body (TB) bone mineral density (BMD), bone mineral content (BMC), bone area (BA) and hip BMD were measured by DXA scanning, bone turnover (a further marker of osteoporosis) was assessed by serum beta-carboxyterminal cross linking telopeptide (CTX) levels. cIMT was measured by high-resolution B ultrasound. We used multivariable linear regression to examine the association between both CTX and DXA-derived variables and cIMT, adjusting for a range of confounders. Results are expressed as partial correlation coefficients with 95% confidence intervals.

Results

Mean (SD) participant age was 48 (4.0) years, BMI 26.2 (5.0) kg/m², and 70% were premenopausal. CTX was positively associated with cIMT (0.064 [0.027, 0.101] p=0.001), but this association attenuated to the null with adjustment for age (0.003 [-0.034, 0.040] p=0.8). Total hip BMD was positively associated with cIMT (0.060 [0.024, 0.097] p=0.001), and this association persisted after adjustment for age, height, lean & fat mass, smoking, education level, estrogen replacement and menopausal status (0.057 [0.017, 0.097] p=0.005). There were also positive (confounder adjusted) associations of TB BMD and TB BA with cIMT, though the latter had 95% confidence intervals that included the null. A positive association was also seen between bone area-adjusted BMC and cIMT. There was no evidence that associations differed between pre- and post-menopausal women (e.g. partial correlation coefficients for association of hip BMD with cIMT were 0.062 [0.016, 0.108] and 0.042 [0.039, 0.122] in pre- and post-menopausal women respectively (interaction p=0.8)).

Conclusion Contrary to previous studies, mostly performed in older populations, which suggest that osteoporosis is associated with greater CVD risk, we found weak positive associations of BMD with cIMT, in a predominantly premenopausal group, which appeared to reflect an association with bone size and volumetric density and was not related to bone turnover. These findings require further replication and exploration in large prospective studies.

Parental Hip Fracture is an Independent Risk Factor for Fracture: A Population-Based Parent-Offspring Linkage Analysis. Shuman Yang^{*1}, William Leslie¹, Lin Yan¹, Randy Walld¹, Leslie Roos¹, Suzanne Morin², Sumit Majumdar³, Lisa Lix¹. ¹University of Manitoba, Canada, ²McGill University, Canada, ³University of Alberta, Canada

Background: A meta-analysis of cohort studies suggests that parental hip fracture (HF) independently predicts fractures in their offspring. However, parental HF information from these studies was self-reported and may be subject to recall bias. We examined the association of parental HF, ascertained from population-based administrative data and parent-offspring record linkage, with major osteoporotic fracture (MOF) and HF.

Methods: We identified 263,368 women and men (age ≥ 40 years) with continuous health coverage in Manitoba, Canada who were able to successfully link to their parental healthcare information (possible for offspring born after 1951). Parental HF was derived from hospital discharge abstracts dating back to 1970 (6.0% maternal, 2.9% paternal and 8.6% either parent). Incident MOF and HF events in the offspring were ascertained from hospital and physician claims data using validated algorithms. Cox proportional hazards models (with time-varying covariates updated annually) were used to estimate the association between parental HF and offspring MOF and HF, adjusted for age, sex, prolonged glucocorticoid use, rheumatoid arthritis, osteoporosis treatment, prior major fracture, and proxies for smoking and high alcohol use.

Results: During 2,827,772 person-years of offspring follow-up, we identified 7,207 incident MOFs (4.3% and 2.6% for those with and without either parent HF, p<0.001) and 374 incident HF (0.3% and 0.1% for those with and without either parent HF, p<0.001). Either parent HF was significantly and independently associated with increased risk of MOF in fully adjusted model (HR: 1.29; 95% CI: 1.19-1.40; Table). Results were similar for women (HR: 1.36; 95% CI: 1.22-1.51) and men (HR: 1.21; 95% CI: 1.07-1.37), without significant interaction between sexes (p=0.16). HRs of MOF associated with a maternal HF (HR: 1.30; 95% CI: 1.18-1.43) or a paternal HF (HR: 1.24; 95% CI: 1.09-1.42) were similar to that seen in either parent analysis. The relationship between either parent HF and offspring HF was even stronger (HR: 1.67; 95% CI: 1.25-2.21), and again there was no significant interaction according to offspring's sex (p=0.29).

Summary: Using population-based data with parent-offspring linkage, we have confirmed parental HF to be an independent risk factor for both MOF and HF. Our findings support a previous meta-analysis based on self-reported parental hip fracture and justify the use of this variable in fracture risk prediction.

Table. Fully adjusted hazard ratios (95% CI) for incident major osteoporotic fracture (MOF) and hip fracture (HF) associated with parental HF.

| | MOF | HF |
|------------------|------------------|------------------|
| Maternal HF | 1.30 (1.18-1.43) | 1.63 (1.17-2.28) |
| Paternal HF | 1.24 (1.09-1.42) | 1.67 (1.05-2.67) |
| Either parent HF | 1.29 (1.19-1.40) | 1.67 (1.25-2.21) |

The Relationship between Smoking Duration, Pulmonary Function and Bone Mineral Density in Korean Men: KNHANES 2008-2011. Ji Hyun Lee^{*1}, Jung Hee Kim², A Ram Hong³, Chan Soo Shin³, Sang Wan Kim³. ¹Seoul national university hospital, South Korea, ²Department of Internal Medicine, Seoul National University College of Medicine, Seoul, South Korea, ³Department of Internal Medicine, Seoul National University College of Medicine, South Korea

Smoking is one of well established risk factors that induce bone loss, however, data on the amount a person has smoked over a long period of time are lacking. We investigated the relationships between pack-years smoked, pulmonary function and bone mineral density (BMD) among Korean men. This cross sectional study was performed using data from the 2008-2011 Korean National Health and Nutrition Examination Survey, including men aged 50 to 64 years. All subjects underwent bone mineral density measurements using dual energy X-ray absorptiometry and pulmonary function tests using standardised spirometry. A total of 1,476 subjects were classified into groups with regard to their pack-years smoked included <1 (n=301), 1-30 (n=693), and greater than 30 pack years (n=482). Forced expiratory volume in 1 second (FEV1) values were decreased according to pack-years smoked (3.17 ± 0.53; 3.16 ± 0.51; 3.02 ± 0.56; p<0.001). The mean BMD at total hip was decreased according to pack-years smoked groups with < 1, 1-30, and greater than 30 pack years adjusted for age, body mass index, alcohol consumption, physical activity, socioeconomic status, and vitamin D level which might affect bone metabolism (1.131 ± 0.142; 1.128 ± 0.156; 1.102 ± 0.143 g/cm³; p<0.05). The mean BMD at femur neck was increased according to forced vital capacity (FVC) quartile and was independent of covariates mentioned above (0.770 ± 0.110; 0.782 ± 0.107; 0.783 ± 0.112; 0.796 ± 0.113 g/cm³; p<0.05). In conclusion, smoking over 30 pack years and low FVC were associated significantly with low hip BMD. They should be considered to be risk factors associated with bone loss in men aged 50-64 years.

Upper Body Center of Mass Location Affects the Factor of Risk for Vertebral Fracture. Julie Choise¹, Celia Amabile², Agathe Nérot², Christophe Travert², Hélène Pillet², Wafa Skalli^{*2}. ¹Arts et Metiers ParisTech, France, ²Arts et Metiers ParisTech, LBM/Institut de Biomecanique Humaine Georges Charpak, France

The factor of risk for vertebral fracture (Φ) is defined as the ratio of spinal loading to vertebral strength and was demonstrated to change depending on the age and gender's population. Another factor to consider in the vertebral fracture risk assessment is the location of the upper body center of mass (COM) situated above the lumbar spine. Previous studies assumed that the upper body COM is located directly over the center of the vertebral column but this location may vary depending on each one posture. The purpose of this study was to determine the change in upper body COM depending on age and gender and its effect on Φ for vertebral fracture calculation.

32 asymptomatic adults were considered (15 male, 17 female, age: 53 yo [21-85]). Head to feet low dose bi-planar X-Rays were acquired in standing position using the EOS system (EOS Imaging, Paris, France). 3D reconstructions of the external body shape and L1 were performed (Figure 1). The upper body weight and COM situated above L1 were calculated with the head, neck and thorax personalized volume and generic densities, and arms mass determined as a percentage of total body mass for each participant. A finite element model of L1 was built with subject-specific 3D geometry and a generic bone mineral density distribution converted in elastic modulus for material properties attribution. Antero-posterior distance between L1 upper plate's center and the upper body COM was determined. Φ was determined with 1) the load applied to the center of L1 and 2) the load applied at the upper body COM location. To assess age specific differences, participants were divided in 3 groups; 12 participants in group 1 (20-40), 10 in group 2 (41-65) and 10 in group 3 (>65). Differences between groups were assessed with a t-test.

The upper body COM was located 13 mm (± 19) anterior to L1 for group 1, 37 mm (± 16) for group 2 and 44 mm (± 27) for group 3. Significant changes in distances were found between group 1 and 2 ($p=0.005$) and between group 1 and 3 ($p=0.005$). Φ significantly increased (worsened) with age when the load was applied at the upper body COM location (Figure 2).

Even though at this step muscle forces were not modeled, the upper body has the tendency to shift forward with age and therefore apply higher forces to the lumbar spine which increases the factor of risk for vertebral fracture. Future factor risk calculation should incorporate the upper body COM location.

Figure 1: Upper body 3D reconstruction with L1 in yellow, L1 center in blue and gravity line in red

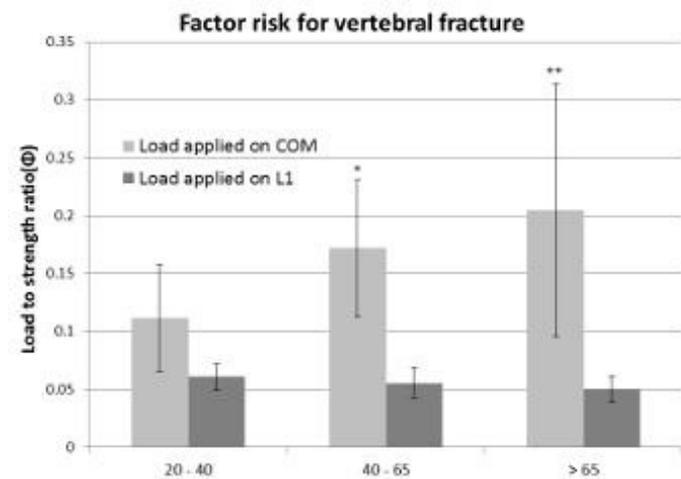

Figure 2: Factor risk for each group; * ($p<0.05$) and ** ($p<0.01$) compared to group 1

Weight Change and Risk of Central Body Fractures in Older Community-Dwelling Men. Kristine Ensrud¹, Stephanie Harrison², Jane Cauley³, Deborah Kado⁴, Cora Lewis⁵, Andrew Hoffman⁶, Eric Orwoll⁷, Carolyn Crandall⁸, Marcia Stefanick⁶, Peggy Cawthon². ¹University of Minnesota & Minneapolis VA Health Care System, USA, ²California Pacific Medical Center Research Institute, USA, ³University of Pittsburgh, USA, ⁴University of California - San Diego, USA, ⁵University of Alabama at Birmingham, USA, ⁶Stanford University, USA, ⁷Oregon Health & Science University, USA, ⁸University of California - Los Angeles, USA

Purpose: Determine associations of weight loss and weight gain in late life on risk of central body (hip, clinical vertebral, or pelvis) fractures in older men.

Methods: We used data from 4523 men attending Visit 2 of the prospective MrOS study. Weight change from baseline to Visit 2 an average of 4.5 years later was classified as moderate weight loss (loss $\geq 10\%$), mild weight loss (loss 5% to $<10\%$), stable weight ($<5\%$ change) or weight gain (gain $\geq 5\%$). At Visit 2, men were asked if they were trying or not trying to lose weight. Men were contacted tri-annually after Visit 2 to ascertain incident fractures confirmed by radiographic reports.

Results: Mean age was 77.5; 283 men (6%) had moderate weight loss, 742 (16%) had mild weight loss, 3076 (68%) had stable weight and 422 (9%) gained weight. During an average follow-up of 7.4 years, 313 men (7%) experienced ≥ 1 central body fracture including 156 hip fractures, 128 clinical vertebral fractures and 47 pelvis fractures. Age-adjusted rates of central body fractures per 1000 person years were higher among men with moderate weight loss (15.5) and men with mild weight loss (10.4) and similarly lower among men with stable weight (8.8) and men with weight gain (8.4). An analogous pattern was seen for hip and clinical vertebral fractures. After adjustment for age, race, smoking and comorbidities, greater weight loss was associated with a higher risk of central body fracture (p trend 0.02) (Table). Men with moderate weight loss had 1.5-fold (HR 1.54 95%CI 1.01-2.33) higher risk compared with those with stable weight or weight gain (referent group); men with mild weight loss had a modest increase in risk that was not significant. Associations of weight loss with fracture risk did not vary by BMI or intention to lose weight (p interaction term ≥ 0.54). Inclusion of potential mediators including physical activity, fall history, gait speed or femoral neck BMD in the model attenuated the association between moderate weight loss and central body fracture by 6 to 13%, with BMD having the greatest impact.

Conclusion: Among community-dwelling older men, men with moderate weight loss compared to those with stable weight or weight gain had an increased risk of central body fractures irrespective of body weight or intention to lose weight. While fall propensity, lower physical activity and mobility play minor roles as mediators, our findings suggest that this association is due in part to lower hip BMD among men with weight loss.

Table: Association between Weight Change and Risk of Central Body Fracture

| Weight Change Category | Fracture Risk Hazard Ratio (95% CI) | | | | |
|--------------------------------------|-------------------------------------|----------------------|-------------------------|----------------------|----------------------|

Applying the Health Action Process Approach to Develop Educational Videos to Improve Vitamin D Adherence in Older Adult with Osteoporosis-A Pilot Knowledge Translation Study. AHMED NEGM¹, Jonathan D. Adachi², Arthur Lau³, Norma J. MacIntyre⁴. ¹McMaster University, Canada, ²St. Joseph's Healthcare/McMaster University, Canada, ³Division of Rheumatology, McMaster University, Canada, ⁴School of Rehabilitation Science, Faculty of Health Sciences, McMaster University, Canada

Purpose: Despite high level evidence that vitamin D is effective in osteoporosis (OP) fracture prevention, adherence to vitamin D supplementation is low. The Health Action Process Approach (HAPA) is a theoretical model used to change health behaviors. This study aimed to pilot four educational videos developed using the HAPA to address self-efficacy, OP fracture risk perception, outcome expectancy and action planning related to vitamin D adherence in people with OP.

Methods: Eligible participants were recruited through OP specialty clinics (≥ 50 years, diagnosed with OP, not taking vitamin D for the last 3 months regularly, fluent

in English and with no cognitive diseases or mal-absorption syndromes). Participants were instructed to select the number and order of videos to watch and reported the following: knowledge gained on a scale from 1 to 7, the most important information and what else they would like to know related to each topic. Descriptive data were summarized.

Results: Fourteen participants (mean age (SD) = 68.4 (8.7) years; 12 females) were recruited during one winter month. The OP fracture risk perception and action planning videos were watched first or second. In contrast, the outcome expectancy video tended to be watched third and the self-efficacy video fourth (F=21.98; P = 0.0001). Figure 1 shows that participants learned significantly more from the OP fracture risk perception video than the self-efficacy video (P = 0.05) and from the outcome expectancy video than the self-efficacy (P = 0.04) and action planning (P = 0.006) videos. The most important knowledge gained in each video was: 'risk of death and disability after hip fracture' (fracture risk perception); 'take vitamin D in the same time and place' (action planning) 'falls prevention' (outcome expectancy); and 'take vitamin D regularly' (self-efficacy).

Conclusion: Most participants watched all four videos. This study supports the administration of all four videos rather than tailoring to assessed phase of the HAPA model. Less was learned from the self-efficacy and action planning videos. Feedback from these knowledge users will be used in revision. Further study will determine if viewing the videos increases vitamin D adherence, as assessed by serum levels, compared to a control group who do not view the videos.

SU0299

Comparing Agreement of Osteoporosis Treatment Guidelines Using Data from the Patient Activation after DXA Receipt Notification (PAADRN) Study. Nicole Wright^{*1}, Peter Cram², Fred Wolinsky³, Douglas Roblin⁴, Stephanie Edmonds³, Kenneth Saag¹. ¹University of Alabama at Birmingham, USA, ²University of Toronto, Canada, ³University of Iowa, USA, ⁴Georgia State University, USA

Purpose: To compare the osteoporosis (OP) treatment guideline concordance in participants of the PAADRN study using the US National Osteoporosis Foundation (NOF) and the International Osteoporosis Foundation (IOF) guidelines.

Methods: We used the control arm (n=2711) of the PAADRN study, a randomized, controlled trial aimed to activate patients around OP treatments, to evaluate guideline concordance in a usual care setting. We defined NOF guideline concordant therapy as either receipt of OP therapy at the 12-week post-DXA survey if the participant had a fracture after age 40, a T-score at or below the OP threshold, or a T-score within the low bone mass range and a FRAX score ≥20%. Instead of one FRAX threshold, the IOF guidelines include aged-based FRAX thresholds. We used the UK thresholds for this study. We used descriptive statistics to compare and contrast the characteristics of participants for whom the treatment indications from the NOF and IOF guidelines did not agree.

Results: Our sample was 85% female, 20% from minority backgrounds, and 60% ≥65 years of age. At baseline, 760 (28%) reported having a fracture after age 40, 576 (21%) had DXA-defined OP, 188 (7%) had low bone mass with a FRAX ≥20%, and 949 (35%) had FRAX scores above the UK age-based thresholds. Using NOF guidelines, OP therapy was indicated for 1,170 and not indicated for 1,541 participants. Using IOF guidelines, OP therapy was indicated for 1,395 and not indicated for 1,316 participants. At the 12-week survey, 38.2% and 35.8% of patients with NOF and IOF based indications for OP therapy reported medication use. Among patients without indications for OP therapy, 15.4% of NOF and 14.0% of IOF patients reported medication use. Two hundred and thirty-five participants who were indicated for therapy using IOF guidelines were not indicated for therapy using NOF guidelines, whereas 10 participants were not indicated for therapy using IOF guidelines but were indicated for therapy using NOF guidelines. These discordant participants differed on a few characteristics (Table).

Conclusion: We found significant overlap in treatment indications when using either NOF or IOF guidelines; however, for a small number of participants, the treatment indications differed based on guideline used. Although, both guidelines are based on cost-effectiveness of OP treatment, clinical judgment takes precedent for treating individuals, which may explain guideline discordance.

Table. Characteristics of Discordant Participants Based on IOF and NOF Treatment Guidelines

| | IOF Treatment Indicated/ NOF Treatment Not Indicated (n=236) | | IOF Treatment Not Indicated/ NOF Treatment Indicated (n=10) | | p-value |
|----------------------------|--|------|---|------|---------|
| | N/Mean | %/SD | N/Mean | %/SD | |
| Age Category | | | | | <0.001 |
| <60 | 110 | 46.8 | 0 | 0.0 | |
| 60-69 | 121 | 51.5 | 0 | 0.0 | |
| 70-79 | 4 | 1.7 | 2 | 20.0 | |
| 80+ | 0 | 0.0 | 8 | 80.0 | |
| FRAX Score | 12.5 | 3.8 | 22.7 | 3.1 | <0.001 |
| Public Insurance | 78 | 33.2 | 8 | 80.0 | 0.002 |

Healthcare costs of osteoporotic fracture in South Korea. Ha Young Kim^{*1}, Deog-Yoon Kim², Sunmee Jang³, Yong Chan Ha⁴, Tae Young Kim⁵. ¹Wonkwang University Sanbon Hospital, South Korea, ²Kyung Hee University, South Korea, ³Gachon University, South Korea, ⁴Chung-Ang University, South Korea, ⁵Hallym University, South Korea

Background: Although many studies have been reporting cost of osteoporotic fractures, study of cost of osteoporotic fracture in South Korea was rarely reported. The present study was to estimate healthcare costs of osteoporotic fractures including spine, hip, distal radius and humerus in Korean people over 50 years of age using national claim data from 2008 to 2011.

Methods: With using KNHI data, we identified all claims records of outpatient visits or hospital admissions of patients who were fifty years of age or older between January 1, 2008 and December 31, 2011. To identify osteoporosis-related fractures, we used certain ICD-10 codes and a patient age cut-off value of 50 years. The healthcare costs were included that acute phase costs accounting for medical care given immediately after osteoporotic fracture was sustained, which includes an emergency room visit and the expected costs due to further hospitalization and surgical procedures, physiotherapy sessions according to the site of the fracture, and outpatient visits after discharge over a one year.

Results: Total number of osteoporosis related fractures among those aged 50 years or older was increased 32% from 192,986 in 2008 to 254,794 in 2011. Total healthcare cost of osteoporotic fracture was increased 41.2% from 2008 to 2011 and portion of total healthcare cost was increased from 3.41% in 2008 to 3.52% in 2011. The average healthcare cost in each person was increased 6.2% from 2,823,324 won in 2008 to 3,013,620 won in 2011. The mean healthcare costs were highest in hip fracture, and followed by humerus fracture, spine fracture, and distal radius fractures.

Conclusion: This study presents increasing trend of total healthcare costs of osteoporotic fractures using the Korean National Health Insurance data and must be acknowledged as an important health problem in elderly population.

SU0301

Online Linkage of FRAX Fracture Risk Assessment to Management Guidance is Used by Clinical Practitioners. An Analysis of Access to National Osteoporosis Guideline Group Guidance in the UK (July 2013-June 2014). Eugene McCloskey^{*1}, Helena Johansson², Nicholas Harvey³, Juliet Compston⁴, John Kanis⁵. ¹University of Sheffield, United Kingdom, ²Centre for Metabolic Bone Diseases, University of Sheffield, United Kingdom, ³MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, ⁴Dept. of Medicine, Cambridge Biomedical Campus, United Kingdom

In several countries, the online output of FRAX is linked to independent country-specific guidelines (e.g. UK, Lebanon, and Finland) which facilitates treatment decisions according to local assessment guidelines. In the UK, guidance provided by the National Osteoporosis Guideline Group (www.shef.ac.uk/NOGG) was made available in 2008. The aim of this study was to determine the uptake of this facility by exploring website activity using GoogleAnalytics software. We have undertaken an analysis of FRAX and NOGG website usage for the year between 1st July 2013 and 30th June 2014 (GoogleAnalytic reports 8th August 2014). During this period, there was a total of 1,774,812 sessions (a user interaction with the website) on the FRAX website with 348,964 of these from UK-based users. Over the same time, 253,530 sessions were recorded on the NOGG website. Of the latter, two-thirds were returning

users, one-third new users and the vast majority (208,766, 82%) arose from users in the UK. The remainder of users were from other countries with the US comprising approximately half of the non-UK use, demonstrating that some users of FRAX in other countries make use of the NOGG guidance. Of the UK-sourced sessions, the majority were from England, but the session rate (adjusted for population) was highest for Scotland (Table 1). Almost all (95.7%) of the UK sessions arose from calculations being passed through from the FRAX tool (www.shef.ac.uk/FRAX) to the NOGG website, comprising FRAX calculations in patients without a BMD measurement (155K, 74.5%) or FRAX calculations with a BMD result (44K, 21.2%). A minority of sessions were conducted for other reasons (manual calculations, document downloads, FAQs etc.). National Health Service (NHS) sites were identified as the major source of visits to the NOGG website, comprising 64% of the identifiable visiting locations, but this is an underestimate as many sites from within the NHS are not classified as such. The study shows that the facilitated interaction between web based fracture risk assessment and clinical guidelines is widely accepted by clinical users. The approach could usefully be adopted in all countries for which a FRAX model is available.

Table 1. Usage of the NOGG website within the UK.

| Country | Total sessions | Population | Session rate/ 100, 000 |
|------------------|----------------|------------|---------------------------|
| England | 163,749 | 53012456 | 309 |
| Scotland | 32,740 | 5295000 | 618 |
| Wales | 7,677 | 3063456 | 251 |
| Northern Ireland | 4,586 | 1810863 | 253 |

SU0302

Osteoporosis Patients Assessed by Telemedicine: A Unique High Risk Cohort. Rachel Johnston^{*1}, Sarah Munce¹, Sonya Allin¹, Alexandra Pearce², Arlene Silverstein², Shelley Bouchard², Tarik Berekat¹, Gillian Hawker¹, Susan Jaglal¹, Sandra A. Kim³. ¹University of Toronto, Canada, ²Women's College Hospital, Canada, ³Women's College Hospital, University of Toronto, Canada

Background:

Evidence in support of telemedicine (TM) for rural populations for chronic conditions has been well described. However, there is limited literature on the role of TM in osteoporosis. In 2005, a multidisciplinary osteoporosis TM program, based on an existing outpatient program, was developed at Women's College Hospital (Toronto, Canada) in conjunction with the Ontario Telemedicine Network, to improve access to specialized osteoporosis care in remote areas of Ontario. The purpose of this study was to describe the demographic and clinical characteristics of osteoporosis patients assessed by TM and to compare them to those assessed in the outpatient clinic (clinic patients).

Methods:

A retrospective chart review of 57 TM patients and 880 clinic patients first seen between February 2013 to August 2014 was performed. T-tests and chi-square analyses were used to compare parametric data for the two groups, and Mann-Whitney U tests were used for non-parametric data.

Findings:

The mean age of TM and clinic patients were 64 and 63 years, respectively ($p=0.639$); patients were 90% female and 10% male in both cohorts. Forty-two percent of TM patients were at high-fracture risk as per the Canadian Association of Radiologists and Osteoporosis Canada tool, compared to 19% of clinic patients (Likelihood ratio (LR) 16.80, $p<0.0001$). Thirty-nine percent of TM patients had sustained a prior fragility fracture, compared to 20% of clinic patients (LR 10.07, $p=0.001$). TM patients were more likely to have co-morbidities (LR 6.946, $p=0.002$), more likely to be smokers (LR 3.49, $p=0.036$), and less likely to have completed post-secondary education (LR 9.71, $p=0.009$). TM patients were referred to allied health professionals more frequently: dietician (LR 12.646, $p=0.000$), pharmacist (LR 10.883, $p=0.000$), occupational therapist (LR 7.866, $p=0.004$), clinical nurse specialist (LR 7.074, $p=0.005$), and physical therapist (LR 1.913, $p=0.163$).

Conclusion:

Significant differences in baseline clinical and demographic characteristics were observed in TM patients, as compared to clinic patients. TM patients were observed to have a higher fracture risk profile, prevalence of fragility fractures, co-morbidities, and greater use of allied health resources. These data enable future research to better understand the financial and social costs associated with osteoporosis care delivered by TM.

Osteoporosis screening and treatment among Veterans with recent low-trauma fracture after implementation of a centralized, interdisciplinary Bone Health Service. Richard Lee^{*1}, Megan Pearson², Patricia Jenkins², Kenneth Lyles², Cathleen Colon-Emeric². ¹Duke University, USA, ²Durham VAMC, USA

Background: In the 2010 Office of the Inspector General report, less than 24 percent of Veterans received appropriate evaluation and/or treatment for osteoporosis within 6 months of an index fracture. While Fracture Liaison Services have been shown to significantly improve osteoporosis treatment, they require timely identification of recent fracture patients by a specialty team, which may be less feasible for patients residing in remote areas and small medical centers with lower fracture volume. **Objective:** To evaluate the effect of a regional post-fracture Bone Health Service through a single, centralized Veterans Affairs Medical Center (VAMC) on osteoporosis evaluation and management, among Veterans with recent low-trauma fracture at 5 VAMCs and affiliated outpatient clinics in North Carolina, Virginia, and West Virginia. **Method:** The Bone Health Service identified Veterans with potential osteoporotic fractures using an automated query of inpatient and outpatient encounters, based on ICD9 diagnosis codes (800-829). The medical record of an eligible patient was reviewed remotely by a bone health physician at the central VAMC, and a consult note was sent to the patient's primary care provider, through the electronic medical record, that specified guideline-based recommendations for further evaluation and management. In 3 of the 5 VAMCs, a bone health nurse liaison then coordinated the ordering and follow-up of laboratory and bone density assessment, osteoporosis education (e.g. medication administration and side effects, calcium and vitamin D supplementation, falls prevention, and exercise), and adherence follow-up via telephone. **Results:** Between Oct 2013 and Dec 2014, the Bone Health Service identified 482 patients with a low-trauma fracture who were not already on osteoporosis treatment. 113 (27%) consults recommended immediate bisphosphonate treatment and 316 (66%) recommended bone density assessments. Bisphosphonates were prescribed in 65 patients (50%) and bone density testing was ordered in 245 (78%) patients. A bone health nurse liaison significantly improved bisphosphonate ordering (from 39 to 70%) and BMD testing completion rates (from 42 to 69%), $P<0.01$. **Conclusion:** A centralized, interdisciplinary Bone Health Service, including a nurse liaison to coordinate care and provide patient education, significantly improved the rate of osteoporosis evaluation and treatment among patients with a recent low-trauma fracture.

Patients Undergoing Their First DXA Receive NOF Guideline Discordant Osteoporosis Pharmacotherapy. Stephanie Edmonds^{*1}, Yiyue Lou¹, Peter Cram², Douglas Roblin³, Nicole Wright⁴, Kenneth Saag⁴, Fredric Wolinsky¹. ¹University of Iowa, USA, ²University of Toronto, Canada, ³Georgia State University, USA, ⁴University of Alabama at Birmingham, USA

Purpose: To examine treatment concordance with NOF guidelines among healthcare providers ordering their patients' first DXA tests, and differences between physician and non-physician providers.

Methods: 7,749 participants were enrolled in a randomized control trial of adults 50 years old or older presenting for DXA at three US institutions from February 2012 to August 2014. Our analyses focused on 2,018 participants who were DXA naive and had never taken OP medications. Treatment indications were based on NOF guidelines using self-reported fracture history, DXA T-scores, and 10-year major osteoporotic and hip FRAX score. At 12 weeks post-DXA, we asked patients if their provider recommended a bone medication and used this data to determine concordance with NOF guidelines. We used Fisher's exact test for crude differences and random effects models to adjust for clustering, site, and percent of provider's patients undergoing their first DXA in concordant and discordant treatment between patients of physician vs. non-physician providers.

Results: The DXA scans for the 2,018 patients were ordered by 515 healthcare providers, with the numbers of providers split evenly among the three study sites. Most providers (78.5%) ordered DXAs for five or fewer DXA naive patients over the course of the study, and most providers were physicians (88.9%). Most patients were either concordantly not recommended for treatment per NOF guidelines (61.9%; Table 1, cell B), or concordantly recommended for treatment (9.1%, cell A). However, 26.9% of patients (cell D) were not recommended for treatment when NOF guidelines recommended pharmacotherapy, and 2.1% of patients (cell C) were recommended for treatment when they not indicated for treatment. Non-physicians were marginally more likely to be guideline concordant than physicians ($p=0.06$). After accounting for clustering of patients within provider, site, and percent of DXA naive patients, non-physicians were significantly more likely to provide guideline concordant recommendations ($p=0.049$).

Conclusion: We found that 29.0% of patients (cells C & D) undergoing their first DXA had providers whose decisions to recommend treatment were not concordant with NOF treatment guidelines. Because NOF guidelines are based on cost-effectiveness, individual treatment plans may be discordant. Further research needs to examine reasons why providers do not follow NOF guidelines and how to improve provider-training in OP-related care.

Table 1: Guideline Concordance of Treatment Recommendations among PAADR N Ordering Providers for Patients Undergoing First DXA Screening, n(%)

| N=2,018 | Treatment Recommended by Provider at 12 weeks | Treatment Not Recommended by Provider at 12 weeks | Total |
|----------------|---|---|---------------|
| NOF Concordant | CELL A 183 (9.1%) | CELL B 1,250 (61.9%) | 1,433 (71.0%) |
| NOF Discordant | CELL C 42 (2.1%) | CELL D 543 (26.9%) | 585 (29.0%) |
| Total | 225 (11.1%) | 1,793 (88.9%) | |

Physicians' Prescribing Considerations and Perceptions of Osteoporosis Patients' Compliance of Oral Bisphosphonate. Tao Gu¹, Debra Eisenberg², Jingbo Yu³. ¹HealthCore, USA, ²healthcore Inc, USA, ³Merck, USA

Objective: To assess physicians' prescribing considerations/preference for osteoporosis and perceptions of patients' compliance with oral bisphosphonates. Methods: This was an online survey of physicians identified in the HealthCore Integrated Research US claims database, as prescribing oral bisphosphonates to women aged ≥ 55 . The survey consisted of 22 questions gauging physicians' prescribing patterns and preferences for various types of osteoporosis medications, predicted patient persistence and compliance, and identified reasons for oral bisphosphonate non-compliance. Physician's demographic and clinical practice characteristics were also queried.

Results: Among the 158 physicians completing the survey, 77.7% were male, 67.5% were aged 45-60, 58.6% had 20 or more years in clinical practice, and on average had 263 (191) osteoporosis patients in clinic. Most were specialists from internal medicine (44.0%) or general practice (34.4%). Bone mineral density, long-term medication use, and a history of fracture were ranked as major considerations by 94.9%, 88.6%, 86.7% of physicians, respectively, when deciding whether to treat an osteoporosis patient. Most physicians expressed a preference of weekly or monthly oral bisphosphonates, for newly diagnosed patients (54.4% and 34.2%, respectively) and for long-term users of oral bisphosphonates (40.5% and 36.1%, respectively). Most physicians (23.4% always, 58.9% sometimes) incorporated a drug holiday into their prescribing patterns. Majority of physicians (N=131; 82.9%) estimated that patients would rate the acceptability of oral bisphosphonates as osteoporosis therapy as 5-8 on a 0-10-point scale. Although most physicians predicted that more than half of patients would comply with the prescribed medication for at least a year, 17.7% predicted that less than half of patients would be compliant in the first year, and 29.7% predicted the same result for compliance beyond 1 year. The major reasons for non-compliance of oral bisphosphonates were gastrointestinal intolerance (71.5%) and experience of medication side effects (69.6%).

Conclusions: US physicians who regularly prescribe oral bisphosphonates consider several relevant risk factors when prescribing and have a preference for weekly or monthly regimens. These physicians estimated a substantial minority of patients to be non-compliant of oral bisphosphonates, for reasons including primarily gastrointestinal intolerance and medication-related side effects.

Risk Factors that are Associated with Osteoporosis Treatment in High Risk Residents Living in Long Term Care (LTC) Homes? The Gaining Optimal Osteoporosis Assessments in Long-Term Care (GOAL) Study. George Ioannidis¹, Alexandra Papaioannou², Denis O'Donnell³, Courtney Kennedy², Hrishikesh Navare³, Lora Giangregorio⁴, Sharon Marr², Angela Cheung⁵, Richard Crilly⁶, Sid Feldman⁷, Ravi Jain⁸, Sophie Jamal⁵, Robert Josse⁵, Sadhana Prasad¹, Lehana Thabane¹, Jonathan Adachi¹. ¹McMaster University, Canada, ²McMaster University & GERAS Centre, Canada, ³Medical Pharmacies Group Limited, Canada, ⁴University of Waterloo, Canada, ⁵University of Toronto, Canada, ⁶University of Western Ontario, Canada, ⁷Baycrest Geriatric Health Care System, Canada, ⁸Osteoporosis Canada, Canada

Background: The GOAL initiative was developed to assess high risk residents and recommend appropriate pharmacotherapy to reduce fractures by utilizing multifaceted knowledge translation strategies.

Methods: GOAL is a delayed-entry stepped-wedge cluster randomized controlled trial in 50 long term care homes in Ontario. Information sources for the study included de-identified clinical/prescribing data from the database of a large pharmacy

provider that services all study homes, chart audits, and the Resident Assessment Instrument Minimum Data Set (RAI-MDS). These data were entered into a pharmacist's electronic decision support tool that generated individual management recommendations and calculated the number of high risk residents living in long term care. High risk was based on the osteoporosis guidelines and was defined as those individuals who had at least one spine/hip fracture, 2 or more non-hip/non-spine fractures, or were currently taking corticosteroids ($>7.5\text{mg/d}$ prednisone equivalent). Residents with previous diagnoses of osteoporosis were also considered at high risk. We determined whether there were associations among risk factors and osteoporosis treatment at baseline using the generalized estimating equations technique with an exchangeable correlation structure. The analysis was adjusted for risk factors and age. Values are expressed as odds ratios and 95% confidence intervals (CI).

Results: Of the 6862 residents from 50 long term care homes who were evaluated, a total of 2949 (43.0%) were considered at high risk. High risk residents had a mean age (SD) of 85.9 (9.0) years, weighed 64 (17.1) kg and were 158.5 (10) cm tall. Overall, osteoporosis medications were taken by 37% (1101/2949) of high risk residents. Adjusted odds ratios indicated that a diagnosis of osteoporosis (3.2; 95% CI: 2.5, 4.0), prior spine fracture (1.9; 95% CI: 1.5, 2.5), and those currently taking corticosteroids (1.9; 95% CI: 1.2, 3.0) were factors associated with the use of osteoporosis treatment.

Conclusion: A total of 43% of residents, living in long term care homes, are at high risk for fracture. Of these individuals, a diagnosis of osteoporosis, a prior spine fracture and those currently taking corticosteroids were characteristics that were found to be related with the use of osteoporosis treatment. Prior hip fractures did not appear to trigger the use of osteoporosis therapy.

Association between Teriparatide Treatment Duration and Fracture Incidence in Taiwan: Analysis Using the National Health Insurance Research Database.

Ding-Cheng CHAN¹, Cecile Hsiao-Chun CHANG², Lay-Chin LIM³, Alan BRNABIC⁴, Jau-Yih TSAU⁵, Russel BURGE⁶, Fei-Yuan HSIAO⁷, Ling JIN⁸, Sirel GURBUZ⁹, Rong-Sen YANG¹⁰.

¹Superintendent Office, Jin-Shan Branch, National Taiwan University Hospital, Taipei, Taiwan; ²Department of Geriatrics & Gerontology, & Department of Internal Medicine, National Taiwan University Hospital, Taipei, Taiwan, Taiwan, ³Eli Lilly & Company, Taipei, Taiwan, ⁴Department of Orthopaedics & Department of Geriatrics & Gerontology, National Taiwan University Hospital, Taipei, Taiwan, ⁵Real World Analytics, Eli Lilly Australia Pty Ltd, Sydney, Australia, ⁶School & Graduate Institute of Physical Therapy, National Taiwan University, Taipei, Taiwan, ⁷Global Health Outcomes, Eli Lilly & Company, Indianapolis, USA, ⁸Graduate Institute of Clinical Pharmacy, College of Medicine, National Taiwan University, Taipei, Taiwan, ⁹Lilly Research Laboratories, Eli Lilly & Company, Indianapolis, USA, ¹⁰Emerging Markets, Eli Lilly & Company, Indianapolis, USA, ¹⁰Department of Orthopaedics, National Taiwan University Hospital, Taipei, Taiwan

Purpose: Teriparatide is approved for treatment of men and women with osteoporosis at high risk of fracture. This study examined the associations between persistence and adherence with teriparatide treatment and the incidence of new-onset non-vertebral and hip fractures in Taiwanese patients with osteoporotic fractures.

Methods: This retrospective, cohort study included patients from Taiwan who were prescribed teriparatide 20 μg daily between 2005 and 2008, were ≥ 50 years, and were diagnosed with a prevalent fracture. Patient data were collected using the Taiwan National Health Insurance Research Database. All patients were followed for 24 months after index teriparatide prescription. Persistence was determined as the time from the start of treatment to the first 90-day gap between 2 teriparatide prescriptions. Patients were classified as persisting with teriparatide for ≤ 12 months or >12 months. Adherence was measured using a medication possession ratio (MPR), determined as the proportion of prescriptions filled over 24 months. The effect of persistence and adherence with teriparatide on fracture incidence was assessed using Kaplan-Meier and Cox proportional hazard models after adjusting for baseline demographics (age, sex, and previous fractures), concomitant medications for osteoporosis, other confounding medications, and comorbidities.

Results: A total of 4,624 patients were included in the study. Of these, 85.0% were female and 65.5% were ≥ 75 years old. Previous hip and vertebral fractures were reported in 20.3% and 87.7% of patients, respectively. Only 1 in 4 (24.9%) patients persisted with teriparatide for >12 months and only 1 in 3 (33.9%) had an MPR $>50\%$. Persistence with teriparatide for >12 months was associated with lower incidence of hip (hazard ratio [HR], 0.61 [95% confidence interval (CI), 0.40-0.93], $p=0.023$) and non-vertebral fractures (HR, 0.79 [95% CI, 0.63-0.99], $p=0.046$) when compared with patients persisting with teriparatide for ≤ 12 months. After adjusting for other covariates, high adherence to teriparatide (MPR $\geq 50\%$) was associated with lower incidence of hip (HR, 0.66 [95% CI, 0.46-0.96], $p=0.029$) and non-vertebral (HR, 0.81 [95% CI, 0.66-0.99], $p=0.038$) fractures compared with low adherence to teriparatide (MPR $\leq 50\%$).

Conclusions: Our results demonstrate that higher persistence and adherence to teriparatide are associated with reduced risk of hip and non-vertebral fractures in Taiwanese patients who had previous fractures.

SU0308

Characteristics of Patients Classified as Low or Moderate Risk Based on Fracture Risk Assessment (FRAX) After a Fragility Fracture. *Louis Rodrigue*¹, Francois Cabana¹, Marie-Claude Beaulieu¹, Nathalie Carrier², Joanna Sale³, Sophie Roux¹, Gilles Boire².* ¹Université de Sherbrooke, Canada, ²Centre hospitalier universitaire de Sherbrooke, Canada, ³St. Michael's Hospital, University of Toronto, Canada

BACKGROUND. Canadian osteoporosis (OP) guidelines recommend an individual's 10-year fragility fracture (FF) risk is determined as Low, Moderate or High by using either FRAX or Canadian Association of Radiologists and OP Canada (CAROC) tools. While treatment decisions for patients at High risk are quite clear, the management of patients at Moderate risk is subject to a number of risk modifiers, which complicate the decision-making process, particularly in the context of a recent FF. **OBJECTIVE.** To describe characteristics and outcomes of patients FRAX-classified as Low or Moderate risk despite a recent FF. **METHODS.** The OPTIMUS program is a program implemented at the Centre hospitalier universitaire de Sherbrooke (CHUS) fracture clinics to educate patients and to empower primary care physicians to diagnose and treat OP after a FF. Women and men over 50 were screened for incident FF, and 1410 patients with a FF were followed by phone calls for a mean period of 4 years. FRAX-BMI scores were calculated at time of the incident FF, defining High ($\geq 20\%$ for major or $\geq 3\%$ for hip FF), Moderate (10 to 20% for major and $< 3\%$ for hip FF), and Low ($< 10\%$ for major and $< 3\%$ for hip FF) risks. **RESULTS.** Prior to the incident FF, 64 patients had at least 1 previous FF (29 Low and 35 Moderate) and did not change risk category. Including the incident FF event increased FRAX scores for major FF from 0 to 18% [median (IQR): 7.1% (4.7-11)], but 337 (23.9%) patients remained classified as Low and 279 (19.8%) as Moderate risk. Recurrent FF occurred in 14.1 and 18.2/1000 patient-years in Low and Moderate risk categories (not significant, NS); mortality rates were 7.9 and 4.3/1000 patient-years in Low and Moderate risk categories, respectively (NS). In comparison, recurrent FF and mortality rates were 35.8 and 35.4/1000 patient-years in our High risk population. Relative to patients at Low risk, those at Moderate risk after a FF were older [mean age (years) 61 vs 55], more frequently female (94.2% vs 62.9%) and already treated for OP (22.3% vs 10.7%) ($p < 0.001$ for all). No FRAX item enabled us to identify those patients at Low or Moderate risk who sustained a recurrent FF over follow up (Low: 4.7%; Moderate: 6.2%). **CONCLUSIONS.** More than 40% of the patients with incident FF are still classified at Low or Moderate 10 year-risk after a FF, with similar rates of recurrent FF and mortality rates. Parameters not yet included in FRAX calculation are required to improve the prediction of recurrent FF risk in patients estimated at Low or Moderate risk after a FF.

Improving the Rate of Bone Mineral Density Testing After Fracture. *Sabita Challagulla*, Veronica Pizjak.* Baylor Scott & white, USA

This study describes a successful quality initiative to improve bone mineral density (BMD) testing compliance in a population of post fracture patients using a team consisting of the BSW Health Plan, Endocrinology, the Emergency department and the Radiology department.

Methods: A monthly list of Baylor Scott and White Health Plan (BSWHP) members age 65 and over presenting to the Emergency Department with fractures between October 2013 and May of 2014 was sent to the BSWHP and forwarded to Endocrinology. Letters were sent informing these patients that the BSWHP would order a bone density scan and explaining the importance of the scan to assess their risk of future fractures and diagnose osteoporosis. An endocrinologist then ordered DXA scans on patients whose scans had not already been obtained and radiology called the patients to schedule promptly. The PCP was sent a copy of the results and patients were sent another letter telling them to contact their PCP for the results to determine if therapy was needed. The percent of patients obtaining a BMD within one year of fracture was obtained after the intervention. The percent of the population obtaining DXA scans ordered by the team was compared to the percent of patients who had the BMD ordered by their primary provider during that time.

Results: The baseline value for BMD compliance for the system in 2014 was 14.9%. 197 patients were included in the quality initiative group and a total of 57 patients (29%) obtained DXA scans, 8 (14%) ordered by a PCP and the 49 (85%) ordered by the team. 32.8% of the patients contacted by Radiology initially agreed to have the DXA scheduled. The reasons given for declining were: patient did not want 11.5%, deceased 5.7% and nursing home 4.1%.

Conclusion: A team approach to post fracture BMD testing was able to increase the number of patients obtaining a BMD from the 8 obtained by their PCPs to 49 obtained by the team because scans were consistently ordered and the patients were contacted at least twice by team members emphasizing the importance of obtaining

the scans. We feel that enlarging this initiative to include lists of fractures from casting rooms for patients who do not go to the emergency room would enhance the collection of post fracture BMD data even more.

SU0310

Dietary potassium intake is beneficial to bone mineral density: Korean National Health and Nutrition Examination Survey 2008 - 2011 (KNHANES IV-V). *Jung Hee Kim*¹, Sung Hye Kong², A Ram Hong³, Jee Hyun Lee³, Kyoung Min Kim⁴, Sang Wan Kim⁴, Seong Yeon Kim⁴, Chan Soo Shin³.*

¹Seoul National University College of Medicine, South Korea, ²Department of Internal Medicine, Seoul National University Hospital, South Korea, ³Department of Internal Medicine, Seoul National University Hospital, South Korea, ⁴Department of Internal Medicine Seoul National University Hospital, South Korea

Potassium intake has been suggested to be beneficial to bone through the neutralization of the endogenous metabolic acid and the reduction urinary calcium loss. We aimed to evaluate the association between daily potassium intake and the bone mineral density (BMD) in Korean population.

We included 3208 men aged over 50 years and 4067 postmenopausal women from the 2008 - 2011 Korea National Health and Nutrition Examination Survey (KNHANES). Subjects were divided into tertiles according to dietary potassium intake (< 2443 , $2443-3616$, > 3616 mg/day for men, < 1833 , $1833 - 2888$, > 2888 mg/day for women). Lumbar spine, total hip, and femur neck BMDs were measured by dual energy X-ray absorptiometry.

Mean age was 63.88 ± 8.66 , and BMI was 23.98 ± 3.08 . In correlation analyses, dietary potassium intake was not associated with lumbar spine BMD, but positively correlated with femur neck and total hip BMDs in men. In women, dietary potassium intake was positively correlated with lumbar spine, femur neck and total hip BMDs. In men, total hip (0.913 ± 0.004 for 1st, 0.926 ± 0.003 for 2nd, 0.927 ± 0.004 or 3rd tertile, p -trend = 0.016) and femur neck BMDs (0.734 ± 0.001 , 0.746 ± 0.003 , 0.751 ± 0.004 , p -trend = 0.004) were highest in the 3rd tertile of dietary potassium intake among groups after adjusting for age, body mass index, serum creatinine, 25[OH]vitamin-D level, total daily food intake, calcium intake, and physical activity. Postmenopausal women in the highest tertile of potassium intake had significantly higher lumbar spine (0.791 ± 0.003 , 0.794 ± 0.003 , 0.806 ± 0.003 across the tertiles), total hip (0.764 ± 0.002 , 0.774 ± 0.003 , 0.781 ± 0.003 across the tertiles) and femur neck BMDs (0.614 ± 0.002 , 0.621 ± 0.002 , 0.630 ± 0.003 across the tertiles).

Dietary potassium intake was positively associated with BMD in men over 50 years old and postmenopausal women, suggesting the beneficial effect of dietary potassium intake on bone health.

Effect of Young Coconut Juice Supplementation on Bone Metabolism in Ovariectomized Rats. *Hiroshi Matsushita*¹, Akira Minami², Yuriko Ohyama³, Hiroaki Kanazawa⁴, Takashi Suzuki², Sanan Subhadhirasakul⁵, Kazushi Watanabe³, Akihiko Wakatsuki³.* ¹Aichi Medical University, Japan, ²Department of Biochemistry, School of Pharmaceutical Sciences, University of Shizuoka, Japan, ³Department of Obstetrics & Gynecology, School of Medicine, Aichi Medical University, Japan, ⁴Department of Functional Anatomy, School of Nursing, University of Shizuoka, Japan, ⁵Department of Pharmacognosy & Pharmaceutical Botany, Faculty of Pharmaceutical Sciences, Prince of Songkla University, Thailand

Estrogen deficiency after menopause is strongly associated with rapid resorption and loss of bone density in women. Hormone replacement therapy (HRT) has been regarded as one treatment option for the prevention of postmenopausal bone loss and fracture. However, whether the benefits associated with HRT outweigh the risks remains controversial, which has heightened interest in dietary and lifestyle factors that may minimize postmenopausal bone loss. *Cocos nucifera* Linn. (Arecaceae), also known as coconut, has many uses in traditional medicine. Young coconut juice (YJC), defined as the juice extracted from the fruit of a 6-month-old coconut, has traditionally been consumed by women in Thailand to alleviate symptoms associated with menopause. The aim of this study was to determine the effects of YJC on bone metabolism in ovariectomized rats. Ten-week-old female Wistar rats were randomized to the following 4 groups: Baseline, Sham, OVX, and OVX/YJC ($n = 8-10$ per group). Rats in the Baseline group were sacrificed immediately, and those in the other groups were subjected to either sham operation (Sham) or bilateral ovariectomy (OVX and OVX/YJC). The rats in the OVX/YJC group were administered YJC at a dose of 50 mL/kg body weight (BW)/day for 6 weeks in experiment 1, and 75 mL/kg BW/day for 12 weeks in experiment 2. After supplementation of YJC, the rats were sacrificed, and indices of bone mass and bone histomorphometry were measured. In experiment 1, the bone mineral content and bone mineral density of the femur were significantly higher in the OVX/YJC group than in the OVX group ($p < 0.05$, respectively). The OVX/YJC group showed significantly higher measurements for mineralizing surface,

mineral apposition rate, and bone formation rate in the proximal tibial metaphyseal cancellous bone than the OVX group ($p < 0.05$, respectively). In contrast, there were no significant differences in parameters examined between the OVX and OVX/YCJ groups in experiment 2. These findings suggest that YCJ supplementation may be helpful in slowing the bone loss observed following menopause, but it may not be able to prevent the development of osteoporosis, even when supplemented at higher doses.

Disclosures: Hiroshi Matsushita, None.

SU0312

Long-term green tea polyphenols supplementation improves bone micro-structure of middle-aged ovariectomized rats: a dose-response study. Chwan-Li Shen^{*1}, Xiao Song², Jia-Sheng Wang², Kylie Corry³, Jiliang Li³. ¹Texas Tech University Health Sciences Center, USA, ²University of Georgia, USA, ³Indiana University-Purdue University Indianapolis, USA

Our previous studies have shown that the osteo-protective effects of green tea polyphenols (GTP) in middle-aged female rats, because of GTP's antioxidant capacity. The project is further to evaluate bone microstructure properties in middle-aged OVX rats supplemented with different dosages of GTP in drinking water. 182 SD female rats were sham (n=39) or ovariectomy (OVX, n=143). Both sham and OVX-control animals receiving no GTP were assigned for sample collection at baseline, 3, and 6 months. The remaining OVX animals were randomized into 0.15%, 0.5%, 1%, and 1.5% (wt/vol) GTP for 3 and 6 months. Bone microstructure was assessed by static and dynamic histomorphometric analysis in proximal tibia and endocortical bone of tibia, respectively. At 3 months, trabecular mineralizing surface/bone surface (MS/BS) and bone formation rate/bone surface (BFR/BS) were elevated in the OVX-control animals compared to the Sham-control animals, resulting in a decrease in trabecular bone volume (BV/TV). Except for the OVX+0.15% GTP group, GTP supplementation suppressed the OVX-induced increase in trabecular MS/BS and BFR/BS relative to the OVX-control. Inhibitory effects of GTP supplementation on the OVX-treated animals was also observed in trabecular bone resorption parameters, such as osteoclast surface/bone surface (OCs/BS), number osteoclasts/bone perimeter (N.Oc/B.Pm), and number osteoclasts/osteoclast perimeter (N.Oc/Oc.Pm). Thus, an increase in BV/TV among GTP supplemented groups was the result of suppression of bone formation and resorption. Both periosteal and endocortical BFR were higher in the OVX-control group compared to the Sham-control group. At 3 months, BV/TV data in OVX+1% GTP and OVX+GTP 1.5% groups were higher than OVX-control, while periosteal mineral apposition rate (MAR) and BFR/BS (OVX+0.5% GTP, OVX+1% GTP, and OVX+1.5% GTP), endocortical MS/BS (OVX+1% GTP and OVX+1.5% GTP), endocortical MAR and BFR (OVX+0.5% GTP, OVX+1% GTP, and OVX+1.5% GTP) were all lower relative to the OVX-control group. The similar impacts of GTP on both trabecular and cortical parameters were also observed at 6 months. This study demonstrates that the osteo-protective benefits of GTP supplementation in OVX-treated animals were mostly observed at high GTP doses (1% and 1.5%), and not at low doses (0.15% and 0.5%); and there is no significant difference in most bone parameters among the OVX-control, OVX+0.15% GTP, and OVX+0.5% GTP groups. Supported by NIH/NCCAM AT006691.

Disclosures: Chwan-Li Shen, None.

SU0313

Nutritional status of calcium and other bone-related nutrients in Type 2 Diabetes Mellitus patients. Sahoko Sekiguchi-Ueda^{*1}, Eri Ninomiya², Eisuke Tomatsu³, Mizuho Ando³, Izumi Hiratsuka³, Yasumasa Yoshino³, Takeshi Takavanagi³, Avako Kakita³, Megumi Shibata³, Masaki Makino³, Akemi Ito², Tadashi Kinoshita², Kazuhiro Uenishi⁴, Atsushi Suzuki³. ¹Fujita Health University, Division of Endocrinology, Japan, ²Food & Nutrition Service, Fujita Health University Hospital, Japan, ³Division of Endocrinology & Metabolism, Department of Internal Medicine, Fujita Health University, Japan, ⁴Laboratory of Physiological Nutrition, Kagawa Nutrition University, Japan

Background: Enough daily intakes of nutrients including Ca and vitamin D are considered to be necessary for both prevention and treatment of osteoporosis. Traditional Japanese foods seem to be good for health, but seems to contain less milk products compared with occidental ones. Type 2 Diabetes Mellitus patients (T2DM patients) commonly reduce their calorie intake in order to control their blood glucose level. On the other hand, the strict control of food intake leads to the reduction of their Ca intake, which could deteriorate bone strength in T2DM patients. The aim of this study is to estimate nutritional status of Ca and other nutrients which could affect bone and Ca metabolism in T2DM patients.

Subjects and Methods: T2DM patients of Fujita Health University Hospital were recruited (n=103, M/F=56/47, age 61.0 ± 13.4 years old). We estimate intake of nutrients including Ca, vitamin D and other nutrients by simple food frequency questionnaire by Uenishi et al (J Nutr Sci Vitaminol 2008). Data are expressed as median with interquartile range.

Results: Median total energy in T2DM patients was 1816 kcal/day (1686-1945). Their daily intake of Ca, vitamin D and vitamin K were 451 mg (416-485), 10.2 µg (9.6-10.7), and 204 µg (172-235), respectively. Only 14.6 % of study subjects were found to take more than 600 mg/day Ca. Protein and salt intake were 62.7 g/day (59-

66.3) and 10.6 g/day (10.2-11), respectively. **Discussion:** Our findings suggest that Japanese T2DM patients seem to restrict well their calorie intake for the prevention of their overweight and metabolic disorder. On the contrary, their daily Ca intake was insufficient, and their median Ca intake was below those in non-diabetic Japanese population. The most of them could take vitamin D and K more than recommended adequate intake (vitamin D, 5.5 µg/day and vitamin K, 65-75µg/day), but the vitamin D intake did not reach the level for the prevention and treatment of osteoporosis.

Conclusion: It seems likely that more Ca and vitamin D intake or supplementation should be recommended to Japanese T2DM patients as well as diabetic diet therapy.

Soluble Corn Fiber Increases Bone-Calcium Retention in Postmenopausal Women in a Dose-Dependent Manner. Steven Jakeman^{*1}, Courtney Henry², Berdine Martin³, George McCabe², Linda McCabe², George Jackson⁴, Munro Peacock⁵, Connie Weaver³. ¹Department of Food Science, Purdue University, USA, ²Department of Statistics, Purdue University, USA, ³Department of Nutrition Science, Purdue University, USA, ⁴Department of Physics & Astronomy, Purdue University, USA, ⁵Department of Medicine, Indiana University, USA

Soluble corn fiber (SCF) significantly improves calcium absorption in adolescents and bone strength and architecture in rodent models. In this study, we aimed to see if PROMITOR® SCF 85, which provides 85% dietary fiber, would also benefit bone retention in postmenopausal women. We used novel technology to determine bone calcium retention—by measuring urinary appearance of ⁴¹Ca from pre-labeled bone—to rapidly and sensitively evaluate the effectiveness of SCF to reduce bone loss. A randomized-order, crossover, double-blinded trial was performed in 14 healthy postmenopausal women to compare 0 g/d, 10 g/d, and 20 g/d fiber from SCF for 50 days. A dose-response effect was demonstrated with 10 g/d SCF and 20 g/d SCF improving bone retention by 4.8% (P = 0.013) and 7% (P = 0.007) respectively. A significant increase in bone-specific alkaline phosphatase was detected between 0 g/d SCF and 20 g/d SCF levels (8%, P = 0.035). There was no change in N-terminal telopeptide and osteocalcin. Daily PROMITOR® SCF consumption significantly increased bone calcium retention in postmenopausal women, improving bone balance by an estimated 50 mg/d, or 2.5% total body bone mineral content per year if the effect persists.

Low bone mass is associated with low vitamin D levels in young healthy Korean adults. Hee-Jeong Choi^{*1}, Byeong Yeon Yu², Han Jin Oh³, Bom Taek Kim⁴, Hyuk Jung Kweon⁵. ¹Department of Family Medicine, Eulji University School of Medicine, South Korea, ²Department of Family Medicine, Konyang University School of Medicine, Korea, democratic people's republic of, ³Department of Family Medicine, Hansoo University, Korea, democratic people's republic of, ⁴Department of Family Medicine, Ajou University School of Medicine, Korea, democratic people's republic of, ⁵Department of Family Medicine, Konkuk University School of Medicine, Korea, democratic people's republic of

Background Although osteoporosis treatment involves the use of pharmacologic agents, it must be considered as the main strategies for prevention of osteoporosis consist of maximizing peak bone mass (PBM) and minimizing the rate of bone loss. Lifestyle habits including nutrition and physical activity during adolescence and early adulthood contribute up to 20% of the observed variation in the attainment of PBM as well as to the rate of bone loss later in life. The aims of this study were to identify the determinants of bone mineral density (BMD) in young healthy adults. **Methods** Data was gathered from 2,673 males and females aged 20 to 49 years after excluding subjects who had history of cancer including breast cancer; taking medications for diabetes; menopause or hysterectomy. Lumbar spinal BMD (L1-4) was measured by dual-energy X-ray absorptiometry. Multivariate linear regression analysis was done to identify the major determinants of the spinal BMD. **Results** The mean age of the 947 males and 1,726 females were 40.6 years and 38.9.6 years, respectively. The mean spinal BMD was 1.178±0.142 g/cm² in males and 1.165±0.128 g/cm² in females. Spinal BMD was correlated with height, weight, eGFR, alkaline phosphatase (ALP), 25(OH)D and insulin levels after adjusting for age, gender, and body mass index (BMI) (P<0.05). In the linear regression models, 25(OH)D levels had significant association with spinal BMD after adjusting for age, gender, BMI, alcohol, smoking, exercise, eGFR, ALP, and insulin levels. Also, gender, BMI, eGFR, ALP, and insulin levels were significantly associated with the spinal BMD. The odds ratio of low BMD (T-score <-1.0) in vitamin D deficiency group (25(OH)D <10 ng/mL) was 1.39 (95% CI, 1.084-1.790, P=0.01) after adjustment for age, gender and BMI. **Conclusions** In young healthy adult males and females, 25(OH)D levels were significantly associated with spinal BMD. These results suggest that the prevention of vitamin D deficiency in young adults must be considered as the main strategies for prevention of osteoporosis.

Peptide analysis of racially linked vitamin D binding protein isoforms in older men. Carrie Nielson^{*1}, Jon Jacobs², Jodi Lapidus¹, Joseph Zmuda³, Tujin Shi², Yuqian Gao², Richard Smith², Eric Orwoll¹. ¹Oregon Health & Science University, USA, ²Pacific Northwest National Laboratory, USA, ³University of Pittsburgh, USA

Introduction: Vitamin D binding protein (DBP) affects circulating concentrations of free and bioavailable 25OHD, which may be more relevant to skeletal outcomes than total 25OHD concentration. DBP has 3 major genetic isoforms whose frequencies differ by race. That is, GC-1F alleles are more common in those of African descent than are GC-1S and GC-2 isoforms, and this difference may contribute to racial differences in DBP detection in serum. In particular, in several studies a monoclonal ELISA has demonstrated lower DBP concentrations in GC-1F individuals, while polyclonal assays have not. We sought to determine the concentrations of DBP peptides representing both non-variant regions of DBP and genetically variant regions.

Methods: In men from the Osteoporotic Fractures in Men (MrOS) study, we determined the relevant GC-genotypes, rs4588 (Thr436Lys) and rs7041 (Asp432Glu), and selected a total of 116 men to represent each of the six GC diplotypes. Selected reaction monitoring (SRM) MS based assays were used to analyze 5 variant DBP peptides from the genetically variant region and 3 non-variant DBP peptides. Associations between GC diplotype and abundance of each peptide were tested by ANOVA, followed by post-hoc pairwise tests.

Results: The serum concentration of nonvariant peptides was similar in all genotypes, including GC-1F. The concentration of one of the nonvariant peptides (THLPEVFLSK, Figure 1 center panel), was slightly lower in participants with GC-22 than in those with 1F1F and 1F1S (both pairwise $p \leq 0.01$). The GC-1F variant peptide was detected in all men whose GC genotypes predicted the presence of the GC-1F isoform (Figure 2).

Conclusions: In contrast with previous reports of low circulating DBP in GC-1F carriers, DBP peptides did not circulate at lower serum concentration in men with GC-1F genotypes than in men with other genotypes. These results support the conclusion that DBP assays yielding lower concentrations of serum DBP in GC-1F individuals are more likely due to lack sensitivity to GC-1F variant proteins than to be a reflection of truly lower DBP concentration.

Figure 1. SRM results for three non-variant peptides per GC genotype (n=116). The distribution of nonvariant peptides showed similar peptide abundance for all genotypes, including for GC-1F. For only one of the peptides (THLPEVFLSK, right panel), participants with GC-22 had lower abundance than 1F1F and 1F1S ($p \leq 0.01$). Box and whisker plots show the 25th and 75th percentiles and median. Whiskers represent 1.5 times the interquartile range.

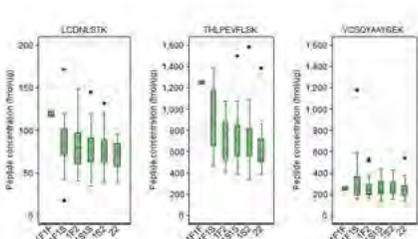

Figure 1

Figure 2. Peptide concentration by GC genotype (x axis) for GC-1F (left), GC-1S (middle), and GC-2 (right) variant peptide sequences. E416D and 1420K substitutions, which define the GC categories are highlighted in each peptide sequence.

Relationships of resting energy expenditure and bone metabolism in postmenopausal Japanese women with type 2 diabetes: 6-month follow-up with vitamin D supplementation. Makiko Ogata^{*1}, Risa Ide², Miho Takizawa², Naoko Iwasaki², Yasuko Uchigata². ¹Tokyo Women's Medical University, Japan, ²Diabetes Center, Tokyo Women's Medical University, Japan

Objective: Bone and glucose metabolisms have a close correlation. Interestingly, despite a high bone mineral density in most type 2 diabetes (T2D) patients, the fracture risk is particularly high in this population. Especially, postmenopausal women have high risks of fracture; among them, the risk is higher in T2D patients. Further, although the resting energy expenditure (REE) increases after menopause, it conversely decreases in women with T2D, indicating that the pathophysiology of bone metabolism in postmenopausal women differs between patients with and without T2D. Various biomarkers for bone metabolism have been reported to correlate with the fracture risk in T2D. This study examined the relationships of REE, respiratory quotient (RQ), and diabetic neuropathy with bone metabolism in postmenopausal Japanese women with T2D in a stable state of diabetic therapy. **Methods:** Postmenopausal women with T2D (n=46) who were not taking any supplements and had no other severe disease except hypertension and dyslipidemia, and without proteinuria and severe obesity (body mass index <30 kg/m²) were included. The procollagen type 1 N-terminal propeptide (PINP) and carboxy-terminal collagen crosslinks-1 (CTX-1) levels were evaluated, along with intact parathyroid hormone, 25-hydroxyvitamin D (25[OH]D), urine microalbumin, motor and sensory nerve conduction velocities, R-R interval, body composition, REE, RQ, and bone mineral density at the non-dominant distal radius. After the first examination, 14 patients with low 25(OH)D were administered alphacalcidol. All patients were reexamined after 6 months. **Results:** The mean T-score was low, with high variance (1.7 ~ 1.6; Mean ~ SD), and 18 patients (39%) met the osteoporosis criteria. At baseline, REE positively correlated with body mass index, serum calcium, mean glycated hemoglobin (prior 6 months, 7.6 ~ 1.2%), and the serum PINP/CTX-1 ratio. RQ positively correlated with serum 25(OH)D only. The motor and sensory nerve conduction velocities did not correlate with the bone markers. At the 6-month follow-up, the changes in REE and PINP/CTX-1 were found to positively correlate. The change in RQ did not correlate with 25(OH)D after vitamin D supplementation, but correlated with the mean glycated hemoglobin in the prior 6 months. **Conclusion:** REE and RQ are useful indices of basal metabolic function and bone metabolism in postmenopausal Japanese women with T2D. Calculating REE may help in the treatment of osteoporosis in such women.

The Association of Vitamin D with Femoral Neck Strength: an Additional Evidence of Vitamin D on Bone Health. HyeonMok Kim*, Seung Hun Lee, JinJu Kim, Kyeong-Hye Lim, Seong Hee Ahn, Beom-Jun Kim, Jae Suk Chang, Jung-Min Koh, Asan Medical Center, University of Ulsan College of Medicine, South Korea

Although bone mineral density (BMD) is a strong predictor of fracture risk, additional parameters, such as bone strength, are needed to predict future fracture risk because of the low sensitivity of BMD for predicting the fracture risk. We aimed to investigate the association of vitamin D with femoral neck (FN) strength in a representative community cohort in South Korea. This cross-sectional study was based on data acquired in the Fourth Korean National Health and Nutrition Examination Surveys (KNHANES IV), which were conducted from 2007 to 2009. This study included 1,209 Koreans (586 men and 623 women) aged 50 years or older. We calculated composite indices of FN strength, such as indices of compression strength (CSI), bending strength (BSI), and impact strength (ISI), by combining BMD, body weight, and height with the femoral axis length and width which were measured by dual-energy X-ray absorptiometry. Multiple regression analysis demonstrated that serum 25-hydroxyvitamin D [25(OH)D] levels were associated with CSI, BSI, and ISI in both genders. When women were categorized into four quartiles of 25(OH)D, FN BMD and composite indices, except for BSI, significantly increased from the lowest (Q1) to the highest quartile (Q4) (P for trend = 0.001–0.004). In contrast, there is no significant association of quartiles with composite indices in men. When women were divided into two groups according to their serum 25(OH)D levels, the composite indices as well as the FN BMD were markedly higher in subjects with higher 25(OH)D levels (more than 51.5 nmol/L). These findings provide the first clinical evidence that high serum 25(OH)D levels exhibit higher composite indices of FN strength in a dose-dependent manner, especially in women.

The effectiveness of Siriraj orthopaedic vitamin D2 supplementation protocol to achieve sufficient vitamin D level. Aasis Unnanuntana, Pojchong Chotiyarnwong*, Wachirapan Narktang, Siriraj Hospital, Thailand

Objective: The objective of this study was to assess the effectiveness of our vitamin D2 supplementation protocol to achieve normal vitamin D status in orthopaedic patients who presented at the metabolic bone disease clinic. **Methods:** After our institutional review board approval, we retrospectively reviewed medical records of patients enrolled in the metabolic bone disease clinic. We included all patients who aged more than 18 years and had serum 25-hydroxyvitamin D (25(OH)D) levels available at both baseline and post-treatment visits. Exclusion criteria were patients who received vitamin D3 supplementation or took calcium formulation that contained some amount of vitamin D; those with medical problems that affect vitamin D absorption and metabolism such as short bowel syndrome, chronic kidney disease, granulomatous disorders; and patients who received anticonvulsants, rifampicin, cholestyramine, or antiretroviral drug. The protocol used to correct low vitamin D level was showed in table 1. In general, serum 25(OH)D level was repeated at an approximately 3 months after treatment. The goal is to keep serum 25(OH)D level in a range of 30-50 ng/mL. **Results:** From a total of 513 patients, 243 patients passed the inclusion/exclusion criteria and were analyzed for this study. Most patients were female with an average age of 72 years. The prevalence of hypovitaminosis D (25(OH)D <30 ng/mL) was approximately 60%. After applying our vitamin D2 supplementation protocol, 187 patients (77.0%) had serum 25(OH)D level > 30 ng/mL. There were 4 patients who had 25(OH)D level >50 ng/ml after treatment; however, these patients were asymptomatic. Fifty six patients (23.0%) still had 25(OH)D level < 30 ng/ml at the latest visit (Table 2). If 20 ng/mL was used as a cut-off value for adequate vitamin D status, our protocol was able to restore serum vitamin D up to 98.4% of the patients. **Conclusion:** Low serum vitamin D status can be treated by using both D2 and D3 formulation. This study showed that our vitamin D2 supplementation protocol was able to restore 25(OH)D levels to more than 20 and 30 ng/mL in 98.4% and 77% of the patients, respectively. Given the high prevalence of hypovitaminosis D, the importance of evaluation and subsequent treatment is necessary to prevent complications that are arisen from low vitamin D levels. Vitamin D2 is cheap, easy to use and can be administered safely by using our protocol.

Table 1. Siriraj vitamin D2 supplementation protocol to achieve normal vitamin D level

| Baseline serum 25-hydroxyvitamin D level* (ng/mL) | Dosage of vitamin D2 supplementation (International Unit, IU) |
|---|---|
| < 20 ng/mL | 60,000 IU/week |
| 20-30 ng/mL | 40,000 IU/week |
| 30-40 ng/mL | 20,000 IU/week |
| >40 ng/mL | No additional D supplementation |

The baseline serum 25-hydroxyvitamin D level was defined as serum vitamin D level without any other vitamin D supplementation.

table 1

Table 2. Serum vitamin D levels after treatment using Siriraj vitamin D2 supplementation protocol

| Serum vitamin D level after treatment | Number of patients (%) |
|---------------------------------------|------------------------|
| <20 ng/mL | 4 (1.6) |
| 20-30 ng/mL | 52 (21.4) |
| 30-50 ng/mL | 183 (75.3) |
| >50 ng/mL | 4 (1.6) |

Vitamin D Status, Bone Health and Depressive Symptoms in Young Women. Emma Callegari*¹, Nicola Reavley¹, Suzanne M. Garland², Alexandra Gorelik³, John D. Wark⁴. ¹The University of Melbourne, Australia, ²The University of Melbourne. Royal Women's Hospital, Murdoch Childrens Research Institute, Australia, ³Melbourne Epi Centre, Royal Melbourne Hospital, Australia, ⁴The University of Melbourne, Bone & Mineral Medicine, Royal Melbourne Hospital, Australia

Vitamin D deficiency has been associated with poor musculoskeletal and mental health outcomes but the interplay between these indices remains uncertain. The Safe-D study is a comprehensive study of vitamin D status and a range of clinical, behavioural and lifestyle factors in young women, an understudied demographic. The aim of this analysis was to investigate the associations between serum 25-hydroxyvitamin D (25OHD), bone mineral density (BMD) and depressive symptoms in young women. Female participants aged 16-25 years living in Victoria, Australia, were recruited through Facebook. Participants completed an extensive online health survey and attended a site visit. Dual-energy X-ray absorptiometry was used to measure BMD at the lumbar spine, total hip and femoral neck. Osteopenia and osteoporosis were defined using WHO criteria (Z-score was used in participants aged <20). Serum 25OHD was measured using liquid chromatography tandem mass spectrometry (LC-MS/MS). The Patient Health Questionnaire (PHQ-9) was used to measure depressive symptoms. To date, 197 participants have been fully evaluated. The mean serum (± SD) 25OHD concentration was 74.3±28.8 nmol/L: 41 (20.8%) participants were vitamin D-deficient (25OHD <50 nmol/L). One hundred and twenty-eight (66%) participants had normal BMD; 59 (30%) had osteopenia and 8 (4%) had osteoporosis at one or more skeletal sites. Serum 25OHD of <50 nmol/L was significantly associated with a diagnosis of osteopenia or osteoporosis when compared to 50 nmol/L or above (39% vs. 27%, p=0.041). There was no association found between serum 25OHD and depressive symptoms nor between BMD and depressive symptoms. Serum 25OHD was associated with BMD at the total hip (β=0.0050, 95% CI 0.0003-0.0096, p=0.036) and femoral neck (β=0.0046, 95% CI 0.0004-0.0087, p=0.033) and approached significance at the lumbar spine (β=0.0036, 95% CI -0.00003-0.0073, p=0.052) in participants with serum 25OHD <50 nmol/L. This association remained significant at the total hip (p=0.035) and femoral neck (p=0.028) after adjusting for body mass index, years since menarche, PHQ score and melanin density at the upper, inner arm. Analysis revealed significant associations between vitamin D deficiency and BMD in vitamin D-deficient young women. The Safe-D study will recruit up to 500 participants to further investigate the associations between vitamin D status, musculoskeletal health and mental health in young women, aiming to optimise their health and wellbeing.

Leptin is a Key Regulator of Bone Turnover and Bone Density in Obese Adults. Amy L Evans¹, Fatma Gossiel¹, Margaret A Paggioli¹, Richard Eastell¹, Jennifer Walsh*². ¹Academic Unit of Bone Metabolism, University of Sheffield, United Kingdom, ²University of Sheffield, United Kingdom

Background: Obese (OB) adults have greater BMD and more favourable bone microarchitecture than normal weight (NW) adults and the difference is greater in older adults. The mechanisms of association of obesity with BMD and microarchitecture are unclear. We aimed to identify relationships between fat distribution, biochemical factors, BMD and bone microstructure.

Methods: 200 healthy men and women age 25-40 or 55-75 years were recruited in individually-matched OB (BMI ≥ 30) and NW (BMI 18.5-24.9) pairs. Whole body, total hip and lumbar spine aBMD were determined by DXA. vBMD and microarchitecture at the radius and tibia were determined by HR-pQCT. Total, trunk, android, gynoid and appendicular fat masses (FM) were determined from whole body DXA. Abdominal subcutaneous (SAT) and visceral (VAT) fat volumes were determined by computed tomography. Bone turnover and regulation was assessed by CTX, PINP, OC, bone ALP, OPG and sclerostin. Potential mechanistic mediators assessed were: PTH, 25OHD, calcium, albumin, oestradiol (totE2), SHBG, free E2 (fE2), bioavailable E2 (bioE2), glucose, insulin, leptin and adiponectin.

Results: All measures of adiposity were higher in OB than NW ($p < 0.001$). Age did not affect BMI or total FM. OB had lower CTX, PINP and OC than NW (all $p < 0.01$). CTX predicted aBMD and vBMD. OB had higher leptin ($p < 0.001$), PTH ($p < 0.05$), glucose ($p < 0.001$) and insulin ($p < 0.001$), and lower adiponectin ($p < 0.001$), IGF-1 ($p < 0.05$), 25OHD ($p < 0.001$), SHBG ($p < 0.001$) and albumin ($p < 0.01$) than NW. TotE2, fE2 or bioE2, calcium, bone ALP, OPG or sclerostin did not differ between OB and NW. BMI had a greater effect on leptin, totE2 and fE2 in older than younger adults ($p < 0.05$). aBMD was best predicted by SAT, gynoid and appendicular FM; vBMD was best predicted by SAT, android and trunk FM; and microarchitecture was best predicted by SAT. SAT negatively predicted CTX ($p < 0.001$). When leptin was added to this model, SAT no longer predicted, but leptin negatively predicted CTX ($p < 0.05$). When leptin and totE2 were added, SAT no longer predicted, but both leptin ($p < 0.05$) and totE2 ($p < 0.01$) negatively predicted CTX.

Discussion: SAT is the key determinant of lower resorption in obese adults, probably acting through greater leptin production. The greater effect of BMI on leptin in older adults may contribute to a greater effect of obesity on BMD and microstructure in older adulthood.

Absence of hypophosphatasia mutations in atypical femur fractures. Timothy Bhattacharyya*¹, Smita Jha², Nicholas Laucis¹, Hongying Wang³, Daniel Kastner³, Elaine Remmers³. ¹NIH/NIAMS, USA, ²NIH/NICHD, USA, ³NIH/NHGRI, USA

Case reports have linked adult hypophosphatasia as a possible cause of atypical femur fractures (AFF) associated with bisphosphonate use. Hypophosphatasia is caused by a mutation in the tissue non-specific alkaline phosphatase (TNSALP) gene resulting in low alkaline phosphatase activity and a buildup in inorganic pyrophosphate (measured through pyridoxal phosphate levels) which further inhibits bone mineralization. We performed a prospective study to identify whether hypophosphatasia is associated with atypical femur fracture.

We recruited 15 control patients who took long term bisphosphonates without complication and 10 patients who sustained atypical femur fractures (9 years mean bisphosphonate use both cohorts). Patients underwent clinical exam and measurement of alkaline phosphatase and pyridoxal phosphate (PLP) levels. In addition, DNA was extracted and the TNSALP gene sequenced in both cohorts.

The AFF cohort satisfied 5/5 Major Criteria and 2 or more Minor Criteria as defined by ASBMR. Low alkaline phosphatase levels (< 55 U/L) were seen in 5/5 AFF patients and 5/7 control patients. One patient in each group demonstrated low alkaline phosphatase levels and elevated PLP. The TNSALP genes and intron splice sites in the atypical femur fracture cohort were sequenced and no coding mutations were identified in any subjects.

In conclusion, we found no evidence of mutations in the TNSALP gene in patients with atypical femur fractures. Laboratory findings of mildly low alkaline phosphatase activity were equally common in atypical and control cohorts and may be due to long term bisphosphonate use.

Cytosolic Proteome Profiling of Monocytes for Male Osteoporosis. Wei Zhu*¹, Hong-Wen Deng¹, Lan Zhang¹, Yao-Zhong Liu¹, Qing Tian¹, Fei-Yan Deng², Yong Zeng¹, Yin-Chun Zhao³, Hua-Lin Huang¹, Ji-Gang Zhang¹. ¹Tulane University, USA, ²Soochow University, China, ³none, USA

Male osteoporosis is a serious public health problem, leading to significant mortality in aging males. Peripheral blood monocytes (PBMs) play important roles in bone metabolism by acting as precursors of osteoclasts and producing cytokines important for osteoclast development. Cytosolic proteins have important functions on bone cells and so far few proteomics studies have been focused on cytosolic proteome. Here, we conducted 2D-nanoLC-ESI-MS/MSE to profile PBMs cytosolic proteome in Caucasian male subjects with extremely discordant hip BMD (29 low BMD vs. 30 high BMD). We successfully identified 15 significant ($P < 0.05$) and additional 17 suggestive ($P < 0.1$) differentially expressed proteins (DEPs) (Fold change > 1.5 or < 0.67) out of a total of 3193 detected proteins. Combining evidence from our other proteomics data (from 34 Caucasian female subjects), PBMs microarray analyses (from ~ 100 Caucasian females) and SNPs association analyses (e.g., the deCODE and GEFOS2 datasets), we identified Ezrin, Gelsolin, Vinculin and Filamin A as potential functional genes for hip BMD variation. In addition, by utilizing bioinformatics tools of The Database for Annotation, Visualization and Integrated Discovery (DAVID) and Search Tool for the Retrieval of Interacting Gene (STRING) for pathways and networks analyses, we identified the enrichment of DEPs in the pathways of actin cytoskeleton regulation ($P = 2.71E-10$) and leukocyte trans-endothelial migration ($P = 4.07E-07$) and functional terms for monocyte proliferation, differentiation and apoptosis. This study represents a pioneering effort in comprehensive characterization of PBMs cytosolic proteome and may shed light on the monocyte-mediated pathogenesis of male osteoporosis.

MicroRNA miR-30e-5p discriminates patients with idiopathic osteoporosis and low-traumatic fractures. Roland Kocjan*¹, Christian Muschitz², Fabian Plachel², Rainer Dormann², Elisabeth Geiger³, Susanna Skalicky³, Heinrich Resch², Patrick Heimerl⁴, Astrid Fahrleitner-Pammer⁵, Johannes Grillari⁶, Heinz Redl⁷, Matthias Hackl³. ¹St. Vincent Hospital Vienna, Austria, ²St. Vincent Hospital – Medical Department II, The VINFORCE Study Group, Academic Teaching Hospital of Medical University of Vienna, Austria, ³TAmiRNA GmbH, Muthgasse 18, 1190 Vienna, Austria, ⁴Ludwig Boltzmann Institute for Experimental & Clinical Traumatology Donaueschingenstraße 13, A-1200 Vienna, Austria, ⁵Department of Internal Medicine, Division of Endocrinology & Metabolism, Medical University of Graz, Austria, ⁶Department of Biotechnology, University of Natural Resources & Life Sciences Vienna, Austria, ⁷Ludwig Boltzmann Institute for Experimental & Clinical Traumatology Austrian Cluster of Tissue Regeneration, Austria

Purpose: Bone turnover markers (BTMs) are proteins or peptides that are meant to reflect the metabolic activity of bone, but which are not involved in the regulation of bone metabolism. In contrast, circulating microRNAs (miRNAs) have been recently reported as a novel class of biomarkers, which can control and reflect the activity of a specific tissue based on their active release from tissues within microvesicles. A number of studies have reported on the intracellular expression and function of miRNAs in bone metabolism, and therefore, circulating miRNAs might have clinical utility for the management of bone disease. **Methods:** We analyzed 187 circulating miRNAs in in otherwise healthy pre-menopausal (n=10), post-menopausal (n=10) and male patients (n=15) with idiopathic osteoporosis and at least one low-traumatic fracture (FX). Secondary causes for osteoporosis were excluded by clinical investigation. Data were compared to respective healthy age-matched control groups (CO) of equal size. **Results:** For each cohort, differential expression analysis was performed using non-parametric tests and p-values were adjusted for multiple testing using BH false-discovery rate ($q < 0.05$). In case of pre-menopausal women, 36 miRNAs were found to be differentially expressed in comparison to healthy controls, 53 in case of post-menopausal women and 56 in case of males. An overlap of 18 regulated miRNAs (4 down-regulated, 14 up-regulated in FX) in all three cohorts was observed and subject to further analysis: classification performance of individual miRNAs was assessed by ROC analysis to find that miR-30e-5p was more than 2-fold up-regulated in serum of idiopathic fracture patients and was able to differentiate FX from controls with AUC-values ranging between 0.92 and 1.00. In order to assess the potential biological impact of all 18 commonly regulated miRNAs, target prediction was performed and KEGG-pathway enrichments were calculated using public bioinformatic tools. Based on this analysis we found that target genes were significantly enriched ($p < 0.05$) in pathways such as WNT-signaling and energy metabolism (Insulin signaling, mTOR signaling). **Conclusion:** Our data provide evidence that patients with idiopathic osteoporosis show distinct profiles of circulating miRNAs. miR-30e-5p in particular discriminates patients with low-traumatic

fractures. This miRNA was previously reported to suppress osteogenic differentiation via IGF2 in vitro and in vivo.

Nrf2 mediates gender specific mechanisms on bone accrual and maintenance.

Gretel G Pellegrini¹, Meloney Cregor¹, Kevin McAndrews¹, Jesus Delgado-Calle¹, Amy Y Sato¹, Hannah M Davis¹, Lilian I Plotkin¹, David Burr¹, Connie M Weaver², Teresita Bellido³. ¹Department of Anatomy & Cell Biology Indiana University School of Medicine, Indianapolis, IN, USA, ²Department of Nutrition, Purdue University, West Lafayette, IN., USA, ³Department of Anatomy & Cell Biology, Department of Medicine, Division of Endocrinology, Indiana University School of Medicine, Indianapolis, IN, Roudebush Veterans Administration Medical Center, Indianapolis, IN, USA

Mice lacking the transcription factor nuclear factor erythroid 2-related factor2 (Nrf2) are prone to develop diseases associated with elevated oxidative stress, suggesting its critical role in endogenous antioxidant responses. However, conflicting results have been published regarding the skeletal phenotype of these mice likely due to differences in genetic background, age, or gender among the studies. Here, we performed a longitudinal analysis of bone mineral density (BMD) and circulating markers of bone remodeling in a cohort of littermates Nrf2+/+ (WT) and Nrf2-/- (KO) mice (10 males and 10 females per genotype) between 2 and 15 months of age. KO mice were generated by injection of targeted I29X1/SvJ-derived JM-1 embryonic stem cells into blastocysts, followed by breeding to C57BL6 mice. Similar to WT littermates, male and female KO mice reached adult peak BMD at ~5 months of age. However, female KO mice attained lower BMD whereas male KO mice reached higher BMD than WT littermates, particularly in the spine (-6.62 for female and +5.33% for male mice). After 5 months of age, both male and female WT mice began to lose spinal BMD (-19.57 and -18.69%, for male and female WT mice, respectively, between 5 and 15 months of age). However, KO mice lost much less BMD (-9.69 and -5.04%, for male and female KO mice, respectively). The higher adult peak BMD in KO male mice was accompanied by higher circulating PINP at 2 and 5 months of age, suggesting that increased bone accrual was a consequence of elevated bone formation. Further, collagen1 expression was increased ~300% vs WT in 15 month old male KO mice, without changes in other osteoblast or osteoclast markers. In contrast, osteoblast (collagen1, osterix, Runx2, and osteocalcin) as well as osteoclast (cathepsin K and TRAPase) markers were markedly reduced to ~10% of WT littermates in 15 month old female KO mice, potentially reflecting a reduction in both osteoblasts and osteoclasts. These results suggest that bone maintenance with aging in male KO mice results from increased collagen accumulation whereas in female KO mice is due to decreased bone remodeling rate. We conclude that Nrf2 is required for full bone acquisition in the female skeleton and has the opposite effect on the male skeleton. Further, the absence of Nrf2 similarly protects both male and female skeletons from bone loss with aging, although by different mechanisms. Thus, Nrf2 regulates bone accrual and maintenance by gender specific mechanisms.

Pathogenesis of Atypical Femur Fractures: Recruitment and Preliminary Results. Sudhaker Rao¹, Shijing Qiu², Elizabeth Warner², Heather Remtema², Mahalakshmi Honasoge², George Divine². ¹Henry Ford Hospital, USA, ²Henry Ford Health System, USA

Background and Purpose: Atypical femur fractures (AFF) are an established complication of long term bisphosphonate (BP) therapy, but considered rare based on retrospective database analyses. However, the true prevalence remains unknown. Accordingly, we initiated a prospective study to determine the prevalence and pathogenesis of AFF. We report preliminary results of recruitment and AFF prevalence.

Methods: In the first 10 months of the study we recruited 108 patients; 50 BP-unexposed and 58 BP-exposed (at least >2 years) with a mean age of 67.1 ± 7.9y. AFFs were diagnosed using Hologic software designed to detect AFF in both femurs in AP projection. Incomplete AFFs were confirmed as cracks by x-ray tomosynthesis. **Results:** BP-exposed patients were about 4y older (69.1 ± 8.4y vs. 64.8 ± 6.6y; p=0.003). The mean duration of BP-exposure was 6.1 ± 3.5y (range 2-18y). Ethnic composition was similar in the 2 groups. Most patients were on one of the three approved oral BPs.

We identified several barriers to recruitment. These included fear of bone biopsy even if AFF were to be detected and needle sticks for blood draw, concerns about transportation arrangements and associated costs, busy schedule, perception that participation would not benefit them, variability in BP exposure or the gap since discontinuation, and previous anabolic therapy (an exclusion criterion). Despite these limitations, we recruited the expected number of subjects during the 10 months.

The prevalence of AFF was 4/65 (or 6%), much higher than previously reported based on retrospective database analyses, but lower than our preliminary estimate of 12% (3/25), and about the same as our predicted estimate of 5% before the study began. Four patients had 6 femur AFFs: one patient had bilateral AFF, one patient

had AFF in one femur and incomplete AFF in the other femur, two patients had incomplete AFF in one femur each. The patient with AFF in one femur had multiple cracks in the other femur (or incomplete AFF), hitherto unreported.

Conclusion: The prevalence of AFF may be higher than previously estimated. There are a few barriers to recruitment, which we plan to overcome. Continued surveillance and research is needed both to determine the true prevalence and pathogenesis of AFF

A Clinical Used Antidepressant Drug Reduces Bone Volume by Increasing Osteoclastogenesis via Ubiquitin E3 Ligase ITCH. Xing Li^{1*}, Wen Sun², Mengmeng Wang², Hengwei Zhang², Zhiyu Wang³, Lingpeng Pei², Brendan Boyce⁴, Lianping Xing¹. ¹University of Rochester Medical Center, USA, ²U of Rochester, USA, ³Hebei Medical University, China, ⁴University of Rochester, USA

Clinical studies report that patients taking antidepressants including Clomipramine (CLP) have a high risk of osteoporotic fracture. CLP belongs to the tricyclic family of antidepressants whose influence on bone has not been studied. Here we investigated the effect of CLP on bone and bone cell functions in mice and molecular mechanisms involved. WT mice were treated CLP (10mg/kg/day, similar to doses given to humans) or vehicle (Veh) for 2 wks, and bones were examined by μ CT and histology. CLP significantly decreased trabecular bone volume (BV/TV: 19.3 vs. 25.3% in Veh) and cortical bone thickness (0.202*0.01 vs. 0.224*0.01mm in Veh) of tibiae, associated with increased osteoclasts (OCs) (OC surface/bone surface: 15*1.5 vs. 12*1.5% in Veh; OC#/mm bone surface: 13*3 vs. 7*1 in Veh), but no change in osteoblasts or bone formation rate. Bone marrow cells from CLP-treated mice formed significantly more OCs in the presence of RANKL/M-CSF (7*0.8 vs. 2.5*0.6/mm2 in Veh). CLP significantly increased OC formation (14*0.5 vs. 6*0.7/mm2 in Veh), resorption pit area (0.24*0.04 vs. 0.10*0.02 mm2 in Veh), and expression of OC-associated genes in vitro. To test if the bisphosphonate, Zoledronic acid (ZA), could prevent CLP-induced bone loss, WT mice were pre-treated with ZA (0.25mg/kg, 2x/wk) for 2 wks (a standard murine regimen), followed by CLP for an additional 2 wks. ZA markedly increased bone volume of CLP-treated mice (BV/TV: 28*3 vs. 20*2% in CLP) and cortical bone thickness (0.230*0.0 vs. 0.209*0.01 mm in CLP), which was associated with decreased OC numbers (OC#/mm bone surface: 8.5*2 vs. 16*1.5 in Veh). A recent study indicated that CLP has a specific inhibitory effect on the ubiquitin E3 ligase, ITCH, which we previously reported negatively regulates OC formation by promoting deubiquitination of TRAF6. To examine if ITCH is involved in CLP-induced OC formation, we treated bone marrow cells from ITCH KO or WT mice with CLP in OC formation assays. ITCH KO cells formed more OCs than WT cells (8*1.4 vs. 3*0.7/mm2). CLP increased OC formation from WT cells (6*0.75 vs. 3*0.65/mm2 in Veh), but not from ITCH KO cells (9*1.4 vs. 8*1.4/mm2 in Veh). Furthermore, CLP did not cause bone loss in ITCH KO mice. Thus, CLP reduces bone volume by increasing OC formation via E3 ligase ITCH. CLP-induced bone loss could be rescued by ZA. Our preclinical study suggests that anti-resorptive medication may have beneficial effects on patients who take antidepressants.

Hijack of RUNX2 in Glucocorticoid-Induced Osteoporosis. Eri Morimoto, Nyam-Osor Chimgé, Baruch Frenkel*. University of Southern California, USA

Glucocorticoid (GC)-Induced Osteoporosis (GIO), the most prevalent drug-induced bone disease, is attributable to myriad mechanisms. Most significantly, GCs attenuate cell replication, differentiation, function, and survival in the osteoblast lineage through deleterious effects on membrane receptor signaling (e.g., Wnt, Notch, RTKs), kinase cascades (e.g., ERK, Akt, Pyk) and downstream transcription factors (e.g., AP1, FoxO, RUNX2). Additionally, GCs stimulate osteoclast function through both cell autonomous and cell non-autonomous mechanisms. Regardless of how bone mass and strength are initially compromised, a perplexing question remains unanswered: given biomechanical feedback loops known to trigger bone formation in response to compromised bone strength, how is it that such loops do not result in increased osteoblastogenesis during GIO development, not even in young patients with a robust osteogenic potential? Because such feedback loop(s) likely entail activation of RUNX2, and because RUNX2 interacts with the GC receptor (GR) physically and functionally, we hypothesized that homeostatic feedback loops that normally compensate for bone weakening by triggering osteoblastogenesis are broken in GIO, and that the GR hijacks RUNX2 to synergistically stimulate genes with deleterious effects on osteoblasts. To address this hypothesis, we profiled mRNA expression in ST2/Rx2dox pluripotent mesenchymal stem cells (MSCs) treated with doxycycline (dox), to induce RUNX2 and/or 1 μ M dexamethasone (dex). Although GCs generally attenuated RUNX2-driven gene expression, there were some exceptional cases of synergism between RUNX2 and GCs. Among them was Wnt-inhibitory factor 1 (WIF1). RT-qPCR analysis confirmed 200-fold stimulation of WIF1 expression by dex+dox compared with 4- to 8-fold by the individual treatments, and Western blot analysis showed robust biosynthesis and secretion of WIF1 by cells treated with dex+dox versus hardly detectable levels in cultures treated with dex or

dox alone. Finally, dex-mediated cell death was dramatically augmented in cultures co-treated with dox, and this did was prevented by two independent shRNAs targeting WIF1. These results support a working model whereby GCs hijack RUNX2 to inhibit Wnt signaling in MSCs that turn on RUNX2 to drive osteoblast differentiation and bone formation. Thus, in the presence of GCs, upregulation of RUNX2 through homeostatic feedback loops might not result in the desirable enhancement of osteoblast differentiation and bone formation, but might instead lead to WIF1-mediated inhibition of Wnt signaling and exacerbation of GIO.

WIF1 Western blot analysis

Osteocyte-Derived RANKL Is Required for the Detrimental Effects of Glucocorticoids on Murine Cortical Bone. Marilyna Piemontese^{*1}, Jinhu Xiong¹, Yuko Fujiwara¹, Priscilla Baltz¹, Stuart Berryhill¹, Stavros Manolagas¹, Charles O'Brien². ¹University of Arkansas for Medical Sciences & Central Arkansas Veterans Healthcare System, USA, ²Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Therapeutic administration of glucocorticoids causes bone loss and previous studies have shown that administration of prednisolone to adult C57BL/6 female mice for 28 days increases bone resorption at the endocortical surface and decreases cortical thickness. Moreover, blockade of glucocorticoid action on osteoblast-lineage cells prevents these changes. Osteocytes are an essential source of the RANKL involved in cancellous bone remodeling as well as the cortical bone resorption caused by mechanical unloading or dietary calcium deficiency. However, whether osteocyte-derived RANKL participates in the bone loss caused by glucocorticoid excess is unknown. To address this question, we generated mice lacking RANKL in mature osteoblasts and osteocytes, designated as conditional knockout (CKO) mice, by crossing RANKL-*fl/fl* mice with Dmp1-Cre transgenic mice. Six-month-old male CKO mice and RANKL-*fl/fl* littermates were then implanted with placebo pellets or pellets releasing prednisolone at a dose of 2.1 mg/kg/day for 28 days. Consistent with previous studies, femoral and vertebral cancellous bone was much higher in placebo-treated CKO mice compared with placebo-treated RANKL-*fl/fl* mice. However, prednisolone had no effect on cancellous bone volume of the femur or vertebra in either genotype. In contrast, prednisolone reduced femoral bone mineral density as well as cortical thickness and bone strength in RANKL-*fl/fl* mice. These changes were associated with increased osteoclast number at the endocortical surface of the femur. Similarly, prednisolone also reduced cortical thickness in vertebral bone of RANKL-*fl/fl* mice. Consistent with the histological results, prednisolone elevated osteoclast-specific gene expression in cortical bone of RANKL-*fl/fl* littermates. However, all of the effects of prednisolone observed in RANKL-*fl/fl* mice were completely prevented in CKO mice. Prednisolone administration significantly reduced osteoprotegerin (OPG) mRNA in osteocyte-enriched cortical bone of both genotypes. As expected, deletion of RANKL from DMP1-Cre expressing cells decreased RANKL mRNA abundance compared to RANKL-*fl/fl* mice but prednisolone did not change RANKL mRNA abundance in either genotype. These results suggest that glucocorticoid suppression of OPG in mature osteoblasts or osteocytes may be one of the molecular mechanisms driving the increase in osteoclast number at the endocortical surface. However, this increase also depends on RANKL produced by osteocytes.

Estrogen Regulates Bone Turnover by Targeting RANKL Expression in Bone Lining Cells. Carmen Streicher¹, Alexandra Heyny¹, Olena Andrukhova¹, Christiane Schüller¹, Karoline Kollmann¹, Ingrid Kantner¹, Veronika Sexl¹, Miriam Kleiter¹, Lorenz Hofbauer², Paul Kostenuik³, Reinhold Erben^{*1}. ¹University of Veterinary Medicine, Austria, ²Technische Universität Dresden, Germany, ³Phylon Pharma Services, USA

Estrogen is critical for skeletal homeostasis and regulates bone remodeling, in part, by modulating the expression of receptor activator of NF- κ B ligand (RANKL), an essential cytokine for bone resorption by osteoclasts. RANKL can be produced by a variety of hematopoietic (e.g. T and B-cell) and mesenchymal (osteoblast lineage, chondrocyte) cell types. The cellular mechanisms by which estrogen acts on bone are still a matter of controversy. Here, we established reconstitution models that allow for selective deletion of estrogen receptor- α (ER α) or selective inhibition of RANKL in hematopoietic vs. mesenchymal cells. We first showed in irradiated wildtype (WT) mice reconstituted with WT bone marrow that irradiation and bone marrow transplantation *per se* are not associated with bone loss. To selectively delete ER α in hematopoietic or mesenchymal cells, we lethally irradiated female WT and global ER α knockout mice (α ERKO), and reconstituted them with sex-matched bone marrow from α ERKO or WT mice, respectively. To selectively inhibit RANKL in hematopoietic or mesenchymal cells, we lethally irradiated female WT and human RANKL knock-in (huRANKL-KI) mice, and reconstituted them with sex-matched bone marrow from hRANKL-KI or WT mice, respectively. huRANKL-KI mice express a chimeric RANKL protein which, unlike murine RANKL, is inhibited by the anti-huRANKL antibody AMG161, and thus AMG161 treatment of the respective reconstituted mice results in selective inhibition of RANKL produced from hematopoietic or mesenchymal cells. All mice were ovariectomized (OVX) 4 weeks after irradiation, and were treated with vehicle, estradiol, or AMG161 over 4 weeks. Both reconstitution models showed that OVX-induced bone loss was only prevented by estrogen stimulation of ER α or inhibition of RANKL expression in mesenchymal, but not in hematopoietic cells. To further refine the mesenchymal cell compartment, we analyzed RANKL expression by immunohistochemistry and by *in situ* mRNA expression profiling using laser capture microdissection. OVX profoundly upregulated RANKL expression in bone lining cells, but not in osteoblasts, and only marginally in osteocytes, indicating that the increase in bone resorption observed in states of estrogen deficiency in mice is mainly caused by lack of ER α -mediated suppression of RANKL expression in bone lining cells. In conclusion, we identified bone lining cells as important gatekeepers of estrogen-controlled bone resorption.

Role of Antiretroviral therapy (ART) on bone mass and bone texture. Esteban Martinez^{*1}, Polyana Monteiro¹, Luis Del Rio². ¹Infectious Diseases Unit, Hospital Clinic, Barcelona, Spain, Spain, ²CETIR Grup Mèdic, Barcelona, Spain, Spain

Rational: The aim of the study is to evaluate effects of different ART on areal bone mineral density (aBMD) and bone microarchitectural texture (TBS) of HIV infected patients.

Methods: 245 men and 80 women aged 45 and older were analyzed. Among them 44 HIV-infected patients are free from antiretroviral therapy (Naive group). Other subjects received either therapy containing Tenofovir plus Ritonavir-boosted protease inhibitor (TeRiPi, n=35) or Ritonavir-boosted protease inhibitor (RiPi, n=51) or Tenofovir (Te, n=141) or therapy not containing Te or RiPi (NoTeRiPi, n=54). Lumbar aBMD were measured by dual energy X-ray absorptiometry using a QDR 4500 device (Hologic, Madison, USA). TBS was computed using TBS iNsight® (v2.1, Med-Imaps, France).

Results: No differences in terms of age was observed between groups (all $p > 0.08$). Subjects in the naive group had mean viral charge of 127215 particles per milliliter of blood whereas those under TeRiPi, RiPi, Te and NoTeRiPi had a viral charge of 37 or lower. Subjects in the naive group had significant lower number of T4 in comparison with subjects under therapies (all $p < 0.001$). Those under TeRiPi and RiPi had a significant decrease in both TBS (all $p < 0.0001$) and aBMD (all $p < 0.03$) when compared to the naive group. Interestingly, those under Te and NoTeRiPi therapies exhibited a significant decrease on TBS (all $p < 0.02$) while aBMD seems to be similar (all $p > 0.33$). We observed a trend to the TeRiPi therapy be the most impacting TBS when compared to other therapies ($0.001 < p < 0.07$). When considering subjects with a low bone mass (T-score ≤ -1 ; n=176), those under TeRiPi, RiPi and NoTeRiPi have a significant lower TBS than the naive group (all $p < 0.01$) while no differences were observed in BMD (all $p > 0.3$) and thus without differences for age or BMI between groups. In multivariate analysis, a low TBS value (lowest tertile) was best explained ($r^2 = 31\%$) by a model combining age, T4basal, BMI (negative association, all $p < 0.02$) and aBMD and T8 (positive association, all $p < 0.05$).

Conclusions: For the first time we observed an impairment on bone micro-architectural texture at spine linked to the ART and thus for all studied therapies while an impairment on aBMD has been observed only for TeRiPi and RiPi. It seems that TeRiPi exhibited the worse effect on TBS but further studies are needed to confirm these preliminary results. TBS could be used in addition to aBMD to monitor effect of ART on bone in HIV infected patients.

Cortisol Circadian Rhythm Changes are associated with low trabecular bone score (TBS) and increased fracture risk, without any influence on bone mineral density (BMD): The OsteoLaus Cohort. Elena Gonzalez Rodriguez¹, Bérenère Aubry-Rozier¹, Delphine Stoll¹, Olivier Lamy¹, Didier Hans². ¹Center of Bone Diseases, Rheumatology Unit, Bone & Joint Department, Lausanne University Hospital, Switzerland, ²Lausanne University Hospital, Switzerland

Aim: In glucocorticoid (GC)-induced osteoporosis, fracture risk is poorly correlated with BMD. TBS is a bone texture analysis which correlates with micro-architecture parameters. It independently correlates to fracture risk. Lower TBS but normal BMD are found in patients with high GC levels, even in subclinical hypercortisolism. Cortisol production and bone turnover exhibit a circadian cycle. Cortisol circadian rhythm changes with age, with globally a greater area under the curve mainly due to an increase of the nadir levels during the 1st half of the night. Bone turnover circadian pattern is inversely correlated to cortisol one with a time lag of 4h. Changes in cortisol circadian cycle with aging could be at the origin of BMD loss. No study has addressed its role on TBS alteration or fracture risk.

Method: OsteoLaus is a population-based cohort of 1500 randomly selected Caucasian women (50 to 80 y old) living in Lausanne. Bone parameters include BMD, TBS and VFA. 754 women also had salivary cortisol circadian rhythm measures (wake-up, 30 min after wake-up, 11 am and 8 pm). Women with more than 3 months of GC therapy were excluded. They were split in tertiles of age, and in tertiles of salivary cortisol values at 11 am and at 8 pm.

Results: Salivary cortisol concentration at 11 am and 8 pm increased with age. On the contrary, hip BMD and spine TBS decreased with age (there was no difference in spine BMD). Comparison between lowest versus highest tertiles of salivary cortisol concentration at 8 pm showed: a) Significantly lower TBS values (1.31 vs 1.27) (but not spine or hip BMD) with highest cortisol concentration, independently of age, BMI or BMD (spine or hip) ($p < 0.0001$); b) Significantly higher number of prevalent vertebral fractures (15.0% versus 8.4%) in the tertile showing the highest concentration of salivary cortisol as well as in the tertile having the lowest TBS values ($p < 0.03$). No statistical difference was found for any of the BMD parameters. These associations were not found when using salivary cortisol at 11 am.

Conclusions: Highest cortisol values at 8 pm are associated with altered microarchitecture, but not BMD decrease, independently of age and BMI. Moreover, highest cortisol values and lowest TBS values are both associated with an increased prevalence of vertebral fractures. If these results are confirmed in other studies, the measurement of cortisol at 8 pm may play a role in the assessment of fracture risk.

Obstructive Sleep Apnea is Associated with Deterioration in Bone Mass and Quality in Type 2 Diabetes. Hataikarn Nimitphong¹, Nantaporn Siwarasanond¹, Chanika Sritara², Sunee Saetung¹, Boonsong Ongphiphadhanakul¹, Sirimon Reutrakul¹. ¹Medicine department, Ramathibodi hospital, Mahidol university, Thailand, ²Radiology Department, Ramathibodi Hospital, Mahidol University, Thailand

Background: Type 2 diabetes (T2D) adversely affects the skeleton and is associated with an increased risk of osteoporosis and fragility fractures despite normal or slightly elevated bone mineral density (BMD). Growing evidence suggests obstructive sleep apnea (OSA) may affect bone biology and cause secondary osteoporosis. The effect of OSA in T2D patients on bone quality and metabolism is less explored. We investigated the impact of OSA on bone markers, BMD, and Trabecular Bone Score (TBS; a bone quality assessment) in T2D subjects. **Methods:** Eighty-nine T2D patients without history of metabolic bone disease were included. OSA was diagnosed using an overnight in-home monitoring device (WatchPAT200). N-terminal propeptides of type I procollagen (PINP) and C-terminal cross-linking telopeptides of type I collagen (CTX-I) were measured. L1-4 lumbar spine and femoral BMD were measured using dual-energy X-ray absorptiometry (DXA) and TBS was computed from DXA images. **Results:** Seventy one patients (80%) were diagnosed with OSA [apnea hypopnea index (AHI) ≥ 5]. There were no differences in PINP and CTX-I between those with or without OSA. Those with OSA had higher L1-4 BMD than those without. The prevalence of low bone mass/osteoporosis was similar between groups. In patients with OSA, bone markers and sleep parameters were not correlated. However, TBS L1-4 negatively correlated with respiratory disturbance index during rapid eye movement (REM) phase of sleep (REM RDI; $r = -0.33$, $p = 0.011$) and REM AHI ($r = -0.28$, $p = 0.031$), while there were no associations between L1-4 BMD and sleep parameters. Femoral neck (FN) BMD negatively correlated with time spent under the oxygen saturation of 90% (T90) ($r = -0.30$, $p = 0.018$) and a trend emerged for REM AHI ($r = -0.26$, $p = 0.05$). In addition, total hip (TH) BMD negatively correlated with T90 ($r = -0.25$, $p = 0.045$). Multiple regression analyses adjusting for age, sex and body mass index revealed that REM RDI significantly correlated to TBS L1-4 and BMD with the hierarchy as follow; FN BMD: $r = -0.35$, $p = 0.003$, TBS L1-4: $r = -0.33$, $p = 0.008$, TH BMD: $r = -0.28$, $p = 0.026$, L1-4 BMD: $r = -0.27$, $p = 0.047$. Furthermore, both FN BMD and TBS L1-4 negatively correlated with AHI REM, and FN BMD negatively correlated with T90. **Conclusions:** In subjects with T2D and OSA, there is a relationship between OSA severity and deterioration of bone mass and

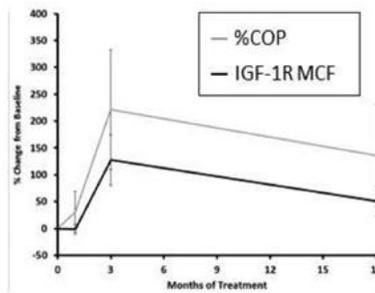

quality. Further studies to investigate the causal relationship of OSA and bone metabolism in T2D are warranted.

SU0334

Circulating osteogenic progenitors (COPs) and COP surface IGF-1 receptor density predict tissue-based bone formation rate and response to teriparatide (TPTD) in premenopausal women with idiopathic osteoporosis (IOP). Adi Cohen¹, J. Sanil Manavalan², Stavroula Kousteni², Robert Recker³, Joan Lappe³, David Dempster², Hua Zhou⁴, Donald McMahon², Mariana Bucovsky², Mafo Kamanda-Kosseh², Julie Stubby³, Elizabeth Shane². ¹Columbia University Medical Center, USA, ²Columbia University, USA, ³Creighton University, USA, ⁴Helen Hayes Hospital, USA

In premenopausal women with IOP, those with low bone formation rate (BFR) on transiliac bone biopsy have the most substantial microarchitectural deficits and respond less well to TPTD. IGF-1 stimulates bone formation and is critical for TPTD action on osteoblasts (OB). Therefore, we measured IGF-1 receptor (IGF-1R) density on COP cells from 25 premenopausal women with IOP (age 38 ± 7), of whom 11 subsequently participated in an open-label study of TPTD. COP cells were isolated by flow cytometry from peripheral blood mononuclear cells (PBMCs) as osteocalcin+ Runx2+ cells after excluding hematopoietic lineage cells. IGF-1R density on COPs was measured by mean channel fluorescence (MCF) of antibodies to IGF-1R. We show that the percentage of COPs in PBMCs correlates directly with cancellous BFR ($r = 0.41$, $p = 0.04$), mineral apposition rate (0.75, < 0.0001) and wall width (0.51, 0.01) on transiliac biopsies of all 25 women. IGF-1R density also correlated with BFR ($r = 0.57$, $p = 0.003$) and was significantly lower on COPs from women with low turnover (LT) than high turnover (HT) IOP (MCF: 863 ± 217 vs 1547 ± 806 ; $p = 0.04$). Compared to the HT group, the LT IOP group also had significantly lower OB number on biopsies (0.7 ± 0.3 vs 1.5 ± 1.1 #/mm; $p = 0.002$) and %COPs (13.3 ± 8.0 vs 29.0 ± 8.8 %; $p = 0.004$). COPs and IGF-1R expression were also investigated at baseline and after 1, 3 and 18 months (M) of TPTD (20 mcg qd) in 11 IOP women (age 38 ± 7). The %COPs increased with TPTD, peaking at 3M by 221% ($p = 0.02$) and remained above baseline at 18M. Similarly, IGF-1R MCF peaked at 3M by 128% ($p < 0.01$). There were substantial 12M increases in BMD (LS: 12.9 ± 5.7 %; FN: 6.9 ± 4.6 %) but response was quite variable. Neither baseline %COP nor 3M increase in %COP predicted BMD response to TPTD. In contrast, the % increase in IGF-1R MCF in COPs at 3M correlated directly and significantly with the 6M increase in BMD in response to TPTD at the spine ($r = 0.70$; $p = 0.02$) and femoral neck ($r = 0.67$; $p = 0.02$), with trends at 12M: spine ($r = 0.55$; $p = 0.08$) and femoral neck ($r = 0.49$; $p = 0.1$). We conclude that %COP and IGF-1R density on COPs are directly associated with indices of bone formation measured on biopsies in the same subjects. Both measures rise markedly in IOP women in response to TPTD and the increase in IGF-1R density on COPs correlates directly with BMD response to TPTD. An early increase in IGF-1R density may both predict and play an important role in the osteoanabolic response to TPTD.

Comparative effect of alendronate and teriparatide on bone mineral density and bone turnover among Japanese postmenopausal women with history of fragility fractures: A clinical practice-based observational study. Jun Iwamoto^{*1}, Mitsuyoshi Uzawa². ¹Keio University School of Medicine, Japan, ²Keiyu Orthopaedic Hospital, Japan

A clinical practice-based observational study was performed to compare the outcome of alendronate (ALN) and teriparatide (TPTD) treatment among Japanese postmenopausal women with a history of fragility fractures. Sixty-one Japanese postmenopausal women with a history of fragility fractures were treated with ALN (35 mg weekly, n = 32) or TPTD (20 µg daily, n = 29) for 2 years in our outpatient clinic. Alfacalcidol (1 µg daily) was combined with ALN. The lumbar spine or total hip bone mineral density (BMD) was measured using dual energy X-ray absorptiometry, and bone turnover markers were monitored. ALN decreased the urinary levels of cross-linked N-terminal telopeptides of type I collagen (NTX) (38.3% after 3 months) and the serum levels of alkaline phosphatase (ALP) (25.7% at 24 months), whereas TPTD increased the serum levels of intact procollagen type I N-terminal propeptide (PINP) and ALP (79% and 14.1%, respectively at 24 months). Both ALN and TPTD increased the lumbar spine BMD (8.8% and 15.9%, respectively) and sustained the total hip BMD at 24 months. One patient treated with ALN experienced vertebral fractures, and one patient treated with TPTD experienced a nonvertebral fracture. These results confirmed the differential effects of ALN and TPTD on bone turnover and the greater effect of TPTD on the BMD among Japanese postmenopausal women with a history of fragility fractures.

Rapid, High Dose vs. Slower, Low Dose Accrual of Bone Mass Following Sclerostin Antibody Treatment in Ovariectomized Rats: Comparison of Effects on Bone Strength. Henry Bryant^{*1}, Matthew Hamang¹, Guilherme V Rocha¹, Qianqiang Zeng¹, Jonathan Lucchesi¹, Sarah E Raines¹, Stuart A Kuhstoss¹, Victor Obungu¹, Venkatesh Krishnan², Yanfei Ma¹. ¹Eli Lilly & Company, USA, ²Eli Lilly & Company, USA

Osteoporotic patients who have experienced a fracture are the highest risk population for future fractures and are ideal patients for bone anabolic therapies that rapidly stimulate new bone formation. Currently in clinical trials for osteoporosis, sclerostin (SOST) antibodies show a robust and rapid gain in vertebral bone mineral density (BMD). Similar effects can be observed in animal models. The speed at which bone can be built by SOST antibodies raises the question: Is bone built rapidly at a higher dose level by this mechanism as biomechanically sound as bone accrued over a longer period of time by a lower dose of the SOST antibody? To address this we compared bone quality in ovariectomized rats given a high or low dose of SOST antibody over a shorter or longer time period, respectively. Athymic nude rats were ovariectomized (OVX) at 4 months of age and allowed to lose bone for 2 months. The animals were then treated with blosozumab (Bmab), a humanized SOST antibody at 3 or 10 mg/kg (sc) once per week. Animals given 10 mg/kg were sacrificed after 6 weeks and the 3 mg/kg group was sacrificed after 10 weeks of Bmab treatment. The 10 week time point was specifically selected as this was the time interval required for the lower dose group to attain a BMD level (as measured by in vivo CT) comparable to that attained by the higher dose Bmab group with the 6 week dosing period. BMD was reduced at both the lumbar vertebrae (LV, 16%) and proximal femur (PF, 14%) at the start of Bmab treatment. As depicted in the table below, the higher Bmab dose given for only 6 weeks produced comparable BMD gain to the lower dose given for 10 weeks in both LV and mid-femur. These effects on BMD translated to comparable effects on peak load, or slightly favorable for the more rapid, high dose Bmab group. Interestingly, the PF responded more robustly (relative to LV) to the shorter, higher dosing regimen than to the longer, lower Bmab treatment, both in terms of BMD and bone strength. This study suggests that even with a shorter treatment period and time to accrue bone mass, a high dose of SOST antibody produces comparable, or possibly, superior effects on BMD and bone strength when compared to a lower dose given for a longer period of time.

BMD and strength changes with Bmab 10mg/kg for 6 weeks vs Bmab 3mg/kg for 10 weeks (% OVX vehicle)

| Endpoint | BMD | BMD | Peak Load | Peak Load |
|--------------------|----------|----------|-----------|-----------|
| Bmab Dose/duration | 10mg/6wk | 3mg/10wk | 10mg/6wk | 3mg/10wk |
| Lumbar vertebra | 23% | 18% | 61% | 62% |
| Mid femur | 5% | 6% | 17% | 11% |
| Proximal femur | 18% | 10% | 43% | 28% |

BMD and strength changes with Bmab 10mg/kg for 6 weeks vs Bmab 3mg/kg for 10 weeks (% OVX vehicle)

Can We Use Bone Turnover Markers as Targets for Antiresorptive Treatment in Postmenopausal Osteoporosis? An Analysis From the DECIDE and STAND Clinical Trials. JP Brown^{*1}, P Dakin², P Hadji³, MR McClung⁴, PD Miller⁵, JY Reginster⁶, RB Wagman², A Wang², E McCloskey⁷. ¹Laval University & CHU de Quebec-(CHUL) Research Centre, Canada, ²Amgen Inc., USA, ³Philips-University of Marburg, Germany, ⁴Oregon Osteoporosis Center, USA, ⁵Colorado Center for Bone Research, USA, ⁶University of Liège, Belgium, ⁷University of Sheffield, United Kingdom

Purpose: Bone turnover markers (BTMs) respond much quicker than BMD as an indicator of response to therapy in osteoporotic patients; however, it remains unclear when and how best to evaluate treatment response using BTMs. Denosumab (DMAB) has a dynamic BTM profile over the 6-mo dosing period (ie, reduction in turnover with release of inhibition at the end of the dosing interval). This analysis assessed the use of potential target values for serum C-telopeptide of type I collagen (CTX) and serum procollagen type I N-terminal propeptide (PINP) to explore guidance to clinicians for monitoring postmenopausal women with osteoporosis (PMO) during treatment.

Methods: BTMs measured at baseline in treatment-naïve PMO entering FREEDOM, a large randomized, placebo-controlled study of DMAB (Cummings *NEJM* 2009), were used to derive threshold values at the 5th percentiles of the observed distributions. The relevant values for serum CTX (N=7594) and PINP (N=1023) were 0.2 ng/mL and 25.8 ng/mL, respectively. These BTM target values were applied to the study populations of DECIDE (Brown *JBMR* 2009) and STAND (Kendler *JBMR* 2010) enabling evaluation of a population-based assessment of BTM target values. DECIDE (N=1189) and STAND (N=504) were phase 3, randomized, double-blind, double-dummy studies to compare the efficacy and safety of DMAB (60 mg SC Q6M) with alendronate (ALN) (70 mg PO QW) in treatment-naïve PMO or PMO already receiving ALN, respectively. The percentage of subjects in each treatment group with BTMs below the predefined target values was evaluated mid-cycle at mo 3 after the 1st dose of DMAB, which also enabled trough values for ALN, and then re-evaluated at mo 9. Subjects with BTM values below the predefined targets at baseline were excluded from the analysis.

Results: A total of 1112 women in DECIDE and 155 women in STAND had CTX values ≥ 0.2 ng/mL and PINP values ≥ 25.8 ng/mL at baseline. Table 1 reports the percentage of subjects with CTX and PINP values below the respective targets at mo 3 and 9. The predefined target values were almost universally achieved at 3 and 9 mo on DMAB, whereas the target for CTX, for example, on ALN was only achieved in 49.1% and 19% of treatment-naïve and ALN-pretreated PMO, respectively, at mo 3.

Conclusion: In this population-based analysis, in both treatment-naïve and pretreated PMO, BTMs have utility in determining response, and awareness of failure to reach a treatment target may help improve clinical management.

Table 1 Percentage of Subjects With CTX <0.2 ng/mL or PINP <25.8 ng/mL at Follow-up

| DECIDE | CTX <0.2 ng/mL | | PINP <25.8 ng/mL | |
|---------|---------------------|-------------------|---------------------|-------------------|
| | Alendronate (N=544) | Denosumab (N=568) | Alendronate (N=544) | Denosumab (N=568) |
| Month 3 | 49.1 | 95.1* | 65.6 | 98.0* |
| Month 9 | 66.5 | 96.4* | 80.7 | 97.0* |

| STAND | CTX <0.2 ng/mL | | PINP <25.8 ng/mL | |
|---------|--------------------|------------------|--------------------|------------------|
| | Alendronate (N=83) | Denosumab (N=72) | Alendronate (N=83) | Denosumab (N=72) |
| Month 3 | 19.0 | 97.1* | 41.0 | 98.5* |
| Month 9 | 15.6 | 100.0* | 52.0 | 100.0* |

N=total number of subjects with baseline CTX ≥ 0.2 ng/mL and PINP ≥ 25.8 ng/mL.

CTX, serum C-telopeptide of type I collagen; PINP, serum procollagen type I N-terminal propeptide. *p<0.0001; Pearson's chi-square test for between-group comparisons.

Changes in Bone Metabolic Markers During Long-Term (>3 Years) Bisphosphonate Treatment. Yuji Kasukawa^{*1}, Naohisa Miyakoshi², Michio Hongo³, Koji Nozaka³, Yoshinori Ishikawa³, Daisuke Kudo³, Toshihito Ebina⁴, Hiroshi Aonuma⁴, Kimio Saito⁴, Yoichi Shimada³. ¹Akita University Graduate School of Medicine, Japan, ²Department of Orthopedic Surgery, Akita University Graduate School of Medicine, Japan, ³Department of Orthopedic Surgery, Akita University Graduate School of Medicine, Japan, ⁴Department of Orthopedic Surgery, Kakunodate General Hospital, Japan

Although bisphosphonates (BPs) suppress bone resorption markers, these markers sometimes become over-suppressed or show re-elevation during long-term treatment with BPs. At present, the precise changes of bone metabolic markers during long-term

treatment with BPs remain unclear. The purpose of this study was to evaluate changes of bone resorption and formation markers during treatment with BPs, including minodronate, for longer than 3 years. We enrolled 55 osteoporotic women to the study who had been treated with BPs for longer than 3 years since 2005. The average age at the beginning of treatment was 73 years. BP types included alendronate (ALN) in 22 cases (monotherapy in 13 cases, combined therapy with calcium [Ca] and activated vitamin D [Vit.D] in 9 cases), and risedronate (RIS) in 33 cases (monotherapy in 20 cases, combined therapy with Ca and Vit.D in 4 cases, and combined therapy with menatrenone in 9 cases). BP treatments were switched in 6 cases, from ALN to RIS in 3 cases and from ALN to minodronate in 5 cases. Serum cross-linked N-telopeptide of type-1 collagen (NTX) and bone alkaline phosphatase (BAP) were measured at the beginning of treatment and 1, 2, 3, and 5 years post-treatment. Average levels of NTX (nmol of bone collagen equivalent [BCE]/L) and BAP (units [U]/L) at the beginning of treatment were 19.5 and 21.7, respectively. After treatment with BPs, the average levels of NTX and BAP, which were 14.1 ($p < 0.0001$) and 12.8 ($p < 0.0001$) at 1 year ($n = 45$), 13.8 ($p < 0.0001$) and 10.6 ($p < 0.0001$) at 2 years ($n = 37$), 15.9 ($p < 0.0001$) and 12.6 ($p < 0.0001$) at 3 years ($n = 42$), and 15.2 ($p = 0.02$) and 12.2 ($p = 0.0004$) at 5 years ($n = 18$), respectively, were significantly lower than those at the beginning of treatment at all time points post-treatment. The percentage decreases of NTX and BAP were not significantly different between ALN and RIS BP treatments. BP treatment for longer than 3 years significantly decreased serum levels of NTX and BAP in the study patients.

Characteristics Associated with Bone Mineral Density Increase by 1-Year ALN/D5600 Treatment in a Randomized, Controlled Study on Postmenopausal Osteoporosis in Chinese Women. Zhen Lin Zhang¹, Er Yuan Liao², Wei Bo Xia³, Hua Lin⁴, Qun Cheng⁵, Li Wang⁶, Yong Qiang Hao⁷, De Cai Chen⁸, Hai Tang⁹, Yong De Peng¹⁰, Li You¹⁰, Liang He¹¹, Zhao Heng Hu¹², Chun Li Song¹³, Fang Wei¹⁴, Jue Wang¹⁴, Lei Zhang¹⁴, Arthur C Santora^{*15}. ¹Shanghai Sixth People's Hospital, Shanghai Jiaotong University, China, ²The Second Xiangya Hospital, Central South University, China, ³Peking Union Medical College Hospital, China, ⁴Nanjing Drum Tower Hospital, China, ⁵Huadong Hospital Affiliated to Fudan University, China, ⁶Tianjin Hospital, China, ⁷Shanghai Ninth People's Hospital, China, ⁸West China Hospital, West China School of Medicine, Sichuan University, China, ⁹Beijing Friendship Hospital, Capital Medical University, China, ¹⁰Shanghai First People's Hospital, China, ¹¹Beijing Jishuitan Hospital, China, ¹²Peking University People's Hospital, China, ¹³Peking University Third Hospital, China, ¹⁴Global Medical Affairs, Merck Sharp & Dohme China, China, ¹⁵Merck Research Laboratories, Rahway, NJ, USA, USA

Purpose: Little is known about the characteristics of Chinese postmenopausal women who gain greater bone mineral density (BMD) on antiresorptive therapy. We explored characteristics associated with changes in 1-year lumbar spine (LS) BMD in a 12-month randomized controlled study comparing the efficacy of weekly alendronate 70 mg/vitamin D3 5600 IU (ALN/D5600) versus calcitriol 0.25µg daily in Chinese patients.

Methods: patients who had on-treatment BTM (PINP/s-CTX) and 1-year LS-BMD measurements were eligible for the analysis. Baseline characteristics [age, weight, LS-BMD, vertebral fracture, dietary calcium, 25(OH)D, BTMs] and BTM changes at Month 6 were selected for univariate analysis based on clinical discretion. Continuous or categorical variables with a p value < 0.25 in a linear regression or a general linear model were included in multivariate analysis. A multiple regression model by least squares method was constructed to explore variables significantly correlated with 1-year LS BMD change. Hierarchical forward selection with switching was applied for variable elimination until all remained in the model had a p -value < 0.1 for a standardized coefficient (β).

Results: In the ALN/D5600 group ($n=96$), mean change in 1-year LS-BMD was 0.03 g/cm². Age, weight, dietary calcium, baseline BTMs and 25(OH)D, and changes of BTMs at Month 6 entered into multivariate model. LS-BMD change at 1 year was negatively associated with age ($\beta=-0.27$, $p<0.01$), baseline s-CTX ($\beta=-0.66$, $p<0.01$), and dietary calcium ($\beta=-0.17$, $p=NS$). An increase in 1-year LS-BMD was correlated with s-CTX decrease at Month 6 ($\beta=-0.62$, $p=0.001$). Baseline PINP was positively associated with the BMD change ($\beta=0.25$, $p=NS$). In calcitriol treated group ($n=104$), mean change in LS-BMD at the end of 1 year was 0.01 g/cm². Age, baseline BTMs, baseline 25(OH)D, prior vertebral fracture(s), and s-CTX change at Month 6 were analyzed in the multivariate model. One-year LS-BMD change was negatively correlated with baseline 25(OH)D ($\beta=-0.23$, $p=0.01$). Patients had more increases in the LS-BMD at 1 year if they had prior vertebral fracture(s) ($\beta=0.37$, $p<0.001$).

Conclusion: In this exploratory analysis, Chinese patients in the ALN/D5600 group with lower baseline s-CTX or greater on-treatment s-CTX decreases had larger increases in the spine BMD at 1 year. On the other hand, lower baseline vitamin D or prior vertebral fracture significantly predicted 1-year spine BMD increases by calcitriol treatment.

Denosumab Compared With Zoledronic Acid in Postmenopausal Women With Osteoporosis Previously Treated With Oral Bisphosphonates: Efficacy and Safety Results From a Randomized Double-blind Study. PD Miller^{*1}, N Pannacciulli², JP Brown³, E Czerwinski⁴, BS Nedergaard⁵, MA Bolognese⁶, J Malouf⁷, HG Bone⁸, JY Reginster⁹, A Singer¹⁰, C Wang², RB Wagman², SR Cummings¹¹. ¹Colorado Center for Bone Research, USA, ²Amgen Inc., USA, ³Laval University & CHU de Québec (CHUL) Research Centre, Canada, ⁴Krakow Medical Center, Poland, ⁵Center for Clinical & Basic Research, Denmark, ⁶Bethesda Health Research Center, USA, ⁷Hospital de la Santa Creu i Sant Pau, Spain, ⁸Michigan Bone & Mineral Clinic, USA, ⁹University of Liège, Belgium, ¹⁰Georgetown University Medical Center, USA, ¹¹San Francisco Coordinating Center, CPMC Research Institute, USA

Purpose

Oral bisphosphonates (BP) are the most common osteoporosis (OP) treatment, but inconvenient dosing regimens and side effects lead to low adherence. Less frequently dosed BP, eg, once yearly zoledronic acid (ZOL), are part of the treatment algorithm for patients who have failed or are intolerant to oral BP. Yet there is no evidence that cycling through BP offers therapeutic benefit. Denosumab (DMAB) has shown BMD increases in subjects previously treated with oral BP, in contrast to ZOL (McClung, 2007). This study evaluated DMAB compared with ZOL in postmenopausal women with OP previously treated with oral BP.

Methods

This was a 12-month, multicenter, randomized, double-blind, double-dummy study in postmenopausal women ≥ 55 years who had received oral BP for ≥ 2 years; had a BMD T-score ≤ -2.5 at the lumbar spine, total hip, or femoral neck; and a serum C-telopeptide of type 1 collagen (sCTX) ≤ 0.5 ng/mL. Subjects were randomized 1:1 to DMAB 60mg every 6 months (Q6M) + placebo (IV once yearly) or ZOL 5mg IV once yearly + placebo (SC Q6M), and received calcium and vitamin D daily. Endpoints included percentage change from baseline in BMD at the lumbar spine (primary endpoint), total hip, femoral neck, and 1/3 radius at month 12. sCTX and procollagen type 1 N-terminal propeptide (PINP) were measured post baseline in a subset of subjects. Safety was also assessed.

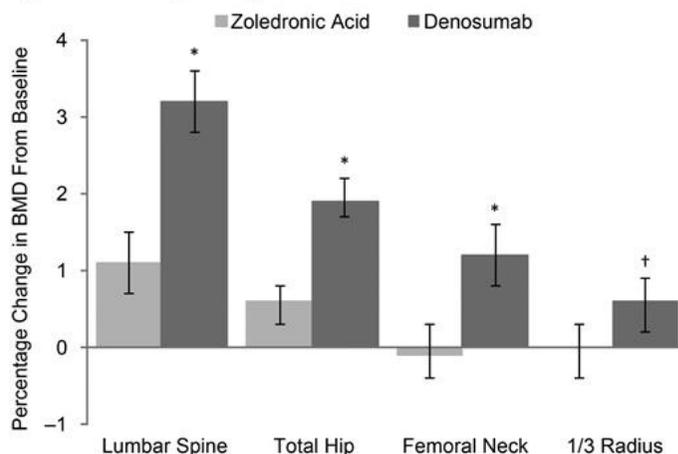

Results

643 subjects were randomized (321 DMAB; 322 ZOL). Mean (SD) age was 69 (7) years, mean (SD) lumbar spine BMD T-score was -2.7 (0.8), and mean (SD) duration of prior oral BP use was 6.3 (3.8) years. BMD change from baseline at month 12 was significantly greater with DMAB compared with ZOL at the lumbar spine (3.2% vs 1.1%; $p<0.0001$; Figure) and all other measured skeletal sites (Figure). Median decrease from baseline was greater with DMAB compared with ZOL for sCTX at months 1 (-78% vs -68%), 6 (-63% vs -22%), and 12 (-63% vs 2%; all $p<0.01$), and for PINP at months 6 (-48% vs -30%) and 12 (-50% vs 4%; both $p<0.01$). Overall and serious adverse events were similar between groups. There were no cases of osteonecrosis of the jaw, hypocalcemia, or delayed fracture healing. Three events consistent with the definition of atypical femoral fracture were observed (2 DMAB vs 1 ZOL).

Conclusions

In postmenopausal women with OP previously treated with oral BP, DMAB treatment increased BMD at all measured skeletal sites and reduced bone remodeling more than ZOL. No new safety risks were identified.

Figure. Percentage Change From Baseline in BMD at Month 12

* $p < 0.0001$ and † $p < 0.02$ denosumab vs zoledronic acid.

Data displayed are least-squared means and 95% CIs based on an ANCOVA model adjusting for treatment, sCTX stratification variable (< 0.3 ng/mL vs 0.3 to 0.5 ng/mL), baseline BMD, DXA machine type, and baseline value by DXA machine-type interaction.

Ectosteric inhibitors of cathepsin K prevent bone resorption. PREETY PANWAR*¹, Liming Xu², Kent Soe³, Simon Law², Jean-Marie Delaisse³, Dieter Bromme⁴. ¹University of British Columbia, Canada, ²UBC, Canada, ³Vejle Hospital, University of Southern Denmark, Denmark, ⁴University of British Columbia, Canada

The potent collagenase activity of cathepsin K (CatK) in osteoclasts is of major interest for the development of anti-osteoporosis drugs. In this study, we evaluated low molecular weight ectosteric inhibitors that specifically block the collagenase activity of CatK without interfering with its catalytic site. Ectosteric inhibitors prevent the formation of collagenolytically active oligomers of CatK. Two compounds (T01 and T06) that differentially inhibit the *in vitro* CatK-mediated degradation of soluble and fibrillar collagen were analyzed for their antiresorptive efficacy in human osteoclasts. In addition, T06 efficacy was tested in ovariectomized (OVX) mice. Here, we demonstrate that T06 is the most potent ectosteric inhibitor of CatK for both soluble and fiber collagen degradation whereas T01 primarily inhibits soluble collagen degradation. Neither of the compounds affected the metabolic activity and viability of osteoclasts. T01 and T06 strongly inhibited the overall bone resorption in osteoclast pit formation assays by about 55 %, reduced the release of C-terminal telopeptide of type I collagen (CTX) fragments by more than 60%, and abolished the formation of trenches. μ CT analysis of femur and vertebra of OVX mice revealed a significant reduction in bone mineral density loss and an improvement of trabecular bone parameters by oral treatment with T06.

This study indicates that ectosteric inhibitors effectively prevent osteoclast-mediated bone resorption in cellular and in *in vivo* disease models. This opens a therapeutic window for the potential treatment in osteoporosis with a novel class of drugs which selectively block the collagenase activity of CatK without inferring with other functions of the multifunctional target protease.

Effects of weekly risedronate with cholecalciferol on bone mineral density in Korean patients with osteoporosis. Ho-Yeon Chung*¹, Hyoung-Moo Park². ¹Kyung Hee University, South Korea, ²Chung-ang University, South Korea

Introduction: We have previously reported that a single pill of risedronate combined with cholecalciferol demonstrated efficacy in correction of 25-hydroxyvitamin D(25OHD) and reducing bone markers. However, the short duration of previous study prevented meaningful evaluation of bone mineral density (BMD). Therefore, we performed a phase 4, randomized, open, prospective, 12-month clinical trial to evaluate the efficacy and safety of weekly risedronate with and without cholecalciferol on 25OHD levels and BMD in Korean patients with osteoporosis. **Methods:** we randomly assigned 1076 adults with osteoporosis to one of two treatment groups: RSD+ (weekly risedronate 35 mg and cholecalciferol 5,600 IU combined in a single pill, n=820) or RSD (weekly risedronate 35 mg alone, n=256). We measured serum levels of 25(OH)D, parathyroid hormone (PTH), and BMD at baseline and after 12 months of treatment. **Results:** After 12 months of treatment, mean serum 25(OH)D increased significantly from 18.3 to 30.4 ng/mL in the RSD+ group and increased from 17.8 to 18.6 ng/mL in the RSD group. The RSD+ groups had decreases in serum PTH from 40.6 to 39.4 pg/mL during the study, but the RSD group showed significant increase of PTH from 38.7 to 44.6 pg/mL. At 12-months, BMD at lumbar spine, femoral neck and femur total increased by 4.9%, 2.5%, 1.9% in the RSD+ group and 4%, 2.1%, 2.1% in the RSD group, respectively. The overall incidence of clinical adverse events was not significantly different between groups. **Conclusion:** In patients with osteoporosis, a once-weekly pill of risedronate and cholecalciferol significantly increased BMD and efficiently improved 25(OH)D level over a 12-month treatment period without significant adverse events.

Lasofloxifene 0,25 mg compared with raloxifene 60 mg for effects on bone mineral density and markers of bone turnover. Results from the Phase III Comparison of Raloxifene and Lasofloxifene (CORAL) Trial. Michael McClung*¹, Andrea LaCroix², James Simon³, James Symons⁴, David Portman⁵. ¹Oregon Osteoporosis Center, USA, ²UCSD, USA, ³James Simons Associates, USA, ⁴James Symons, USA, ⁵Pfizer, USA

There are few comparator trials between different selective estrogen receptor modulators (SERMs) for osteoporosis. The Phase 3 CORAL clinical trial is a head-to-head comparison of the SERMs lasofloxifene, a potent 3rd generation SERM, and raloxifene for osteoporosis prevention. The study was prospective, double-blind, randomized, placebo- and active-controlled, and multicenter. Subjects were women, ages 48-75 years inclusive, at least 3 years from last menses with baseline bone mineral density (BMD) T-score values by dual energy X-ray absorptiometry of the lumbar spine L1-L4 (LS) between <0.0 and >-2.5.

Subjects received lasofloxifene 0.25 mg/d, raloxifene 60 mg/d, or matching placebo for 2 years and were provided a daily supplement of approximately 1000 mg calcium

and 400 IU Vitamin D. The primary endpoint compared the effects on LS-BMD (% change from baseline and % of responders at Month 24); a secondary endpoint compared change in total hip (TH) BMD. For the primary endpoint, Bonferroni's method and a 1-sided a priori fixed sequence procedure were used to control the type I error rate at 5%.

A total of 540 subjects were enrolled (218 lasofloxifene, 215 raloxifene, and 107 placebo). Baseline demographics were similar across treatment groups. Mean baseline LS-BMD T-scores were -1.4, -1.3, and -1.3 in the lasofloxifene, raloxifene, and placebo treatment groups, respectively.

The LS-BMD and TH-BMD responses to lasofloxifene 0.25 mg/d were significantly greater than with raloxifene 60 mg/d or placebo at Month 24; % change LS-BMD from baseline vs raloxifene: least squares mean (LSM) difference 0.896 (95% CI: 0.26, 1.53), p-value=0.003; vs placebo: LSM difference 3.16% (95% CI: 2.38, 3.94), p-value <0.00001. Superiority of BMD changes was observed by Month 6 and sustained over time.

Logistic regression analysis of proportion of responders (no decrease from baseline in LS-BMD at a given time point) indicated the odds of subjects treated with lasofloxifene 0.25 mg/d responding positively were 1.9 times (95% CI: 1.2, 2.9) higher compared with those treated with raloxifene (p-value=0.003). Lasofloxifene 0.25 mg/d was superior to placebo and raloxifene in reducing markers of bone resorption and formation.

In the CORAL trial, lasofloxifene was effective and superior to raloxifene in preventing bone loss, reducing bone turnover, and for responder rates in postmenopausal women at risk for osteoporosis.

SU0344

Monthly Oral Ibandronate 100mg Is as Effective as Monthly Intravenous Ibandronate 1mg in Japanese Patients with Primary Osteoporosis: the Phase III MOVEST Study. Toshitaka Nakamura*¹, Masako Ito², Junko Hashimoto³, Kenji Shinomiyama³, Yoshihiro Asao³, Hiroshi Hagino⁴, Tomoyuki Inoue⁵, Tetsuo Nakano⁶, Hideki Mizunuma⁷. ¹National Center for Global Health & Medicine, Japan, ²Nagasaki University Hospital, Japan, ³Chugai Pharmaceutical Co. Ltd., Japan, ⁴Tottori University Faculty of Medicine, Japan, ⁵Taisho Pharmaceutical Co. Ltd., Japan, ⁶Tamana Central Hospital, Japan, ⁷Hiroshima University School of Medicine, Japan

Purpose: The randomized, double-blind MOVEST (Monthly Oral Versus intravenous ibandronate) study compared the efficacy and safety of monthly oral ibandronate (IBN) with the licensed monthly intravenous (IV) dose in Japanese patients (pts) with primary osteoporosis. We present efficacy and safety data after 12 months of treatment and conclude the optimal dose of monthly oral IBN in Japanese osteoporotic pts. **Methods:** Ambulatory pts aged \geq 55 years with primary osteoporosis were randomized to receive monthly oral IBN 100mg + monthly IV placebo, or monthly IV IBN 1mg + monthly oral placebo. The primary endpoint was the non-inferiority of oral versus IV IBN with respect to bone mineral density (BMD) gains at the lumbar spine (L2-L4) after 12 months. **Results:** 422 pts were randomized. The per-protocol set comprised 372 pts: 183 and 189 in the oral and IV IBN groups, respectively. Baseline characteristics were balanced across the treatment groups. Over 12 months, BMD gains were substantial at all sites and significantly improved from baseline with all treatments after just 4 months. The mean relative changes from baseline in lumbar spine BMD at 12 months were 5.22% (95% CI 4.65-5.80) with oral IBN and 5.34% (95% CI 4.78-5.90) with IV IBN. The least squares mean difference between the two groups was -0.23% (95% CI -0.97-0.51), showing the non-inferiority of oral to IV IBN (non-inferiority limit -1.60). BMD gains at the total hip and femoral neck were also evident throughout the study. The proportion of responders at all sites was comparable between the two groups. Reductions in bone turnover markers were substantial with both treatments after 4 months. There were no apparent differences in the safety profiles of the two treatment groups. The incidence of acute phase reaction (APR) was comparable with oral (11.2%) and IV (11.8%) IBN; most APRs were mild in intensity and transient, and decreased with each subsequent dose of medication. No renal function-related adverse events, hypocalcemia, osteonecrosis of the jaw, or atypical fracture of the femur were reported. **Conclusions:** Monthly oral IBN 100mg demonstrated non-inferiority to monthly IV IBN 1mg in terms of lumbar spine BMD gains in Japanese pts with primary osteoporosis. These data suggest that two different monthly regimens of one agent are effective alternative treatment options for pts with osteoporosis in Japan, in accordance with their lifestyle and disease conditions.

Retrospective Study of the Safety of Intravenous Bisphosphonate (Zoledronic Acid) in Patients with Chronic Kidney Disease. Ali Achira*, Wael Taha, Dania Abushanab, Maria Diab, Bayan Chaker, Krishna Chalasani. Wayne State University, USA

Background

Bisphosphonates are anti-resorptive bone agents that effectively treat cancer related hypercalcemia, Paget's disease and osteoporosis. However, their usage is restricted due to the prevailing concern regarding their nephrotoxicity.

Objectives

To study the safety of intravenous zoledronic acid (ZOL) in patients with Chronic Kidney Disease (CKD) with estimated Glomerular Filtration Rate (eGFR) ≤ 50

Methods

Our study is a retrospective review of patients, aged 18 to 80 years, with chronic kidney disease with eGFR ≤ 50 mL/min/1.73m² based on the MDRD formula, who were treated in Detroit Medical Center with IV ZOL between 2010 to 2014. We excluded patients who were on dialysis before the treatment, who had nephrotoxic treatment and who had insufficient data to analyze. We compared creatinines at up to 12 months before and up to 6 months after treatment with ZOL. The baseline renal function is defined as average of at the most recent two eGFRs in two different periods before date. Periods defined are three before, and three after admissions: 1-3 months, 3-6, 6-12 months before, and 0-3, 3-6 and 6-12 months after admission. The creatinine is considered the average in each period. The patient should have at least 2 eGFRs in 2 occasions after ZOL infusion. We considered a minimum of 10 mL/min/1.73m² change in eGFR between average before and average to be significant. We considered acute kidney injury (AKI) on admission if Cr is ≥ 15% from baseline.

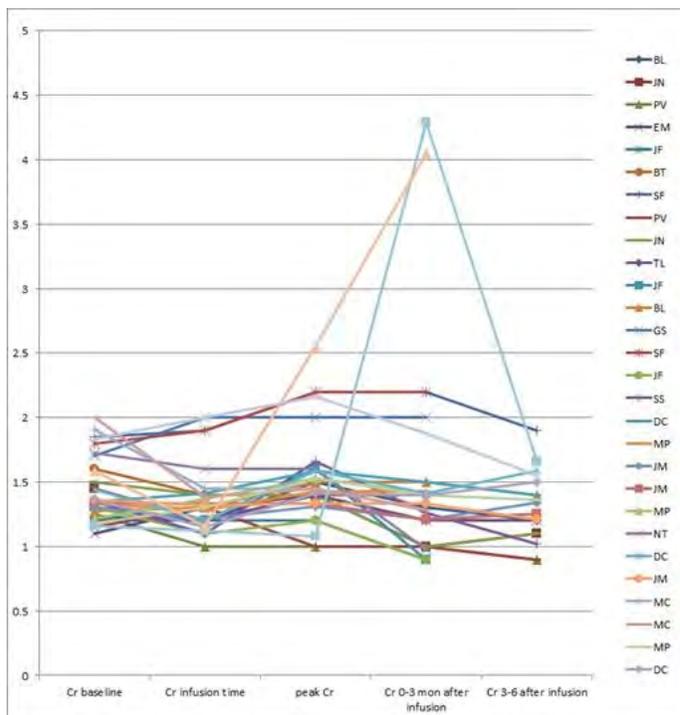

Results

We found 3742 patient who were treated with Zoledronic acid. So far we reviewed 912 charts, of which, 108 patients had eGFR of < 50 (average eGFR 36.5). None of which had significant decrease in eGFR in the 6 month period before the infusion. The rest were excluded due to eGFR > 50, or not enough data before infusion. Further only 31 patients had enough data after infusion and were included. Six of 31 had hypercalcemia.

The average eGFR was 42.25 mL/min/1.73m² (n=31). 28 of 31 (90.3 %) had maintained stable, or had some improvement of eGFR up to 6 month after ZOL infusion. Three patients (9.6 %) had a drop of eGFR at 0-3 month after infusion. Two of the 3 had improvement of renal function in period 3-6 month after. One of 3 had no data of renal function after. One of the two who had renal failure improved to his baseline eGFR. Therefore, two of 31 patients (6.5%) possibly had permanent drop of eGFR after ZOL infusion

Conclusion

IV ZOL caused no renal harm in 90.3%, reversible renal impairment in 3.2% and permanent renal impairment in 6.5% of the patients. Therefore, we believe ZOL treatment has good safety data in CKD and should be given if indicated.

Safety Observations With Three Years of Denosumab Exposure: Comparison Between Subjects Who Received Denosumab During FREEDOM and Subjects Who Crossed Over to Denosumab During the FREEDOM Extension. NB Watts*¹, JP Brown², S Papapoulos³, EM Lewiecki⁴, DL Kendler⁵, P Dakin⁶, RB Wagman⁶, A Wang⁶, NS Daizadeh⁶, S Smith⁶, HG Bone⁷. ¹Mercy Health, USA, ²Laval University & CHU de Québec Research Centre, Canada, ³Leiden University Medical Center, Netherlands, ⁴New Mexico Clinical Research & Osteoporosis Center, USA, ⁵University of British Columbia, Canada, ⁶Amgen Inc., USA, ⁷Michigan Bone & Mineral Clinic, USA

Purpose: Denosumab (DMAb) is approved for the treatment of postmenopausal women with osteoporosis at increased risk for fracture. In the 3-year FREEDOM trial comparing placebo (Pbo) and DMAb, questions arose regarding imbalances of low-frequency adverse events and some common adverse reactions. Here, we examined the incidences of these events in women who originally received Pbo during FREEDOM and then received DMAb for 3 years during the FREEDOM Extension (cross-over group). This provided a unique opportunity for comparison with the original 3-year Pbo and DMAb FREEDOM observations.

Methods: In FREEDOM, postmenopausal women with osteoporosis received Pbo or DMAb for 3 years. Women were eligible for the Extension if they completed the 3-year FREEDOM visit, missed no more than 1 dose of investigational product (IP) during FREEDOM, and agreed to enroll. During the Extension, all women received DMAb. Three-year cumulative incidences of selected adverse events of interest observed during FREEDOM for the Pbo and DMAb groups also were determined for the first 3 years of DMAb exposure during the Extension for the cross-over group. For each of these 3 groups, the safety analyses included women who received ≥ 1 dose of IP during the respective 3-year periods (FREEDOM Pbo: N=3883; FREEDOM DMAb: N=3879; Extension cross-over DMAb: N=2206). Selected safety events of interest included malignancy, pancreatitis, endocarditis, delayed fracture healing, serious infections, serious opportunistic infections, and serious cellulitis or erysipelas, in addition to the top 5 most frequent adverse events in the US prescribing information (USPI; back pain, pain in extremity, musculoskeletal pain, hypercholesterolemia, and cystitis).

Results: The incidences of these adverse events in the cross-over DMAb group during the first 3 years of the Extension were similar to or lower than the incidences reported in FREEDOM and did not show a trend for increasing risk of any of these events (Table). For example, the incidence of serious adverse events of cellulitis or erysipelas observed in FREEDOM DMAb subjects (0.31%) was not observed in the FREEDOM Pbo subjects who crossed-over to DMAb (0.05%) in the Extension.

Conclusions: Analyses of 3-year safety data from FREEDOM (Pbo and DMAb groups) and 3-year safety data from the Extension (cross-over DMAb group) did not show an increasing trend regarding the imbalances of low-frequency events and some common adverse reactions observed in FREEDOM.

Table. Incidences of Events of Interest

| Event of interest - n (%) | FREEDOM (3 years) | | Extension (3 years) |
|---|---------------------|-----------------------|-------------------------------------|
| | Placebo N = 3883 | Denosumab N = 3879 | Cross-over Denosumab N = 2206 |
| Adverse Events | | | |
| Malignancy* | 167 (4.30) | 187 (4.82) | 108 (4.90) |
| Pancreatitis [‡] | 3 (0.08) | 7 (0.18) | 2 (0.09) |
| Endocarditis | 0 (0.00) | 3 [†] (0.08) | 0 (0.00) |
| Delayed fracture healing [§] | 5 (0.13) | 2 (0.05) | NA |
| Delayed fracture healing [¶] | 1 (0.03) | 0 (0.00) | 1 (0.05) |
| Serious Adverse Events | | | |
| Infections | 134 (3.45) | 160 (4.12) | 81 (3.67) |
| Opportunistic infections* | 3 (0.08) | 4 (0.10) | 2 (0.09) |
| Cellulitis or erysipelas | 1 (0.03) | 12 (0.31) | 1 (0.05) |
| Top 5 Most Frequent Events in USPI | | | |
| Back pain | 1343 (34.59) | 1344 (34.65) | 318 (14.42) |
| Pain in extremity | 432 (11.13) | 451 (11.63) | 171 (7.75) |
| Musculoskeletal pain | 291 (7.49) | 297 (7.66) | 118 (5.35) |
| Hypercholesterolemia | 236 (6.08) | 280 (7.22) | 145 (6.57) |
| Cystitis | 225 (5.79) | 228 (5.88) | 125 (5.67) |

Treatment groups are the original randomized assignments in FREEDOM. Seven placebo subjects received one dose of denosumab in FREEDOM were analyzed in the denosumab column in US PI.
 N = Number of subjects who received ≥ 1 dose of investigational product.
 Includes only treatment-emergent adverse events; based on MedDRA version 13.0.
 * Based on neoplasms benign, malignant and unspecified (including cysts and polyps) system organ class excluding benign events used in the FREEDOM Extension
[‡] Based on acute pancreatitis event of interest search strategy
[§] Based on delayed fracture healing response collected on Clinical Fracture Summary CRF II in FREEDOM
[¶] Based on AE reporting of delayed fracture healing events and subsequently selected by search strategy
[†] Includes aspergillosis, herpes zoster, pulmonary tuberculosis, and tuberculosis
[‡] No causative pathogen was identified in any of the 3 cases reported as endocarditis. One subject was hospitalized for treatment with antibiotics. One had endocarditis listed as a consideration in a fatal event of multi-organ failure due to sepsis; however, no treatment details from the case were available. The third case was listed as "non-serious," and the patient did well without long-term antibiotic therapy. Further information is not available.

The Effect of Bisphosphonate Treatment on Bone Turnover and Bone Balance in Postmenopausal Women with Osteoporosis. Fatma Gossiel¹, Richard Jacques², Kim Naylor², Eugene McCloskey², Nicola Peel², Jennifer Walsh², Richard Eastell². ¹The University of Sheffield, United Kingdom, ²University of Sheffield, United Kingdom

Postmenopausal osteoporosis is characterised by increased bone turnover, a negative balance (resorption>formation) and increased fracture risk. Bisphosphonates reduces bone turnover and fracture risk but their effect on bone balance is yet to be fully investigated. We have compared the effects of bisphosphonates on turnover and balance in postmenopausal women with osteoporosis using a T-score bone marker plot. 165 postmenopausal women (hip and spine BMD T-score ≤ -2.5 or < -1 with a prior fracture) were recruited, mean age 67 years. They were provided with calcium and vitamin D supplements and randomised to receive ibandronate (n=55, 150mg/month), alendronate (n=54, 70mg/week) or risedronate (n=56, 35mg/week). A fasting serum sample was collected at baseline and weeks 1,2,4,12,13, 48 and 96 on treatment. A control group of 200 healthy premenopausal women received no treatment. PINP and CTX were measured using the iSYS-IDS analyser. Values were log₁₀-transformed and normalised. The T-scores for PINP and CTX value were calculated for each postmenopausal woman using the mean and standard deviation values from the premenopausal group.

By week 96 bisphosphonates reduced mean levels of turnover to -2.1SD units (95% CI: -2.322, -1.848) below the mean of the premenopausal women $p < 0.001$. Bone balance was positive for all agents in the early phase of treatment. At week 96, mean levels of balance were positive in all treatments combined, (0.3SD units, 95% CI: 0.145, 0.559), $p < 0.01$ but bone balance was more positive with alendronate only, $p < 0.01$, (Figure).

In postmenopausal osteoporosis treatment with bisphosphonates improves bone balance by making it more positive and reduces bone turnover, relative to healthy premenopausal women. Bisphosphonates have differing effects on turnover and balance.

The concept of ectosteric cathepsin inhibitors. Dieter Bromme^{*}. The University of British Columbia, Canada

Cathepsins K, V, and S are potent extracellular matrix protein-degrading proteases exhibiting either elastase and/or collagenase activities. The collagenase activity of cathepsin K is a major anti-resorptive drug target in skeletal diseases, whereas the elastase activities are considered detrimental in cardiovascular, respiratory, and potentially skin diseases. Substantial efforts have been invested to design highly

potent and selective active site-directed cathepsin K inhibitors for the treatment of osteoporosis which all showed efficacy in preclinical and/or clinical studies but were plagued with serious side effects leading either to the termination of clinical studies or ongoing delays in the regulatory approval process. To our opinion, side effects are not only due to off-target problems but also due to the inhibition of non-matrix protein degradation functions of the drug target cathepsin. All active site-directed inhibitors developed to date will affect these regulatory activities as well and thus a different concept of inhibition is needed if matrix degradation is the target.

We have identified specific ectosteric sites associated with matrix protein degradation in cathepsins. These sites are needed for the binding to substrates such as elastin and collagen, for the binding of ligands or for protease oligomerization. In contrast to allosteric sites, they do not affect the active site. For example, cathepsin K requires glycosaminoglycans (GAGs) as ligand for the formation of oligomeric protease complexes. Only these complexes are collagenolytically active whereas the monomer exhibits all other proteolytic functions. Preventing oligomerization, GAG binding or non-active site-based interactions with matrix proteins allows for the selective inhibition of the therapeutically relevant elastase and collagenase activities of cathepsins without interfering with their other functions. These inhibitors represent a new class of drugs which specifically block only the disease-relevant activity of a target enzyme and thus avoid potential side effects intrinsic to a multifunctional drug target.

Adherence to Osteoporosis Medications in Japanese Patients after Hospitalization for Acute Osteoporotic Fracture. Shusuke Ota^{*}, Yoshiaki Tsuboi, Yasuyoshi Okamoto, Takanobu Doi. Shizuoka Medical Center, Japan

PURPOSE: Osteoporosis Medications are reduced osteoporotic fracture risk and increased of bone mineral density in elderly patients. The aim of this study were (1) to investigate the baseline demographics in hospitalized patients with osteoporotic hip fracture (HF) compared with vertebral fracture (VF) and upper extremity fracture (UEF), including distal radius fracture and proximal humeral fracture, and (2) to quantify the use of and adherence to osteoporotic medications following the osteoporotic fractures. **METHODS:** A retrospective chart review was conducted of 384 hospitalized Japanese patients (97 males and 288 females) with acute HF, VF or UEF (221 patients with HF, 80 patients with VF, and 97 patients with UEF) between January 2011 and December 2012. We calculated the proportion receiving more than one osteoporosis drug after discharge. Adherence to the osteoporosis treatment was measured as the proportion of days covered (PDC) during the second year following the osteoporotic fracture. **RESULTS:** The patients with HF were significantly older age and longer length of hospital stay than that with VF or UEF (mean age, HF; 85.0 \pm 10.0 years, VF; 81.0 \pm 9.0 years, UEF; 76.0 \pm 11.2 years, length of hospital stay, HF; 29.0 \pm 30.0 days, VF; 16.6 \pm 11.1 days, UEF; 14.5 \pm 13.2 days). The percentage of patients taking an osteoporosis medication at the time of discharge and 2 years after the discharge was 69.2% and 25.3% in HF group, 75.0% and 35.0% in VF group, and 24.7% and 22.7% in UEF group, respectively. The mean PDC in 2-year following the fracture was 0.25 (HF), 0.35 (VF), and 0.23 (UEF). The second fracture occurred at the rate of 7.2% in HF group, 22.5% in VF group, and 0% in UEF group over the 2-year period following the initial fracture. **CONCLUSIONS:** While the adherence rate of osteoporosis treatment was decreased over time in HF and VF groups, the low compliance in VF group was an increased risk of secondary osteoporotic fracture. Despite of lower rates of initiation of osteoporosis medications at the discharge, the UEF group was not occurred secondary osteoporotic fracture for 2 years after the initial fracture.

NHS Lanarkshire Osteoporosis Therapeutic Review Project. Eamonn Brankin^{*}¹, Wendy Feeney², Robin Munro². ¹NHS Lanarkshire / University of Glasgow, United Kingdom, ²NHS Lanarkshire, United Kingdom

From 2013 to 2014 NHS Lanarkshire worked with an independent pharmacy service to undertake osteoporosis therapeutic reviews on patients in general practices in the county. 59 of 109 practices took part in ongoing annual review. Parameters measured included diagnosis, residential status (own home vs in care), current treatment with calcium & vitamin D, (Ca & D3) bisphosphonates and oral steroids, prevalent fragility fracture, (age 50-74) (+/- subsequent diagnosis of osteoporosis), and concordance with oral therapy. 15203 patients were identified as being at risk and 4621 patients had a case note review by a pharmacist. Therapeutic interventions (therapy initiation, change and/or information and concordance advice) were made in 1900 cases. 3971 patients had a diagnosis of osteoporosis. Of these 3517 were on Ca & D3. 4675 were on bisphosphonates (including those with osteopenia) 394 (8%) of these were not on concurrent Ca & D3. 428 were on steroids of whom 90 (21%) were not on Ca & D3. Of those with prevalent fragility fracture (2719) only 2216 were on Ca&D3. 1726 were found to be non compliant with Ca & D3 therapy and 1025 had appropriate medication started. 77 new diagnoses of osteoporosis were made & 164 patients were started on a bisphosphonate. Concordance with osteoporosis therapies, particularly with Ca & D3 is known to be very variable. Of those who underwent case note review, 1619 patients were identified as likely to benefit from therapeutic intervention but were clinically contraindicated. 1794 patients were identified as having had a possible

fragility fracture (age 50-74) but who had not been subsequently investigated and managed according to current national guidelines to confirm that the fracture was fragility in nature, indicating potential significant inadequacies in clinical coding. Current gaps in coding practice leave open the possibility of a significant shortfall in clinical care. Multidisciplinary working, including therapeutic review by a pharmacist was found to be helpful in identifying diagnostic code gaps and concordance issues in at risk patients. This data allowed targeted pilot concordance clinics to be run by an osteoporosis specialist nurse (OSN) & offered more cost effective use of her time. As a result a large number of patients received better, more focused disease education and support & therapeutic advice in an attempt to increase patient awareness and education, with subsequent benefits in medication concordance.

Persistence and Compliance with Subcutaneous Denosumab in Routine Practice. Richard Pikner^{*1}, Zlata Fejfarkova², Michaela Heidenreichova³. ¹Klatovska Hospital, Czech republic, ²Dept. of Clinical Laboratories, Klatovska Hospital, Czech republic, ³Dept. of Bone Metabolism, Klatovska Hospital, Czech republic

We evaluated all women that received denosumab during the period from August 2011 to March 2015 in our center. We evaluated 320 women, that represents 1174 denosumab applications. Women received first dose of denosumab within the period from September 2014 to March 2015 were excluded. We evaluated persistence and compliance with denosumab used according to approved reimbursement criteria in the Czech Republic (T-score $>2.5SD$ and osteoporotic fracture, or intolerance to other osteoporosis treatment).

From 320 treated women, 79.1 % were older than 75 years at the start of denosumab administration. 100 women of them discontinued the denosumab administration (non-persistent group), represents persistence 68.75%. The average number of doses in non-persistent patients was 2.7 doses and 4.12 in persistent group. Compliance was estimated as a percentage of doses administered within the interval of 6 months \pm 4weeks between doses. In persistent group the compliance was 93.1 %, in non-persistent group 94.8 % respectively. We analyzed reasons for therapy discontinuation in non-persistent group. From 100 non-persistent women, 24 died (23 were older 70 years), 35 women do not continue with therapy and in 41 women denosumab was stopped due to clinician decision.

Denosumab is medication having high compliance over 90 % even in routine practice. Persistence is highly influenced by age, comorbidities and reimbursement criteria and will be detailed discussed in presented work.

Effect of Teriparatide or Risedronate on Pertrochanteric Hip Fractures Recovery: 26-Week Results of a Randomized Clinical Trial. Per Aspenberg^{*1}, Jorge Malouf², Umberto Tarantino³, Pedro A. Garcia-Hernandez⁴, Costantino Corradini⁵, Soeren Overgaard⁶, Jan Stepan⁷, Lars Borris⁸, Eric Lespessailles⁹, Frede Frihagen¹⁰, Kyriakos Papavasiliou¹¹, Helmut Petto¹², José Ramón Caero¹³, Fernando Marin¹⁴. ¹Orthopaedic Surgery, Linköping University, Sweden, ²Internal Medicine, Hospital San Pablo, Spain, ³Orthopaedic Surgery, Univeristy Tor Vergata, Italy, ⁴Osteoporosis Centre, University Hospital, Mexico, ⁵Orthopaedic Institute; University of Milan, Italy, ⁶Orthopaedic Surgery, University of Southern Denmark, Denmark, ⁷Institute of Rheumatology, Charles University, Czech republic, ⁸Orthopaedic Surgery, University Hospital, Denmark, ⁹IPROS Unit, Hospital Porte Madeleine, France, ¹⁰Orthopaedic Surgery, University Hospital, Norway, ¹¹Orthopaedic Surgery, Aristotle University, Greece, ¹²Eli Lilly & Company, Austria, ¹³Orthopaedic Surgery, University Hospital, Spain, ¹⁴Eli Lilly & Company, Spain

There is few data on the effect of anti-osteoporosis drugs on fracture healing in weight-bearing bones. We present 26-wk interim results of an ongoing, prospective, randomized, multicenter, active-control trial of 78-wk duration, comparing the effect of teriparatide (TPTD:20 μ g/d) and risedronate (RIS:35 mg QW) initiated within 2 weeks after the surgical treatment of a pertrochanteric hip fracture. Methods: 224 patients were randomized and 171 (TPTD: 86, RIS: 85) contributed to the efficacy analysis. Main inclusion criteria were BMD T-score $<-2.0SD$, 25-OH-vitamin D (>9.2 ng/mL) and a recent low-trauma pertrochanteric hip fracture (AO/OTA 31-A1 or A2) treated with osteosynthesis. During the first 26-wk, patients received double-dummy study medication with either an oral or injected placebo plus Ca+vitD3 supplements. We here report secondary and exploratory endpoints related with function, hip pain, quality of life (QoL), radiology outcomes and safety. Results: Mean (SD) age was 77 (8) yr, 77% were women, and 26% had a history of a prior low-trauma fracture after the age of 50. There were no significant between-group differences in the SF-36 QoL questionnaire, Charnley's scale hip pain, ability to walk or the use of walking aids during follow-up. A significantly shorter time to complete

the timed up-and-go (TUG) test was recorded in the TPTD group at all the post-randomization visits (6, 12, 18 and 26 wk) (range: -3.1 to -5.7 seconds; $p<0.05$ full-adjusted Mixed Model for Repeated Measures). The 100 mm hip pain Visual Analog Scale during the TUG test also showed statistically significant lower values (adjusted absolute difference range: -10.6 to -11.9 mm) in the TPTD group at 12 and 18 wk, with a trend at 26 wk (-10.1 mm; $p=0.053$). There were no significant between-group differences in radiographic fracture healing at 6 or 26 wk, mechanical failure of the implant (TPTD:7, RIS:8), loss of reduction (TPTD:2, RIS:4) or non-union (0 cases). AEs were similar between groups. Seven deaths unrelated to treatment were reported. Hypercalcemia and hyperuricemia were more frequently observed in the TPTD group. There were 3 and 8 non-vertebral fractures in the TPTD and RIS group respectively ($p=0.14$). Conclusions: TPTD or RIS showed similar results in several fracture-related outcomes. TPTD-treated subjects reported significantly less pain and a shorter time to complete the TUG test. These results should be interpreted with caution given the exploratory nature of the data.

Histochemical examination on bone of postmenopausal model rats with switched administration from PTH to eldcalcitol. Hiroshi Hongo^{*1}, Sadaiki Sakai², Tomomaya Yamamoto³, Tomoka Hasegawa³, Satoshi Takeda², Koichi Endo², Hitoshi Saito⁴, Norio Amizuka³. ¹Hokkaido University, Japan, ²Product Research Dept., Chugai Pharmaceutical CO., LTD., Japan, ³Department of Developmental Biology of Hard Tissue, Hokkaido University, Japan, ⁴Medical Science Dept., Chugai Pharmaceutical CO., LTD., Japan

Introduction: Parathyroid hormone (PTH) has been shown to accelerate bone formation accompanying with the increased proliferation of preosteoblasts, while eldcalcitol (ELD) induces bone formation by mini-modeling and inhibits osteoclast differentiation and bone resorption. However, there is a limitation of administration period of PTH, so that, it seems of interest to investigate whether ELD would show the biological effects after the PTH administration. In this study, we have attempted to histologically examine the bone tissue of postmenopausal model rats with switched administration from PTH to ELD. Materials and Methods: Six months old Wister female rats were ovariectomized, and after two months later, we administered human PTH (1-34; 10 μ g/kg, 5 days/week) during 4 weeks, and then, continuously administered hPTH in the same manner, switched to administer ELD (20ng/kg, 5 days/week) or discontinue for medication. After 4 weeks or 8 weeks administration, the treated rats were fixed, and the femurs were processed for paraffin or MMA embedding in order for histochemical examination and Villanueva bone staining. Result and Discussion: The rats administered with PTH for 4 weeks showed an elevated bone mineral density (BMD) and increased trabecular thickness, compared with those of the vehicle group. The specimens which continuously had the PTH administration or switched from PTH to ELD administration revealed a tendency to increase or keep the same level of BMD and trabecular thickness as the ones administered with PTH for 4 weeks. In the rats switched to ELD administration, bone deposition seemed to be mediated by mini-modeling, featuring convex calcein labeling and focal budding of bone matrix. In contrast, the specimens with drug discontinuation displayed attenuated trabecular thickness and BMD. Taken together, it seems likely that ELD is a strong candidate to induce bone formation by means of mini-modeling after the PTH administration.

Small molecules targeting the NXI-motif-binding pocket abrogate suppression of wnt-beta-catenin signaling by sclerostin. Myengmo Kang^{*1}, Eunjin Kim², Jiwon Choi², Sungkil Lim². ¹College of Medicine, Yonsei University, Seoul Korea, South Korea, ²50 Yonsei Seodeamungu, South Korea

Wnt-b catenin signaling has been reported to play an important role for bone homeostasis. Both sclerostin and DKK1 can bind to LRP5/6 and inhibit the canonical Wnt signaling. Recently, clinical trial of monoclonal antibodies against sclerostin revealed a significant increase in bone mineral density remarkably. Sclerostin binds to LRP5/6 through NXI motif of the loop 2 region. To identify the small compounds which can inhibit binding of sclerostin to LRP5/6 and abrogate Wnt3a mediated b catenin signaling suppressed by sclerostin in MC3T3E1 stable cell lines, we screened small compounds library through the high throughput put system. Further SPR analysis, Alp assay and ex vivo calvarial bone formation assay were also performed. Here we show that Chromen-4-one derivative could abrogate the suppression of Wnt3 mediated b catenin signaling by sclerostin and DKK1. It bound to the E1-E2 domain of LRP5/6 in SPR analysis and stimulated ex vivo calvarial bone formation. In vitro cytotoxicity was low in both MC3T3E1 cells and 293 cells. Consequently, these results suggest that Chromen-4-one derivatives can antagonize the endogenous inhibitor, sclerostin and DKK1 in bone, and thereby have the beneficial effects on management of fracture healing and metabolic disease such as osteoporosis.

Modeling and Simulation to Link Concentration of Urinary C-terminal Telopeptide of Type I Collagen and Percent Change in Hip Bone Mineral Density with Fracture Risk: MOVER Study with Monthly Intravenous Ibandronate. Kiyohiko Nakai^{*1}, Masato Tobinai², Masayuki Matsunaga², Masao Yamamoto², Junko Hashimoto², Satofumi Iida², Takehiko Kawanishi². ¹Chugai Pharmaceutical Co., Japan, ²CHUGAI PHARMACEUTICAL CO., LTD., Japan

Purpose: Modeling & simulation (M&S) using the results of population pharmacokinetics and pharmacodynamics analyses can accelerate the efficient development of new drugs. By predicting efficacy and safety, MS using data from the MOVER study showed links between ibandronate (IBN) dosage, urinary concentration of C-terminal telopeptide of type I collagen (uCTX), and lumbar spine bone mineral density (BMD). In this study, in addition to IBN dosage, uCTX, and BMD, the modeling of relationships between IBN dosage, uCTX, and BMD, the modeling of relationships was extended to include the prevention of fractures regarded as the primary endpoint for the osteoporosis treatment. Methods: IBN (0.5 or 1.0 mg) was administered intravenously to Japanese osteoporosis patients once a month for 3 years in the MOVER study. uCTX, percentage change in hip BMD, and fracture data obtained from 758 patients (per protocol set) in the MOVER study were used to develop the mathematical model to link these data. To develop this mathematical model, statistical analysis software TIBCO Spotfire S+ version 8.2J and nonlinear mixed effects modeling software NONMEM version 7.2 were utilized. Results: As before, a K-PD model was used to link IBN dosage and uCTX. Next, an indirect model was used to link uCTX with the percentage change in hip BMD (which was a newly employed marker used as a representative value of BMD instead of the lumbar spine BMD used previously). This procedure resulted in good agreement between observations and predictions. Finally, percentage change in hip BMD and fracture risk were connected by a logistic regression model represented by the following equations 1 and 2 using both percentage change in hip BMD and fracture data at 3 years after initiation of IBN treatment. $\text{Logit} = \text{Baseline} + \text{Slope} \times \% \text{ change in hip BMD} \dots$ Equation 1 $\text{Fracture risk} = \exp(\text{Logit}) / (1 + \exp(\text{Logit})) \dots$ Equation 2 Conclusions: We successfully developed a mathematical model to describe the relationships between IBN dosage, uCTX, percentage change in hip BMD, and fracture risk. This mathematical model quantitatively connected uCTX with fracture risk. It also suggests that the degree of reduction in uCTX by treatment with IBN has great potential to predict the decrease of future fractures.

Health Related QoL of Osteoporosis Patients with Daily Teriparatide in the Japan Fracture Observational Study (JFOS): Interim Report. Hiroyuki Enomoto^{*1}, Saeko Fujiwara², Ryoichi Takayanagi³, Masayo Sato¹, Mika Tsujimoto⁴, Takanori Yamamoto⁴, Satoshi Soen⁵. ¹Medicines Development Unit Japan, Eli Lilly Japan K.K., Japan, ²Health Management & Promotion Center, Hiroshima Atomic Bomb Casualty Council, Japan, ³Department of Medicine & Bioregulatory Science, Graduate School of Medical Sciences, Kyushu University, Japan, ⁴Medicines Development Unit Japan, Eli Lilly Japan K.K., Japan, ⁵Department of Orthopaedic Surgery & Rheumatology, Nara Hospital, Kinki University Faculty of Medicine, Japan

Background: In addition to reducing the risk of fragility fractures, the improvement of health related quality of life (HRQoL) is also important for osteoporosis treatment. The Japan Fracture Observational Study (JFOS) was conducted to investigate the impact of teriparatide 20 µg/day (TPTD) on clinical fractures and HRQoL in osteoporosis patients in a daily clinical setting. We report an interim analysis of results of 12-month observation. Methods: JFOS is a 24-month, multicenter, prospective, observational study in Japan. TPTD-naïve patients with osteoporosis at high risk of fracture were included. The cumulative incidence of clinical fracture at 12 month was reported. Change in back pain was assessed by visual analogue scale (VAS). Changes in HRQoL were assessed by European quality of life questionnaire-5 dimensions (EQ-5D) and Japanese osteoporosis quality of life questionnaire (JOQOL; maximum total score of 152). Instrumental activities of daily living (IADL) scale was also used to assess independent living skills. Results: A total of 1810 (90.1% women) patients were analyzed at baseline. Mean age (SD) was 76.9 (7.9) years. Two-thirds of patients had prevalent vertebral fractures and 34.3% of patients had 2 or more fractures. One-third of patients received bisphosphonates prior to TPTD. Cumulative incidences of any clinical fractures, mean VAS scores, mean EQ-5D Index scores, mean total scores of JOQOL, and mean IADL scales for 12 months are shown in Table 1. Conclusion: JFOS is the first large observational study to investigate the effectiveness of TPTD as a primary objective in osteoporosis patients in Japan. TPTD treatment resulted in a reduction of back pain over time and improvement of HRQoL and IADL at 6 months. These findings are consistent with the results of previous studies.

Table 1 Cumulative incidences of any clinical fractures, and mean scores of VAS, EQ-5D Index, JOQOL (total score), and IADL

| | Baseline | 3 months | 6 months | 12 months |
|---|----------|----------|----------|-----------|
| Cumulative incidences of any clinical fractures (%) | - | - | 2.9 | 3.7 |

Improvement of Spinal Alignment and Quality of Life after Corrective Spinal Instrumentation for Spinal Kyphosis in Patients with Osteoporosis. Naohisa Miyakoshi^{*1}, Michio Hongo¹, Takashi Kobayashi², Toshiki Abe², Eiji Abe², Yoichi Shimada¹. ¹Akita University Graduate School of Medicine, Japan, ²Akita Kousei Medical Center, Japan

Introduction: With the increased aging of society, the demand for corrective spinal instrumentation for spinal kyphosis in osteoporotic patients is increasing. However, previous studies have not focused on the improvement of quality of life (QOL) after corrective spinal surgery in patients with osteoporosis, compared to non-operated control patients. This study evaluated changes in spinal sagittal alignment and QOL after corrective spinal instrumentation for patients with postmenopausal osteoporosis and spinal kyphosis, and to compare these results with non-operated patients with postmenopausal osteoporosis. Methods: Participants comprised 39 patients with postmenopausal osteoporosis >50 years old who underwent corrective spinal surgery using multilevel posterior lumbar interbody fusion (PLIF) for symptomatic thoracolumbar or lumbar kyphosis, and 82 age-matched patients with postmenopausal osteoporosis with no prevalent vertebral fractures. Spinopelvic parameters were evaluated with standing lateral spine radiography, and QOL was evaluated with the Japanese Osteoporosis QOL Questionnaire (JOQOL), SF-36, and Roland-Morris Disability Questionnaire (RDQ). Results: Lumbar kyphosis angle, sagittal vertical axis, and pelvic tilt were significantly improved postoperatively ($p < 0.05$). QOL evaluated with all three questionnaires also significantly improved after 6 months postoperatively, particularly in domain and subscale scores for pain and general/mental health ($p < 0.05$). However, these radiographic parameters, total JOQOL score, SF-36 physical component summary score, and RDQ score were significantly inferior compared with non-operated controls ($p < 0.05$). Conclusions: The results indicate that corrective spinal surgery using multilevel PLIF for patients with osteoporosis and spinal kyphosis significantly improved spinal global alignment and QOL after surgery, but did not reach the level of non-operated controls.

Bone Resorption Assessed by Serum Type I Collagen C-terminal Telopeptide (Crosslaps) is Inversely Associated with Bone Mineral Density and Change in BMD but Not with Change in Calcified Atherosclerotic Plaque in African Americans with Diabetes (AA-DHS). Thomas C. Register^{*1}, J. Jeffrey Carr², Leon Lenchik¹, Jasmin Divers¹, Gregory B. Russell¹, Nicholette D. Palmer¹, Lynne E. Wagenknecht¹, S. Carrie Smith¹, Jianzhao Xu¹, Donald W. Bowden¹, Barry I. Freedman¹. ¹Wake Forest School of Medicine, USA, ²Vanderbilt, USA

Background: Age independent inverse relationships between the degree of calcified atherosclerotic plaque (CP) and bone mineral density (BMD) suggest that there is a mechanistic relationship between the two phenotypes. In order to explore the relationships between bone resorption, bone density, and calcified plaque, we

assessed the levels of serum C-terminal cross-link of type I collagen (Crosslaps) in relation to bone and atherosclerosis phenotypes in 545 unrelated African Americans with type 2 diabetes (T2D). We also assessed associations of Crosslaps with change over time in CP and BMD.

Methods: Computed tomography (CT) was used to measure aorta, coronary and carotid artery CP, as well as thoracic (T-) and lumbar (L-) vertebral trabecular volumetric bone mineral density (vBMD). Associations between serum Crosslaps and bone and CP phenotypes were assessed.

Results: At baseline, participants were 56.9% female with mean±SD age 55.7±9.6 years, T2D duration 10.3±8.2 years; 288 subjects had follow-up CT scans after 5.1±0.9 years. Serum Crosslaps, 25-hydroxy vitamin D, and bioavailable vitamin D (BAVD) were associated ($p<0.05$) with aortic and carotid CP and T-vBMD and L-vBMD before but not after adjustment for age, sex, BMI, duration of diabetes, and smoking. Crosslaps was associated with baseline T-vBMD and L-vBMD in unadjusted and fully adjusted models which included the above plus % African ancestry, use of HRT, steroids, bisphosphonates, and calcium supplements, smoking, and change in eGFR, BMI, HbA1c and systolic BP. There was no association between baseline serum Crosslaps and change in CP in the aorta, carotid, or coronary arteries before or after adjustment for age, sex, diabetes duration, and other variables (all $p>0.3$). In contrast, baseline Crosslaps was significantly associated with future change in BMD in the lumbar but not thoracic spine.

Conclusions: Bone resorption activity, as estimated by serum Crosslaps, was associated with change in L-vBMD but not with change in T-vBMD or change in calcified plaque. Additional exploration of potential links between the two phenotypes is required for mechanistic explanations for the age independent inverse relationships between BMD and CP.

Effects of Uncontrolled Type II Diabetes on Vertebral Bone Marrow Fat Distribution. Mona Al Mukaddam*, Chamith Rajapakse, Mahdieh Bashoor Zadeh, Jeremy Magland, Wenli Sun, Helen Peachey, Peter Snyder, Felix Wehrli. University of Pennsylvania, USA

Purpose: Osteoporosis and increased risk of fractures are newly-recognized complications of Type 2 diabetes mellitus (T2DM). Paradoxically, bone mineral density (BMD) by DXA is higher in T2DM, so BMD underestimates the risk of fractures. Osteoblasts and adipocytes are derived from the same precursor mesenchymal stem cell in the bone marrow. Prior studies suggest that higher marrow fat is associated with impaired bone quality independent of BMD (1, 2), and poor control of diabetes is strongly correlated with mean vertebral bone marrow fat (BMF) (3). The aim of this cross-sectional pilot study was to determine if vertebral BMF measured by MRI is higher in diabetics than nondiabetics.

Methods: We selected 16 post-menopausal women with poorly controlled T2DM (DM) and 16 age-, race- and BMI- matched non diabetic (non-DM) post-menopausal women (table 1). BMF content of the lumbar vertebrae (L1-L5) was assessed using a clinical 3-Tesla MRI scanner (Siemens). A 2D interleaved multiple-gradient-echo chemical-shift imaging (IMGE-CST) sequence was implemented using the manufacturer's spine and body matrix coils. At each 2.5 mm² voxel a full spectrum with relative contributions from fat and water was obtained. The BMF was calculated as the ratio of these two signal values averaged across nine central voxels in each of five lumbar vertebrae(4).

Results: In non-diabetic women, BMF significantly increased from L1 to L5 ($R=0.31$, $p<0.005$, Figure 1a), which is similar to what has been reported (5). However, in women with poorly controlled diabetes, BMF did not change across the vertebrae ($R=0.09$, $p=0.49$, Figure 1b). There was a trend towards a higher bone marrow fat at L1 in subjects with poorly controlled diabetes than in nondiabetics (DM: $63.5 \pm 6.7\%$ vs non-DM: $58.8 \pm 8.0\%$; $p=0.08$). There was no significant difference in the average L1-L5 BMF (DM: $63.8 \pm 9.1\%$ vs non-DM: $61.2 \pm 7.5\%$; $p=0.39$).

Conclusion: This pilot study suggests that diabetes could affect the bone-fat-axis in L1 more than L5. That data highlights the need to evaluate different vertebral sites when monitoring effects of disease/treatment on bone. A potential explanation for the difference in the fat fraction gradient across L1-L5 could be the differences in the loading mechanics at L5 compared to L1, so that the effects of diabetes are blunted by the higher mechanical loading observed at the lower vertebrae. A study in larger patient cohort is needed to confirm these findings.

| Mean (SD) | DM (N=16) | Non-DM (N=16) | p |

Microalbuminuria has additional negative impact on trabecular bone score and bone mineral density in postmenopausal women with longstanding type 2 diabetes. Tomaz Kocjan*¹, Moica Jensterle¹, Gaj Vidmar², Andrej Janez³. ¹University Medical Centre Ljubljana, Slovenia, ²University Rehabilitation Institute, Slovenia, ³University Medical Centre Ljubljana, Slovenia

Objective: Microalbuminuria (MA), a marker of renal microvascular disease, is associated with fracture risk. Our aim was to examine the impact of MA on trabecular bone score (TBS), bone mineral density (BMD) and bone turnover markers in postmenopausal women with longstanding type 2 diabetes (T2D).

Methods: A cross-sectional study included a total of 27 T2D subjects (mean age 63.4 years, BMI 28.0 kg/m², duration of T2D 10.1 years, HbA1c 7.4%) treated with oral antihyperglycemic agents. They were divided into normoalbuminuric group (n=11) and microalbuminuric group (n=16) according to urinary albumin excretion rate (UAER; threshold > 2.2 mg/mmol). BMD at lumbar spine, total hip, femoral neck and distal radius was measured by DXA and trabecular bone microarchitecture was assessed by TBS. Procollagen type 1 N-terminal propeptide (PINP) and C terminal cross-linked telopeptide of type-I collagen (CTX) were determined. The association of MA with all variables was tested using regression models, adjusting for the effect of BMI.

Results: The average serum HbA1c in study subjects did not differ between normo- and microalbuminuric group. There were also no statistically significant differences in other baseline characteristics (age, years since menopause, BMI, waist circumference, duration of T2D) between the two groups (all $p > 0.10$ from exact Mann-Whitney test). The observed associations of MA were negative with TBS and the four standard BMD measurements, and positive with CTX and PINP values (Pearson and Spearman correlations, as well as corresponding coefficients in the regression models). However, statistical significance could only be verified for lumbar spine BMD (logistic regression model for predicting MA from BMI and BMD: estimated adjusted odds ratio 0.57 with 95% CI 0.33-0.98 per 0.1 g/cm² increase in BMD, $p=0.044$). Multivariate testing (using MANOVA with BMI as numerical covariate) of the

combined four BMD measurements confirmed the effect of MA ($p=0.049$ for the difference between normo- and microalbuminuric group). Conclusions: Our results suggest that presence of MA in T2D has additional negative effect on bone.

RISK FACTORS FOR FRAGILITY FRACTURES IN TYPE 1 DIABETES. Giulia Leanza^{*1}, Dario Pitocco², Concetta Suraci³, Anna Maria Altomare³, Andrea Palermo¹, Claudio Pedone¹, Roberto Sacco¹, Simone Alfieri¹, Sergio Leotta³, Paolo Pozzilli¹, Ann Schwartz⁴, Nicola Napoli¹. ¹Campus Bio-Medico university, Italy, ²Università Cattolica Sacro Cuore, Italy, ³Ospedale Pertini, Italy, ⁴University of California, San Francisco, USA

Type 1 diabetes (T1D) is an autoimmune disease characterized by chronic hyperglycemic state, which incidence has been globally rising during the past decades. Besides the well-known diabetic complications, poor bone health has been reported as a clinical concern, leading to an increased risk of fractures. Although some factors like hypoinsulinemia, low levels of insulin-like growth factor-1 and vitamin D have been reported as possible causes, clinical risk factors for fracture risk in T1D patients are still unknown.

Aim of this study was to evaluate the effect of glycaemic control, complications and diseases duration on fracture risk in T1D patients.

We have enrolled 247 T1D patients (116 males) referring to the IMDIAB group clinical network (Rome, Italy). All recruited patients underwent clinical evaluation and screening for bone fragility risk factors. Glucose control was assessed through the average of HbA1c levels measured in the last 5 years. Fractures were assessed through a validated questionnaire. Vitamin D levels were analyzed by RIA while calcium intake by a weekly evaluation form.

Patients were 43.47 ± 12.87 years old (range 18-76), had a BMI of 24.13 ± 4.21 kg/m² (15.6-44) and disease duration of 20.28 ± 12.49 years (1-63). The mean of HbA1c of the last five years was $7.54 \pm 1.08\%$ (5.31-12.87). HbA1c was $< 7\%$ in 31.5%, $\geq 7\%$ $< 9\%$ in 60% and $\geq 9\%$ in 8%. Insulin requirement was 19 ± 8.98 IU/daily for fast-acting and 19.17 ± 9.65 IU for long-acting.

Patients had in average low 25(OH)Vitamin D serum levels (16.38 ± 2.74 ng/mL) and low daily calcium intake (634.84 ± 159.97 mg). 56 patients (22.6%) reported at least one fracture after the diagnosis, whom 14.6% had only 1 fracture, 6.1% 2 fractures and 1.2% had 3 or more. Most common fractures sites were: hand (18.6%), foot (17.1%), tibia/fibula (10.5%), wrist (9.3%) and ribs (8%).

T1D related complications were more common in patients with fractures than in patients without ($p=0.03$). Disease duration was associated to an increased risk of any fractures (OR 1.2, 95% CI: 1.02-1.42). Insulin requirement and glycaemic control were not associated to risk of fractures. In conclusion, our data confirm that T1D patients should be carefully screened for fracture risk. Glycaemic control over the last 5 years did not influence risk of fractures. Prevention of complications may be crucial to preserve bone health in T1D. Calcium and vitamin D intake should be adequately replaced.

Site Specific Prevalence of Fragility Fractures and their Relationship with Body Mass Index in Patients with Type 1 Diabetes. Tayyab Khan^{*1}, Lisa-Ann Fraser². ¹Department of Medicine, Western University, Canada, ²Western University, Canada

Background: The increased risk of fragility fractures associated with type 1 diabetes (T1DM) is thought to be mediated by mechanisms different from those of primary osteoporosis. However the effects of these mechanisms on fracture risk at different bone sites, and the relationship between BMI and fracture site, is unknown. We aimed to study the relative prevalence of fragility fractures at different sites, and their relationship with Body Mass Index (BMI), among patients with T1DM followed at a tertiary care center.

Methods: Consecutive patients, over age 40 years, with T1DM completed a bone health questionnaire during their appointment with their Endocrinologist between May to December 2013. Fragility fractures were defined as fractures occurring from standing height or less, and excluded fractures of the skull, fingers or toes. Characteristics of patients with a prior fragility fracture were reviewed using descriptive statistics. For BMI analysis, only patients whose fractures occurred within 5 years of BMI measurement were included.

Results: Among 201 patients with T1DM, median age 52 (range 40 – 82), who were included in the study, 52 fragility fractures were identified. Of these, most occurred at the ankle/metatarsal (13/52; 25.0%), followed by the hip (11/52; 21.1%), and wrist (10/52, 19.2%). No association between BMI and fracture site was identified. However, we noted that the BMI of most patients who experienced a fragility fracture was high (average 28.3 ± 4.8), with 5.9% of patients in the overweight, and 52.9% in the obese category. The average age of patients with fragility fractures was 42.1 (± 14.7) years for the ankle, 57.2 (± 7.1) years for the hip, and 49.2 (± 13.7) years for the wrist.

Conclusions: In this cohort of patients with T1DM, fragility fractures occurred at younger ages than expected. Similarly, although low BMI is thought to be important

in the pathophysiology of fracture in T1DM, we found patients were more likely to be overweight/obese. This study confirms that the characteristics of patients with T1DM who fracture are different from those of other populations and need further evaluation to facilitate appropriate preventative care and treatment.

FES-Rowing Attenuates Bone Loss Following Spinal Cord Injury as Assessed by HR-pQCT. Robin Gibbons¹, Gary Beaupre², Galateia Kazakia^{*3}. ¹Brunel University, United Kingdom, ²VA Palo Alto Health Care System, USA, ³University of California, San Francisco, USA

Introduction: Motor complete spinal cord injury (SCI) leads to rapid bone loss in the lower limbs and individuals with chronic SCI are at high risk of fragility fracture in the tibia and femur. We recently demonstrated the potential for attenuation of bone loss using Functional Electrical Stimulation (FES)-rowing, a hybrid exercise that combines voluntary upper limb movement concurrent with FES-assisted lower limb actions [1]. To test the hypothesis that FES-rowing attenuates bone loss post-SCI, we used high resolution peripheral quantitative computed tomography (HR-pQCT) to: (1) characterise the density, microstructure, and strength of the ultradistal radius and tibia in an FES-rower with chronic SCI, and (2) compare these to previously published data on a group of FES-untrained individuals with chronic SCI [2] and two normative groups [3,4,5]. **Materials and methods:** Individual and group characteristics are presented in Table 1. Over the previous 24-months, the FES-rower performed an average of three weekly 30-min rows at 30 strokes/min, exposing the lower limbs to ~2,700 loading cycles/wk. The FES-rower was imaged using an HR-pQCT scanner (XtremeCT I, Scanco Medical AG) and analyzed using established protocols [6]. **Results:** At the tibia, the FES-rower metrics were 0.7 to 2.4 SD better than the untrained group means (Table 2). FES-rower densitometric and trabecular parameters were within 1 SD of normative control group means, while cortical porosity was 4.6 SD higher and biomechanical indices were 1.2 to 3.5 SD lower compared to normative means. At the radius, FES-rower densitometric and trabecular metrics were 0.9 to 2.0 SD better than the normative group means, while cortical and biomechanical indices were within 1 SD of normative group means. **Discussion:** Based on a single FES-rower, we speculate that: (1) in the tibia there is evidence that bone loss has been mediated compared to an FES-untrained group; (2) in the radius of the rower the superiority of key bone metrics compared to controls reflects a greater daily bone stimulus for an active manual wheelchair user; and (3) the positive effects on bone from FES-rowing have the potential to reduce fracture risk in individuals with chronic SCI. **References:** [1] Gibbons et al, 2014; [2] Wuermser et al, 2015; [3] Burghardt et al, 2010; [4] Sode et al, 2010; [5] UCSF Normative Cohort; unpublished data; [6] Kazakia et al, 2014.

SU0365

Grip Strength and Mortality in Osteoporotic Hip Fractures Among Latin American Elderly Patients. Hugo Gutierrez Hermosillo¹, ENRIQUE DIAZ DE LEON GONZALEZ². ¹Hospital aranda de la parraConacyt.IMSS, UMAE I CMN BAJIO, Mexico, ²IMSS, Mexico

Most of hip fractures in the upcoming years will occur in developing countries, but the risk for these fractures has not been studied in many of those countries. Therefore we carried out a cohort study; our general objective was to evaluate the low hand grip strength (HGS) as a risk for death among elderly patients with osteoporotic hip fracture in a tertiary hospital in Monterrey, Mexico.

Material and Methods

This is a prospective cohort study, we included patients older than 69 years old, admitted to a tertiary hospital in Monterrey, Mexico, with the diagnoses of osteoporotic hip fracture and were taken to surgery repair. The study was approved by the local Ethics and Research Committee.

Data such as age, gender, and education were asked. Medical history including chronic diseases. Clinimetric variables that were asked include: Barthel's index Score, Folstein's test, Mini Nutritional Assessment scale and the Charlson's Co morbidity Index. HGS measurement was performed by a trained physician using a Jamar® Hydraulic Hand Dynamometer, with standard method. The average result was recorded; the data was clustered in tertiles according to the HGS of the non-dominant using the standard method.

Statistical Analysis

All data was analyzed using the IBM SPSS version 21 software.

Results

A total of 644 patients were included, after one year of follow up there were 112 deaths (17.4%), mean age 83 for those dead and 81 for those alive (p=0.002), according to their tertile distribution, 61 in the first tertile (27.5%), 37 in the second tertile (17.1%) and 14 in the third (6.8%), died (p=0.021).

In the multivariate analysis the low HGS remained significant, tertile 2 p=0.021, HR 2.10 (CI95 1.21-3.95), tertile 1 p=0.006, HR 2.58(CI95 1.35-5.67), Charlson's Co morbidity Index p=0.031, HR 1.23 (CI95 1.01-1.22), age p=0.022 HR 1.032 (CI95 1.005-1.059), and Barthel's index Score p=0.029 HR0.98 (CI95 0.967-0.998). None of the rest of the variables seen on table 1 remained significant.

Conclusions

In elderly patients with osteoporotic hip fracture, low HGS is a risk factor for death one year after the fracture, as well as being older, poorer performance in ADL prior the fracture and having more comorbidities.

Fracture Diagnosis in Women compared with Men Veterans. Jennifer Lee^{*1}, Po-Yin Chang², Jimmy Lee³, Fay Saechao³, Susan Frayne⁴. ¹Stanford University Medical Center Palo Alto Veteran Affairs Health Care System, USA, ²Department of Medicine, Stanford Medical Center, USA, ³Veterans Affairs Palo Alto Health Care System, USA, ⁴Veterans Affairs Palo Alto Health Care System & Stanford Medical Center, USA

Purpose: Impact of fractures is not well known in women veterans (WV) and men veterans (MV). We aimed to characterize the prevalence and risk of fracture diagnosis in WV and MV within the Veterans Health Administration (VHA) nationally.

Methods: 355,352 WV and 5,021,151 MV who used VHA in FY2012 were examined cross-sectionally. Veterans with a fracture diagnosis were identified if ICD-9 code for fracture was included in inpatient/outpatient records in VHA or fee-basis services. Logistic regression models estimated sex-specific odds ratios (OR) and 95% confidence intervals (CI) for having a fracture diagnosis and included age (18-44, 45-64, and 65+ years), race/ethnicity (non-Hispanic White (NHW), Black, Hispanic, Native American, and Asian/Pacific Islander), number of primary care visits, number of mental health visits, urban/rural residence, and service-connected disability.

Results: Prevalence of any fracture diagnosis and hip fracture diagnosis were, respectively, 2.65% and 0.15% in all WV and 2.11% and 0.18% in all MV. For WV ages 18-44, 45-64, or 65+ years, prevalence of any fracture diagnosis were 1.81%, 3.06% and 4.09%, respectively, whereas for MV, 2.70%, 2.46%, and 1.62%. Hip fracture diagnosis was 1.3-fold greater in MV than WV ages 45-64 years (0.10% vs 0.13%, P<0.001), particularly in Black (0.05% vs 0.13%, P<0.001) and Hispanic (0.09% vs 0.17%, P=0.005); yet prevalence was 2.6-fold higher in WV than MV ages 65+ years (0.66% vs 0.26%, P<0.0001). In women and men, 2+ primary care visits or any mental health visit (versus none) was associated with greater odds of any fracture diagnosis (for 5+ primary care visits: WV OR 3.34, CI: 2.99-3.72; MV, 2.81, CI: 2.73-2.89). Among WV and MV, those with 5+ mental health visits had higher odds of fracture diagnosis (WV OR 1.55, CI: 1.46-1.64; MV, 1.63, CI: 1.60-1.66). **Conclusions:** Having a fracture diagnosis differed by age and race/ethnicity. Hip fracture diagnosis was more common in middle-aged MV than WV but not in the 65+ group. Veterans with any fracture diagnosis had more primary care and mental health visits. Primary care and mental health clinics may provide windows of opportunity for age-, race/ethnic-, and sex-specific interventions against fracture risk factors.

Disclosures: Jennifer Lee, None.

High prevalence of reduced bone mineral density and undertreatment of osteoporosis in patients with systemic sclerosis. Moon J Spanjer¹, Alexandre E Voskuyl¹, Willem F Lems², Irene EM Bultink*². ¹Department of Rheumatology, Amsterdam Rheumatology & immunology Center, location VU University Medical Center, Netherlands, ²Amsterdam Rheumatology & immunology Center, location VU University Medical Center, Netherlands

Purpose: Systemic sclerosis is a systemic inflammatory rheumatic disease with a very low prevalence (10-275/million persons), which has been associated with an increased risk of low bone mineral density (BMD)(1), but data on risk factors associated with bone loss in systemic sclerosis are scarce. The objective of this study was to investigate the prevalence of and risk factors for low BMD in patients with systemic sclerosis.

Methods: Demographic and clinical data of 61 patients with systemic sclerosis were collected. BMD measurements of the lumbar spine, total hip and femoral neck were performed using DXA. Osteoporosis was defined as a T score less than -2.5 SD and osteopenia as a T-score between -1.0 and -2.5 SD, according to WHO definitions. Systemic sclerosis disease severity was defined by the Rodnan skin score and by the Medsger disease severity score (2). Multiple linear regression analyses was used to assess factors associated with BMD. Results: Patient characteristics are shown in table 1. BMD measurements revealed osteopenia or osteoporosis in at least one measurement site in 67% of the patients, of whom 30% had osteoporosis. Low body mass index (BMI) and postmenopausal state were significantly associated with low BMD in all skeletal sites (table 2). No significant associations were found between age, Rodnan skin score, Medsger disease severity score, glucocorticoid treatment and BMD. Of the 30% of patients who had an indication for anti-osteoporosis treatment, 91% did not receive anti-osteoporosis medication.

Conclusions: The results of this cross-sectional study demonstrate a high frequency of osteoporosis or osteopenia in 67% of our patients with systemic sclerosis. Low BMI and postmenopausal state were identified as the most important risk factors. No relationship between disease severity and BMD was found, which finding could be related to the sample size, although it can be argued that low BMI is, at least partly, a marker of disease severity. This study also shows a high frequency (91%) of undertreatment of osteoporosis in this patient group. These results underline the importance of monitoring and treatment of low BMD in systemic sclerosis.

High Bone Turnover is Independently Related with Left Ventricular Stiffness in Primary Hyperparathyroidism – the EPATH Trial. Nicolas Verheyen*¹, Astrid Fahrleitner-Pammer², Cristiana Catena³, Evgeny Belvavkiy⁴, Johann Martensen², Julia Wetzel², Martin Gaksch², Martin Grüberl², Jakob Voelkl⁵, Florian Lang⁵, Elisabeth Kraigher-Kraimer⁴, Andreas Meinitzer², Burkert Pieske⁴, Stefan Pilz², Andreas Tomaschitz². ¹Medical University Graz, Austria, ²Medical University of Graz, Austria, ³University of Udine, Italy, ⁴Charite Universitaetsmedizin Berlin, Germany, ⁵University of Tübingen, Germany

Purpose: Accumulating evidence suggests a direct link between bone metabolism and cardiovascular stiffening which may be clinically pronounced in hyperparathyroid state. We therefore hypothesized that markers of bone turnover are associated with left ventricular (LV) stiffening in a large cohort of patients with primary hyperparathyroidism (pHPT).

Methods

We analyzed patients with pHPT who participated in the “Eplerenone in Primary Hyperparathyroidism” (EPATH) Trial. Blood sampling was performed after overnight fasting and standard laboratory parameters were determined immediately. Markers of bone formation (osteocalcin, bone-specific alkaline phosphatase [BALP] and procollagen type 1 [P1NP]) and resorption (beta-crosslaps [b-CTX]) were measured in serum that had been stored at -80°C. Transthoracic echocardiography was performed applying tissue Doppler imaging. Following international recommendations average of both septal and lateral early diastolic peak velocity of the mitral annulus (e') was used to quantify LV stiffening (lower e' indicates a higher degree of LV stiffening).

Results

We enrolled 131 patients with pHPT (mean age: 67 +/- 10 years, 107 were females [79%]). Median parathyroid hormone (PTH) (IQR) was 99 pg/mL (83 – 124), mean calcium was 2.63 +/- 0.15 mmol/L, 61 (45%) had a diagnosis of osteoporosis and mean e' was 7.1 +/- 2.3 (reference range: >7). e' was directly correlated with P1NP (r=0.154, P=0.07), osteocalcin (r=0.205, P=0.02), BALP (r=0.147, p=0.09) and b-CTX (r=0.149, P=0.09). We performed four separate multivariate linear regression analyses with e' as the dependent variable, with adjustment for age, sex, diabetes mellitus, smoking status, body mass index, systolic nocturnal blood pressure, GFR, PTH, calcium and treatment for osteoporosis. Markers of bone formation were independently and directly related with e' (osteocalcin: adjusted beta=0.243, P=0.01; BALP: beta=0.234, P=0.01; P1NP: beta=0.215, P=0.03), respectively, and b-CTX with borderline significance (beta=0.165, P=0.09).

Conclusions

We found that stimulated bone turnover in the setting of pHPT was independently and inversely related with LV stiffening and, thus, with a favorable cardiac phenotype. These data warrant further experimental studies on the effects of osteoblast or osteoclast activation on cardiac function.

SU0368

Increased body weight as a risk factor of intertrochanteric fracture severity in elderly women. Hyung Min Ji¹, Jun Han¹, Dong San Jin², Ye-Yeon Won¹. ¹Ajou University Hospital, South Korea, ²Mary's Orthopedics Hospital, China

Purpose

Risk factors for intertrochanteric fracture severity were not studied thoroughly despite the high failure rate of osteosynthesis previously reported. The purpose of this study was to identify the risk factor for each fracture type using AO/OTA classification in female patients who experienced intertrochanteric fractures.

Materials and Methods

This cross-sectional study identified 240 women over 50 years old with an incident intertrochanteric fracture in whom dual-energy x-ray absorptiometry (DEXA) was obtained. Two independent orthopaedic specialists graded the fracture severity by AO/OTA classification. Age, body weight, height, BMI and trochanteric T-score were used in univariate and multivariate logistic regression analysis to identify risk factor for each fracture type, and unstable intertrochanteric fracture.

Results

44.4% (106 hips) were graded as unstable intertrochanteric fracture. Lower BMD (OR 0.743, p=0.049), body weight (OR 0.970, p=0.031) and BMI (OR 0.927, p=0.045) predicted AO/OTA 31 A1 fracture while higher BMD (OR 1.443, p=0.010), body weight (OR 1.036, p=0.010), and BMI (OR 1.089, p=0.023) predicted 31 A2 fracture after univariate logistic regression. Increased body weight (OR 1.027, p=0.044) was the only independent risk factor for unstable intertrochanteric fracture after multiple logistic regression.

Conclusion

The higher the body weight, the greater the likelihood of experiencing an intertrochanteric fracture that is more unstable and displaced.

Progressive Cortical and Trabecular Bone Loss Four Years After Bariatric Surgery. Emily Stein^{*}, Angela Carrelli, Mariana Bucovsky, Nientara Anderson, Chengchen Zhang, Melissa Bagloo, Marc Bessler, Beth Schroppe, Elizabeth Shane, Shonni Silverberg. Columbia University College of Physicians & Surgeons, USA

Recent data suggest that fracture rates increase after bariatric surgery, particularly after procedures associated with the most weight loss. These emerging fracture data highlight the importance of understanding the long-term skeletal consequences of these procedures. Substantial skeletal changes are known to occur in the first year after surgery, but data are limited thereafter. To our knowledge, this 4-year study of 22 women represents the longest duration of follow-up of BMD and skeletal microarchitecture in the bariatric population. We hypothesized that bone loss at all sites would cease after weight loss stabilized.

At baseline and annually after surgery, we measured calcitropic hormones, bone turnover markers, areal BMD (aBMD) by DXA at the lumbar spine (LS), total hip (TH), femoral neck (FN) and 1/3 radius (1/3R), volumetric BMD (vBMD) and cortical (Ct) and trabecular (Tb) microstructure at the distal radius (RAD) and tibia (TIB) by high resolution peripheral quantitative CT (HRpQCT). Subjects (age 44±12; 65% Latina; mean BMI: 44±5 kg/m²) had normal baseline Z-scores. After Roux-en-Y gastric bypass (n=15), sleeve gastrectomy (n=2) and gastric banding (n=5) weight declined by 25% the 1st year and then remained stable (Table). All women received supplemental calcium and vitamin D and 25OHD was stable. However, PTH increased through year 3 (46%; p<0.01). CTX increased over the first 2 years (135%; p<0.01) and then trended toward baseline. aBMD at the TH and FN declined progressively over the 4 years. Declines at the LS and 1/3R BMD only became significant in years 3 (LS) and 4 (1/3R). HRpQCT did not change in the 1st year, but over the next 3 years, there were progressive declines in Ct bone (density, area and thickness), total and Tb density at both radius and tibia. Tb microarchitecture did not significantly change except for Tb thickness, which declined between years 2 and 4 at both sites.

In summary, after early declines in hip aBMD, we find significant progressive deterioration of cortical and trabecular microarchitecture. We conclude that while the initial bone loss at the hip may reflect skeletal unloading, pathologic changes affecting both cortical and trabecular bone continue long after cessation of weight loss. These findings suggest a structural mechanism for fracture in this population. Given the burgeoning number of bariatric procedures, additional studies are critical to further investigate the extent and sequelae of these changes.

Transient Regional Osteoporosis of the Hip: Case study with use of bisphosphonate as a treatment option. Susan Williams-Judge, MN, CNS, ARNP^{*}, Julie Carkin, M.D.¹, Yuli Son, M.D.², Camelia Whitten, M.D.³. ¹University of Washington/Northwest Hospital, USA, ²University of Washington, USA, ³Via Radiology, USA

Abstract:

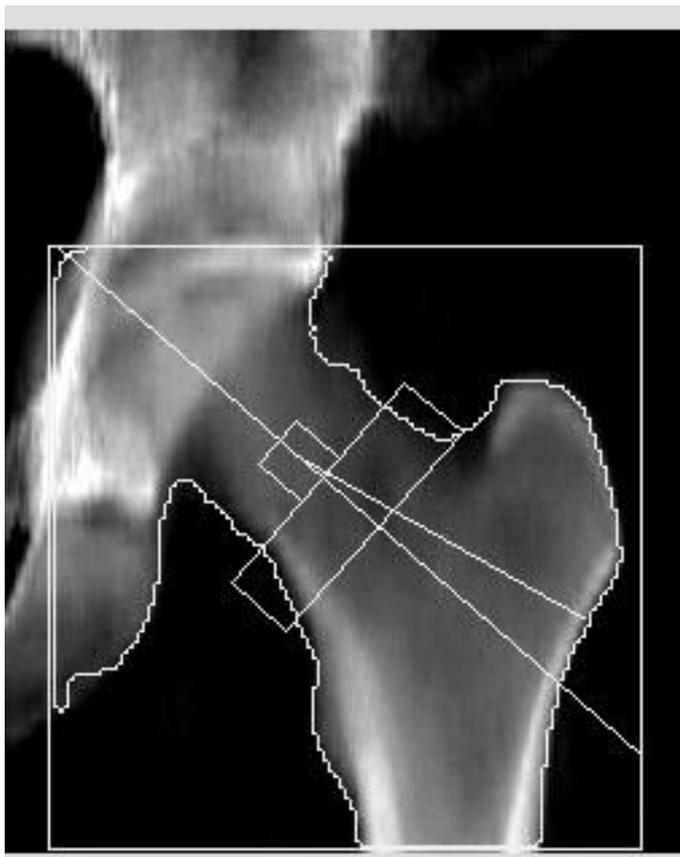

Transient regional osteoporosis is an uncommon, self-limited, transient disease resulting in osteoporosis at one site predisposing one to fragility fractures. Identification of this disorder is often difficult with MRI being the gold standard to differentiate it from other disorders such as avascular necrosis, stress fracture, infection, malignancy, and reflex sympathetic dystrophy. It generally affects middle aged men in a M:F 3:1 distribution, and is seen predominantly in women during the third trimester of pregnancy. Etiology is unknown, but thought to represent a vascular disease possibly driven by the sympathetic nervous system. Treatment options can range from conservative therapy with non-weightbearing, NSAIDs, and tincture of time to treatment with bisphosphonates which can prevent further fracture, and treat pain. Using this case study we hope to provide recognition of a rare disease, and the measures taken to make the diagnosis which is essentially a diagnosis of exclusion.

Case study A 45 year old male presented to the Sports Medicine Clinic with three weeks of acute onset left hip pain without prior trauma. He had prophylactically tried NSAIDs, and his primary care physician had performed x-ray imaging which was normal, and had placed the patient on steroids with referral to the sports medicine clinic. Medical history was significant for brain aneurysm rupture age 18, no past history of fracture, smoking or alcohol use. Remote history of marijuana and cocaine use 20 years prior. Clinical exam, laboratory and imaging studies will be included in the case study including normal baseline x-ray results with further imaging showing changes consistent with transient osteoporosis of the left hip. Subsequent arthrogram MRI findings, and DEXA scan, again supporting a diagnosis of transient osteoporosis, are also included.

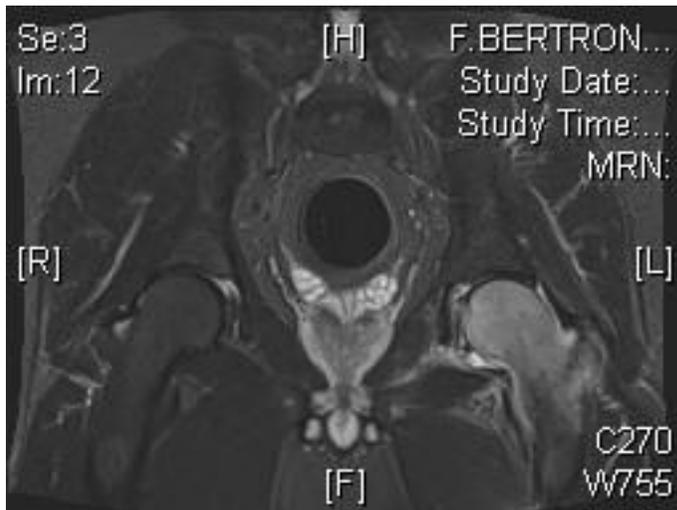

IV bisphosphonates were used in this case to decrease fracture risk, and help with pain control. Decision-making strategy will be included in the case study.

Relevant references will be included in the case study.

Efficacy and Safety of Denosumab for the Treatment of Patients With Low Bone Mineral Density Post Renal Transplantation: An Investigator-Initiated Pilot Study. Medi Aloosh^{*1}, Anthony A. Karaplis², Mark Lipman², Andrew C. Karaplis¹. ¹Lady Davis Institute for Medical Research, & Division of Endocrinology, Jewish General Hospital, McGill University, Canada, ²Lady Davis Institute for Medical Research, & Division of Nephrology, Jewish General Hospital, McGill University, Canada

BACKGROUND: Renal transplant recipients are at particular risk of fractures (vertebral greater than lower extremity). The overall fracture risk after kidney transplantation is 3.6–3.8-fold higher than in healthy individuals, and is 30% higher during the first 3 years after transplantation than in patients on dialysis. In bone biopsy studies, the main alteration in bone remodeling after renal transplantation is decrease in bone formation and mineralization in face of persistent bone resorption, which may lead to an imbalance in remodeling favoring resorption. The KDIGO guidelines recommend treatment with bisphosphonates in patients with estimated GFR >30 mL/min/1.73 m² and low BMD.

The development of a human monoclonal antibody to RANKL, denosumab, constitutes a novel approach to prevent fragility fractures in osteoporosis. Denosumab reduces osteoclastic resorption and, hence, could be beneficial in the treatment of osteoporosis in renal transplant recipients. This agent however has not been studied in this patient population. Although in a number of published clinical trials the overall rate of infections was similar with denosumab and placebo, the risk of severe infections in immunocompromised patients remains to be carefully scrutinized.

OBJECTIVE: Evaluate denosumab therapy in patients with low BMD post kidney transplantation.

METHOD: This was an investigator-initiated open-label pilot study conducted in the osteoporosis clinic at our hospital. The participants included 3 women and 2 men (mean age 64 ± 9 years) post renal transplantation (median time 10 years) who received denosumab 60 mg SC every 6 months (mean observation time 2.9 ± 0.6 years). All patients were on calcium and vitamin D. The main outcome measures were changes in BMD and safety.

RESULTS: During treatment, BMD increases occurred with denosumab administration (8.6% lumbar spine; 1.9% femoral neck; 2.7% total hip). There was no discontinuation of study treatment because of adverse events. One patient sustained a new vertebral fracture while off treatment. No serious adverse events such as infection or deteriorating renal function were reported.

LIMITATIONS: This was a short period, open-label pilot study with small sample size.

CONCLUSIONS: Denosumab treatment in a small number of patients with low BMD following kidney transplantation increased BMD and was well tolerated. No new safety signals were identified.

Adipokines Visfatin and Adiponectin Promote Inflammatory Phenotype for Human Nucleus Nulposus Cells. Stephanie Miller^{*1}, Rachel Willardson², Dezba Coughlin², Jeffrey Lotz². ¹University of California, San Francisco, USA, ²UC San Francisco, USA

Inflammation is a potential unifying clinical feature of intervertebral disc (IVD) degeneration and low back pain (LBP). Human nucleus pulposus (NP) cells have been shown to have direct inflammatogenic properties, separate from an immunologic mechanism. Adipokines, a class of cytokines produced by adipose tissue, have been implicated as active proinflammatory molecules in a variety of inflammatory conditions, including those correlated with LBP. We hypothesized that adipokines drive human NP cells towards an inflammatory phenotype, and we aimed to quantify the effects of various adipokines on human NP expression of genes associated with inflammation. Human NP cells were suspended in alginate beads and treated with low and high doses (2-100 ng/mL range) of the adipokines adiponectin, visfatin, resistin, leptin, fibroblast growth factor 21, or fatty acid binding protein 4 for seven days. The cells were collected and mRNA expression of markers of inflammation and remodeling were quantified via PCR analysis: including interleukin 1B (IL1B), IL 6, IL 8, IL 10, transforming growth factor β , matrix metalloproteinase 1 (MMP1), MMP3, collagen type 1a1, and aggrecan. Visfatin treatment (100 ng/mL) resulted in significant upregulation of the widest array of genes, including a 60-fold increase in IL1B expression, a 19-fold increase in IL8 expression, and four-fold increase in IL6, MMP1, and MMP3 expression. Treatment with 10 ng/mL adiponectin resulted in a three-fold increase in MMP3 expression. None of the tested treatments resulted in significant downregulation of any of the evaluated genes. These results suggest a potential role for the adipokines visfatin and adiponectin in NP-associated IVD inflammation. Additionally, MMPs 1 and 3 may play a central role in translating the effects of these two adipokines on disc degeneration.

Interleukin-1 β Suppresses Expression of Osteoblastic Genes as well as the Regulators of Ecto-nucleotides and Pyrophosphate That Negatively Regulate Bio-mineralization in Mouse Bone Marrow Stromal Cells. Yoichi Ezura^{*1}, Arina Hatta², Shin Lin², Yayoi Izu², Tadayoshi Hayata³, Masaki Noda². ¹Tokyo Medical & Dental University, Medical Research Institute, Japan, ²Tokyo Medical & Dental University, Japan, ³University of Tsukuba, Japan

Heterotopic ossification (HO) in arterial walls, cardiac valves, peri-articular tissues and spinal ligaments can cause serious clinical symptoms depending on the situations. The mechanisms involved in bio-mineralization and pathology of HO in various diseases indicate that inflammatory responses of the host individuals could be an important aspect. However, such responses of stromal progenitor cells residing in the host tissues has not been fully investigated on its possible contribution to HO. Recently in 2013, Ferreira et al., reported that pro-inflammatory cytokines including IL-1 β suppresses the expression of the negative regulator of the soft-tissue calcification, ectonucleotide pyrophosphatase/ phosphodiesterase-1 gene (*ENPP1*) in bone marrow derived mesenchymal stem cells of human, suggesting the involvement of this mechanism in the pathogenesis of HO. However, possible contribution of other regulators on soft-tissue calcification including *ANKH*, *NT5E*, *SLC29A1* and *ENTPDs* were not investigated in multiple cell sources. Therefore in this study, we investigated the effects of IL-1 β on the mouse bone marrow stromal cells (BMSCs) for the expression of such genes. As a reference, expression of various osteoblastic marker genes including alkaline-phosphatase, type I collagen, osteopontin, bone-sialoprotein, and osteocalcin was monitored by RT-PCR for BMSCs culture in osteogenic medium periodically for three weeks. Consistent with previous studies, such characteristic expression was suppressed by IL-1 β . In addition, we observed a reduction of *Enpp1*, *Nt5e*, *Ank* and *Slc29a1*. Reduction of extracellular pyrophosphate in the medium was confirmed. Our results suggest that IL-1 β suppresses osteoblastic gene expression as

well as negative regulators of soft-tissue calcification in BMSCs both in human and mouse, and may contribute to the mechanisms of HO in non-skeletal and skeletal soft-tissues.

Loss of TIEG expression results in severe colitis-mediated bone loss. Malayannan Subramaniam*, James Krempski, Kevin Pitel, Konstantinos Papadakis, John R. Hawse, Mayo Clinic, USA

Nearly 1.5 million Americans are afflicted with inflammatory bowel diseases (IBD) such as ulcerative colitis or Crohn's disease and approximately 30,000 new cases are diagnosed in the United States annually. A common consequence of IBD is bone loss and more than 30% of patients with IBD ultimately develop osteoporosis. A number of factors are thought to contribute to bone loss in patients with IBD including increased levels of inflammatory cytokines; however, the cellular and molecular basis for this phenomenon is not understood. Recently, multiple lines of evidence have linked a critical role for TGF β Inducible Early Gene-1 (TIEG) in mediating immune system function and loss of TIEG expression in mice has been shown to result in an enhanced susceptibility to the development of colitis. Therefore, we sought to determine the effects of colitis on the skeleton of wild-type (WT) and TIEG knockout (KO) mice. To induce colitis, male mice were administered 2% dextran sulfate sodium salt (DSS) for 3 cycles on days 1-8, 23-29, and 43-50. Following treatment, mice were monitored for weight loss and disease activity, and colon length and histology were used to assess inflammation between WT and TIEG KO animals. Additionally, tibiae were collected and used for pQCT analysis. In the absence of DSS treatment, TIEG KO mice do not exhibit any skeletal phenotype compared to WT littermates as determined by DXA, pQCT and micro-CT analyses. Following treatment of mice with DSS, TIEG KO animals developed more severe colitis relative to WT mice as indicated by decreased colon length, higher disease activity index and histological score. Interestingly, DSS treatment of TIEG KO mice also resulted in substantial decreases in multiple bone parameters compared to treated WT controls. Specifically, within the tibial metaphysis, significant decreases in total content (21%), trabecular content (30%), trabecular density (9%) and trabecular area (22%) were observed. At the tibial diaphysis, significant decreases in total content (15%), cortical content (15%), cortical area (13%), cortical thickness (5%) and periosteal circumference (8%) were detected in DSS treated KO animals relative to WT mice. These data demonstrate that loss of TIEG expression leads to the development of severe colitis-mediated bone loss in mice and provide a novel model system through which the cellular and molecular basis of IBD associated osteoporosis can be explored.

RANKL Induction of Cytokines in Pre-Osteoclasts In Vitro: Dependence on Cyclooxygenase-2 (Cox2). Trisha Kwarko*, Shilpa Choudhary, Thomas Estus, Carol Pilbeam, University of Connecticut Health Center, USA

Prior to stimulating differentiation of M-CSF-treated bone marrow macrophages (BMMs) into osteoclast-like cells, RANKL induces expression of multiple genes that can potentially mediate effects of inflammation or autoinflammatory diseases on bone. We are interested in the role of prostaglandins (PGs) in this induction. To determine if RANKL induces *Cox2* expression, the major enzyme controlling PG production, we cultured murine BMMs with M-CSF (30 ng/ml) \pm RANKL (30 ng/ml) for 24 h. RANKL induced *Cox2* expression by 30 min and expression peaked at 6 h. Prostaglandin E synthase, *Ptges*, which converts products of *Cox2* to PGE₂, was induced by RANKL at 1.5 h and peaked at 6 h. To examine the effects of *Cox2* absence on cytokine induction by RANKL, we performed a microarray on BMMs from wild type (WT) and *Cox2* knockout (KO) mice, treated for 24 h and 3 d with M-CSF + RANKL. At both time points the most highly differentially expressed genes in WT BMMs compared to KO BMMs were serum amyloid A 3 (*Saa3*) and interleukin-1 β (*Il-1 β*). Both *Saa3* and *Il-1 β* are involved in innate immunity and can mediate local and systemic inflammation. The RANKL induction of *Saa3* was 207-fold greater in WT BMMs compared to KO BMMs at 24 h and 30-fold greater at 3 d. The RANKL induction of *Il-1 β* was 108-fold greater in WT BMMs compared to KO BMMs at 24 h and 26-fold greater at 3 d. We confirmed the microarray results in a 24 h time course study of WT and *Cox2* KO BMMs. *Il-1 β* and *Saa3* were induced by RANKL in WT, but not KO, BMMs at 30 min and 3 h, respectively, and both peaked at 6 h. NS398, an inhibitor of *Cox2* activity, prevented the induction by RANKL in WT BMMs, and addition of PGE₂ restored the induction. To determine if *Saa3* and *Il-1 β* were secreted from RANKL-stimulated BMMs, we cultured WT BMMs with M-CSF \pm RANKL for 24 h and performed ELISAs. *Saa3* protein was not measurable in the culture medium from M-CSF-treated cultures but was secreted by cultures treated with M-CSF + RANKL. *Il-1 β* secreted protein was not detectable, with or without RANKL, suggesting that another factor is needed to activate caspase-driven cleavage and release of *Il-1 β* . We conclude that RANKL induces *Cox2* and *Ptges* in BMMs and that *Cox2*-produced PGs are required for the RANKL induction of *Il-1 β* expression and *Saa3* expression in BMMs. This is an example of how factors that induce both RANKL and *Cox2*, such as parathyroid hormone, could stimulate not only osteoclastogenesis but enhance inflammation.

Gender-Specific Effects of Insulin-like Growth Factor Binding Protein 4 in Body Composition and Skeletal Maturation. David Maridas*¹, Victoria DeMambro¹, Phuong Le¹, Casey Doucette¹, Subburaman Mohan², Clifford Rosen¹. ¹Maine Medical Center Research Institute, USA, ²Loma Linda University, USA

Insulin-like Growth Factor Binding Protein 4 (IGFBP4) is highly expressed in human adipose tissue and in osteoblasts. *In vitro* models have revealed IGFBP4 as an inhibitor of IGF-I signaling. However, previous reports showed that systemic injections of IGFBP4 in mice induced bone formation while local injections inhibited IGF-I actions making it unclear whether IGFBP4 enhances or inhibits IGF-I signaling *in vivo*. Our purpose was to determine how IGFBP4 mediates adipose differentiation and if this impacts skeletal acquisition *in vivo*. Thus, we investigated the skeletal and adipose phenotypes of IGFBP4 null (IGFBP4^{-/-}) mice at 8 and 16 wks. Whole body DXA revealed a significant decrease of fat proportion and lean mass in IGFBP4^{-/-} males and females (p<0.05). At 16 weeks, IGFBP4^{-/-} females had a reduction (p<0.04) of areal and femoral BMD and BMC while males were unaffected. Reductions in femur length, inguinal (iWAT), gonadal white adipose tissues, and interscapular brown fat were observed in IGFBP4^{-/-} mice. MicroCT of femurs showed reductions in BV/TV (p=0.06) and trabecular and cortical thicknesses (p=0.05) in IGFBP4^{-/-} females. Surprisingly, males had higher connectivity density (p=0.02) and trabecular number (p=0.005). Gene expression analysis showed that femoral *Sost* expression was decreased in IGFBP4^{-/-} males but not females. *Ppar γ* expression was reduced in iWAT of both genders. When challenged with a high fat diet (HFD, 60%kcal) or a control diet (10%kcal), IGFBP4^{-/-} mice were protected against HFD-induced obesity. Histology of iWAT revealed a hypertrophy of adipocytes in HFD-fed control mice that was not observed in IGFBP4^{-/-} females. To measure adipogenesis, outer ear mesenchymal stem cells (eMSCs) were isolated from 3-wk-old mice and differentiated into adipocytes. IGFBP4^{-/-} eMSC showed a significant decrease in adipogenesis compared to control cells (p<0.001). In summary, our data suggest that IGFBP4 is an important modulator of bone and fat development, but there is clear gender and tissue specificity. Indeed, males appeared to be protected against the reduction in bone parameters observed in females. Reduction of *Sost* expression in males but not in females may contribute to this gender-specific phenotype. Impaired adipocyte differentiation and function may contribute to reduction of adipose tissue and the resistance to HFD-induced obesity. Taken together, our results support the hypothesis that IGFBP4 regulates fat and bone tissues *in vivo*.

Bone Mineral Density in Hypophosphatasia. Franca Genest*, Franz Jakob, Nicole Luksche, Michael Schneider, Lothar Seefried, Musculoskeletal Center Wuerzburg, Germany

Hypophosphatasia (HPP) is a rare inherited metabolic disease caused by inactivating mutations in the ALPL gene, coding for the Tissue-nonspecific alkaline phosphatase (TNAP). Clinical manifestation is associated with a broad range of symptoms with increased risk of insufficiency fractures and bone marrow edema being a well-known hallmark of the disease especially in adult patients. Little is known as to how Bone Mineral Density is altered in adult patients and about the clinical significance of BMD measurement in HPP.

From November 2014 to March 2015, in total 60 adult HPP patients were examined at our department. DXA was performed in 56 Pat. using Hologic Discovery A. Lumbar spine BMD was valid in all patients, total hip BMD could be determined in 52 patients.

Mean age of the 56 patients (45 female) with available DXA was 43.6 years (SD 10.8, range 24-72). Mean T-Score was -0.49 (SD 1.2) for lumbar spine and -1.06 (SD 1.0) for total hip. Comparing BMD with age/gender matched reference groups using Z-Scores revealed normal results for lumbar spine BMD (Z-Score 0.0, SD 1.2) and a slight decrease (Z-Score -0.64, SD 1.0) for total hip. In total 29 patients reported at least one fracture in their medical history with 9 patients having experienced 5 or more fractures. Differential analysis of DXA results pertaining to fracture history displayed lumbar spine BMD at Z=-0.02/T=-0.57 and Z=0.02/T=-0.4 for the fractured (n=29) and unfractured (n=27) group, respectively. Similarly, total hip BMD did not reveal substantial between-group differences. Mean levels of residual ALP activity were 21.7 U/I (SD 8.65) and 28.6 U/I (SD 14.24) for the fractured and unfractured group, respectively. So far we were not able to identify an association between ALP activity and BMD.

HPP is commonly reflected to be associated with deficient bone mineralization. According to our cross-sectional analysis, HPP in adults is not generally associated with reduced BMD as compared to age/gender matched reference cohort as measured by Z-Score. Basically, BMD values were lower in total hip as compared to lumbar spine. Comparing subgroups of patients with/out fractures did not find differences in their T- and Z-Score, suggesting that BMD is not a good predictor of fracture risk in HPP. Accordingly, BMD in moderate adult HPP seems not to be a function of residual ALP activity, while the latter might be associated with fracture risk. Examinations are ongoing and more substantiated data with higher patient numbers can be expected by the time of data presentation in October.

Disclosures: Franca Genest, None.

Establishing Reference Intervals for Pyridoxal 5'-Phosphate: the National Health and Nutrition Examination Survey 2007-2008 Data. Philip Nicklin*¹, Richard Eastell², Kim Naylor². ¹University of Sheffield, United Kingdom, ²Academic Unit of Bone Metabolism, United Kingdom

Diagnosis of adult-onset Hypophosphatasia (HPP) is particularly important in patients with osteoporosis, as treatment with bisphosphonates may result in atypical femur fractures. Pyridoxal 5'-phosphate (PLP) is a substrate for alkaline phosphatase (ALP) and so it is high in HPP and thus it is useful in the diagnosis of HPP. It is important to establish reference intervals for PLP that take into account confounding factors that affect PLP measurement. We determined the factors which influenced PLP results and calculated race and gender specific reference intervals for serum PLP in adults using the National Health and Nutrition Examination Survey (NHANES) 2007-2008 data. We selected adults ages 20 to 80 years (n=4496).

Serum PLP was measured by reversed-phase HPLC with post-column derivatization and fluorometric detection. The 95% reference intervals were calculated for PLP using the Robust method (CLSI Guidelines C28-A3), skewed data was back transformed after logarithmic transformation.

The factors which influenced PLP results included: inflammation (C-reactive protein >5.0mg/L) which was associated with lower PLP (median, 44nmol/L; IQR, 24-77nmol/L; compared to median, 64nmol/L; IQR, 37-114nmol/L; P<0.001), people with low ALP (<36.0 U/L) had higher PLP (median, 107nmol/L; IQR, 59-240nmol/L) compared to normal (median, 58nmol/L; IQR, 33-105nmol/L; P<0.001) and those taking vitamin B6 supplements had higher PLP (median, 73nmol/L; IQR, 47-123nmol/L; compared to no supplement, median, 47nmol/L; IQR, 28-89nmol/L; P<0.001). There was no effect of reduced kidney function (eGFR <60 ml/min) on PLP (median, 62nmol/L; IQR, 32-120nmol/L; compared to median, 58nmol/L; IQR, 34-105nmol/L; P=0.68).

Reference intervals were calculated after excluding the identified confounding factors. Subjects were categorised by race/ethnicity into the following groups: Mexican American, Non-Hispanic white, and Non-Hispanic black. The Kruskal-Wallis test showed a significant effect of race and gender on PLP (P=0.014, P=0.002), but not age (P=0.49) (Kruskal-Wallis). Serum PLP reference intervals for race and gender specific populations are shown in the table. We have established gender specific reference intervals for serum PLP in three race/ethnicity categories after excluding factors that affect PLP measurements. These reference intervals provide useful information for the diagnosis of adult-onset HPP.

| Race/ethnicity | n | Geometric Mean | Lower Limit (90% CI) | Upper Limit (90% CI) |
|----------------------------|-----|----------------|----------------------|----------------------|
| Mexican American Males | 68 | 53 | 13 (10 – 17) | 195 (147 – 253) |
| Mexican American Females | 88 | 45 | 12 (10 – 15) | 147 (119 – 183) |
| Non-Hispanic White Males | 305 | 63 | 10 (9 – 12) | 344 (290 – 402) |
| Non-Hispanic White Females | 361 | 55 | 8 (7 – 9) | 310 (264 – 364) |
| Non-Hispanic Black Males | 73 | 55 | 9 (6 – 12) | 336 (248 – 447) |
| Non-Hispanic Black Females | 84 | 44 | 6 (5 – 8) | 235 (167 – 324) |

Exposure-Response Modeling and Simulation to Support Evaluation of Efficacious and Safe Exposure and Dose Range for Asfotase alfa in Patients with Hypophosphatasia. Rajendra S Pradhan*¹, Marc R Gastonguay², Xiang Gao¹, Jonathon Monteleone¹, Jeannine Fisher³, CJ Godfrey³, Nathanael L Dirks³, Augustin Melian¹, David Thompson¹, Chetan D Lathia¹. ¹Alexion Pharmaceuticals, USA, ²The Metrum Research Group, USA, ³Metrum Research Group LLC, USA

Asfotase alfa is a human recombinant tissue-nonspecific alkaline phosphatase-Fc-deca-aspartate fusion protein in development as a subcutaneous (SC) treatment for hypophosphatasia (HPP). HPP is a rare, serious, and potentially fatal, genetic disorder caused by loss-of-function mutation(s) in the gene encoding the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP).

Sparse, repeated-measures, pharmacokinetic (PK), pharmacodynamic (PD) and immunogenicity data were collected from 5 interventional studies. The PD data selected for analysis covered the continuum of mechanistic biomarkers to clinical efficacy endpoints, starting with the reduction of TNSALP substrate levels (plasma inorganic pyrophosphate or P_i and Pyridoxal-5'-phosphate or PLP), and leading to improvements in bone mineralization, [Radiographic Global Impression of Change (RGI-C) and Rickets severity scale (RSS)], skeletal morphology and musculoskeletal function, [6-minute walk test (6MWT)], Bruininks-Oseretsky Test of Motor Proficiency, Second Edition (BOT-2) and Modified Performance-Oriented Mobility Assessment – Gait subtest (MPOMA-G)]. Safety data selected for analysis included ectopic calcification, injection/infusion associated reactions, and injection site reactions.

The serum asfotase alfa activity-time profiles were described adequately by a linear two-compartment population PK model. The PD-time profiles were described adequately by indirect PD response models linking time-continuous patient-specific predicted serum asfotase alfa activity to each of the PD endpoints. The safety

variables of interest were assessed for relationship between asfotase alfa exposure and safety findings across the clinical program. Model-based simulations were conducted to explore the dose-exposure-response relationships for all endpoints, across a range of possible dosing regimens. The integrated view of the simulated dose/exposure - response relationships for PD efficacy endpoints revealed that all PD endpoints approached a plateau around a weekly dose of 6 mg/kg administered SC as 3 or 6 times a week. This dose regimen showed normalization of TNSALP substrates from elevated levels prior to treatment, clinically meaningful improvement in bone mineralization and substantial improvement in skeletal morphology and musculoskeletal function. There was no apparent relationship between PK and any safety variables of interest.

Manifestations of Hypophosphatasia in Adults with Pediatric Onset of Symptoms: a Review of the Case Literature. Eileen K Sawyer*, Karen Anderson. Alexion Pharmaceuticals, USA

Purpose. Hypophosphatasia (HPP) is the rare inherited metabolic disease resulting from loss-of-function mutations in the tissue-nonspecific alkaline phosphatase (TNSALP) gene. The natural history in adult patients who first presented with symptoms of HPP as children (i.e. <18 years of age) is not well characterized. We sought to better understand the clinical presentation of HPP in these patients through a comprehensive review of the case literature.

Methods. Cases were identified through searches of PubMed using the keywords “hypophosphatasia” AND (“case report” OR “case study”) and reference lists of identified articles, and filtered for those reporting patients over age 18 with pediatric onset of symptoms. Available information captured for each case included: age of patient, presenting features, pre-specified systemic manifestations of interest including nephrocalcinosis, fractures, and muscle pain, and age at death if applicable.

Results. 293 publications were identified, dating from 1939; 28 publications described a total of 32 adults with pediatric onset of HPP (median age 42.5 years, ranging from 21 to 75 years). Two patients were reported as deceased (1 at age 23 of renal failure; 1 at age 57 of sepsis). Half of the patients were first diagnosed in adulthood, presenting most commonly with fractures and pain. Overall, the systemic manifestations of interest most frequently reported were fractures (24 patients), pain (22 patients), and early tooth loss (17 patients). Other common complications included limited mobility/function (9 patients), and short stature or loss of height (6 patients). Of note, few patients reported current or past characteristic pediatric symptoms such as nephrocalcinosis, respiratory complications, seizures (1 patient each), and craniosynostosis (5 patients).

Conclusions. Pain and fractures are prominent features of HPP in patients with pediatric-onset HPP surviving to adulthood. All symptoms of HPP should be queried in adult patients presenting with these symptoms. Missed diagnosis of pediatric-onset HPP is common in these patients, and highlights the need for increased recognition of HPP symptoms in childhood.

PHEX 3'-UTR c.*321A>G demonstrates X-linked recessive inheritance in a large American family. Gary S. Gottesman*¹, Katherine L. Madson¹, Valerie Wollberg¹, Steven Mumm², William H. McAlister³, Michael P. Whyte¹. ¹Center for Metabolic Bone Disease & Molecular Research, Shriners Hospitals for Children - St Louis, USA, ²Division of Bone & Mineral Diseases, Washington University School of Medicine, USA, ³Department of Pediatric Radiology, Mallinckrodt Institute of Radiology at St. Louis Children's Hospital, Washington University School of Medicine, USA

X-linked hypophosphatemia (XLH) is considered an X-linked dominant disorder. This year we reported (*JBMR*, 2015; 30:138-43) six American children (5 boys, 1 girl) diagnosed with sporadic XLH who carried a mutation (c.*231A>G 3'-UTR) in *PHEX* three base pairs upstream of the putative polyadenylation signal. Therefore, we found this mutation in ~12% of the 52 patients with “sporadic” XLH in our previous report. Further study revealed that four of these boys' mothers harbored the mutation, yet were considered unaffected by their families and we verified their lack of physical findings of XLH (e.g. short stature, bowed lower limbs, scapulocephaly, disproportionately long arms). For this *PHEX* mutation, we established a mild biochemical phenotype that could masquerade as sporadic or X-linked recessive hypophosphatemic rickets (HR).

Subsequently, we documented this *PHEX* mutation in 4-generations of an American kindred with HR spanning 7 generations who we followed for ~30 years. The proband presented at age 2 years with HR in 1985. His maternal grandfather had hypophosphatemic bone disease, but this boy's mother and the mother's three sisters were normal in stature without physical features of XLH. Here, we document the X-linked recessive inheritance pattern of HR in this kindred (including two additional branches), evaluating a total of 9 affected boys for whom we prescribed therapy, and 6

obligate "carrier" women of normal stature and appearance. In addition to the carrier women's normal stature, sequential measurements of fasting serum phosphate, in the five women who were tested, averaged 2.64 and 2.48 (NL: 2.5 – 4.5 mg/dL) at 2 hours and 4 hours, respectively. Four of these six women had TmP/GFR results, which averaged 2.28 and 2.43 (NL: 2.5 - 4.2) at 2 and 4 hours, respectively. Arm spans were commensurate with height in these women. FGF23 levels have not yet been measured, but were normal in a mother and daughter carrying this *PHEX* mutation in our previous report. Hence, this kindred demonstrates an X-linked recessive inheritance pattern resulting from this unique *PHEX* 3'-UTR mutation.

Modification of hydroxyapatite involves carbonate ion substitution in both patients with XLH and HYP mice. Eva Amenta^{*1}, Helen King², Catherine Skinner³, Steven Tommasini⁴, Carolyn Macica¹. ¹Department of Medical Sciences, Frank H. Netter, M.D., School of Medicine at Quinnipiac University, USA, ²Department of Earth Sciences, Utrecht University, Netherlands, ³Department of Geology & Geophysics, Yale University, USA, ⁴Department of Orthopaedics & Rehabilitation, Yale University School of Medicine, USA

X-linked hypophosphatemia (XLH) is the most common form of the familial phosphate-wasting disorders, arising as a consequence of an inactivating mutation in the phosphate-regulating neutral endopeptidase, X-linked (*PHEX*) gene. While persistent osteomalacia characterizes this disorder, the impact of insufficient phosphate on hydroxyapatite composition, the major inorganic component of bone, is unknown in patients with XLH. We previously showed that the ratio of phosphate to carbonate in cortical bone mineral matrix is increased in HYP mice, a murine model of XLH, compared to wild type mice (Tommasini et al., ASBMR 2014). To determine if this phenomenon is reproduced in human mineralized tissues, tooth dentin was studied as a human proxy for bone. Dentin is deposited by odontoblasts, a cell of neural crest origin that appears in the 17-18th week of gestation and exists throughout the lifespan. We hypothesized that there would be an increase in carbonate ion substitution in permanent teeth as a consequence of the hypophosphatemia associated with the osteomalacia of XLH. We measured and compared the phosphate to carbonate ion ratio in both primary and permanent teeth from patients with XLH to those who are not affected using Raman spectroscopy. The carbonate ion substitution levels were higher in permanent teeth (0.39 ± 0.11 vs. 0.19 ± 0.01 $p = .5E-9$), but not statistically significant between the primary teeth (0.28 ± 0.11 vs. 0.24 ± 0.01 $p = .05$). These preliminary data suggest that, during early development, the fetus has sufficient phosphate mineral available for normal dentin mineralization to occur. However, in permanent tooth dentin deposition during the 2nd through 5th year of life, accelerated carbonate ion substitution occurs due to the phosphate-poor environment. Consistent with our previous data that showed bone mineral carbonate content increased during pregnancy and lactation in both wild type and HYP mice, the substitution of carbonate ions into the hydroxyapatite may be a means of compensating for increased mineral demand and hypophosphatemia. However, although carbonate ion substitution appears to provide adequate mineral for permanent tooth formation, calcium carbonate is more easily resorbable than hydroxyapatite. Thus, the increase in carbonate content may contribute to the clinical sequelae of multiple dental caries and abscesses that XLH patients experience throughout their lifetime.

Mouse Model with Uncleavable Type I Collagen C-propeptide Processing Site has Extremely Brittle Bones. Aileen Barnes^{*1}, Joseph Perosky², M. Helen Rajpar¹, Kenneth Kozloff², Joan C. Marini¹. ¹NICHD/NIH, USA, ²University of Michigan, USA

Classical osteogenesis imperfecta (OI) is caused by mutations in type I collagen. Mutations in the C-propeptide cleavage site of both *COL1A1* and *COL1A2* cause high bone mass OI, characterized by bone hypermineralization and normal to increased DXA Z-scores. To elucidate the role of type I procollagen C-propeptide processing in bone formation, we generated a mouse with a heterozygous C-propeptide cleavage site defect (high bone mass, HBM) in which both residues of the *COL1A1* cleavage site were mutated to prevent cleavage by BMP1. Procollagen processing by HBM calvarial osteoblasts was severely decreased, with a 75% reduction in fully cleaved trimeric C-propeptide. Western blots of HBM long bone extracts revealed the presence of pC-collagen, in which the C-propeptide is attached to the collagen helix, and an increased amount of cleaved C-propeptide. Dermal collagen fibril diameters were smaller and more homogeneous in HBM than WT, consistent with uncleaved C-propeptide in fibroblast matrix. Fibroblast secretion of collagen into media was reduced 40% in HBM vs WT cells, consistent with HBM osteoblasts depositing half the normal amount of matrix. Multiple osteoblast (*Runx2*, *Alpl*, *Spp1*, *Bglap*) and osteocyte (*Mepe*, *Phex*, *Sost*) markers were decreased in differentiated HBM osteoblasts. In vitro mineralization by HBM osteoblasts was decreased ~20% ($p < 0.001$); direct assays of tissue mineralization are ongoing. Impaired C-propeptide processing affects skeletal size and biomechanics. At 2 months, male HBM mice are

significantly smaller in weight and length and have shorter femurs (92%). Femoral areal BMD in HBM mice is decreased 25% ($p < 0.001$), but vertebral BMD is normal. All 2 month HBM mice have pelvic deformities, and 40% have kyphosis. On μ CT, HBM femora have a thinner cortex with decreased cortical area. Four point bending revealed an extremely brittle phenotype; post-yield displacement is only ~10% of WT (0.03 vs 0.23, $p < 0.001$). HBM femoral stiffness, yield load, and ultimate load are also significantly decreased. At 1 year, male HBM mice remain smaller overall. However, femoral length is normalized and femoral aBMD is improved to 93.5% of WT. Vertebral aBMD remains normal. The HBM mouse phenotype demonstrates that the skeletal elements of *Bmp1/1111* deficiency are reproduced by a substrate defect in type I C-propeptide cleavage. Processing of the type I procollagen C-propeptide influences collagenous, cellular and mineral properties of bone.

A Case of Progressive Bony and Soft Tissue Overgrowth. Doriel Pearson¹, Manish Butte², Joy Wu^{*3}. ¹Lucille Packard Children's Hospital, USA, ²Stanford University School of Medicine, USA, ³Stanford University School of Medicine, Us

A 14 year-old female was referred to the metabolic bone disease clinic for bony and soft tissue overgrowth. Her early childhood history has previously been reported (Am J Med Genet Part A 146A:543, 2008) and is briefly summarized here. The patient was born at term following an uneventful pregnancy, with weight, length and head circumference all approximately 50th percentile. At 3 months of age she developed symmetric and progressive overgrowth of supraorbital ridges, followed at 6 months by enlargement of bilateral posterior neck masses, biopsy of which demonstrated normal muscle and fat tissue. By 22 months growth parameters were above 90th percentile. At 33 months she underwent decompression for spinal cord impingement. Excision of excess supraorbital bone revealed normal-appearing bone, but regrowth occurred within 3 months. Motor and cognitive development was normal. Her parents are from Ethiopia, there was no familial consanguinity, and family history was unremarkable. Since age 6 her clinical course has been notable for continued bony overgrowth in the skull and facial bones, complicated by frontal sinusitis and osteomyelitis, as well as marked overgrowth involving the upper cervical spine and 3rd and 4th digits of her hands and feet. Menarche occurred at age 13, and since then her scoliosis has significantly worsened. In addition, since puberty she has developed massive bulbous hypertrophy of areolar tissue. She has not experienced any fractures. She suffered severe respiratory failure following influenza A infection, but has shown no other susceptibility to infections or autoimmunity. Immunological testing of adaptive immune cells and function was normal. Exome sequencing of the patient and her parents did not detect any deleterious mutations in disease genes related to clinical phenotype. Several variants of unknown significance were identified, including a heterozygous c.1348C>T (p.R450W) variant in TNFRSF11A (encodes RANK), a heterozygous c.578G>C (p. R193P) variant in SOST (encodes sclerostin), and a heterozygous c.4589T>C (p.V1530A) variant in FLNA (encodes filamin A); however, the patient's mother is also heterozygous for these variants. In summary, we report on a female of Ethiopian descent with progressive symmetric bony and soft tissue overgrowth involving the skull, facial bones, cervical spine, 3rd and 4th digits with severe scoliosis and areolar hyperplasia, of unknown etiology.

A novel *GNAS* deletion identified among 58 patients affected by the sporadic form of pseudohypoparathyroidism type Ib (PHP1B). Rieko Takatani^{*1}, Angelo Molinaro², Monica Reyes², Lucy Raymond³, Harald Jüppner². ¹Massachusetts General Hospital & Harvard Medical School, USA, ²Endocrine Unit, Massachusetts General Hospital & Harvard Medical School, USA, ³Medical Genetics Department, Addenbrooke's Hospital, United Kingdom

Introduction: Pseudohypoparathyroidism type Ib (PHP1B) is caused by proximal tubular resistance to parathyroid hormone (PTH) that occurs in most cases in the absence of Albright's Hereditary Osteodystrophy (AHO). Patients affected by PHP1B have epigenetic changes that involve one or multiple differentially methylated regions (DMRs) in *GNAS*, the gene encoding Gsx and several splice variants thereof. Maternally inherited microdeletions within *STX16* (encoding syntaxin 16), or within *GNAS* cause familial forms of PHP1B. Most sporadic cases of PHP1B show broad *GNAS* methylation abnormalities, but the underlying molecular mechanism remains unknown.

Objective: To determine whether maternally inherited deletions can cause sporadic PHP1B.

Methods: We investigated 58 sporadic PHP1B cases, who had presented with PTH-resistant hypocalcemia and hyperphosphatemia, some of whom had mild AHO features. The *GNAS* methylation status was evaluated by different methods including Methylation-Specific Multiplex Ligation-dependent Probe Amplification (MS-MLPA), copy number was determined by Multiplex Ligation-dependent Probe Amplification (MLPA); the *GNAS* region was furthermore analyzed with micro-satellite markers.

Results: DNA from all investigated sporadic PHP1B patients (n=58) showed broad *GNAS* methylation changes. Their mothers revealed no evidence for *GNAS* methylation changes and microsatellite analysis for this chromosomal region provided no evidence for discordance thus excluding paternal uniparental isodisomy of large portions of chromosome 20q. Furthermore, none of the 74 siblings of sporadic PHP1B patients were affected, and none of the 19 children of the adult patients were affected. Only one patient showed evidence for an allelic loss within the *GNAS* region as determined by MLPA, which resulted in the discovery of two adjacent novel deletions (37,597 and 1,427bp, respectively) removing exon NESP55 and two noncoding *GNAS* antisense exons. The same deletion was identified in the healthy mother, who therefore showed a complete loss of NESP55 methylation, indicating that she had inherited the deletion from her father.

Conclusion: Our findings confirm that the *GNAS* region comprising antisense exons 3 and 4 is required for establishing all maternal *GNAS* methylation imprints. Some "sporadic" PHP1B cases can be carriers of an inherited *GNAS* microdeletion that had not led to symptomatic disease in other family members, possibly because it was transmitted only through males in earlier generations. The genetic defects leading to PTH-resistance in the other investigated sporadic PHP1B patients remains unknown.

Disclosures: Rieko Takatani, None.

Activating Calcium Sensing Receptor Mutations Result in Abnormal Bone Quality Indices Independently of Parathyroid Hormone (PTH) Deficiency.

Diana Ovejero^{*1}, Barbara Misof², Rachel Gafni³, Beth Brillante⁴, Hua Zhou⁵, David Dempster⁶, James Reynolds⁷, Jaime S. Brahimi⁸, Paul Roschger⁹, Klaus Klaushofer², Michael T Collins³. ¹National Institutes of Health, USA, ²Ludwig Boltzmann Institute of Osteology at the Hanusch Hospital of WGKK & AUVA Trauma Centre Meidling, Austria, ³National Institute of Dental & Craniofacial Research, National Institutes of Health, USA, ⁴National Institutes of Dental & Craniofacial Research, National Institutes of Health, USA, ⁵Regional Bone Center, Helen Hayes Hospital, USA, ⁶Columbia University College of P&S, USA, ⁷National Institute of Child Health & Human Development, National Institutes of Health, USA, ⁸University of Maryland Medical Center, USA, ⁹Ludwig Boltzmann Institute of Osteology, Austria

The role of the calcium sensing receptor (CaSR) as a regulator of PTH secretion is well-established, but its function at the bone is less well-defined. Autosomal dominant hypocalcemia (ADH) is a genetic form of primary hypoparathyroidism (HPTH) caused by activating mutations in the *CASR* gene. Thus, ADH bone analysis could offer insight into the CaSR's skeletal function. Iliac crest biopsies from 6 ADH patients (2 male, 4 female, ages 11-48 years, duration of HPTH 11-48 years) and 10 postsurgical (PS) HPTH patients (10 women, ages 25-47 years, duration of HPTH 2-11 years) were evaluated by histomorphometry and backscattered electron microscopy (qBEI). BMD was also measured by DXA at the time of the biopsy. Only patients that had been hypoparathyroid for ≥ 2 years and had never received PTH therapy were included. To normalize for age and gender all values were transformed to Z-scores. The association of length of disease with all outcomes was analyzed through linear regression. T-tests were used to compare groups (mean \pm SEM). Structural parameters (bone volume/trabecular volume, trabecular width, number and separation, and cortical width) were not statistically different. Of dynamic parameters (mineral apposition rate (MAR); mineralized, osteoid and eroded perimeters; bone formation; and adjusted apposition rate), only MAR was significantly different between the ADH vs PS group (2.15 ± 1.07 vs -2.78 ± 0.78 , respectively, $p < 0.01$). Bone mineral density distribution assessed by qBEI revealed that ADH bone had lower calcium content than PS bone: CaMean (mean calcium concentration): -1.6 ± 0.56 vs 0.83 ± 0.4 , $p < 0.01$; CaPeak (the mode calcium concentration): -1.78 ± 0.6 vs 0.68 ± 0.55 , $p = 0.01$; CaLow (% of bone with low mineral content): 3.5 ± 1 vs -0.45 ± 0.15 , $p = 0.01$. Further, mineral distribution was more heterogeneous in ADH bone: CaWidth (variation in mineral density): 3.37 ± 0.7 vs 0.24 ± 0.2 , $p < 0.01$. The % of areas of highly mineralized bone (CaHigh) was not significantly different. Mean BMD was lower at all sites (spine, femoral neck, total hip, forearm) in the ADH vs PS group, but only mean forearm BMD yielded a significant difference (ADH: -0.48 ± 0.3 vs PS: 0.69 ± 0.3 , $p = 0.03$). Length of disease was not associated with any of the observed differences between groups. These results indicate that despite the structural similarities between groups, ADH bone is less mineralized and more heterogeneous than PS bone, suggesting a direct role of bone CaSRs in skeletal mineralization.

Biochemical evidence for increased bone formation in patients with osteopetrosis. Christine Simpson^{*1}, Lisa Basso², Anna Maria Cusano¹, Paul Orchard², Karl Inosona¹. ¹Yale University School of Medicine, USA, ²University of Minnesota, USA

Osteopetrosis (OPT) is characterized by defective osteoclast formation or function resulting in high bone mass. In autosomal recessive (AR) OPT, hematopoiesis is

severely impaired and perinatal lethality occurs unless bone marrow transplantation is performed. The most common molecular defects in AR OPT are loss of function mutations in the *TCIRG1* gene, which encodes the α_3 subunit of the vacuolar H^+ -ATPase proton pump. In the autosomal dominant (AD) intermediate forms of OPT, patients can survive into young adulthood but suffer a variety of complications including osteomyelitis and optic nerve compromise due to bony encroachment. Common molecular defects in AD OPT include loss of function mutations in *CLCN7*, which encodes a H^+/Cl^- exchange transporter. Most patients with AR and AD OPT have increased numbers of osteoclasts in bone perhaps representing a compensatory response to the defect in resorption. Recent evidence suggests an important paracrine role for osteoclasts in bone formation and is consistent with the notion that in osteoclast-rich osteopetrosis, an increase in bone formation in vivo further compounds the defect in bone resorption leading to a progressive increase in bone mass. There are very few histomorphometric data available to evaluate this hypothesis and limited data on biochemical markers of bone formation, particularly P1NP. We therefore measured bone turnover markers in 9 patients with AR OPT, 7 of whom had mutations in *TCIRG1*, one patient with a mutation *CLCN7* and one in whom a genotype was not identified. We also measured bone markers in 7 patients with AD OPT, 2 of whom had mutations in *CLCN7*, 2 with mutations in *TCIRG1* and three in whom a genetic mutation was not identified. The table summarizes the findings in these individuals. The exaggerated increase in P1NP with relatively low CTX values is consistent with an "uncoupling" of bone turnover in favor of formation, consistent with the common clinical course of a progressive increase in bone mass over time in OPT. Interdicting anabolic signals from osteoclasts to osteoblasts may ameliorate symptoms in some forms of OPT.

| | Age (M/F) | Normal Range | CTX (pg/mL) | P1NP (ng/mL) | Ocn (ng/mL) | Sclerostin (pmol/L) | BSAP (ng/mL) | PTH (nLEq/mL) |

Case Report: Clinical and genetic analysis in a unique systemic skeletal disorder characterised by high bone turnover and bone expansion.

Huilin Jin¹, Alison Meynert², Martin Williams³, Jon H Tobias⁴, Stuart Ralston¹, Celia Gregson^{*5}. ¹Centre for Genomic & Experimental Medicine, University of Edinburgh, United Kingdom, ²MRC Human Genetics Unit, University of Edinburgh, United Kingdom, ³Department of Radiology, North Bristol NHS Trust, United Kingdom, ⁴Musculoskeletal Research Unit, School of Clinical Sciences, University of Bristol, United Kingdom, ⁵University of Bristol, United Kingdom

Background

Major advances have been made in understanding the molecular basis of rare bone diseases over recent years. Here we describe the results of clinical and genetic analysis of a patient with unique bone dysplasia characterised by high bone turnover, with radiological features of generalised osteosclerosis and bone expansion alternating with areas of osteolysis with features that overlap with but were distinct from those in Paget's disease of bone (PDB).

Case

A 34 year old man presented with generalized weakness, an inability to squat, and lower limb pain on persistent exertion since his mid-teens. He reported limb fractures aged 2, 7, 15 and 21. Sensory neural hearing loss required hearing aids from aged 28. After delayed primary tooth eruption, he experienced normal puberty, skeletal growth and schooling. He has mildly shortened terminal phalanges, quadriceps wasting and BMI 18kg/m². He is the eldest of two sons from a non-consanguineous healthy family. Routine biochemistry was normal except that alkaline phosphatase was raised (134U/L; normal 30-130). Levels of serum β CTX 1.7 μ g/L (0.1-0.5) and P1NP 179 μ g/L (20-76) were both raised. Radiographs showed abnormal bone architecture throughout the skeleton, with areas of osteosclerosis alternating with osteolysis, coarse trabecular markings and cortical thickening. Bone density as assessed by DXA was high at the spine and hip (T-score $>+4.0$). Nerve conduction studies and EMG were normal. Muscle biopsy showed mild non-specific myopathic changes.

Genetic analysis

We performed whole-exome sequencing on the index patient and three unaffected family members on an Ion Proton™ Sequencer using standard techniques. On average, each exome generated 42 million mapped reads and 90% were covered more than 20x. We identified 64 damaging variants that might have been responsible for the disorder but were unable to narrow the list down further to conclusively define the

responsible variant(s). Of note, the exome analysis excluded mutations in known candidate genes for PDB (*TNFRSF11A*, *TNFRSF11B*, *TNFSF11*, *SQSTM1*, *VCP*, *TM7SF4*, *CSF1*, *RIN3*, *OPTN*) and high bone mass syndromes (*TCIRG1*, *CLCN7*, *PLEKHM1*, *OSTM1*, *CA2*, *IKBKG*, *ITGB3*, *LRP5*).

Conclusion

We describe a novel skeletal disorder, presumed to be genetic in origin with features overlapping with, but distinct from, PDB which appears to have a novel molecular basis. Further investigations are in progress to define the cause.

Fig. 1: Pelvis X-ray

Table 1: Exome variant metrics

Figure 1

| Genetic Model | Autosomal recessive | X-linked (male) | De novo* |
|--|---------------------|-----------------|----------|
| Original variants | 2110 | 122 | 895 |

Characterization of Biological Interaction between Steroid and Palvarotene. Savantani Sinha^{*1}, Kenta Uchibe², Haruna Shimizu², Jiveon Son², Arima Naoko², Maurizio Pacifici², Masahiro Iwamoto². ¹Children's Hospital Of Philadelphia, USA, ²Divison Of Orthopedic Surgery, USA

Heterotopic Ossification (HO) is a multifaceted pathological condition that leads to the formation of excess endochondral bone at extraskelatal sites. Fibrodysplasia Ossificans Progressiva (FOP) is a severe form of HO caused by mutations in *ALK2* and is characterized by intermittent flare-ups. Prednisone is thus used as a standard-of-care anti-inflammatory agent for FOP patients since there is no effective treatment to prevent HO itself. Previous studies from our group showed that the retinoic acid receptor gamma agonist Palovarotene inhibited HO in injury and genetic mouse models. Though promising, those studies did not determine whether a combination therapy involving Palovarotene plus prednisone may be more effective or whether the two drugs would actually negatively impact each other. To this end, we used our

standard HO model in which rhBMP-2 mixed in Matrigel is implanted subcutaneously in 8 weeks old CD-1 female mice, eliciting HO in about 2 weeks. Freshly implanted mice were treated by gavage with pre-established doses of Palovarotene, prednisone or combination at different times/regimens. For comparison, companion mice received vehicle. Micro-CT scans showed that prednisone and dexamethasone given singly reduced HO, but co-treatment with Palovarotene was more effective. Early treatment appeared to be important for effectiveness of steroid action. To exclude non-specific systemic drug effects, mice were subjected to body weight measurements and blood analyses showed no obvious detrimental effects. To uncover mechanisms of drug action, we analyzed signaling pathways in mesenchymal progenitor cells in vitro. Cells were reverse-transfected with various reporter plasmids and quantified for activity with or without drug treatment. Treatment with dexamethasone increased glucocorticoid-response elements/GRE-Luc activity within 24hrs, while co-treatment with dexamethasone and palovarotene did not further increase or decrease GRE-Luc activity. Similar results were obtained with a retinoic acid receptor reporter plasmid (RARE) in response to palovarotene or in combination. Interestingly, co-treatment did result in appreciable decreases in NFkB activity. In sum, our data indicate that there is no major negative interactions of palovarotene and steroids against HO and a combination therapy may in fact offer alternative regimens, possibly making the therapy as effective and safe as possible for FOP patients.

Dysregulated TGF-β signaling and oxidative DNA damage as the cause for osteoporosis in the progeroid disorder geroderma osteodysplastica. Magdalena Steiner^{*1}, Hardy Chan², Thorsten Schinke³, Michael Amling³, Danny Chan⁴, Stefan Mundlos², Uwe Kornak⁵. ¹Charité, Germany, ²Charité Universitätsmedizin, Germany, ³Universitätsklinikum Hamburg Eppendorf, Germany, ⁴The University of Hong Kong, China, ⁵Charité Universitätsmedizin, Germany

Geroderma Osteodysplastica (GO) is a premature ageing disorder characterized by wrinkled, lax skin and infantile osteoporosis. It is caused by loss-of-function mutations in *GORAB*, encoding a golgin with poorly understood function. A conditional Gorab mouse model was created and crossed with *Px1cre* to inactivate Gorab starting in the limb mesenchyme. The *Gorab^{Px1cre}* mutants showed mild growth retardation, a reduction of trabecular and cortical bone volume, mineralization defects, and spontaneous long bone fractures. Further analysis revealed a significant increase in osteoblast and osteocyte numbers with a delay in terminal osteoblast differentiation. *Gorab^{Px1cre}* mutant bone cells and GORAB-deficient fibroblasts exhibited increased levels of reactive oxygen species (ROS) leading to an accumulation of DNA damage and subsequently to cellular senescence. In mutant cells as well as bone tissue upregulated TGF-β signaling and expression of the ROS-producing enzyme Nox4 were evident. Enhanced TGF-β levels in Gorab-deficient tissues were correlated with a striking decrease in decorin glycosylation known to regulate the bioavailability of TGF-β. Finally, treatment with the antioxidant N-acetyl cysteine (NAC) not only rescued the accumulation of DNA damage in Gorab-deficient cells, but also improved the trabecular bone volume as well as the organization of collagen fibers in the cortical bone of *Gorab^{Px1cre}* mice. Taken together, our results demonstrate that oxidative DNA damage and cellular senescence secondary to elevated TGF-β signaling caused by abnormal glycosylation of extracellular matrix components plays a pivotal role for the pathomechanism of GO.

Improvement in Giant Cell Tumor of the Jaw treated with Denosumab. Jessica Abramowitz^{*1}, Stuart Weinerman², Salvatore Ruggiero³. ¹Hofstra North Shore LIJ, US, ²Hofstra North Shore LIJ, USA, ³Long Island Jewish Medical Center, USA

Introduction: Giant cell tumors of the bone are known to express RANK ligand which contributes to the osteoclastic nature of these lesions. Traditional treatment for giant cell tumors of the jaw are: surgical, intralesional steroid injections, subcutaneous calcitonin, and alpha interferon. Denosumab a monoclonal antibody against RANK ligand, inhibits osteoclast formation and thereby decreases bone resorption. Denosumab has been studied and used successfully in treating giant cell tumors of bones of the extremities. We report the use of denosumab in a patient with giant cell tumor of the jaw.

Case presentation: An 18 year old female with Noonan's syndrome was referred to our clinic for management of benign giant cell tumor of the jaw. Giant cell tumors of the jaw were initially noted 12 years prior and confirmed on multiple biopsies. 9 years after initial diagnosis she was treated with subcutaneous calcitonin injections for an expansile jaw lesion. The lesion initially responded to calcitonin but then re-growth occurred. Initial laboratory testing included a bone specific alkaline phosphatase of 13 mcg/L, urine N telopeptides of 71 nmol BCE/mmol creatinine. Treatment was initiated with denosumab 60mg/mL. 4 months after the initial dose her urine N telopeptides decreased to 9 nmol BCE/mmol creatinine, bone specific

alkaline phosphatase decreased to 7.7 mcg/L. 7 months after the initial dose of denosumab bone specific alkaline phosphatase increased to 9.4 mcg/L, urine N telopeptides increased to 46 nmol BCE/mmol creatinine. A second dose of denosumab 60mg/mL was given at that time. 3 months following the second dose of denosumab bone specific alkaline phosphatase decreased to 6.1 mcg/L and urine N telopeptides decreased to 12 nmol BCE/mmol creatinine. Panoramic jaw x-rays performed 6 months after the initial denosumab showed some resolution of the jaw lesion and repeat x-ray 1 year after treatment showed complete resolution of the giant cell tumor.

Conclusions: We report clinical and radiologic improvement in a patient with giant cell tumor of the jaw following treatment with denosumab. Denosumab is a targeted therapy for treatment of giant cell tumor of the bone. It is a potential agent for use in patients with giant cell tumor of the jaw given the over expression of RANK ligand in giant cells. Evidence of response in this patient includes a decrease in bone turnover markers and resolution of the lesion on imaging following treatment.

New protocol to optimize iPS cells for genome analysis of fibrodysplasia ossificans progressiva. Yoshihisa Matsumoto^{*1}, Makoto Ikeya², Makoto Fukuta¹, Takanobu Otsuka¹, Junya Toguchida². ¹Nagoya city university, Japan, ²Center for iPS Cell Research & Application, Kyoto University, Japan

Fibrodysplasia Ossificans Progressiva (FOP) is a rare genetic disease characterized by progressive ectopic ossifications, which are often initiated after physiological stimuli. The responsible gene for FOP is the ACVR1 gene, which is one of type I receptors for BMP. The replacement of one amino acid in ACVR1 seems to activate downstream genes regulating bone formation, although the precise mechanisms are still to be investigated. Application of patient-derived iPS cells will be useful for the research of this disease, because harvesting target tissues from patients is strictly prohibited because tissue damage accelerates the ectopic ossification. Recently we have reported that iPSCs derived from FOP patients showed enhanced osteogenic and chondrogenic differentiation properties. Here we addressed this issue by a new approach using the differentiation system through the neural-crest cell lineage. Multi-potent neural crest cells (NCCs) were efficiently induced from iPSCs, from which multipotential mesenchymal stromal cell (MSC)-like cell (iMSCs) population can be obtained. Therefore we are able to analyse the signal pathway at each of iPSC, NCC, iMSC, and terminally differentiated stage. In addition, to minimize the effect of genetic background other than ACVR1 mutation, we established genetically rescued cell lines from parental FOP-iPSCs by the homologous recombination. FOP-iMSCs possessing enhanced chondrogenic ability were transcriptionally distinguishable from reFOP-iMSCs and activated the SMAD1/5/8 and SMAD2/3 pathways at steady state. Using this method, we identified responsible genes for accelerating the chondrogenesis of FOP-iMSCs. This indicates that iMSCs through NCC lineage are useful for investigating the molecular mechanism of FOP and corresponding drug discovery.

Non-osteoporotic post-menopausal women do not have elevated concentrations of autoantibodies against osteoprotegerin. Isabelle Picc^{*1}, Christopher Washbourne², Jonathan Tang², Julie Greeves³, Sarah Jackson³, Stuart Ralston⁴, Philip Riches⁵, Helen MacDonald⁶, William D Fraser⁷.

¹BioAnalytical Facility, University of East Anglia, United Kingdom, ²University of East Anglia-Bioanalytical Facility, United Kingdom, ³HQ Army Recruiting & Training Division, United Kingdom, ⁴University of Edinburgh, United Kingdom, ⁵Rheumatic Disease Unit, Institute of Genetics & Molecular Medicine, United Kingdom, ⁶University of Aberdeen, United Kingdom, ⁷University of East Anglia- Bioanalytical facility, United Kingdom

Introduction: Osteoprotegerin (OPG) plays a protective role in bone remodelling as it provides a "decoy" site for RANKL, modifying the stimulation of osteoclasts. Autoantibodies to OPG allow a sustained reaction between RANKL and RANK which in turn will increase bone resorption. Autoantibodies against OPG (α -OPGAb), first isolated in patients with autoimmune conditions associated with high bone turnover, have been shown to be present in 14% of an apparently healthy young adult population. Bone resorption is increased in the elderly, particularly in women who may demonstrate increased α -OPGAb.

Objective: To define a reference range for OPG autoantibodies in non-osteoporotic post-menopausal women.

Method: Using a previously developed sandwich ELISA assay we were able to detect α -OPGAb in serum samples taken from non-osteoporotic post-menopausal women (ANSAVID study - 60-65yrs). Briefly, α -OPGAb are captured by the use of an immobilized full-length human recombinant OPG and detected by the sequential addition of a biotinylated antibody and a horseradish-peroxydase-labelled streptavidin. The concentration of human α -OPGAb in the samples is determined directly from a 4PL-fit standard curve.

Results : We established that the population of normal post-menopausal women who do not have osteoporosis also do not have elevated concentrations of α -OPGAb when compared to a younger female population (17-32yrs). The reference ranges obtained were 134-190ng/mL and 131-184ng/mL for control and post-menopausal women, respectively. This suggests that α -OPGAb is not positively associated with increasing age suggesting that the increased production of α -OPGAb is mainly related to pathologic conditions which can result in significant bone resorption.

Conclusion: Comparison of osteoporotic patient samples to non-osteoporotic post-menopausal women would be interesting to determine whether α -OPGAb can be used to detect patients at high risk of bone resorption and identify appropriate treatment for this particular subgroup of patients.

Pathophysiology of Melorheostosis: A Theoretical Framework. Smita Jha^{*1}, Nicholas Laucis², Timothy Bhattacharyya². ¹National Institutes of Health, USA, ²NIH, USA

Melorheostosis is a rare sclerosing bone disease with a prevalence of "one in a million." We report on five subjects with melorheostosis seen at National Institutes of Health, Maryland. All subjects were adult females. Subjects reported an average Patient Reported Outcome Measurement Information System (PROMIS) score of: pain - 60; physical function - 40; depression - 50 (norm: 50 ± 2 SD; 1 SD = 10) All subjects described the pain as neuropathic. No subject had other relatives affected with the disease. One subject showed evidence of bilateral disease. Three subjects had the disease affecting lower extremity while the remaining two had melorheostosis in the upper extremity. Physical exam revealed limb thickening in all subjects. No skin lesions associated with melorheostosis was noted in any subject. The distribution of the disease was limited to long bones affecting the appendicular skeleton. All subjects had normal serum calcium, phosphorus, magnesium, Vitamin D 25-hydroxy, 24 hour calcium excretion and tubular reabsorption of phosphorus. Imaging studies showed the classing "candle-wax" appearance described by Leri and Joanny. MRI showed evidence of soft tissue extension in three subjects. Lesion in all subjects was noted to be metabolically active on a ¹⁸FNa bone scan. All subjects showed progressive disease on comparison with prior images. None of these subjects described any successful intervention thus far.

It has been proposed that the distribution of the disease can be explained by sclerotomes. Sclerotomes are zones of skeleton supplied by an individual spinal sensory nerve. The existence of sclerotome remains controversial. We propose that the disease distribution can be better explained by clonal expansion of a somatic mutation in the limb bud. The somatic mutation hypothesis is supported by equal gender preponderance, sporadic occurrence and asymmetrical distribution. We suspect this is likely a disease of the osteoblast given its origin from the mesenchymal stem cell which can better explain the disease distribution. In the future, we plan to study the affected bone tissue with whole exome sequencing to identify the genetic cause of the disease. A better understanding of melorheostosis will help enhance our knowledge of bone biology and develop therapeutic agents not only for melorheostosis but for other common bone diseases.

Distribution of body composition parameters and sarcopenia in Finnish female population – comparison of two geographically comparable cohorts. Samu Sjöblom^{*}, Juha Suuronen, Toni Rikkinen, Risto Honkanen, Heikki Kröger, Joonas Sirola. University of Eastern Finland, Finland

Purpose: The aim of the study was to examine the differences of body composition and muscle strength between young and elderly women and also changes during aging. **METHODS:** The present study was based on 1) Young reference population (YRP), 400 healthy women aged 20 to 40 years (mean 30.4, SD 6.0) and 2) Postmenopausal women from the population-based OSTPRE study (N=397), aged 63 to 75 years (mean 68.6 years, SD 2.9) in 15-year follow-up point. The same subjects were remeasured 5 years later, (aged 68 to 80 years mean 73.6, SD 2.7) at 20-year follow-up visit. Both samples underwent weight, height, grip strength (GS), quadriceps strength (QS) and total body DXA (TB-DXA) measurements including RSMI i.e relative skeletal muscle index (The appendicular lean mass divided by the square of their height) and fat percent (FP). Based on the distributions (SD) of the indices in the YRP, the distributions of GS, QS, FP and RSMI were determined in the OSTPRE sample. Both study populations were divided into three groups (A < -2SD, -2SD-1SD C > -1SD) based on the distribution of the measures in the YRP. Results In the YRP sample, the mean (SD) values were: RSMI 6.7 (0.8) kg/m², GS 37.6 (5.6) kPa, QS 49.8 (10.0) kg, FP 29.6 (7.1), while at the OSTPRE 15-year follow-up point sample these were: RSMI 6.7 (0.8), GS 26.3 (6.3), QS 30.5 (7.8), FP 40.4, respectively. At the 20-year follow-up point sample these were: RSMI 6.6 (0.9) kg/m², GS 27.6 (5.6) kPa, QS not measured, FP 39.7 (6.5). The cut-off points, based on the YRP data (A: -2sd and B: -1sd) were for RSMI; A: 5.1 and B: 5.9 kg/m², for GS; A: 26.4 kPa and B: 32 kPa, for QS; A: 29.8 kg and B: 39.8, for FP; A: 15.4 and B: 22.5. **CONCLUSIONS:** Among postmenopausal women, muscle strength i.e grip strength and quadriceps strength are mostly deteriorated. The decreasing of RSMI during aging is quite minimal. The study will provide new cut-off points for diagnostics of sarcopenia in

Western European women. Acknowledgements The study was supported by Kuopio University Hospital EVO-grants and Ministry of Education and Culture and Finnish Cultural Foundation.

Effects of life-style factors on body composition in healthy Finnish women aged 20-40 years. *Juha Suuronen*¹, *Samu Sjöblom*², *Marjo Tuppurainen*³, *Risto Honkanen*², *Toni Rikkinen*², *Heikki Kröger*⁴, *Joonas Sirola*⁴.

¹University of Eastern-Finland, Kuopio Musculoskeletal Research Unit (KMRU), Finland, ²Kuopio Musculoskeletal Research Unit (KMRU), Finland, ³Kuopio Musculoskeletal Research Unit (KMRU) & Departments of Obstetrics & Gynaecology, Kuopio, Finland, Finland, ⁴Kuopio Musculoskeletal Research Unit (KMRU) & Surgery/Orthopaedics, University of Eastern Finland, Kuopio, Finland, Finland

Purpose:

The aim of the study was to investigate the effects of life-style factors on body composition and muscle strength in healthy female population.

Methods:

400 Finnish women (aged 20-40) were measured with DXA, hand-held dynamometer and knee extension bench between 2011-2014. Inclusion criteria for the study were: no chronic diseases or permanent medication. Life-style factors were assessed with inquiries parallel with the measurements and included: alcohol consumption, pregnancies, hormonal contraception, smoking, self-rated health and physical activity. Body composition variables (lean and fat mass) were measured with DXA. Effects of life-style factors on body composition and muscle strength were investigated with AN(C)OVA.

Results:

Women aged 35-40 had higher appendicular skeletal muscle mass (ASM), BMI, relative skeletal muscle index (RSMI), fat-%, grip (GS) and quadriceps strength (QS) and total lean mass (TLM) compared to women aged 20-25 (p<0.001). They also had lower skeletal muscle index (SMI) (p<0.01). Significance prevailed after adjustment for multiple variables (p<0.01). Women using oral contraception (progesterone + ethinyl estradiol) had lower GS (p<0.001), ASM, RSMI and TLM (p<0.01) compared to the women without hormonal contraception. After adjustment ASM, SMI and GS remained lower (p<0.05) as well as RSMI and TLM (p<0.01). Women who exercised 4 ≤ times/week had significantly higher ASM, RSMI, SMI and TLM (p<0.001) and lower fat-% (p<0.001) compared to women exercising once a week or less. In addition women exercising 4-6 times/week had higher GS (p<0.01) and QS (p<0.001) while in women who exercised daily QS was higher (p<0.01) but GS was not significantly different in comparison. After adjustment, women exercising 4 ≤ times/week had higher ASM, RSMI, SMI, QS and TLM as well as lower fat-% (p<0.001) while women exercising 4-6 times/week had higher GS (p<0.01) after adjustment. There were no significant difference in BMI according to amount of exercise/week. Those who self-rated their health as "very good" had lower BMI and fat-% and higher SMI (p<0.001) and TLM (p<0.05) compared to women with moderate health. After adjustment BMI (p<0.01) and fat-% was lower and SMI higher (p<0.001).

Conclusions:

Muscle and fat mass increases between 20-40 years. Hormonal oral contraception has negative effect on muscle mass. Higher self-rated health has connection to lower fat-% and BMI. Exercise increases muscle mass and strength and lowers fat mass.

Forearm Bone Density is Not Related to Lean Body Mass in Postmenarcheal Girls Who Habitually Consume Less Than 2 Servings of Dairy per Day: Preliminary Results of the FAMILY Study. *May Slim*^{*1}, *Catherine Vanstone*¹, *Suzanne Morin*¹, *Elham Rahme*², *Hope Weiler*¹. ¹McGill University, Canada, ²McGill University Health Center, Canada

Humans achieve peak skeletal muscle mass and bone density in young adulthood. Data on how measures of bone health relate to lean body mass (LMI) in adolescent girls are lacking. Dietary Reference Intakes for calcium range from 1100 to 1300 mg/d for adolescent girls. In Canada, more than 50% of females 14 to 18 y of age do not meet these targets with usual intakes of 917 (SE 21) mg/d and < 2 dairy servings/d. Our objective was to examine the relationship between lean tissue and bone health indicators at multiple skeletal sites in postmenarcheal (PM) girls participating in the Family Milk product 2-Year (FAMILY) dose response study to enhance bone health in youth. We present a preliminary cross sectional analysis of baseline data on healthy white girls 14 to 18 y (n=16) recruited from Montreal (Canada). We measured weight and height to calculate body mass index (BMI, kg/m²) and WHO z-scores. Bone area (BA, cm²), bone mineral content (BMC, g) and bone mineral density (BMD, g/cm²) of the whole body (WB), non-dominant forearm (FA), femoral neck (FN), total hip (TH) and lumbar spine (LS) as well as LBM (kg) and lean mass index (LMI, kg/m²) were measured using DXA (Hologic Discovery, Apex software version 13.5). The LMS method was used to compute LMI Z scores (LMIZ) based on NHANES reference data (2008) which were stratified into tertiles. Differences in LMIZ tertiles

were tested using mixed model ANOVA adjusting for covariates. The participants, aged 15.5 ± 1.6 y, showed healthy mean BMI z-scores of 0.35 ± 0.94. LBM positively correlated to all bone parameters at all sites except TH area (table 1). Participants in LMIZ Tertile 1 had significantly lower BMC and BMD at LS, FN, TH, WB and lower BA at WB only compared to tertile 2 and 3, whereas tertile 2 and 3 were comparable (table 2). Interestingly, there were no differences among tertiles in any of the FA parameters, which could be attributed to the fact that FA is a non-weight-bearing site and the non-dominant side was assessed. Age at menarche was greater in tertile 1 compared to tertile 2 and 3 (table 2) suggesting that late maturing girls display lower muscle mass, as surrogated by LMIZ, in association with lower BMD. Lean tissue relative to height had a significant beneficial relationship to BMD in PM girls especially at weight-bearing sites. Further research using computed tomography would be of interest to examine the relationship of lean mass to cortical and trabecular bone, particularly at the FA site.

Table 1: Correlation between Bone Measurements at WB, FN, TH, LS and FA and Whole Lean Body Mass, Lean Mass Index, Appendicular Lean Mass Index, and Height

| | WB Lean mass (kg) | LMI (kg/m ²) | Appendicular LMI (kg/m ²) | Height (cm) |

High Prevalence of Muscle-Skeletal Abnormalities in Patients with Chronic Obstructive Pulmonary Disease. *Tatiana Costa*¹, *Fabio Costa*², *Carolina Moreira*¹, *Thaís Jonasson*¹, *Leda Rabelo*², *César Boguszewski*¹, *Victoria Borba*^{*1}. ¹Serviço de Endocrinologia do Hospital de Clínicas da UFPR (SEMPR), Brazil, ²Serviço de Pneumologia da UFPR, Brazil

Introduction: Loss of fat free mass (sarcopenia), is associated with reduced exercise capacity and poor quality of life in patients with COPD. Besides, in conjunction with the bone loss, contributes to the bone fragility and increased fractures prevalence.

Purpose: To evaluate the relationship between the severity and prognosis of COPD with the prevalence of morphometric vertebral fractures (MVF), bone mineral density (BMD) and body composition data compared with two control groups.

Methods: A group of COPD patients (DG) and two control groups, smokers without COPD (SG) and a healthy group (HG) underwent a body composition, VFA (Vertebral Fracture Assessment) and BMD evaluation by DXA. DG patients were classified by BODE prognosis index (B-body mass index, O-airway obstruction, D-dyspnea and E-exercise capacity); the clinical stage GOLD and the degree of obstruction (FEV1). The diagnosis criterion of densitometric sarcopenia (DS) was based, for the low weight patients on Baumgartner method, and all the others were adjusted for fat mass based on Newman reference. The groups consisted of 91 patients (50 females), 67.4 ± 8.7 years old in DG; 72 patients (38 females) 63.7 ± 9.80 years in

SG and 86 patients (47 females) 69.5±7.15 years in HG (p=0.11). DG showed a reduction in lumbar spine (LS), total femur (TF) and femoral neck (FN) BMD that was associated to an increase in the disease severity and prognosis, p<0.05. A correlation between lower lean mass and lower BMD was found in all bone sites p<0.001 (LS r=0.339, TF r=0.465 and FN r=0.459) in DG. The DG mean BMD was low in all sites compared to SG (p=0.007) and the HG (p=0.003). DS was present in 40.6% of DG, 29.7% of SG and 26.9% of HG. In DG, the quartiles of best prognosis were different from those of worst prognosis (p=0.009) and, the multivariate analysis showed that regardless of age, gender and clinical stage, the BODE index was associated with DS, OR = 3,12 (95% CI 1,04 - 9,38). MVF were seen in 62,6% of the DG patients and was associated with the FN BMD (p=0,022).

Conclusions: Patients with COPD had higher prevalence of DS and low BMD compared to controls groups, the low BMD was correlated with lower fat free-mass, disease severity and prognosis. The DS was associated with BODE that may suffer great influence of lean mass, since it is considered a parameter of physical capacity. MVF was also highly prevalent.

Perceptions of Elderly Women with Osteoporosis and Back Pain by Using a Spinal Orthosis. Helena Salminen*¹, Nathalie Frisendahl², Ann-Charlotte Grahn Kronhed³, Christina Kaijser Alin¹. ¹Karolinska Institutet, Sweden, ²Umea university, Sweden, ³Linköping University, Sweden

Purpose: The aim of this study was to explore the perceptions of elderly women with osteoporosis and back pain, with or without vertebral fractures, by using a spinal orthosis. Methods: A qualitative study with five focus group interviews using a semi-structured interview guide, with a total of 18 women (mean age 78 years) who had all used the Spinomed spinal orthosis during six months in a RCT. The interviews were analyzed using qualitative content analysis with an inductive approach. Results: One overall theme was found: The spinal orthosis could be perceived as an integrated part of everyday life, if it met the needs of the individual woman. The four main categories found under this theme were: 1) The meaning of the spinal orthosis; the orthosis being an integrated part of the woman and giving support 2) The perceived physical changes in posture, decreased pain and increased mobility and increased muscle strength 3) Possibilities in everyday life with increased autonomy and facilitating daily activities 4) The importance of the individual shaping of the spinal orthosis, to be easy to use and not to attract too much attention. Conclusions: The spinal orthosis showed perceived positive effects on the participants' everyday life by supporting the woman's autonomy. It was perceived to facilitate performing daily activities and to relieve back pain, to increase mobility and positively affect the woman's posture. Because the orthosis was perceived as an integrated part of the woman, it was of utmost importance for the orthosis to fit well.

Sarcopenia – prevalence, incidence, and association with osteoporosis: A four-year follow-up of the ROAD study. Noriko Yoshimura*¹, Shigeyuki Muraki², Hirovuki Oka³, Sakae Tanaka⁴, Hiroshi Kawaguchi⁵, Kozo Nakamura⁶, Toru Akune⁶. ¹22nd Century Medical & Research Center, The University of Tokyo, Japan, ²Department of Clinical Motor System Medicine, 22nd Century Medical & Research Center, The University of Tokyo, Japan, ³Department of Medical Research & Management for Musculoskeletal Pain, 22nd Century Medical & Research Center, The University of Tokyo, Japan, ⁴Department of Orthopaedic Surgery, Sensory & Motor System Medicine, Graduate School of Medicine, The University of Tokyo, Japan, ⁵JCHO Tokyo Shinjuku Medical Center, Japan, ⁶National Rehabilitation Center for Persons with Disabilities, Japan

The present 4-year follow-up study was performed to clarify the prevalence of sarcopenia (SP), coexistence of SP and osteoporosis (OP), and contribution of SP to the occurrence of OP in the general population. The second survey of the Research on Osteoarthritis/Osteoporosis Against Disability (ROAD) study—a large-scale population-based cohort study—was conducted between 2008 and 2010. We enrolled 1,099 participants (aged >=60 years, 377 men, 722 women) from the second survey of the ROAD study who had completed assessments of handgrip strength, gait speed, skeletal muscle mass measured by bioimpedance analysis, and bone mineral density measured by dual X-ray absorptiometry (DXA). The third survey was conducted between 2012 and 2013; 767 of the 1,099 individuals who were enrolled from the second survey (69.8%, 253 men, 514 women) had completed assessments identical to those in the second survey. SP was defined as per the algorithm of the Asian Working Group for Sarcopenia, whereas OP was defined based on the World Health Organization criteria. The prevalence of SP in the second survey was found to be 8.2% (men, 8.5%; women, 8.0%). The co-existing rate of SP and OP at the lumbar spine L2-L4 and/or the femoral neck was 57.8%. The cumulative incidence of SP during the 4-year period between the second and third visits was 2.0%/yr (men, 2.2%/yr; women, 1.9%/yr). There were no gender differences in the prevalence or incidence of SP. After adjustment for age (yrs), gender (0:men, 1:women), regional differences (0:mountainous area, 1:coastal area), and emaciation (0:body mass index (BMI) >=18.5 kg/m2,

1:BMI <18.5 kg/m2), a logistic regression analysis using the occurrence of SP as the objective variable and the presence of OP as the explanatory variable indicated that the presence of OP was significantly associated with the occurrence of SP in the near future (odds ratio, 2.86; 95% confidence interval, 1.41-5.79; p = 0.003). This prospective study suggests that the presence of OP might predict the incidence of SP in the near future. The treatment of the OP might reduce the risk not only of osteoporotic fracture but also that of SP.

SARCOPENIA IN UKRAINIAN WOMEN: ASSESSMENT AND DETERMINATION OF LEAN BODY MASS DEFICIENCY. Vladyslav Povorozyuk*¹, Dzerovych Nataliia², Povorozyuk Roksolana². ¹Institute of Gerontology AMS Ukraine, Ukraine, ²D.F. Chebotarev Institute of gerontology NAMS Ukraine, Ukraine

The aim of this study was to evaluate the normative data of lean mass in the healthy Ukrainian women.

Materials and methods. 301 women aged 20-87 years (mean age – 57.6±0.9 yrs; mean height – 1.62±0.004 m; mean weight – 63.5±0.5 kg, body mass index – 24.2±0.2 kg/m2) were examined. No subject had any systemic disorders (endocrine, renal, hepatic et al.) or took medications known to affect the skeletal and muscle metabolism. The women were divided into the following age-dependent groups: 20-29 yrs (n=25), 30-39 yrs (n=27), 40-49 yrs (n=22), 50-59 yrs (n=62), 60-69 yrs (n=91), 70-79 yrs (n=59), 80-87 yrs (n=15). The lean and fat masses, bone mineral density (BMD) were measured by the DXA method (Prodigy, GEHC Lunar, Madison, WI, USA). Appendicular skeletal mass (ASM) was measured at all the four limbs with DXA. We've also calculated the appendicular skeletal mass index (ASMI) according to the formula: ASM/height (kg/m2). Low muscle mass values conform to the following definitions: European guidelines (ASMI <5.5 kg/m2) [Cruz-Jentoft A.J. et al., 2010], less than 20% of sex-specific normal population and two SD below the mean of the young adult Ukrainian females (20-39 yrs).

Results. We observed a significant decrease of ASM with age (20-29 yrs – 16.5±0.4 kg, 30-39 yrs – 16.4±0.3 kg, 40-49 yrs – 17.0±0.5 kg, 50-59 yrs – 16.9±0.3 kg; 60-69 yrs – 16.5±0.2; 70-79 yrs – 15.8±0.3; 80-87 yrs – 15.3±0.3; F=2.7; p=0.01). The ASMI values corresponding to a cutoff of low muscle mass by the definitions used were as follows: <5.5 kg/m2 (European guidelines), <5.7 kg/m2 (<20th percentile of sex specific population), <4.8 kg/m2 (two SD below the mean of young Ukrainian females aged 20-39 yrs). The prevalence of low muscle mass in women aged 65 yrs and older based on the above three criteria was 12%, 16% and 1.7%, respectively. ASM was positively correlated with the total fat mass (r=0.20, p=0.0006) and BMD at all sites (p<0.0001).

Conclusion. Peak muscle mass among the Ukrainian women is achieved in the fifth decade. The cutoff value of ASMI (<4.8 kg/m2) defined as two SD below the mean of reference young population was lower in this study compared with the Rosetta Study (<5.5 kg/m2). As for the sex specific cutoff (ASMI <5.7 kg/m2), this index was similar to the data of the Health ABC study (<5.67 kg/m2) [Cruz-Jentoft A.J. et al., 2010]. Appendicular skeletal mass was positively correlated with total fat mass and BMD at all sites.

The Effects of Vitamin D and Sarcopenia on Bone Mineral Density in Korean women. Sung Won Yang*¹, Duck Joo Lee, Bom Taek Kim. Ajou University School of Medicine, South Korea

A osteoporotic fracture has become a global health issue that causes tremendous impact on mortality as well as heavy socioeconomic burden. Previous studies suggested that vitamin D may prevent fractures by improving muscle mass as well as via increasing bone density directly. The purpose of the study is to determine that the influence of vitamin D on bone mineral density depends on its effects on muscle mass.

We analyzed the data from Korean National Health and Nutritional Survey IV in 2009. Women older than age 20 were included for the analyses. Bone mineral density and muscle mass were measured by DXA. serum vitamin D concentration was tested.

Vitamin D and muscle mass affected BMD at proximal femur, but not at lumbar spine. Vitamin D deficiency and sarcopenia increased odd ratio for osteoporosis before and after adjusted for multiple variables. The effects of vitamin D deficiency on BMD still remained significant after adjustment for sarcopenia, which was vice versa.

Though vitamin D deficiency and sarcopenia shared common effects on BMD, they their own effects on BMD independent from each other.

Using the European Working Group of Sarcopenia in Older People (EWGSOP) criteria for identifying sarcopenia and sarcopenic obesity in a group of community dwelling Seniors. Angela Juby*, Christopher Davis, Suglo Minimaana, Marilyn Cree. University of Alberta, Canada

Purpose

Sarcopenia prevalence increases with age, and is associated with increased risk for frailty, drug side effects, worsening chronic disease, falls/fractures, and dependence. Sarcopenia and sarcopenic subtypes have been defined by the European Working Group of Sarcopenia in Older People (EWGSOP). This classification is based on presence or absence of low muscle mass, plus/minus low muscle strength or low performance. This is baseline data from participants in a twelve month study evaluating the impact of exercise.

Methods

All are > 65 years, mobile, and community dwelling in Edmonton, Alberta, Canada. All had baseline assessments including dual energy Xray absorptiometry (DXA) body composition (BC) analysis, grip strength measurement (dynamometer) and gait speed (10 metre walk test). BC allowed calculation of appendicular lean mass/height² (aLM/ht²) and body percentage fat. Data was evaluated as per EWGSOP guidelines, using the following cut offs: aLM/ht² of <5.67 (women) <7.26 (men); grip strength of <20 (women), <30 (men); and gait speed <1m/s for both. Based on these each participant was classified into a body type. (Low grip strength and gait speed, with normal aLM/ht² were classified as "weak" for want of a better description, to differentiate them from normal). Presarcopenics had only low aLM/ht², sarcopenics had low aLM/ht² plus one abnormal level in one of the other parameters, and severe sarcopenics were defined as those having abnormal levels in all the parameters. Obesity was defined by DXA BC percentage fat of >40% (women), >28% (men).

Results

39 participants were evaluated, 32 women and 7 men, with an average age of 75.9 years (67-90 years), and an average MOCA 25.5/30. All were independently mobile (with or without walking aids) and community dwelling. EWGSOP classification of the women: 9 normal; 2 presarcopenia; 2 sarcopenic obesity; 1 sarcopenia; 1 severe sarcopenia; 1 severe sarcopenic obesity; 3 sarcopenic obesity; 10 obese; 1 normal "weak"; 2 obese "weak", for a total of 32. Of the 7 men: 2 normal; 1 sarcopenia; 3 sarcopenic obesity; and 1 obese. The groups were comparable for age. Baseline BMI was 27.5 (18.8 – 37.5) and BMI did not discriminate the body types.

Conclusions

In these independently living, highly functioning Seniors, there was a surprising diversity of body composition. BMI alone was of limited use in classifying body type. The EWGSOP classification is useful to stratify an outwardly homogenous group of Seniors.

Effect of Aging on Bone Properties in Male and Female Transgenic Mice Carrying the Human LRP5^{G171V} (HBM) Mutation. Nuria Lara*¹, Mark Begonia², Mark Dallas², Ganesh Thiagarajan², Mark L. Johnson². ¹University of Missouri - Kansas City, USA, ²University of Missouri-Kansas City, USA

We have previously shown that a single point mutation in the human LDL receptor-related protein 5 (LRP5) results in a high bone mass trait. It has been published that transgenic mice expressing this same mutation under the expression of 3.6-kb type I collagen promoter results in high bone mass and maintains this phenotype up to 52 weeks of age. In this current study we sought to determine the effect of aging on maintaining bone properties in this animal model. We sought to determine whether aging would result in parallel declines in HBMtg mice compared to C57Bl/6 control littermates or if the high bone mass trait would be maintained.

MicroCT analysis of femurs from 88 week old female transgenic mice (n=4) demonstrated increased cortical compartment parameters compared to wild type or littermate controls (n=5). Cortical BMD (mgHA) (1237.8±17.4 vs 1196.3±26.8, p<0.05), cortical thickness (mm) (0.24±0.04 vs 0.18±0.01 p<0.001) and cortical bone area (mm²) (1.3±0.2 vs 0.9±0.13, p<0.05) were all higher in HBMtg mice. In the trabecular compartment, female HBM transgenic mice had increased BV/TV (%) (4.6±2.4 vs 0.3±0.2, p<0.05), and trabecular thickness (mm) (0.071±0.015 vs 0.043±0.008, p<0.05). Biomechanical studies showed transgenic female bones had higher work to failure (mJ) (4.6±1.1 vs 2.4±0.9, p<0.05), ultimate load (N) (25.4±6.3 vs 16.02±4.21, p<0.05) and elastic stiffness (N/mm) (154.6±26.0 vs 86.4±34.6, p<0.01) compared to controls. In the male group, no significant differences were observed in the cortical and trabecular material parameters or biomechanical properties of HBMtg (n=8) mice vs littermate controls (n=4). In both male and female, bone parameters of control and HBMtg mice were lower compared to previously published data from younger mice.

These studies demonstrate that aging results in a reduction in cortical and trabecular bone properties in both male and female HBMtg mice. However, the female HBMtg mice appear to retain their enhanced properties to a greater extent. Given that the HBM transgene is driven by the 3.6-kb type I collagen promoter, studies are currently underway to determine if this sex difference is due to differential

regulation of the promoter or reflects general differences in male vs female mice as they age. These data support a central role for the LRP5/Wnt/β-catenin in bone mass maintenance across aging.

SU0406

Vascular Endothelial Growth Factor: Relationship to Bone Mineral Density (BMD), Size and Strength: The Osteoporotic Fractures in Men Study (MrOS). Jane Cauley*¹, Stephanie Harrison², Joseph Zmuda³, Elizabeth Barrett-Connor⁴, Jodi Lapidus⁵, Eric Orwoll⁵. ¹University of Pittsburgh Graduate School of Public Health, USA, ²California Pacific Medical Center Research Institute, USA, ³University of Pittsburgh, USA, ⁴University of California, USA, ⁵Oregon Health & Science University, USA

Vascular endothelial growth factor (VEGF) is a major coupling factor for the osteogenic-angiogenic interface. Activation of angiogenesis mediated via VEGF leads to increased bone mass. However, little is known about circulating VEGF and skeletal strength in humans.

To test the hypothesis that levels of VEGF are positively correlated to areal (a) and volumetric (v) BMD, bone size and skeletal strength, we chose a random sample of 500 men enrolled in MrOS who had QCT scans of the proximal femur and lumbar spine. The first 650 participants at each clinic and all minority men were referred for QCT. Of the 5,994 men enrolled in MrOS, 3,563 men had usable QCT scans. VEGF was measured in baseline serum by enzyme linked immunoassay; minimum detectable concentration, 5pg/ml; intra-assay CV%, 5.4%; inter-assay CV%, 7.3%. aBMD was measured by DXA and remaining bone parameters, by QCT. QCT scans were acquired using standardized protocols (Black DM, JBMR 2008;23(8):1326). Image processing was performed using the methods of Lang et al (Lang TF, JBMR 2006;21:1224). We examined the characteristics of men and bone parameters across quartiles of VEGF.

Men with highest VEGF (Quartile 4, > 444.4 - < 1563 pg/ml were more likely to report difficulty with at least one instrumental activity of daily living (IADL) compared to Quartile 1 (< 129pg/ml) but other characteristics e.g., age, BMI, health status, smoking, fall history or comorbidities did not differ across quartiles of VEGF. There was no association between VEGF and hip or spine aBMD. There was no association between VEGF and lumbar spine vBMD (integral, or trabecular), trabecular bone volume or vertebral strength or femoral neck vBMD (integral, trabecular, or cortical) and cross-sectional area (CSA). However, we found significant interactions between VEGF and IADL impairment for femoral shaft medullary area, CSA and cortical bone area (Table). Among men with > 1 IADL impairment, shaft medullary area, CSA and cortical bone area increased with increasing VEGF. Among men with no IADL impairment medullary area and CSA decreased with increasing VEGF. There was no association with femoral shaft BMD. We found no relationship between VEGF and either aBMD or vBMD. There was some suggestion that the association between VEGF and femoral shaft size differs by whether or not a man reported an IADL impairment but this may have occurred by chance. Future research will need to confirm these results.

Table: Femoral Shaft Parameters by VEGF Quartiles Stratified by IADL Impairment (age adjusted) (All P Interaction <0.05)

| | At least one IADL Impairment | |
|--------------------------------|------------------------------|------------|
| | Yes (n=103) | No (n=385) |
| Medullary Area (cm) | | |
| VEGF Quartile 1 | 3.05 | 3.19 |
| Quartile 2 | 2.96 | 3.15 |
| Quartile 3 | 3.04 | 2.99 |

Histomorphometrical Characteristics of Cortical Bone in Male Subtrochanteric Femoral Shaft. Xiaoyu Tong*¹, Markus Malo², Inari Burton³, Hanna Isaksson⁴, Jukka Jurvelin², Heikki Kröger⁵. ¹Kuopio Musculoskeletal Research Unit (KMRU), Finland, ²Department of Applied Physics, University of Eastern Finland, Finland, ³Kuopio Musculoskeletal Research Unit (KMRU), Institute of Clinical Medicine, University of Eastern Finland, Finland, ⁴Department of Biomedical Engineering, Department of Orthopaedics, Lund University, Sweden, ⁵Department of Orthopaedics, Traumatology, & Hand Surgery, Kuopio University Hospital, Finland

The underlying morphometric changes at the proximal femur that might predispose for subtrochanteric fractures are poorly understood. The aim of this study was to investigate the age-dependent variations and regional differences of histomorphometric properties in the cortical bone of subtrochanteric femoral shaft, and to compare the histological characteristics with those in the femoral neck, as well as to cortical characteristics found with scanning acoustic microscopy. Undecalcified histological sections of the subtrochanteric femoral shaft (n=20, aged 18-82 years, males) were cut (15µm) and stained using modified Masson-Goldner stain. Histomorphometrical parameters of cortical bone were analysed with low (x50) and high magnification (x100), after identifying cortical bone boundaries with our previously validated method. The cortical widths of the medial and lateral quadrants were significantly higher than those measured for the anterior and posterior quadrants (p<0.01). Osteonal area/cortical area and porosity in the posterior quadrant were significantly lower and higher than the other quadrants (p<0.05). Several cortical bone parameters (e.g. osteonal area/cortical area, erosion perimeter/endocortical perimeter) of the middle aged group (40-60 years) were significantly different from the younger and older subjects (< 40 years and >60 years) (p<0.05). Compared to the femoral neck, each osteonal parameter (e.g. osteonal area/cortical area, osteon number) was significantly higher in the femoral shaft (p<0.01). The values of porosity were significantly lower in the anterior and lateral, and higher in the posterior femoral shaft compared to the corresponding quadrants of the femoral neck. When comparing to cortical bone parameters measured by using the scanning acoustic microscopy, the values measured by both techniques were strongly correlated (0.73 ≤ R² ≤ 0.97, p<0.001). However, the histomorphometrically measured parameters were generally lower (p<0.001). This study describes the changes in cortical bone of the subtrochanteric femoral shaft during ageing in healthy males, which may aid to reveal the underlying morphometric changes that might predispose to subtrochanteric fractures.

The Association between Spinal Curvature and Balance in Elderly Women at High Risk of Osteoporotic Fractures in Primary Healthcare. Helena Salminen¹, Ann-Charlotte Grahn Kronhed^{*2}, Christina Kaijser Alin¹. ¹Karolinska Institutet, Sweden, ²Linköping University, Sweden

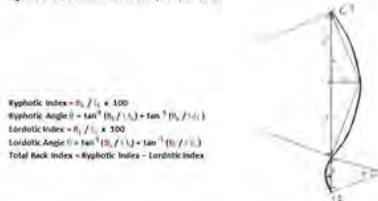

Purpose: The aim was to study the associations between kyphotic and lordotic measurements and balance in elderly women at high risk of osteoporotic fractures. Further, the associations of vertebral fractures to balance and spinal curvature were studied.

Methods: The population in this study, 88 women (mean age 84 years), survivors from the population based cohort PRIMOS of 351 women, originally included in 1999-2000, were re-examined in a follow-up study in 2011-2013. Static timed standing and dynamic balance tests were performed and spinal curvature was measured by using the Flexicurve ruler and X-ray data on vertebral fractures were gathered. Several calculation methods were used to describe the spinal curvature (see Figure 1).

Results: Positive correlations between the presence of hyperkyphosis and tandem standing eyes open ($r_s = 0.24, p < 0.05$) and standing on right leg eyes closed ($r_s = 0.27, p < 0.05$), tandem gait forwards ($r_s = 0.24, p < 0.05$), and also tandem gait backwards ($r_s = 0.30, p < 0.01$) were found. Lordotic Index and Lordotic Angle were positively associated to one leg standing eyes closed, to right leg eyes closed and left leg eyes closed. The Total Back Index was negatively related to left leg standing eyes open ($\beta = -0.3, p < 0.05$). However, there were no associations between the Kyphotic Index or Angle and balance. Presence of vertebral fractures had no associations to balance.

Conclusions: A larger lumbar lordosis was associated with better balance performance. Both thoracic kyphosis and lumbar lordosis should be calculated to describe spinal curvature.

Figure 1 Calculation methods for the spinal curvature

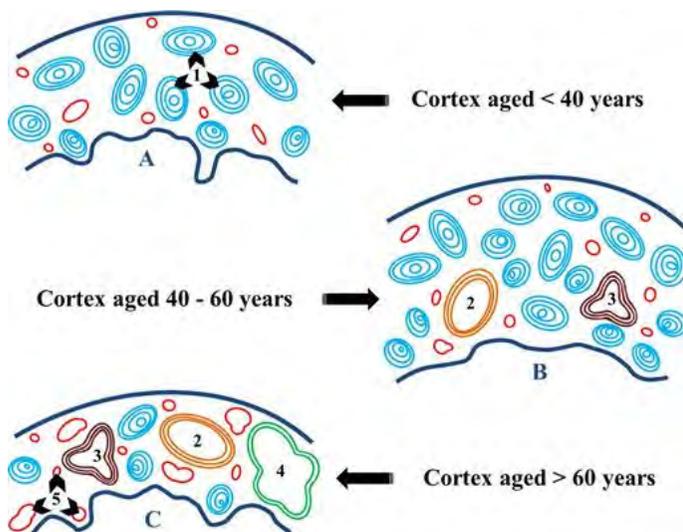

The Kyphotic Index, the Kyphotic Angle, the Lordotic Index, the Lordotic Angle, and the new method "Total Back Index" were used. A reference line through the traced curves between the points of C7 and S1 was drawn and measured the lengths of the kyphosis and, if present also the lordosis. The width of both curves at the widest point and the lengths of the halves of the curves were measured and divided through their widest point. Cut-off values for the presence of hyperkyphosis was set to 15. Since it was desirable to take the lengths of both curves into account, a new measurement the "Total Back Index" was constructed, subtracting the Lordotic index from the Kyphotic Index.

Effect of Treatment on Back Pain and Back Extensor Strength with a Spinal Orthosis in Elderly Women with Osteoporosis; a Randomized Controlled Trial. Helena Salminen¹, Christina Kaijser Alin^{*1}, Ann-Charlotte Grahn Kronhed², Hans Lundin¹. ¹Karolinska Institutet, Sweden, ²Linköping University, Sweden

Purpose: The aim of the study was to evaluate effect of treatment with the spinal orthosis Spinomed on pain and back extensor strength, compared to a physiotherapy equipment training group and a control group, in elderly women with osteoporosis and back pain.

Methods: A randomized controlled trial of six months duration with a total of 113 women (46 with vertebral fractures), randomized in three arms: 1. Training in spinal orthosis Spinomed. 2. Training in a physiotherapy equipment training group and a home exercise training program. 3. Control group. Inclusion criteria: Women > 60 years old with back pain, osteoporosis and/or vertebral fractures. Exclusion criteria: Spinal stenosis. Difficulty to follow the study program. The RCT started in spring 2011 and was completed in December 2014. Main outcome was back extensor strength measured with ISO-Check, Digimax (Messtechnik).

Results: A total of 96 women, mean age 76 years, completed the RCT at the six months follow-up. Back extensor muscle strength increased with 27% in the spinal orthosis group, 22% in the exercise training group and 10% in the control group.

Conclusions: Treatment with the spinal orthosis Spinomed increased the back extensor muscle strength to the same degree as training with a physiotherapist group. Treatment with the spinal orthosis may be a good alternative method to strengthen the back extensor muscles in elderly women with osteoporosis.

3D scaffold with VEGF/FGF9 conjugated fibrin, nano calcium sulfate and BMP2 genetically engineered mesenchymal stem cells promotes vascularized bone formation. Xue Yuan*¹, Randall J Smith Jr², Huiyan Guan³, Zunpeng Liu¹, Stelio T. Andreadis⁴, Ciprian N Ionita⁵, Parag Khobragade², Manhui Pan⁶, Changdong Wang¹, Guoqiang Guan³, Shuving Yang⁷. ¹Department of Oral Biology, State University of New York at Buffalo, USA, ²Department of Biomedical Engineering, State University of New York at Buffalo, USA, ³Department of Orthodontics, State University of New York at Buffalo, USA, ⁴Department of Biomedical Engineering; Department of Chemical & Biological Engineering; Center of Excellence in Bioinformatics & Life Sciences, State University of New York at Buffalo, USA, ⁵Toshiba Stroke & Vascular Research Center; Department of Biomedical Engineering, State University of New York at Buffalo, USA, ⁶Clinical & Translational Research Center, State University of New York at Buffalo, USA, ⁷Department of Oral Biology; Center of Excellence in Bioinformatics & Life Sciences, State University of New York at Buffalo, USA

Bone defects including bone fractures are increasing social and medical problems in the world, which dramatically decreased overall health and quality of life and caused huge medical costs of nearly \$20 billion per year in United State. Therefore, there is an urgent need for bone reconstruction. Bone tissue engineering has been extensively studied as an alternative to overcome clinical disadvantages of current bone grafts. In our previous study, we developed an injectable nano-scale calcium sulfate and alginate paste (nCS) to support the delivery and growth of BMP2 genetically engineered mesenchymal stem cells (nCS+M/B2), which significantly repaired bone defects. Because effective bone formation, especially for critical size bone defects, also requires vascular intervention, in this study, we developed a new fibrin gel system, in which angiogenic factor VEGF, FGF9 or both were conjugated to fibrin to increase their stability meanwhile control the release. To investigate whether this system combined with nCS+M/B2 would synergistically promote vascularized bone regeneration, nCS+M/B2 was coated with VEGF- or/and FGF9- conjugated fibrin to form a sandwich-like 3D scaffold, and then subcutaneously implanted into mice to test the osteogenic and angiogenic activity. MicroCT, alkaline phosphatase activity assay and histological analysis were used to evaluate bone formation while immunostaining were employed to indicate newly formed blood vessels. Coating with fibrin greatly preserved the nCS+M/B2 scaffold structure and also promoted de novo bone formation. Conjugated FGF9 alone did not significantly elevate ectopic bone formation, however, FGF9 combined with VEGF significantly promoted vascularized bone formation. We also compared different ways to load M/B2 and found that the group equally loaded M/B2 to fibrin gel and nCS showed best bone formation compared with the groups loaded a same amount of M/B2 to fibrin or nCS only, suggesting M/B2 may have different functions in nCS and fibrin. Overall, our results suggested that integration of nCS+M/B2 (support bone formation) with fibrin-based VEGF/FGF9 release system (support vascular formation) is an innovative strategy to improve bone regeneration.

Mesenchymal Cell-Based Biological Enhancement of Porous Titanium Orthopedic Implants. Eric Lewallen*¹, Dakota Jones¹, Amel Dudakovic¹, Carolina Bonin¹, Matthew Getzlaf¹, Roman Thaler¹, Scott Riester¹, Emily Camilleri¹, Jennifer Westendorf¹, Allan Dietz¹, Robert Cohen², David Lewallen¹, Andre van Wijnen¹. ¹Mayo Clinic, USA, ²Stryker Orthopedics, USA

More than 4 million yearly hip and knee replacements are expected by 2030 in the US. A small percentage of these implants fail, yet these failures are often catastrophically detrimental to limb function (e.g., major bone loss, infection) and result in a significant clinical challenge and health care burden. Motivated by this pressing clinical need, we address the central hypothesis that autologous cell transplants onto porous metallic implants can favorably alter the microenvironment of the bone-implant interface to improve osseointegration. Mesenchymal stromal cells (MSCs) are recognized for their potential to restore bone loss or damage, because of their ability to differentiate into osteoblastic precursors. Specifically, we focus on clinical-grade MSCs derived from the stromal vascular fraction of adipose tissue that are expanded in human platelet lysate and can be obtained in large quantities. High resolution comparisons using mRNASeq, microRNASeq, scanning electron microscopy, and histomorphometry were used to compare MSCs from four patients cultured on porous structured titanium (psTi) disc inserts in osteogenic medium vs. controls. Differential expression analysis on mRNASeq data revealed 55 genes of special interest, which were further investigated via RT-qPCR. Significant differences in gene expression between culture plastic and titanium substrate were confirmed for twelve biomarkers: *ATF4*, *BGLAP*, *CD44*, *COL3A1*, *DCN*, *DLX3*, *DLX5*, *EZH1*, *KLF10*, *PRRX1*, *RUNX3*, *TRPS1* ($p < 0.05$). Expression of the epigenetic regulator *EZH2* exhibited a decreasing trend in psTi-attached cells, a pattern consistent with

our recent demonstration that pharmaceutical inhibition of *EZH2* improves bone formation. Imaging of MSCs revealed distinct adhesive properties as they attach, proliferate and differentiate into osteoblast-like cells on psTi. This behavior varies among MSCs from different patients and may be modifiable by changing the physical properties of psTi, or conditions and duration of autologous cell culture.

Bone Loss in C57BL/6J-OlaHsd Mice, a Substrain of C57BL/6J Carrying Mutated Alpha-Synuclein and Multimerin-1 Genes. Tamar Liron*¹, Bitva Raphael², Itai Bab³, Yankel Gabet¹. ¹Tel Aviv University, Israel, ²Tel Aviv University, Israel, ³Hebrew University, Israel

The inbred mouse strain C57BL/6 is commonly used for the generation of transgenic and knockout mice and is a well-established strain in bone research. Different vendors supply different sub-strains of C57BL/6J as wild-type animals when genetic drift did not incur any noticeable phenotype. However, we sporadically observed drastic differences in the bone phenotype of the WT C57BL/6J controls originating from different labs and speculated that these variations are attributable at least in part to the variation between C57BL/6J sub-strains, which is often overlooked. C57BL/6J-OlaHsd is a commonly used sub-strain that despite a well-defined deletion in the alpha-synuclein (*Snc*) and multimerin-1 (*Mm1*) genes, was reported to display no obvious phenotype and is still commonly used as WT control. Here we compared the bone phenotype of C57BL/6J-OlaHsd (6J-Ola) to C57BL/6J-RccHsd (6J-Rcc), the parent strain of the 6J-Ola lacking the deletion and closest genetically to the original 6J sub-strain developed by the Jackson labs. Both sub-strains are supplied by Harlan Laboratories. Using micro-CT analysis, we found that 6J-Ola mice display a significantly lower trabecular BV/TV, Conn.D, Tb.N, and Tb.Th. 6J-Ola mice also demonstrate reduced cortical thickness and a general cortical expansion. PCR analysis revealed that both the *Snc* and *Mm1* genes are detectable in RNA derived from bone marrow cells and bone tissue of 6J-Rcc animals but not of 6J-Ola mutants. Up to date, there is no data in the literature linking *Snc* and/or *Mm1* to bone remodeling but our data implies that either or both genes may play a role. Our findings not only highlight the potential new role of these genes in bone biology but they further emphasize the critical importance of sub-strain unity. The use of littermate controls may also be questioned in the case of cross breeding between different sub-strains. Our data may help elucidating some of the unexplained differences in basal bone measurements between different research centers and reiterate the need of specifying the exact sub-strain type.

Bone Mineral Density of the Bottlenose Dolphin: Establishing a Definitive Region of Interest and Clinical Reference Dataset. James Powell*¹, Wayne McFee², Gangming Luo³, Jonathan Kaufman³. ¹Portland State University, USA, ²National Ocean Service, USA, ³CyberLogic, Inc., USA

The study reported herein has been developed to overcome a knowledge gap in anatomy of the common bottlenose dolphin, *Tursiops truncatus*, through examination of bone mineral density (BMD) of the radius in the dolphin pectoral flipper. The critical necessity to comprehensively define a target skeletal site for osteodensitometric assessment is addressed, and a normative bone density distribution curve is proposed for the species. Statistical support for the use of the available specimens as a normative reference dataset is provided by tests to examine differences within the dataset based on sex, age, total body length, handedness, nutritional status, and geographical affinity. Radii from 280 bottlenose dolphins were analyzed using dual energy x-ray absorptiometry (DXA), the accepted gold-standard in human medical studies. Bone density increases with age and total body length but not with enough statistical accuracy to use bone density to estimate age ($R^2=0.58$, $p<0.05$) as suggested in previous studies. No statistically significant differences were observed in BMD measurements for subsets of male vs female dolphins ($t=-1.60$; $p>0.05$) or right vs left flipper ($t=-1.76$, $p>0.05$). BMD was corrected for age and total body length using Principle Component Analysis to collapse these three variables into a synthetic variable, Principle Component I (PCI). PCI accounts for 88% of the variance in BMD, age, and total body length in the dataset. No statistically significant differences were observed in age- and length- corrected BMD within the subsets examined, including nutritional status ($F=0.83$, $p>0.05$) and geographical region ($t=-0.190$, $p>0.05$). These results support the total inclusion of all specimens as a normative reference dataset for bone density values in bottlenose dolphins.

Development of Peak Bone Traits in Young Men – Estimations by pQCT and DXA. Erik Lindgren^{*1}, Magnus Karlsson¹, Mattias Lorentzon², Jan Åke Nilsson¹, Bjorn Rosengren¹. ¹Skåne University Hospital Malmö, Lund University, Sweden, ²Geriatric Medicine, Institute of Medicine, Sahlgrenska University Hospital & Gothenburg University, Sweden, Sweden

Introduction

Studies with DXA, gold standard when determining bone mass, have defined peak bone mass for areal BMD (aBMD) in hip to age 17-18, in spine to age 25-30 and in distal forearm as late as age 35-40 years. DXA however provides a combined measure of both the amount of mineral and bone size, does not separate cortical and trabecular bone and cannot estimate volumetric BMD (vBMD) or structural bone parameters separately. These estimations are possible by pQCT, but data in a broad age span around the time of peak bone mass is not available. We aimed to identify peak values for pQCT traits in young men and their relation to peak values in DXA traits.

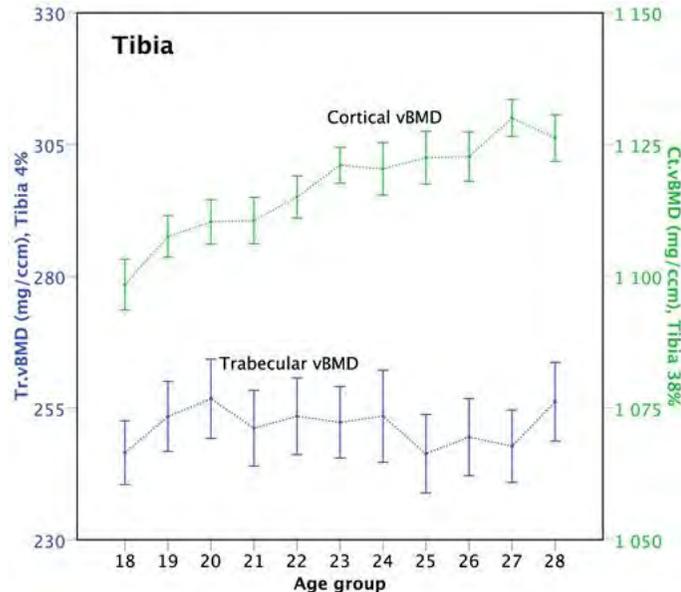

Methodology

We recruited a population based random sample age stratified (in 1-year age classes) that included 1083 young men aged 18-28 years and assessed trabecular vBMD (g/cm³), cortical vBMD, cortical thickness (mm) and cortical cross sectional area (CSA, mm²) by pQCT-scans (Stratec XCT2000) at *radius and tibia* in an *ultra-distal site*, where trabecular bone largely dominates, and at a *diaphyseal site*, where cortical bone dominates. We also assessed aBMD (g/cm²) by DXA-scans (Lunar Prodigy) at the hip [femoral neck (FN)], the spine and total body (TB).

Results

At *ultra-distal sites* we found no statistically significant differences in trabecular vBMD between age groups in either of the extremities (Tibia 4% shown in Figure). At *diaphyseal sites* cortical (Ct) vBMD, Ct CSA and geometrical variables showed increment by age throughout the examined age span (Tibia 38% in Figure). With DXA we found another pattern in that FN aBMD diminished by 6.7% from the highest (age 19 years) to the lowest (age 26 years) value ($p < 0.05$) and the opposite was found for TB.aBMD which increased 4.9% between the lowest value at age 18 years to the highest at age 28 years ($p < 0.01$). No statistically significant differences between age groups were found for spine aBMD.

Conclusions This study shows that the peaks of different bone traits (estimated by pQCT) are reached at different ages. This has important implications for inferences from previous research as it indicates that DXA, that reflects a combination of bone size and amount of mineral, may confer a biased estimate of peak bone mass.

Different regulation of limb development by p63 transcript variants. Manabu Kawata^{*1}, Daisuke Mori², Yuki Taniguchi¹, Fumiko Yano², Keita Okada¹, Song Ho Chang¹, Kosuke Kanke³, Sakae Tanaka¹, Taku Saito². ¹Department of Orthopaedic Surgery, Graduate School of Medicine, The University of Tokyo, Japan, ²Department of Bone & Cartilage Regenerative Medicine, The University of Tokyo, Japan, ³Center for Disease Biology & Integrative Medicine, The University of Tokyo, Japan

Mutations in p63 gene cause genetic disorders with split hand-foot malformations in humans, such as Ectrodactyly-ectodermal dysplasia-cleft (EEC) syndrome and Ankyloblepharon-ectodermal defects-cleft lip/palate (AEC) syndrome. Meanwhile, p63-null mice show severely truncated limbs. Previous studies indicate that these phenotypes are mainly caused by hypoplasia of apical ectodermal ridge (AER) where p63 is abundantly expressed; however, the underlying molecular mechanisms and specific roles of p63 transcript variants are not fully understood. In the present study, we investigated expression of TA and deltaN (dN) isoforms of p63 during limb development, and their functions using p63-flox mice and mouse ES cells. FACS analysis of limb bud cells obtained from mouse E11.5 embryos showed that dNp63 was expressed more abundantly in ectodermal cells than in mesenchymal cells, while TAp63 was also expressed in both cells at about one-tenth level of dNp63. In AER-specific p63 knockout mice, forelimb autopod was truncated, and hindlimb zeugopod and autopod were hypoplastic. mRNA expression levels of Fgf8 and Jag2, essential molecules in AER, were decreased in the limb buds of E11.5 AER-specific p63 knockout embryos. When we introduced dNp63 and TAp63 into mouse ES cells in feeder-free condition, Fgf8 and Jag2 were induced, respectively. Luciferase assay using B16 melanoma cells showed that dNp63 enhanced promoter activity of Fgf8, while TAp63 enhanced that of Jag2. Deletion of p63 consensus sequences in these regions significantly decreased both promoter activities, and chromatin immunoprecipitation assay using mouse ES cells confirmed the binding of p63 protein to the responsive elements identified in Fgf8 and Jag2 promoters. Considering that Fgf8 is essential for maintenance of AER and that Jag2/Notch signaling negatively regulates growth and function of AER through apoptosis induction, dNp63 and TAp63 may regulate limb development in different ways through transcriptional induction of different target genes in AER.

Effects of vivarium temperature on body composition and bone architecture in young, growing male C57Bl/6J mice. Maureen Devlin^{*}, Katarina Alajbegovic, University of Michigan, USA

Mouse models of human skeletal biology and metabolism require experimental conditions that are physiologically relevant to humans. There is a recent lack of consensus about whether the standard vivarium temperature of 22°C creates an inadvertent cold stress for laboratory rodents, with some data suggesting the thermoneutral temperature for mice is as high as 30°C, but other studies concluding that 22°C is an appropriate model for the thermal environment of clothed humans. If vivarium temperature perturbs mouse physiology, this finding would have important implications for interpreting experimental data. Thus here we test the hypothesis that skeletal acquisition and body composition vary in mice raised at different temperatures. To test this hypothesis, male C57Bl/6J mice were housed in pairs from 3 wks of age to 6 or 12 wks of age at 26°C (WARM) or 22°C (STD, standard vivarium temperature), with access to food and water ad libitum (N=4-6/group). Outcomes included body mass, food intake, body and tail length, femur and tibia length, %body fat and whole body bone mineral density (BMD) via pDXA, and cortical and trabecular microarchitecture via μ CT. Overall, there were no differences between STD and WARM in body mass, body length, or limb length between groups. STD mice ate more than WARM mice at 6-7 wks of age (GLM; $p < 0.05$). Housing temperature altered body composition throughout the experiment. In STD vs. WARM, %body fat increased more from 3-6 wks of age (+86% vs. +58%, GLM; $p = 0.02$), decreased more from 6-9 wks of age (-33 vs. -26%, GLM; $p = 0.05$), and increased more from 9-12 wks of age (+27% vs. +8%, GLM; $p = 0.05$). There were no differences in BMD between STD and WARM from 3-12 wks of age. At 6 wks of age, trabecular bone in the distal femur and proximal tibia showed no significant differences in bone volume fraction, trabecular number or thickness, and cortical bone from the midshaft femur and tibia showed no significant differences in cross-sectional geometry or bone area fraction. Thus, our results indicate that housing mice at 26°C vs. 22°C does not alter cortical or trabecular microarchitecture at 6 wks of age. However, increasing housing temperature from 22°C to 26°C significantly decreases food intake and has complex effects on body composition from 3-12 wks of age in male C57Bl/6J mice, potentially confounding the results of metabolic studies.

MicroRNA Profiling of the Early Phases of Fracture Repair. Michael Hadjiargyrou*¹, David Komatsu², Jizu Zhi². ¹New York Institute of Technology, USA, ²Stony Brook University, USA

Fracture repair is a complex tissue regeneration process that involves multiple biological processes requiring the temporal and spatial expression of thousands of genes within multiple cell types and tissues. Although the regulation of many of these genes is known at the DNA level, our knowledge at the mRNA/protein level is extremely limited. Recently, microRNAs (miRNAs) have emerged as potent regulators of gene expression by binding to their target mRNAs and promoting their degradation or blocking translation. Thus, knowledge of which miRNAs are expressed during the early phases of fracture repair is essential in our complete understanding of the molecular mechanisms controlling the regulation of this regenerative process. In an effort to identify the expression of all known miRNAs during fracture repair, we generated transverse femoral fractures in mice and isolated miRNA-enriched RNA from Intact (IN) and post fracture day (PFD) 1, 3, 5, 7, 11, and 14. RNA from each time point (n=3) was hybridized to Mouse miRNA Microarrays (n=3, Agilent Release 21, containing 1881 miRNAs). Following hybridization, background subtraction and normalization, 959 (51%) genes were absent across all samples and were removed from further analysis. 922 (49%) displayed expression in at least one sample and were further characterized. Of these 922 miRNAs, 306 (33.2%) were up-regulated and 374 (40.6%) were down-regulated in the PFD calluses in comparison to IN bone. In addition, 20 (2.2%) miRNAs displayed differential expression (up/down, down/up, up/down/up and down/up/down) among the PFD calluses, also in comparison to IN. The remaining 222 (24%) miRNAs did not exhibit any changes between PFD and IN. To explore the biological significance of the up and down-regulated miRNAs, we first identified the target genes of these miRNAs using miRDB. 2048 target genes were unique to the up-regulated miRNAs and 4782 target genes were unique to the down-regulated miRNAs. Next, gene ontology and pathway enrichment analyses on the two target gene lists were conducted using the Database for Annotation, Visualization and Integrated Discovery (DAVID) Bioinformatics Resources and indicated several relevant biological processes (i.e. wound response; various signaling pathways). Moreover, about 15 target genes of the down-regulated miRNAs were identified as members of the PPAR signaling pathway which has been implicated as a major catabolic regulator of bone mass. These and additional analyses are still on-going. Taken together, these data provide the first complete analysis of miRNA expression during fracture repair and will aid in deciphering some of the molecular mechanisms responsible for the early phases of this tissue regenerative process. In addition, the results will reveal regulatory miRNAs as potential therapeutic targets for treating delayed or nonunions as well as accelerating normal repair.

Specific deletion of Ebf1 within the kidney mesangium results in renal osteodystrophy, growth reduction, and premature death. Jackie Fretz*¹, Li Li², Rose Webb², Tracy Nelson², Ben-hua Sun², Nancy Troiano². ¹Yale University School of Medicine, USA, ²Yale University School of Medicine, USA

Globally deficient mice lacking the transcription factor Ebf1 (Ebf1 KO) are extremely sick owing to the multiple functions of Ebf1 across the body. While Ebf1 is present in osteoblast-lineage cells, specific deletion of Ebf1 using Osterix-cre and Runx2-cre resulted in a normal bone phenotype. We recently described a novel role for Ebf1 in kidney development and function. Within the kidney Ebf1 is present within multiple cell types including distinct tubular epithelium, interstitial pericytes, glomerular mesangium, and podocytes. In this study we made a specific deletion of Ebf1 within the Foxd1+ lineage using a cre-driver that targets the progenitors of the kidney glomerular mesangium and interstitial pericytes. Restricted deletion of Ebf1 from these cells resulted in development of hypoplastic kidneys and renal insufficiency at P21 (one week later than Ebf1 KO mice), with the appearance of proteinuria and 2+ leukocytes in urine. Growth is normal until P25. Approximately half of the Foxd1+, Ebf1fl/fl mice die before they are 3 months old. Mechanistic investigation of the pathways involved in Ebf1-directed renal development identified impaired Cox2 signaling within both the Ebf1-KO mice and targeted Foxd1+, Ebf1fl/fl animals have. Bone quality, assessed by micro-CT on femur, shows no differences between genotypes at 1 month, but significant reductions in connective density, trabecular thickness, and SMI and increased BS/BV within trabecular bone at 3 months. Cortical bone was more severely affected. Targeted Ebf1-deletion correlated to decreases in TV, BV, BV/TV, CtTh, apparent density, bone tissue density and pMOI, while BS/BV increased here as well. Taken together these results suggest that the renal insufficiency imposed on mice deficient for Ebf1-mediated signaling within the renal Foxd1-lineage accounts for significant reductions in bone quality as a secondary outcome of impaired renal mineral homeostasis. Furthermore, the delayed onset of the kidney phenotype in this model, compared with global Ebf1 KO mice, suggests a significant second role for Ebf1 in another cell type that influences renal development.

Study of a PLGA film / Titanium Nanotubes Compound Growth Factor Sustained Releasing System. Sun Shengjun*¹, Yu Weiqiang², Zhang Yilin³, Zhang Fuqiang². ¹Shandong University, Peoples republic of china, ²Shanghai 9th People's Hospital, China, ³Shandong Province Hospital, China

Purpose: The application of growth factors around the implants is an effective method to improve osseointegration. TiO₂ nanotube array can improve the biocompatibility of titanium implants and anti-corrosion. Polymerized α -polyester type lactic acid - glycolic acid copolymer (PLGA) by the poly(lactic acid - polyglycolic acid) is a biodegradable organic compound, which have good biocompatibility and film-forming ability. It is possible to become an ideal carrier material to build up a drug delivery system. The purpose of this research is to build a bone growth factor delivery system with anodized TiO₂ nanotube arrays and PLGA film on the surface of the titanium implant surface, and study its biological efficacy both in vivo and in vitro, to provide evidence for the development of new implanting system.

Methods: (1). TiO₂ nanotube array was prepared and filled with recombinant human bone morphogenetic protein -2 (rhBMP-2) growth factors, then PLGA was deposited on the surface of this material. Scanning electron microscopy (SEM), atomic force microscopy (AFM) was used to study the characterization, and ELISA assay was used to detect the pharmacokinetic release rate in vitro. (2). The osteoblast cells were cultured on the surface of the material, SEM, MTT and alkaline phosphatase activity test was used to study the behavior of osteoblasts. (3). The method was applied to titanium implant screws, and embedded in rabbits on tibia. After implantation, the experimental animals were killed and samples were taken out and evaluated.

Results: (1). When the PLGA solution is certain concentration, PLGA membranes of different thickness can be deposited on the surface of TiO₂ nanotube layer. A certain thickness PLGA membrane can sustain release rhBMP-2 during four weeks' time, and have a more suitable surface of nano-roughness. (2). In vitro, PLGA film / TiO₂ nanotube sustained release system can promote the adhesion of MC3T3-E1 osteoblasts, and can improve the osteogenesis of osteoblasts. (3). In vivo, PLGA film / TiO₂ nanotube sustained release system has the ability of promoting osteogenic for a long time in experimental animals.

Conclusion: The PLGA film / TiO₂ nanotube growth factor delivery system can be effectively sustained release the bone growth factor rhBMP-2, the delivery system can promote osteoblast adhesion and osteoblast function in vitro and promote bone integration in vivo. It can be used as a good surface material of implants.

Study of Body Composition and Bone Measures Acquired from Osteoporotic Measurement Sites using Regional DXA Scans. Louise Marquino¹, Bo Fan², Bennett Ng², Vicente Gilsanz³, Heidi Kalkwarf⁴, Joan Lappe⁵, Sharon Oberfield⁶, Karen Winer⁷, Babette Zemel⁸, John Shepherd².
¹University of California, San Francisco, USA, ²UCSF, USA, ³USC, USA, ⁴CCHMC, USA, ⁵Creighton Univ, USA, ⁶CUMC Columbia, USA, ⁷NICHD, USA, ⁸CHOP, USA

Background: Accurately measuring body composition at regional locations is a useful measurement when studying mechanical loading and development of the skeleton. DXA is increasingly being used as a safe, low-cost tool for body composition measurement across the lifespan. Currently body composition data is only available from adult and infant whole body scans for GE and Hologic DXA systems. We are investigating methods to derive fat and fat-free masses from dedicated forearm and femur scans. The purpose of this study was to derive methods and present pilot findings of body composition measures derived from forearm DXA scans.

Methods: We retrospectively analyzed forearm and whole body DXA scans acquired on 34 participants from the Bone Mineral Density in Children Study (BMDCS). The participants' forearm scans were analyzed to mimic infant whole body scans. Fat, fat-free, and percent fat masses were quantified within a 1.0-cm wide region located at the 4/10th distal forearm. This region was picked because it was the most proximal region that could be analyzed on all standardly acquired forearm scans and maximized muscle cross-sectional area. A similar region was defined on the whole body scans. All scans were acquired on Hologic DXA systems and analyzed using Hologic, Apex 5.5.

Results: Of the 34 participants (18 male), the average age, height, weight, and BMI was 10.8, 143.4 cm, 39.9 kg, and 18.5 kg/m². The correlation between the forearm and whole body percent fat was R² 0.63 and RMSE of 4.1 %. Including age and BMI improved the R² values to 0.61 and 0.64 respectively.

Conclusions: In this pilot, we demonstrated a method to assess body composition from dedicated forearm scans that agree well with similar measures from whole body scans. Further work will be to include more participants and to quantify the association of our measures to forearm pQCT muscle cross sectional area measures available in this population.

The Essential Role of Connective Tissue Growth Factor (CTGF/CCN2) in Palatogenesis. Joseph Tarr^{*}, Honey Hendsi, Alex Lambi, James Bradley, Steven Popoff. Temple University School of Medicine, USA

Nonsyndromic cleft palate is a common craniofacial birth defect with an incidence of 1 in 700 live births. Connective tissue growth factor (CTGF/CCN2) has emerged as an essential player in normal craniofacial skeletal formation. Recent studies suggest that CTGF acts as a necessary downstream mediator of TGF- β -dependent mesenchymal stem cell proliferation in palatogenesis. Previous work in our laboratory identified numerous craniofacial defects such as failure of formation of the bony palate in CTGF knockout (KO) mice. In this study, microCT and histological analyses showed that in the absence of CTGF, the growth of the palatal shelves is arrested at an early stage in the process of palatogenesis. We isolated mesenchyme-derived pre-osteoblasts from crania of WT and CTGF KO mice for in vitro studies. CTGF KO cells exhibited decreased proliferation with a significant reduction in the number of cells in the S phase and a concomitant increase in the number of cells accumulating on the G0/G1 phase compared to WT cells. CTGF KO cells exhibited decreased ability to adhere to extracellular matrices, reduced spreading, altered cytoskeletal organization, and reduced levels of total and activated Rac1 compared to WT cells. The reduction in Rac1 resulted in decreased focal adhesion formation in CTGF KO cells. Since all of these cell functions are necessary for proper formation of the secondary palate during craniofacial development, we conclude that these defects contribute to the failure of the palatal shelves to form and grow in CTGF KO mice. Future studies will focus on elucidating how CTGF regulates the activity of other factors (e.g. TGF β /BMPs, SHH/IHH, Wnt-5a), known to play key roles in palatal development.

CKD effects on cortical bone are age-independent. Karl Foley, Emily Stein, Natalia Cortez, Kyle Nishiyama, Donald McMahon, Elizabeth Shane, Thomas Nickolas*. Columbia University, USA

Chronic kidney disease (CKD) and aging are common causes of osteoporosis. However, the skeletal effects of these processes differ. This is relevant because highest fracture risk in CKD patients occurs after age 65 and the joint effects of CKD and aging on cortical (Ct) and trabecular (Tb) compartments are poorly described. In CKD high levels of parathyroid hormone are catabolic for Ct bone and may be anabolic for Tb bone. In contrast, in aging hypogonadism is associated with Ct and Tb loss. Thus, strategies to prevent fractures in older CKD patients may require a multifaceted approach that targets several pathogenetic mechanisms of bone loss. In a cross-sectional cohort of patients with and without CKD between 50 and 85 years, we used high-resolution peripheral computed tomography (HRpQCT, XtremeCT, Scanco, 82µm³) to assess the effects of CKD and age on Ct and Tb geometry, volumetric bone mineral density (vBMD) and microarchitecture at the distal radius and tibia. We hypothesized that compared to an age, race and sex matched healthy reference group without CKD or diabetes that: (1) older age would modify the effect of CKD on the severity of Ct defects; and (2) Older age alone would account for the severity of Tb defects. We enrolled 180 CKD patients from the renal clinics. A reference group of 73 patients was enrolled from the General Medicine clinics. eGFR was assessed by MDRD. Linear regression models were used to assess relationships between CKD status, age and their first-order interaction; all models were adjusted for sex and race. CKD and Reference groups were well matched for age, sex and race, and between-group differences were not significant (Table 1). Contrary to our hypothesis, there was no effect modification of age on CKD for radius and tibia Ct measures. Thus, CKD and age had independent effects on Ct bone. CKD status and each 10-year increase in age were associated with less dense and thinner cortices (Table 2). Consistent with our hypothesis Tb vBMD and microarchitecture did not differ by CKD status. Surprisingly older age had no effect on Tb measures. These findings suggest that CKD and age independently drive Ct defects, which may have broad implications for preventing bone loss and fractures in older CKD patients. Pathogenetic mechanisms for these relationships are currently being explored.

Table 1: Demographics of CKD patients and an age, race and sex matched healthy Reference Group

| | CKD (N=180) | Reference Group (N=73) |
|---|-------------|------------------------|
| Age (mean±SD yrs) | 69±9 | 64±9 |
| Women % (N) | 46 (82) | 58 (46) |
| White % (N) | 55 (99) | 49 (39) |
| HD % (N) | 27 (49) | NA |
| eGFR for non-dilaysis patients (mean±SD mL/min) | 34±17 | 82±15 |

Diminished bone quality in tissue formed following the onset of moderate Chronic Kidney Disease in C57BL/6 mice. Chelsea Heveran*¹, Moshe Levi², Karen King², Virginia Ferguson¹. ¹University of Colorado, USA, ²University of Colorado School of Medicine, USA

Chronic Kidney Disease (CKD) increases fracture risk, yet fragility in human CKD is not explained by decreased bone mass. CKD disrupts systemic mineral homeostasis and is characterized by abnormal osteocyte activity. Thus we hypothesize that skeletal fragility in CKD results primarily from impaired bone material quality. In this study, 10-week-old male C57BL/6 mice were subjected to 5/6th Nephrectomy (5/6Nx) to establish CKD, or Sham surgeries (n = 6 / group). Mice were fed a standard chow diet and euthanized after 11 weeks post surgery.

Elevated BUN (83%, p < 0.05) and creatinine (26% p < 0.05) confirmed moderate CKD status in 5/6Nx. Bone material quality was evaluated in cortical bone at the tibia mid-diaphysis in “New” bone, determined to be formed following Sham or 5/6 Nx surgeries, and “Extant” bone deposited prior to surgery. Tibiae were embedded in PMMA, sectioned at the mid-diaphysis, polished (0.05 µm finish), carbon coated, and evaluated using quantitative backscattered electron microscopy with calibrated glass reference standards. Nanoindentation (5mm spherical tip; Hysitron TI-950) evaluated indentation modulus (E) in arrays extending through New bone and Extant bone; mineral volume fraction (minVf) measurements were collected at matched sites.

In Sham, E increased in New bone with distance from the periosteal surface and plateaued in Extant bone - a pattern indicative of expected tissue maturation. The minVf did not change with distance in Sham. Analysis of mean E and minVf showed no significant difference between New and Extant bone in Sham. Conversely, for 5/6Nx, both mean E and minVf were reduced in New vs. Extant bone (-10.3%, -5.5%; respectively, p < 0.01). Regression analysis showed E in New 5/6Nx bone at the periosteal surface is lower than in Sham (-13.5%, p < 0.01); however, E increased more rapidly with distance in 5/6Nx (+52.6%, p < 0.01) to achieve equal E values in Extant bone in both groups. Preliminary observations via Raman spectroscopy imply that altered mineral chemistry is a contributor to diminished bone quality with 5/6Nx. In summary, cortical bone material formed following the onset of moderate CKD in skeletally mature mice has diminished minVf and E. These results suggest that deleterious bone material changes may impart skeletal fragility in human CKD.

Nanomechanical properties of cortical bone in dialysis patients. Yoshiko Iwasaki¹, Ryota Kawamata², Yuko Mikuni-Takagaki², Junichiro Kazama³, Masafumi Fukagawa⁴. ¹Oita University of Nursing & Health Sciences, Japan, ²Division of Biochemistry & Molecular Biology, Kanagawa Dental University, Japan, ³Dialysis center, Niigata University Medical & Dental Hospital, Japan, ⁴Division of Nephrology, Endocrinology, & Metabolism, Tokai University School of Medicine, Japan

Bone histology in dialysis patients is conventionally classified into three types based on bone histomorphometry with tetracycline labeling i.e., mild change type (M), osteitis fibrosa (OF), and adynamic bone disease (ABD). Although mineralization and bone turnover varies in dialysis patients, common abnormality is increasing bone fragility. Recent report demonstrates that reducing mechanical properties accompanied with chemical composition changes are observed in trabecular bone biopsy samples from dialysis patients, which have not been examined with cortical bone. In this study, we analyzed biopsy samples of cortical bone from dialysis patients. Double tetracycline-labeled bone specimens were obtained by iliac crest bone biopsies from dialysis patients. As controls, we obtained control bone specimens from healthy volunteers with normal kidney function. Bone turnover was assessed by conventional bone histomorphometry using the section from bone specimens. The remaining tissue blocks were analyzed by direct raman spectroscopy measurement, nanoindentation assessment, and microfocus computed tomography (MCT). Although the ratio of carbonate to phosphate seemed higher in OF group, significant differences were not confirmed among three groups. The level of crystallinity in ABD group was tended to be low. Young's modulus (shape-independent material stiffness) in cortical bone was 26% and 17% less in bone with OF compared with bone with normal or Mild change type. Hardness (the ability of resistance) of bone in OF was 30% less compared with ABD. In addition, wider variations in ten indentation data were observed in OF and ABD groups compared with normal group. The degree of porosity in cortical bone increased in both OF and ABD groups. These results suggest that nanomechanical property of cortical bone in dialysis patients is affected by microarchitecture changes, but not by alterations of chemical composition, mineralization or bone turnover.

MO0004

The impact of dementia in hip fractures in patients receiving dialysis therapy. Milka Maravic¹, Agnes Ostertag², Pablo Urena Torres³, Martine Cohen-Solal⁴. ¹department of rheumatology, hopital Lariboisiere, France, ²Inserm U1132, hopital Lariboisiere, France, ³Unité de nephrologie et de dialyse, clinique du Landy, France, ⁴Centre Viggo Petersen, France

Objectives: Hip fractures (HF) are associated with significant morbidity and the incidence is further increased in patients with chronic kidney disease (CKD). Higher morbidity in dialysis patients is related to several risk factors. We have shown that proportion of dementia is significantly higher in CKD patients. We here aimed to investigate 1) the impact of dementia in FH in patients on dialysis therapy and 2) to assess if the risk of HF in demented patients is increased CKD patients compared to non CDK patients. **Methods:** Data are obtained from the National Database of Hospitalizations over the period 2011-2013. Three populations of subjects aged 60 and over were extracted and analyzed: population with hip fracture, population in dialysis and population of demented patients (whatever the reason for hospitalization in connection or not with dementia). These populations were crossed to estimate fracture risk based on the presence of dementia or dialysis, adjusted for age and sex. The fracture risk was calculated using a multiple logistic regression model.

Results: Over the period 2011-2013, 213 180 patients had a HF (70% women), 660 434 patients were diagnosed for dementia (64% women) and 47 430 patients were on dialysis (39% women). There was a strong effect of age and gender in the incidence of fractures and dementia in CKD and non CKD patients. In dialysis patients, the risk of HF was higher in patients with dementia than without dementia: OR 1.99 [95% CI: 1.66-2.38], this being the same for men OR 2.37 [1.81-3.05] and women OR 2.56 [1.97-3.29] at any age. In patients with dementia, the fracture risk is independent of dialysis OR: 1.25 [0.99-1.59] in each sex and age categories. However, the risk of dementia is not increased by dialysis therapy in the population with HF: OR 1.52 [0.77-3] after adjustment for age and gender.

Conclusion: Dementia significantly increases the risk of hip fracture in dialysis patients, but this risk in demented patients is equally high whether receiving dialysis therapy or not. These results highlight dementia as a major risk factor for FH in dialysis therapy and suggest that attention should be paid to dementia in order to prevent hip fracture.

The Role of Activin in the Pathogenesis of the CKD-MBD. Toshifumi Sugatani¹, Olga Agapova¹, Yifu Fang¹, William Smith², Hartmut Malluche³, Keith Hruska⁴. ¹Washington University, USA, ²Celgene Corporation, USA, ³University of Kentucky, USA, ⁴Washington University in St. Louis School of Medicine, USA

Introduction: At its inception the CKD-MBD includes vascular calcification, osteodystrophy, loss of klotho and stimulation of FGF23, and its pathogenesis is unknown. Here we report the role of activin in the pathogenesis of renal osteodystrophy in a model of type 2 diabetes with a low turnover osteodystrophy prior to the induction of CKD equivalent to stage 3-4 human CKD.

Methods: CKD with hyperphosphatemia, elevated FGF-23 and PTH, and 60% reduction in GFR (CKD-3) was induced at 14 weeks of age in the *ldlr*^{-/-} high fat fed model of atherosclerotic vascular calcification. CKD mice were treated with RAP-011, an ActRIIA ligand trap, 10mg/kg (n=15) or VEH, (n=13), IP twice weekly beginning at 22 weeks of age and studied at 28 weeks by skeletal histomorphometry and microCT.

Results: Relative to CKD-3 mice receiving vehicle, microCT of long bones revealed that RAP-011 significantly increased cortical bone volume and cortical thickness. Induction of CKD caused high turnover bone disease in VEH mice, that also demonstrated a reduction in TBV (11.22%) that was reversed by six weeks of RAP-011 treatment (13.28%). Histomorphometry revealed that relative to SHAM, CKD caused an increase in erosion surface/bone surface (1.05 & 1.83% respectively) and osteoclast number/100mm bone length (33.40 & 62.32/100mm respectively), that were reduced by RAP-011(1.23% and 38.37/100mm). Relative to SHAM, CKD caused an increase in osteoblast surface/bone surface (0.76 & 1.58% respectively) and osteoblast number/100mm bone length (45.03 & 110.63/100mm respectively, p<0.05 WT vs SHAM and SHAM vs VEH). RAP-011 significantly reduced, relative to VEH, both osteoblast surface/bone surface and osteoblast number/100mm bone length (0.68% and 43.18/100mm, p<0.05). Despite the significant reduction in osteoblast number relative to VEH, the mineral apposition rate in RAP-011 was maintained (0.42 and 0.40 $\mu\text{m}^3/\text{day}$, respectively), with a significant increase in the bone formation rate/osteoblast (0.17 and 0.48 $\mu\text{m}^3/100$ cell/year, respectively, p<0.05), to a rate similar to wild type (0.42 $\mu\text{m}^3/100$ cell/year).

Conclusion: Increased circulating Activin during CKD contributes to the high turnover osteodystrophy produced by CKD-3, and its inhibition through an ActRIIA ligand trap increased bone volume by inhibiting bone resorption and counteracting the negative effects of CKD, at the cellular level, on osteoblasts normalizing the mineral apposition rate and bone formation rate/osteoblast.

MO0006

LIM-Domain Protein AJUBA Is A Required Co-Factor For Gfi1 Suppression Of Runx2 In Pre-Osteoblasts In Multiple Myeloma. Juraj Adamik¹, Jixin Ding², Peng Zhang¹, Sun Quanhong¹, G. David Roodman³, Deborah L. Galson¹. ¹University of Pittsburgh, USA, ²Indiana University, USA, ³Indiana University & Veterans Administration Medical Centre, USA

We previously reported that the transcriptional repressor Gfi1 is increased in multiple myeloma (MM) exposed bone marrow stromal cells (BMSC) and represses the *Runx2* gene. Gfi1 directly binds to the *Runx2* promoter and recruits various chromatin modifiers causing long-term epigenetic inactivation of *Runx2* expression, which results in impaired osteoblast (OB) differentiation. In this study, we explored if the LIM-domain protein family member AJUBA plays a role in MM-induced Gfi1 repression of *Runx2*. AJUBA, which doesn't bind DNA directly, is known to act as a co-repressor of SNAI1 and SNAI2/SLUG-dependent repression and as an HDAC-dependent co-repressor for a subset of Gfi1 target genes in myeloid cells. We hypothesized that AJUBA functions as a corepressor of Gfi1 to epigenetically repress the *Runx2* gene in MM-exposed pre-OB. To address this question we co-cultured pre-OB (MC4) with 5TGM1 MM cells and used ChIP to assay for the presence of AJUBA on the *Runx2* promoter. After 36-48h MM exposure of MC4 cells, enrichment of AJUBA occupancy was co-localized to the previously mapped Gfi1 binding site in the *Runx2* promoter concurrently with the recruitment of Gfi1. Biotin-oligo pulldown of Gfi1 brought down AJUBA as well. Further, cotransfection of AJUBA and Gfi1 revealed that AJUBA enhanced repression by suboptimal doses of Gfi1 of both a *Runx2*-luciferase reporter as well as the endogenous *Runx2* gene in pre-OB. Studies using deletion constructs showed that the LIM region of AJUBA in conjunction with Gfi1 is necessary and sufficient for *Runx2* repression, and the pre-LIM portion of AJUBA does not affect *Runx2* luciferase expression. Transfected AJUBA exhibits cytoplasmic localization in MC4 cells unless co-expressed with full-length Gfi1, which brings it into the nucleus. Nuclear co-localization of AJUBA with Gfi1 was uncoupled in MC4 cells when transfected with Gfi1 containing only the DNA binding region (aa 239-423). Transfected 239-423 Gfi1 binds the endogenous *Runx2* promoter, but fails to repress transcription, likely due to impaired recruitment of AJUBA. Importantly, knockdown of AJUBA caused decreased recruitment of Gfi1 to the *Runx2* gene in pre-OB and prevented the Gfi1 repression of a *Runx2* reporter. Consistent with these observations, lack of AJUBA in MC4 pre-OB prevented the MM-induced sustained repression of *Runx2* mRNA. Our study reveals that AJUBA functions as a required Gfi1 co-factor for *Runx2* suppression in OB lineage cells in MM bone disease.

Knee Loading Enhances Vessel Remodeling and Bone Healing in a Rat Femoral Head Osteonecrosis Model. Daquan Liu¹, Jie Li¹, Xinle Li¹, Hiroki Yokota², Ping Zhang^{*1}. ¹School of Basic Medical Sciences, Tianjin Medical University, China, ²Department of Biomedical Engineering, Indiana University Purdue University Indianapolis, USA

Osteonecrosis of the femoral head is a serious orthopedic problem. Moderate loads with knee loading promote bone formation, but its effects on the healing of osteonecrosis have not yet been investigated. Using a rat model, we examined a hypothesis that knee loading enhances vessel remodeling and bone healing through the modulation of the fate of bone marrow-derived cells.

Eighteen male SD rats (~12 wks) were divided into 3 groups such as the sham-operated control, osteonecrosis, and loaded osteonecrosis (n=6). Osteonecrosis was induced by transecting the ligamentum teres followed by a tight ligature around the femoral neck. For knee loading, 5 N loads were laterally applied to the knee at 15 Hz for 5 min/day for 35 days. Changes in bone mineral density (BMD) and bone mineral content (BMC) of the femur were measured by pDEXA, and ink infusion was performed to evaluate vessel remodeling. Femoral head were harvested for histomorphometry, and bone marrow-derived cells were isolated to examine osteoclast development and osteoblast differentiation.

Osteonecrosis induced a significantly bone loss, and knee loading stimulated vessel remodeling and bone healing. Among these 3 groups, osteonecrosis exhibited a shorter height of the femoral head ($p<0.01$), lower trabecular BV/TV ($p<0.001$) in femoral head, and lower femoral BMD ($p<0.05$) and BMC ($p<0.01$). However, knee loading restored femoral head BMD/BMC (both $p<0.05$) and trabecular BV/TV ($p<0.001$). Osteonecrosis decreased the vessel volume and vessel number (both $p<0.001$), while knee loading increased them (both $p<0.001$). A significant positive correlation was observed between bone quality (BMD/BMC and BV/TV) and vessel remodeling (vessel volume and vessel number) ($r=0.89-0.92$, $p<0.001$). Osteonecrosis activated osteoclast development, and knee loading reduced its formation, migration and adhesion (all $p<0.001$). In addition, knee loading attenuated the level of "pit" formation to base level. Furthermore, knee loading significantly increased CFU-F and CFU-OBL (both $p<0.01$).

The results indicate that in response to knee loading vessel remodeling is associated with bone healing. Further studies are needed to clarify the molecular mechanism underlying the vessel remodeling and bone remodeling, and the role of bone marrow-derived cells. The current study suggests that knee loading can non-invasively enhance the healing of osteonecrosis through vessel remodeling.

acromegaly and bone health: combined effects of disease activity and gonadal status. giuseppe guglielmi¹, claudia battista², francesca di chio¹, antonio salcuni³, michelangelo nasuto¹, renaud winzenrieth^{*4}, doris tran⁴, alfredo scillitani³. ¹Department of Radiology, University of Foggia, Italy, ²Unit of Endocrinology, "Casa Sollievo della Sofferenza" IRCCS, Italy, ³Unit of Endocrinology, "Casa Sollievo della Sofferenza" IRCCS, Italy, ⁴Department of Clinical Research, Medimaps Group, France

The effects of GH excess on bone architecture and strength are still unclear. Vertebral fractures have been observed in acromegalic patients with areal Bone Mineral Density (BMD) T-score > -2.5 . Previous study also reported unclear effects of disease activity and gonadal status on bone parameters at spine. The aim of this study was to assess in acromegalic patients the effects of disease activity and gonadal status on bone health assessed by bone mineral density (BMD) and Trabecular Bone Score (TBS), respectively.

This cross-sectional study involved 47 acromegalic patients (27 women and 20 men; mean age and BMI of 54.9 ± 11.5 years and 29.6 ± 4.5 kg/m² respectively). Subjects were stratified in respect to disease activity (active, ACT, or controlled, CTR) and gonadal status (hypogonadal, HYP, or eugonadal, EUG). Thirty-two patients were hypogonadal (22 female and 10 male). Among 22 hypogonadal female, 9 patients had an active disease and 13 patients had a controlled disease. Among 10 hypogonadal male, 4 patients had an active disease and 6 patients had a controlled disease.

BMD and TBS were evaluated at PA Spine (L1-L4) using a iDXA GE encore 13.60 device and TBS iNsight® (v2.1, Med-Imaps, France).

In respect to normative data, TBS Z-score of patients with controlled disease and hypogonadism (CTRL/HYP) was significantly lower ($p<0.001$), while TBS Z-score of the other 3 subgroups were not different. Regarding BMD Z scores, there was not any difference between each subgroup and the normative data. Moreover, BMD Z-scores were not different among the 4 groups, while TBS Z-score of patients with controlled disease and hypogonadism (CTRL/HYP) was significantly lower than the other 3 groups.

The prevalence of vertebral fractures (VFs) in our population of acromegalic patients was 21.3%. In an univariate analysis TBS associated with the presence of VFs (OR=2.69 [1.13-6.41]), and among the variable evaluated, only TBS associated with VFs in multiple regression analysis.

In conclusion, bone microarchitectural texture at lumbar spine is impaired in acromegalic patients with controlled disease and hypogonadism.

Clinical and Biochemical Features of Adults with Hypercalcemia, Hypercalciuria, Elevated Calcitriol and Nephrolithiasis due to CYP24A1 Mutations in a Single Family. Derek O'Keeffe^{*}, Peter Tebben, Rajiv Kumar, Ravinder Singh, Yanhong Wu, Robert Wermers. Mayo Clinic, USA

Background: We identified a 60 year old male (proband) with intermittent hypercalcemia, hypercalciuria, elevated 1,25-OH₂D (calcitriol), undetectable 24,25-OHD, chronic nephrolithiasis and osteopenia. His family history was significant for several family members with a similar clinical phenotype. Genetic analysis revealed two mutations in the *CYP24A1* gene: (A) p.R396W and (B) c.428_430delAAG which encodes 1,25-OH₂D 24-hydroxylase, the key enzyme of 1,25-OH₂D inactivation. **Objective:** To identify the clinical, biochemical and genetic features of *CYP24A1* mutations in a single family. **Methods:** After Institutional Review Board approval 4 siblings, 2 nieces and the daughter of the proband consented to take part in the study, which included measurement of calcium biomarkers, CYP24A1 gene analysis, and a review of their medical history. **Results:** The pedigree of the syndrome was autosomal recessive, with subjects either inheriting, A, B, A/B or none (Table 1). Clinically, including the proband (subject 1), 4 subjects had a history of symptomatic nephrolithiasis (passed kidney stones) while 4 did not. Two subjects were compound heterozygous (A/B) and had more severe clinical features (Table 1). One subject without stone passage had no evidence of a mutation. Of the remaining 4 subjects with a single heterozygous mutation (either A or B), 2 had nephrolithiasis. Four subjects had hypercalciuria (> 300 mg/spec) but only 2 had hypercalcemia (> 10.1 mg/dl). Six subjects had 1,25 Vit D > 60 pg/ml. The 25-OHD / 24,25 OH₂D ratio, in the 2 subjects with A/B mutations was > 100 . **Conclusion:** Adult familial *CYP24A1* mutations have a heterogeneous clinical and biochemical spectrum. A gene dose effect is apparent given that subjects with compound heterozygous mutations (A/B) have more severe clinical and biochemical patterns. However, subjects with a single heterozygous mutations (A or B) also developed clinical disease (2 subjects), likely influenced by environmental factors such as hydration, 25 OHD levels, and calcium intake.

| Subject | Mutation | Symptomatic Nephrolithiasis | 25-OHD / 24,25 OH ₂ D | Urinary Calcium (mg/24 hours) |
|---------|----------|-----------------------------|----------------------------------|-------------------------------|
| 1 | A/B* | Yes | 477 | 493 |
| 2 | None | No | 13 | 289 |
| 3 | A | No | 17 | 311 |
| 4 | A/B | Yes | 104 | 672 |
| 5 | A | Yes | 30 | 229 |
| 6 | B | No | 13 | 139 |
| 7 | A | No | 23 | 359 |
| 8 | A | Yes | 16 | 289 |

Increased MicroRNA-34a Expression Levels in Paget's Disease of Bone. Daniela Merlotti^{*1}, Guido Sebastiani², Simone Bianciardi², Marco Valentini², Stefano Gonnelli², Carla Caffarelli², Isabella Evangelista², Simone Cenclì³, Ranuccio Nuti², Francesco Dotta², Luigi Gennari². ¹University of Siena, Italy, ²Department of Medicine, Surgery & Neurosciences University of Siena, Italy, Italy, ³Division of Genetics & Cell Biology, San Raffaele Scientific Institute, Milan, Italy, Italy

MicroRNAs (miRs) have recently emerged as important regulatory factors involved in the developmental processes and in the regulation of bone cell activity. Despite different miRs have been associated with modulation of osteoblast activity, two miRs have been mainly associated with osteoclast activity and bone resorption, miR-21 and miR-34a. While the former (miR-21) is up-regulated during RANKL-induced osteoclastogenesis and seems to be essential for osteoclast activity (Blood 2011;117:3648-57), the latter (miR-34a) is a suppressor of osteoclastogenesis and its overexpression attenuated ovariectomy-induced bone loss as well as the development of bone metastases in mice models (Nature 2014;512:431-5). Here, we analysed the expression levels of miR-21 and miR-34a in peripheral blood mononuclear cells from patients with Paget's disease of bone (PDB), a disease characterized by a marked increase in osteoclast activity and bone turnover at affected skeletal sites. Peripheral blood mononuclear cells were obtained from 30 patients with active PDB (10 with SQSTM1 mutation) and 20 age-matched controls. Quantitative analysis of miR-21 and miR-34a was performed using specific stem-loop primers followed by real-time

polymerase chain reaction. All values were normalized to endogenous control U6. Expression levels of miR-34a were 4.4¹.7-fold increased in peripheral blood mononuclear cells from patients with PDB with respect to controls (p<0.0001). A similar but not significant trend was observed concerning miR-21, which was 2-fold increased in PDB cases than controls. A statistically significant inverse correlation was observed between bone turnover markers and miR-34a levels in controls but not in patients with PDB. Moreover, miR-34a expression did not significantly differ between monostotic and polyostotic PDB cases or in relation to SQSTM1 mutation status. Taken together these results show for the first time an inverse relationship between miR-34a expression and bone turnover, *in vivo*, in elderly individuals. However, miR-34a expression levels were unexpectedly increased in patients with active PDB (despite the increase in bone turnover markers typically observed in this condition) and this might account, at least in part, for the delayed time to bone metastases and the improved overall survival of patients with prostate cancer and PDB than patients with prostate cancer alone, recently reported in a large retrospective analysis (Br J Cancer 2012;107:646-51).

MVNP Alters The Balance Of TBK1 And Optineurin In Osteoclast Lineage Cells To Generate Pagetic Osteoclasts. Quanhong Sun^{*1}, Peng Zhang¹, Juraj Adamik¹, Jolene J Windle², Laëtiti Michou³, Jacques P Brown³, Noriyoshi Kurihara⁴, G. David Roodman⁵, Deborah Galson¹. ¹University of Pittsburgh, USA, ²Virginia Commonwealth University, USA, ³Laval University, CHU de Quebec Research Centre & CHU de Quebec, Canada, ⁴Indiana University, USA, ⁵Indiana University & Veterans Administration Medical Center, USA

Paget's disease of bone (PDB) is characterized by abnormal osteoclasts (OCL) with increased nuclei/OCL. Measles virus nucleocapsid protein (MVNP) was reported to play a key role in the development of pagetic OCL. Additionally, MVNP expression targeted to OCL in mice (Tg-MVNP) induces pagetic bone lesions *in vivo* and aberrant OCL *in vitro*. MVNP's upregulation of IL-6 is essential for the pagetic phenotype. We recently reported that MVNP activation of TBK1, an IKK family member, is a critical mediator of MVNP-dependent generation of pagetic OCL. We also reported that another IKK family member, optineurin (OPTN), is a novel negative regulator of OCL formation that also blocks MVNP and TBK1 induction of IL-6. We demonstrated that Tg-MVNP pre-OCLs and MVNP^{p62^{P392L}}-Paget's patient OCLs had increased TBK1 and decreased OPTN protein levels, resulting in an increased TBK1:OPTN ratio. Further, MVNP transduced into normal human CFU-GM also increased TBK1 and decreased OPTN in both pre-OCLs and mature OCLs.

We demonstrate here that endogenous OPTN and TBK1 interact in the pre-OCL cell line 4B12 by co-IP. IP of OPTN also pulls down MVNP in cotransfected cells. Immunohistochemistry of Tg-MVNP pre-OCL revealed that MVNP colocalized with both endogenous TBK1 and OPTN in large perinuclear puncta. Lentiviral transduced TBK1-GFP and dsRed-OPTN were almost entirely colocalized with MVNP in Tg-MVNP pre-OCL. Ectopic TBK1 increased OCL formation and IL-6, whereas ectopic OPTN decreased OCL formation and IL-6. MVNP's interaction with OPTN may be how MVNP activates TBK1, by preventing OPTN from repressing TBK1 activity. In turn, TBK1 phosphorylation of OPTN induces its degradation. Inhibition of TBK1 in pre-OCL with BX795 elevated OPTN mRNA and protein. We recently generated a new mouse model with TBK1 targeted to the OCL lineage (Tg-TBK1). Tg-TBK1 pre-OCL from 3 founder lines displayed a pagetic phenotype *in vitro* with increased OCL, IL-6, and nuclei/OCL. Further, Tg-TBK1 pre-OCL have higher activated TBK1 and lower OPTN levels. OPTN knockdown increased OCL formation by WT and Tg-MVNP pre-OCL 2-3 fold, but only increased Tg-TBK1 OCL formation slightly since ectopic TBK1 already repressed OPTN levels. However, ectopic OPTN in Tg-TBK1 pre-OCL decreased OCL formation. These results confirm OPTN as a negative OCL regulator and reveal that MVNP's interaction with the TBK1-OPTN complex in pre-OCL decreases OPTN and plays an important role in generating pagetic OCL.

Paget's disease of Bone in Thai: Clinical Characteristics and Genetic Studies of Three Sporadic Cases. Lalita Wattanachanya^{*1}, Sumittra Charoenhirunyingyos², Voranuch Thanakit³, Weerapan Khovichunkit². ¹Kingchulalongkorn memorial hospital, Thailand, ²Division of Endocrinology & Metabolism, Departments of Medicine, Faculty of Medicine, Chulalongkorn University & King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, 10330 Thailand, Thailand, ³Departments of Pathology, Faculty of Medicine, Chulalongkorn University, & King Chulalongkorn Memorial Hospital, Thai Red Cross Society, Bangkok, 10330 Thailand, Thailand

Paget's disease of bone (PDB) is considered rare in Asians and there are scant published studies regarding genetic basis of PDB in this population. Here, we reported clinical features and genetic studies of three Thai patients with PDB. The first case was a 35-year-old man who presented with progressive low back pain, left hip tenderness

and generalized muscle weakness. Serum alkaline phosphatase (ALP) level was elevated. Bone surveys revealed generalized lytic and blastic lesions at skull, clavicles, lumbar spines and femurs corresponding to the increased uptake on bone scans. PDB was confirmed by an iliac bone biopsy showing a mosaic-like pattern with increased number of cement lines of bone matrix, prominent osteoclasts, foci of new bone formation with osteoblastic rimming and vascular-intervening stroma. The second case was a 59-years-old man presented with low back pain and right leg weakness with elevated ALP level. Radiographs demonstrated lytic lesions at the 5th lumbar vertebra. Bone metastasis was initially considered, however, extensive investigations failed to show any evidence of malignancy. Thoracic and abdominal CT scans demonstrated mixed expansile blastic and lytic lesions at left acetabulum, left iliac bone, and the 5th lumbar vertebra. Bone scans showed increased uptake at sacrum and left pelvis. The iliac bone biopsy result was compatible with the diagnosis of PDB. The two patients responded well to oral bisphosphonate treatment and achieved normalized ALP levels and pain relief. The third case was a 79-year-old woman who was asymptomatic and presented with an isolated raised ALP level during routine testing. Bone surveys found a sclerotic change at occipital bone with thickening of the diploic space. The mixed regions of sclerosis and lucency were seen at the temporal bone, left iliac bone and acetabulum. Bone scans showed increased uptake at skull and left pelvis. She denied bone biopsy; however, the investigations suggested the diagnosis of PDB. Mutational analysis of the sequestosome1 gene was performed in our patients; however, no mutation was detected. In conclusion, we reported three cases of PDB in Thai. Although it is rare in Asian, PDB should be considered in the differential diagnosis in Asian patients with isolated elevation in ALP level or with bone lesions resembling bone metastasis. Further studies regarding clinical features and genetics of PDB in Asian population could provide important insights into its pathogenesis and could explain the ethnic disparity in PDB.

Changes in BMD and TBS up to 2 years after Surgical or Medical Management of Primary Hyperparathyroidism. Alice Abraham^{*1}, Cristiana Cipriani², Zhang Chengchen³, Didier Hans⁴, Bilezikian John⁵. ¹Endocrinology fellow, USA, ²Sapienza University of Rome, Italy, ³Columbia College of Physicians & Surgeons, Division of Endocrinology, USA, ⁴University of Lausanne, Switzerland, ⁵Columbia University College of Physicians & Surgeons, Division of Endocrinology, USA

It is well known that BMD improves after parathyroidectomy (PTX) in primary hyperparathyroidism (PHPT) but little is known about post-PTX changes in skeletal microstructure. We report post-PTX results in 15 subjects (10 women and 5 men) two years after surgery and compare these with 5 female subjects with PHPT observed without surgery for two years. We compared BMD and TBS between surgical and non-surgical patients at baseline, 1 and 2 years.

There were no significant between group differences in patient age (64 ± 14 vs 68 ± 8 years; p=0.54), BMI (31 ± 6 vs 29 ± 3 ; p=0.25), TBS scores, BMD at lumbar spine, femoral neck, total hip or 1/3 radius at baseline.

After one year, the non-surgery patients had no significant changes in TBS, BMD at lumbar spine, femoral neck, and total hip. After two years, there were no significant differences from baseline in BMD at the lumbar spine, radius, femoral neck and TBS.

At one year post PTX, patients had a significant gain in BMD at the lumbar spine ($+4.96\% \pm 1.31\%$; p=0.002), as well as at the femoral neck ($+3.00\% \pm 1.20\%$; p=0.02) and total hip ($+3.11\% \pm 0.82\%$; p=0.002). There were no significant differences at one year follow up in 1/3 radius and TBS among post-surgical patients. Two years after PTX, patients had sustained gains in BMD from baseline at the lumbar spine ($+4.23\% \pm 1.52\%$; p=0.01), as well as at the femoral neck ($+4.13\% \pm 1.09\%$; p=0.002) and total hip ($+4.12\% \pm 1.21\%$; p=0.004).

At one year of follow up, there were no significant differences in BMD and TBS scores between surgery and non-surgery subjects. At two years, post-PTX patients had greater gains in BMD at the lumbar spine ($+4.234\% \pm 1.518\%$ vs $-0.433 \pm 0.493\%$; p=0.01) and femoral neck ($+4.128\% \pm 1.089\%$ vs $-0.483 \pm 1.284\%$; p=0.03). There were no significant differences at two years of follow up in BMD at the radius, total hip and TBS among post-PTX patients and controls. Although not significant, there were positive changes in TBS in the medical group ($+1.4\%$) and surgical group ($+1.7\%$) at 24 months.

In the present study, we demonstrate there are significant gains in BMD at the lumbar spine and femoral neck two years after PTX in patients with hyperparathyroidism compared with nonsurgical controls. However, there were no significant differences in TBS after two years of observation. Postoperative changes in skeletal microstructure may take longer than 2 years to be appreciated by TBS.

MO0016

Table. Percent Change From Baseline

| | | 12 months* | 24 months* |
|------------------|------------|--------------------|---------------------|
| Lumbar spine BMD | Surgery | 4.96 (0.11) | 4.23 (0.001) |
| | Nonsurgery | 0.65 | -0.43 |
| Femoral neck BMD | Surgery | 3.0 (0.46) | 4.13 (0.04) |
| | Nonsurgery | 1.2 | -0.48 |
| Total Hip BMD | Surgery | 3.11 (0.28) | 4.12 (0.23) |
| | Nonsurgery | 0.01 | 1.35 |
| 1/3 Radius | Surgery | -0.28 (0.18) | 0.47 (0.40) |
| | Nonsurgery | -2.87 | -1.29 |
| TBS | Surgery | 2.8 (0.35) | 1.71 (0.92) |

Comparative Effect of PTH(1-84) on Bone Mineral Density and Trabecular Bone Score (TBS) in Hypoparathyroidism and Osteoporosis. Cristiana Cipriani^{*1}, Barbara Silva², Mishaela Rubin³, Natalie Cusano³, Donald J. McMahon³, Jessica Pepe⁴, Sara Piemonte⁵, Wen-Wei Fan³, Juviza K. Rodriguez³, Federica De Lucia⁵, Federica Biamonte⁴, Salvatore Minisola⁵, John P. Bilezikian³. ¹"Sapienza", University of Rome, Italy, ²Santa Casa de Belo Horizonte & Felicio Rocho Hospital, Division of Endocrinology, Brazil, ³Metabolic Bone Diseases Unit, Division of Endocrinology, Department of Medicine, College of Physicians & Surgeons, Columbia University, USA, ⁴Department of Internal Medicine & Medical Disciplines, "Sapienza" University of Rome, Italy, ⁵Department of Internal Medicine & Medical Disciplines, "Sapienza" University of Rome, Italy

We have shown previously in hypoparathyroidism (hypoPT), a disorder associated with above average BMD, that PTH(1-84) improves lumbar spine (LS) BMD and TBS over a 5-year treatment period. Studies in osteoporosis, a disorder associated with low BMD, have shown with PTH(1-34) a significant increase also in LS BMD and TBS. No data are yet available on the effects of PTH(1-84) on TBS in osteoporosis and no study has compared the two populations each treated with PTH(1-84). In this report, we provide data on the effects of PTH(1-84) on BMD and TBS in HypoPT and osteoporosis patients over an 18-month treatment period.

We studied 35 HypoPT women (19 PreM and 16 PostM; mean age 48.2 ± 13.4 yrs) and 40 women with post-menopausal osteoporosis (71 ± 8.3 yrs) treated with PTH(1-84) for 18 months. 3-site DXA (Hologic) [LS, femoral neck, total hip and distal 1/3 radius (Rad)] were assessed. Site-matched LS TBS data were extracted from the DXA image using TBS iNsite software. Within group comparison of % change in BMD and TBS relative to baseline and between-group comparison adjusting for age, BMI, baseline values and average monthly PTH(1-84) dose were assessed.

We observed a significant increase in LS BMD in hypoPT (3.3 ± 0.9%, p < 0.001) and osteoporosis (6.7 ± 1.1%, p < 0.002) patients after 18 months. There was a tendency towards an increase (1.9 ± 1.1%, p = 0.09) in TBS in hypoPT patients, while no difference in TBS was observed in osteoporosis patients. Rad BMD significantly declined in hypoparathyroid (-1.6 ± 0.7%, p < 0.02) and osteoporosis (-6.3 ± 1.2%, p < 0.0001) patients. The between-group comparison showed a significantly greater increase in TBS in hypoPT (1.9 ± 1.1%) compared to osteoporosis (0.3 ± 0.9%) patients (p < 0.001). No association was found between TBS and LS BMD in both groups. Similar results were obtained comparing postmenopausal hypoparathyroid and postmenopausal osteoporosis patients.

Our data show significant and similar increases in LS BMD in hypoparathyroid and osteoporosis patients treated with PTH(1-84) for 18 months. As shown by TBS, PTH(1-84) seems to stimulate a greater improvement in trabecular microstructure in hypoparathyroid patients (low bone turnover) than in osteoporosis patients (normal bone turnover). Mechanisms associated with gains in LS-BMD in hypoparathyroid and osteoporosis patients, however, are not significantly associated with changes in bone microarchitecture as captured by TBS, confirming that changes in TBS and BMD are independent of each other.

Prevalence of Normocalcemic Primary Hyperparathyroidism among Blood Donors. Federica De Lucia^{*1}, Federica Ferrone¹, Vittoria Danese¹, Valeria Fassino¹, Giancarlo Ferrazza², Enrico Panzini³, Jessica Pepe¹, Cristiana Cipriani¹, Frank Block⁴, Salvatore Minisola¹. ¹Department of Internal Medicine & Medical Disciplines University of Rome 'Sapienza', Policlinico Umberto I, Viale del Policlinico, 155, 00161 Rome, Italy, ²Department of Immunohematology & Transfusion Medicine, University of Rome 'Sapienza', Policlinico Umberto I, Viale del Policlinico, 155, 00161 Rome, Italy, ³Department of Immunohematology & Transfusion Medicine, University of Rome 'Sapienza', Policlinico Umberto I, Viale del Policlinico, 155, Italy, ⁴DiaSorin, 1951 Northwestern Avenue, Stillwater, MN, USA, USA

Normocalcemic primary hyperparathyroidism (NPHPT) is a variant of the traditional hypercalcemic presentation of PHPT; it is characterized by consistently elevated PTH concentrations with normal total and ionized serum calcium concentration in the absence of secondary causes for elevated PTH concentrations. Few studies have addressed the issue of its prevalence. Here we report the results of an ongoing study aimed at evaluating the prevalence of NPHPT in blood donors volunteers.

MATERIAL AND METHODS. We enrolled 1053 normal blood donors aged 18-66 (40 ± 12) years (781 males and 272 females). After informed consent was obtained, a blood sample was taken for measuring serum ionized calcium (Nova 8; Nova Biochemical, Waltham, MA), 25(OH)vitamin D and serum immunoreactive, N-terminal specific-PTH (DiaSorin, LIAISON, PTH 1-84).

RESULTS. We found that there were 113 patients with serum PTH levels above normal range (88 males and 25 females, 10.7% of the total). Serum 25(OH)D levels were below 20 ng/ml in 69 of 113 subjects and below 30 ng/ml in 100 of 113 individuals. Forty-one of these patients volunteered to be studied again after vitamin D supplementation (50,000 UI cholecalciferol weekly for one month), for the determination of serum ionized and total calcium, phosphorus, 25(OH)vitaminD, 1-84 PTH, anti-transglutaminase antibodies, 24-hour urine calcium and creatinine clearance. In 35 of the subjects studied (including one with positive anti-transglutaminase antibodies) PTH normalized after vitamin D supplementation. In one of the remaining six patients, the increased serum PTH was due to renal hypercalciuria (24hours Ca/Cr ratio > 0.20). No other biochemical abnormalities were found in the remaining five subjects.

CONCLUSIONS. This study demonstrates that hypovitaminosis D in normal blood donors is the most frequent cause of raised serum PTH levels. Even though the study is ongoing, there is an unexpected high prevalence of increased PTH levels in the face of normocalcemia (12%), not related to identifiable causes. These subjects with PTH values above the normal range, are being followed prospectively in order to evaluate the long term natural history of this disease.

MO0017

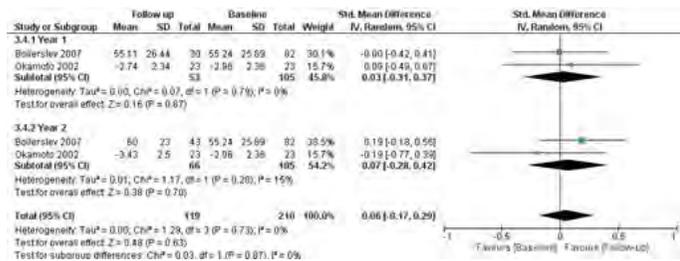

Quality of Life Changes in Patients with Asymptomatic Primary Hyperparathyroidism. Systematic Review and Meta-analysis. Navkky Singh Ospina^{*1}, Spyridoula Maraka², Ana E Espinosa De Ycaza³, Rene Rodriguez Gutierrez⁴, Sina Jasmin⁵, Michael Gionfriddo⁴, Ana Castaneda-Guarderas⁴, Alaa Al Nofal⁶, Victor Montori², Robert Wermers⁷. ¹Mayo Clinic, Rochester, MN, USA, ²Endocrinology, Mayo Clinic, USA, ³Mayo Clinic, USA, ⁴Knowledge Evaluation Research Unit, Mayo Clinic, USA, ⁵Endocrinology, Mayo Clinic, ⁶Pediatric Endocrinology, Mayo Clinic, USA, ⁷Endocrinology, Mayo Clinic, USA

Patients with primary hyperparathyroidism (PHPT) without strong clinical indications for surgery face a treatment decision between active surveillance and parathyroidectomy. The aim of this study was to identify the literature for quality of life (QOL) and neuropsychiatric symptoms (NPS) changes in patients with asymptomatic PHPT treated with active surveillance or parathyroidectomy. A literature search was performed by a medical librarian. We included randomized (RCT) and observational studies of patients with asymptomatic PHPT without strong indications for surgery managed with parathyroidectomy or active surveillance where changes in QOL or NPS were reported. Screening for eligible studies, assessment of risk of bias and data extraction was performed in duplicate by trained reviewers. The random effect model was used for statistical analysis. We standardized to the mean to combine different scales measuring the same construct. A clinically important difference is defined as 0.5 SD. The search yielded 3141 articles of which 6 studies using 17 scales for different constructs of QOL and NPS were included for qualitative assessment (3 RCTs, 3 observational studies of surgical patients). In surgical patients there was a standard mean difference (SMD) of 0.08 (95%CI: -0.26, 0.42) and 0.00 (95%CI: -0.28, 0.27) in the mental health construct at 1 and 2 years of follow up as compared to baseline. For the vitality construct in surgical patients there was a SMD of 0.03 (95%CI: -0.31, 0.37) and 0.07 (95%CI: -0.28, 0.42) at 1 and 2 years of follow up as compared to baseline. The studies had moderate risk of bias due to unclear allocation, follow up and patient selection. Three RCTs (262 patients) showed a

statistical significant change favoring those who had surgery in specific domains of the included scales but the effect size was unavailable in 2. Two observational studies following 163 surgical patients found a statistical significant improvement in non specific symptoms at 1-2 years of follow up. The available comparative evidence suggests a statistically significant improvement in subdomains of QOL/NPS scales in surgical patients with asymptomatic PHPT. However, the magnitude of this effect in surgical patients appears to be minimal. Overall, the confidence in these estimates is decreased due to imprecision and indirectness. The use of disease specific QOL tools in RCTs is needed to clarify the magnitude of potential benefits in this otherwise low risk population.

Mental Health Meta-analysis

Vitality Meta-analysis

Table 1. Summary of included studies of patients with asymptomatic PHPT without strong indications for surgical intervention.

| Author | Year | Type of study | Inclusion Criteria | Scale Used | Patients with Surgery | Patients with Observation | Last follow up (months) |

Spontaneous Remission of Primary Hyperparathyroidism - A Case Report.

Barbara Silva^{*1}, Jessica Fleischer², Zachary Lenane², Wen-Wei Fan², Donald McMahon², John Bilezikian². ¹Uni-BH, Santa Casa de Belo Horizonte & Felicio Rocho Hospital, Brazil, Brazil, ²Columbia University, USA

Natural history studies of Primary Hyperparathyroidism (PHPT) have shown that in patients who do not have parathyroid surgery the disease persists and complications can ensue. Spontaneous remissions are rare and usually related to parathyroid infarction or hemorrhage. Another possible explanation for spontaneous remission of PHPT would be the onset of an autoimmune process. We report an unusual case of a woman with unequivocal PHPT for 13 years who experienced spontaneous remission of her disease in association with the diagnosis of psoriatic arthritis.

A 42-yr-old woman was referred for evaluation of persistent hypercalcemia 2 months after unsuccessful parathyroid surgery for PHPT, in which a single, hyperplastic parathyroid gland was removed. Further evaluation confirmed persistent PHPT evidenced by hypercalcemia (12.1 mg/dL), elevated PTH level (118 pg/mL), normal calcium urinary excretion and increased bone turnover markers. During the first 11 years of follow up, she remained hypercalcemic, with serum calcium values ranging between 10.3 and 12.5 mg/dL. Serum PTH levels continued to be above normal, ranging from 63 to 125 pg/mL. Approximately 5 years following the parathyroidectomy, the patient experienced a downward trend of her serum calcium and PTH, while the phosphorus followed an upward trend. She reported no neck trauma, further neck surgery, general anesthesia, nor any episodes of hypotension. Six years later (11 years after surgery), serum calcium and PTH had become normal for the first time, which coincided, remarkably, with the development of psoriatic arthritis. Since the patient was diagnosed with an immune disease, we considered the possibility that the remission was due to the development of antibodies interfering with parathyroid gland function. However, measurements of anti calcium-sensing receptor (anti-CaSR) and the NACT leucine-rich-repeat protein 5 (NALP5) antibodies were negative. Since return to normal of the serum calcium and PTH level, the PHPT has remained in remission for 10 years without any signs of recurrent disease. During this time, the psoriatic arthritis remained active.

Spontaneous remission of PHPT is exceedingly rare. The patient's clinical course was not characteristic of parathyroid hemorrhage or infarction. The concomitant appearance of psoriatic arthritis, an immune disease, raises the possibility of an immune-mediated process accounting for spontaneous long-term remission of PHPT in this patient.

Vitamin D Deficiency and Insufficiency in Primary Hyperparathyroidism: Effects on the Trabecular Bone Score. Marcella Walker¹, Elaine Cong¹, Melissa Sum^{*1}, James Lee¹, Anna Kepley¹, Chengchen Zhang¹, Didier Hans², Shonni Silverberg¹. ¹Columbia University, USA, ²Lausanne University, Switzerland

Data regarding the skeletal effects of vitamin D (25OHD) deficiency and insufficiency in primary hyperparathyroidism (PHPT) are limited. We have shown that lower 25OHD in PHPT is associated with higher PTH levels and modestly lower 1/3 radius BMD by DXA, but no BMD differences at the lumbar spine (LS) and hip. We compared the trabecular bone score (TBS) at the LS in PHPT patients with 25OHD deficiency (<20ng/ml), insufficiency (20-29ng/ml) or sufficiency (≥30ng/ml). Participants were mostly women (n=88; 81% women; mean±SD age 62±13yrs) with mild PHPT (calcium 10.7±0.6mg/dl, PTH 86±51pg/ml). Mean 25OHD was 29±10ng/ml (3.4% <10ng/ml; 19.3% <20ng/ml, mean 14±3ng/ml; 37.5% 25OHD 20-29ng/ml, mean 25±3ng/ml; and 43.2% 25OHD≥30ng/ml, mean 38±7ng/ml). Those with lower vitamin D were younger (<20: 57±14 vs. 20-29: 59±14 vs. ≥30: 67±9yrs, p=0.006) but did not differ by sex, race/ethnicity, height, weight, PHPT duration, history of osteoporosis, fragility fracture, nephrolithiasis or meeting 2008 surgical criteria except for age <50yrs (p=0.03). Those with lower 25OHD had higher PTH (130±64 vs. 81±43 vs. 71±39pg/ml, p=0.0001) and lower PO4 (2.8±0.4 vs. 3.0±0.4 vs. 3.2±0.4mg/dl, p=0.003) levels but serum and urine calcium and 1,25-dihydroxyvitamin D did not differ. Renal function was worse in those with 25OHD ≥30 vs. <20ng/ml (77±17 vs. 92±18ml/min, p=0.04). LS T-Score was normal (-1.0±1.7) and did not differ by 25OHD level (-0.9±1.5 vs. -1.0±1.8 vs. -1.0±1.7, p=0.96). TBS (1.302±0.124) was in the partially degraded range. Neither PTH (r=-0.14, p=0.21) nor 25OHD (r=-0.12, p=0.27) levels correlated with TBS. TBS did not differ by vitamin D status before (<20ng/ml: 1.306±0.134 vs. 20-29: 1.221±0.105 vs. ≥30: 1.274±0.132, p=0.15) or after adjusting for age, weight, GFR (p=0.24). TBS did not differ in those with 25OHD <20 vs. ≥20ng/ml (1.306±0.134 vs. 1.301±0.123, p=0.87) or <30 vs. ≥30 (1.323±0.115 vs. 1.274±0.132, p=0.07) before or after adjusting for covariates (p=0.81 and 0.10). TBS results were similar in the subset of women only: partially degraded (1.293±0.121), not associated with 25OHD levels (r=-0.04, p=0.73), and no between-group differences in adjusted (p=0.55) or unadjusted (p=0.81) TBS by vitamin D status. In conclusion, TBS values were in the partially degraded range in PHPT. While 25OHD deficiency and insufficiency were associated with higher PTH levels in PHPT, vitamin D status did not affect TBS in a cohort in whom severe 25OHD deficiency was uncommon.

Primary Hyperparathyroidism: Investigating Mechanisms of Cognitive Dysfunction. Elaine Cong, Marcella D. Walker, Melissa Sum*, Ronald M. Lazar, Yunglin Gazes, Anna Kepley, Kevin Slane, Chen Cheng Zhang, Donald J. McMahon, Randolph S. Marshall, Shonni J. Silverberg. College of Physicians & Surgeons, Columbia University, USA

We previously reported cognitive dysfunction in primary hyperparathyroidism (PHPT) reversible with cure (PTX). We have also shown that the extent of PTH elevation in PHPT positively correlates with aortic/carotid vascular stiffness. We hypothesized that PTH-dependent intracerebral vascular dysfunction may impair blood flow and cognition in PHPT. Pre- and 6 mos. post-PTX, postmenopausal women with PHPT underwent cognitive testing, functional magnetic resonance imaging (fMRI) and transcranial Doppler to measure intracerebral vasomotor reactivity (VMR). Patients (n=10; age±SD 65±7yrs) had mild PHPT (calcium 10.5±0.3mg/dl, PTH 78±22pg/ml) and normal vitamin D (37±17ng/ml), renal and thyroid function. Age-, gender- and education-adjusted Z-scores for visuospatial memory, verbal memory and motor speed were slightly below average but not abnormal. VMR was worse in 8 PHPT vs. 9 controls (3.2±0.9 vs. 4.2±1.1%, p=0.02). VMR did not correlate with PTH (r=0.35, p=0.35) or calcium (r=0.46, p=0.21) levels, but higher (better) VMR tended to be positively associated with better verbal (Hopkins Verbal Learning Test total recall: r=0.67, p=0.07) and symbolic memory (r=0.64, p=0.09). On fMRI, PHPT (n=9) had reduced activation in the cerebellum during non-verbal abstraction (t(25)=4, k=29 voxels, p<0.001) vs. 21 controls. In PHPT, activation was inversely correlated with PTH but not calcium level in several areas involved in decision-making and executive function [anterior cingulate BA 25 (r=-0.97, t(7)=10, k=61), inferior frontal area (r=-0.95, t(9)=8, k=65), claustrum (r=-0.99, t(7)=8, k=62), all p<0.0001]. Post-PTX (n=5 to date), only depressive symptoms improved (23±7 vs. 9±4, p=0.02), while verbal fluency (0.0±1.2 vs. 0.5±1.4, p=0.07) and motor speed tended to improve (dominant/non-dominant hand: -0.9±1.2 vs. 0.2±1.4, p=0.07; -0.9±1.2 vs. 0.2±1.4, p=0.08). VMR (3.1±1.4 vs. 3.3±0.8, p=0.81) and fMRI task-related activation did not change. In summary, very preliminary data suggest that PHPT may be associated with lower VMR. In PHPT, brain activation in areas controlling executive function was worse in those with highest PTH levels. Post-PTX, depressive symptoms and some aspects of cognition tended to improve. Further work is needed to determine if VMR improves post-PTX. If extended and confirmed, these results could suggest that reduced intracerebral vascular reactivity may underlie cognitive dysfunction in PHPT and that elevated PTH may play a role in executive function.

MO0021

In vivo RPI by BioDent, but not OsteoProbe, Correlates with Bone Tissue-Level Mechanical Properties. Erin McNerny*¹, Jason Organ¹, Christopher Newman¹, Drew Brown¹, Joseph M. Wallace², Matthew R. Allen¹. ¹Indiana University School of Medicine, USA, ²Indiana University-Purdue University Indianapolis, USA

In vivo measures of bone material properties could significantly improve estimates of patient fracture risk. Two reference point indentation (RPI) devices, BioDent and OsteoProbe, were developed to address this issue. BioDent is a reference probe-based device that cyclically indents the bone surface to yield several measures of tissue properties (indentation depth [ID], ID increase [IDI], unloading slope, energy dissipation [ED]). OsteoProbe lacks a reference probe, using a pre-load reference force followed by a single high-force impact to test the depth of indentation. It yields a single variable, bone material strength index (BMSi), which is inversely related to indentation depth. The goal of this study was to test the hypothesis that RPI measures, obtained in vivo, would correlate with measures of whole bone mechanical properties. Skeletally mature female beagle dogs (n=48) were treated daily with oral raloxifene (RAL; 0.5 mg/kg/day), alendronate (ALN; 0.2mg/kg/day), both RAL and ALN, or saline vehicle (VEH; 1.0 mL/kg/day). After 1 year of treatment, cortical bone properties were measured in vivo at the tibia mid-diaphysis using BioDent (right tibia, 3 tests per bone) and OsteoProbe (contralateral tibia, 5 tests per bone). Ex vivo pQCT imaging and 3 point bending mechanical tests were performed on the right femur mid-diaphysis. Associations between tissue mineral density (TMD), BioDent & OsteoProbe measures, and tissue level mechanical properties calculated from 3-pt bending using beam theory to account for differences in bone size were evaluated by Pearson correlation. OsteoProbe BMSi did not correlate with TMD, mechanical properties, or any BioDent outcome. In contrast, the BioDent measures of 1st cycle ID (ID 1st), 1st cycle ED (ED 1st), 1st cycle unloading slope, total ID (TID), and total ED (Tot ED) were significantly correlated to TMD (Table 1). Excluding unloading slope, these measures, as well as 1st cycle creep ID (CID) and IDI, significantly correlated with femur toughness. Stepwise linear regression was used to test the hypothesis that combined with TMD and bone size, RPI would improve predictions of whole bone mechanical properties. The best model (adjR²=0.274, p=0.001) to predict work to fracture included cortical area (β=0.399, p=0.004) and ED 1st (β=0.394, p=0.005). These data demonstrate the ability of in vivo BioDent, but not OsteoProbe, to provide insight into bone tissue quality at a remote site.

Age and Sex Dependence of Human Vertebral Body Composite Traits Determined Using Statistical Shape and Density Modeling. Jessica Coogan¹, Travis Eliason¹, Donald Moravits¹, Arthur Nicholls¹, Ellen Quillen², Daniel Nicoletta¹, Todd Bredbenner*¹. ¹Southwest Research Institute, USA, ²Texas Biomedical Research Institute, USA

The structural integrity of bone under mechanical load is a complex function of interrelated characteristics, including macroscopic bone morphology and bone density. We hypothesize that combinations of vertebral traits are dependent on both age and sex. Using quantitative CT, we imaged 29 human L1 vertebrae (15 male 14 female, age range 25-88 years), along with a density calibration phantom, in order to

investigate composite variation in geometry and bone mineral density (BMD) distribution with sex and age. Vertebral body models describing geometry and spatial BMD distribution were created, each consisting of 115,084 variables (i.e. spatial location and density at mesh nodes located at corresponding anatomic positions for all vertebrae). Variation in 3D bone geometry and BMD distribution within the set of 29 vertebral bodies was described using statistical shape and density modeling (SSDM) [1]. The ~115,000 highly correlated variables for each model were reduced to a set of 28 uncorrelated and independent principal components (e.g. composite geometry and BMD traits) without loss of information. In addition, discrete vertebral body measures (i.e. minimum cross-sectional area, anterior height, posterior height, volumetric BMD) were determined. Two-way unbalanced ANOVAs were used to test composite trait weighting factors and discrete measurements for dependence on sex and age, where subjects were grouped into young (age < 45 years), old (> 65 years), and middle-aged (others). Three weighting factors were significantly associated with sex, one with age grouping, and 2 with age x sex interaction, while discrete measures were not significantly associated with age, sex, or age x sex interaction. Sex and age-based differences in geometry (Fig. 1) and density (Fig. 2) were observed, with a general decrease in vertebral body size and increase in BMD for females with age and converse changes for males. Age- and sex- based variations in structural bone traits are complex and were not detected with simple measures; however, variation in complex patterns of traits were identified using SSDM. Previous studies have related structural bone traits to vertebral fracture risk [2-3], supporting the notion that age and sex differences in structural bone traits contribute to vertebral fracture risk.[1] Bredbenner TL, et al. J. Bone Miner Res, 29(9):2090-2100, 2014. [2] Ruysen-Witrand A, et al. Osteoporos Int, 18:1271-1278, 2007. [3] Bruno AG, et al. J. Bone Miner Res, 29(3):562-569, 2014.

Assessment Of A Finite Element Model To Reproduce An Ex-Vivo Forward Fall Protocol Leading To Fractured And Non-Fractured Radii. Helene Follet¹, Edison Zapata^{*2}, Francois Duboeuf³, Jean-Baptiste Pialat⁴, David Mitton⁵. ¹INSERM, UMR1033 ; Universite De Lyon, France, ²Universite de Lyon, F-69622; IFSTTAR, LBMC, UMR_T9406. INSERM UMR1033, Universite de Lyon, France, ³INSERM UMR1033, Universite de Lyon, France, ⁴INSERM UMR1033, Universite de Lyon, Department of radiology, Hospital E. Herriot, Hospices Civils de Lyon, France, ⁵Universite de Lyon, F-69622 ; IFSTTAR, LBMC, UMR_T9406., France

Forward falls represent a risk of injury for the elderly, in particular those suffering from bone diseases, such as osteoporosis. Finite element models (FEM) have been proposed to improve the bone strength prediction. However, these models have considered quasi-static loadings and a loading orientation along the distal radius. The aim of this study was then to design an ex vivo protocol on radii with a non-axial loadings and a loading speed of 2m/s in average and compare to FE model. Results attempt to assess the predictive capability of finite element models (FEM).

Six distal radii from elderly donors (50 to 96 y.o.) were cut and cleaned of soft tissues. They were placed with an alignment of 15° between the frontal anatomical plane and the anterior face and then potted in a polyurethane resin on a steel cylinder, reproducing the most common forward fall¹. The load was applied using a mold, specifically done for each radius, at 2m/s (LF technologies, France). Loads, acceleration and displacement were recorded. Previously acquired cone beam CT scans (NewTom 5G, QR, Italy) were used to create the specimen-specific FEM. Dicom was segmented using an adaptive threshold in CTAn (Bruker, Belgium). Bone was meshed using an in-house software in hexahedral of 450µm element size and exported to Hypermesh (Altair Engineering, USA) in order to reproduce all experiment conditions (linear and isotropic behaviour law, Young's moduli: 10 GPa, Poisson ratio: 0.3). Simulations were performed using LS-dyna (LSTC, Usa). Fig. A.

Reaction loads from the experiment were compared with the results from the simulation. Among the 6 radii, 4 fractured and 2 did not. Experimental peak forces are in agreement with those reported in the literature². Comparison between model and experiment is shown in Fig. B. Peak forces are overestimated in a 2.2 factor. Nevertheless, there is a good correlation (R²=0.91) between predicted and experimental load.

Experimental data shown that one impact, in same loading conditions, will not systematically end in bone fracture. The high predicted load might be due to the resolution of the model, which overestimate the trabecular bone. Compromise has to be done between resolution and number of elements. Further tests are in process to refine the model (law, heterogeneity...) on 24 more oncoming samples. These models will be useful to identify factors affecting fracture during a forward fall. Ref: 1. Greenwald et al, 1998. 2. Burkhart et al, 2014.

Combining Microindentation and Monotonic Macroscopic Testing to Bridge Scales in Human Osteonal Bone. Mohammad Mirzaali, Jakob Schwiedrzik, Suwanwadee Thaiwichai, Philippe Zysset^{*}, Uwe Wolfram. Institute for Surgical Technology & Biomechanics, University of Bern, Switzerland

The growing incidence of skeletal fractures poses a significant challenge to ageing societies. Since a major part of physiological loading in the lower limbs is carried by cortical bone, it would be desirable to better understand the structure-mechanical property relationships and scale effects in this tissue. This study aims at assessing whether micro-mechanical properties measured by microindentation combined with morphological information may be used to predict macroscopic elastic and strength properties in a donor- and site-matched manner.

Specimens for microindentation and quasi-static macroscopic tests in tension, compression, and torsion were prepared from a cohort of 19 male and 20 female donors (46 to 99 years of age). All tests were performed under fully hydrated conditions. The results of the micro-mechanical tests were combined with

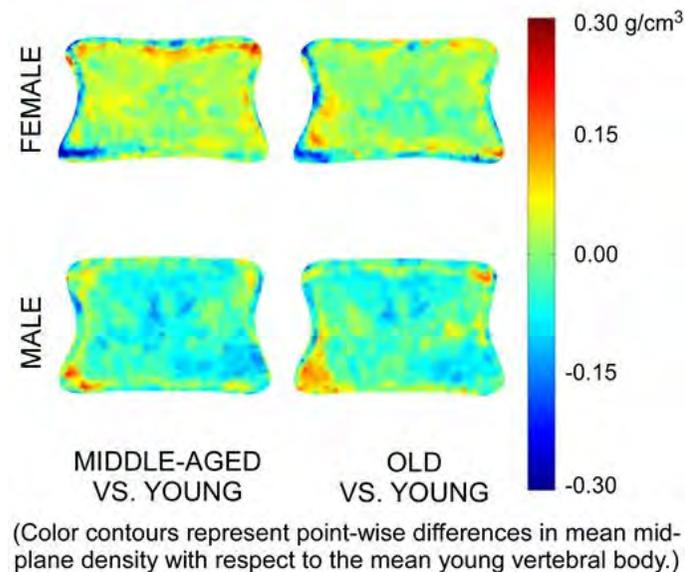

Figure 2: Variation in mid-plane vertebral body density

Disclosures: Todd Bredbenner, None.

morphological properties such as porosity and cement line density using a power law relationship to predict the macroscopic properties.

Microindentation properties were not gender dependent, remarkably constant over age, and showed an overall small variation with standard deviations of approximately 10%. Macro-mechanical stiffness and strength were significantly related to porosity for all load cases ($p < 0.05$). In cases of macroscopic yield strain and work-to-failure this was only true in torsion and compression, respectively. The correlations of macro-mechanical with micro-mechanical and morphological properties showed no significance for cement line density or variations in the microindentation results and were dominated by porosity with a moderate explanatory power of most often less than 50%.

The results confirm that gender and age have negligible effect on the tissue microindentation properties of human lamellar bone. Furthermore, our findings suggest that a microindentation experiment is not suitable to predict macroscopic mechanical properties. The presented data may help to form a better understanding of the mechanisms of ageing in bone tissue and of the length scale at which they are active. This may be used for prediction of fracture risk in the elderly in the future.

MO0025

Effects of vitamin C and teriparatide on bone mineral density, quality, and strength in vitamin C-deficient rats. Masashi Fujii¹, Naohisa Miyakoshi², Yuji Kasukawa², Koji Nozaka², Tovahito Segawa², Kentaro Ouchi², Hayato Kinoshita², Chie Sato², Yoichi Shimada². ¹Akita University, Japan, ²Akita university graduate school of medicine, Japan

Introduction

A deficiency of vitamin C (ascorbic acid, AA) has been considered to be one reason for reduced bone quality and bone strength in elderly individuals with severe osteoporosis. AA-deficient rats (Osteogenic Disorder Shionogi Rats) showed decreased bone strength in our previous study. Teriparatide (TPTD) promotes osteoblast formation and improves bone strength, particularly in terms of bone quality. However, the efficacy of TPTD on bone strength under AA-deficient conditions remains unclear. The objective of this study was thus to evaluate the efficacy of AA and TPTD administration on bone mineral density (BMD) and bone strength in AA-deficient rats.

Materials and Methods

AA-deficient rats were bred with normal-concentration AA water (2 mg/mL) until 4 months of age and with low-concentration AA water (0.5 mg/mL) thereafter until 8 weeks to develop vitamin C-deficient rats ($n = 40$). After that, rats were assigned to one of the following four groups: 1) AA-deficient (AA-) group receiving a low concentration of AA water, 2) AA-supplementation (AA+) group receiving a normal concentration of AA water, 3) AA-deficient and TPTD (30 µg/kg body weight, three times a week subcutaneous injection) administration (AA-T) group, and 4) AA-supplementation and TPTD administration (AA+T) group ($n = 10$ for each group). After 12 weeks of experiment, bilateral femora were harvested. The left femur was used for BMD measurement, and the right femur was evaluated for bone strength by a three-point bending test of the diaphysis and a condyle compression test. These examinations were also performed for Wistar rats of the same age ($n = 10$) as a control group.

Results

BMD was significantly lower in the AA- group than in other groups ($p < 0.05$). BMD in the AA-T and AA+T groups was comparable to that in controls. Parameters of bone strength indices including bone breaking force, breaking energy, and maximum load in the three-point bending test showed no significant difference among experimental groups. In the condyle compression test, maximum load was significantly higher in the AA+T group than in the AA- and AA+ groups ($p < 0.05$ each).

Discussion and Conclusion

BMD was decreased by AA deficiency. AA supplementation and TPTD administration with and without AA recovered BMD to the same level as controls. TPTD treatment with AA supplementation significantly improved bone strength at the epiphysis, but not at the diaphysis, which contained a higher proportion of cancellous bone.

Finite Element Methods on Multi-Row Detector CT Imaging to Estimate Elastic Modulus of Human Trabecular Bone. Cheng Chen*, Elena Letuchy, Ryan Amelon, Anneliese Heiner, Kathleen Janz, Trudy Burns, James Torner, Steven Levy, Punam Saha. The University of Iowa, USA

Multi-row detector computed tomographic (MD-CT) imaging generates unique bone quality information, such as volumetric bone mineral density (vBMD), isolation of trabeculae from cortical bone, and characterization of trabecular bone (TB) micro-architecture. Novel image processing algorithms and finite element methods (FEM) were applied to MD-CT images to estimate the elastic modulus (EM) of human TB.

Twenty-two cadaveric ankle specimens and a pilot sample of young (age 19) healthy participants from the Iowa Bone Development Study (IBDS) cohort (12 males and 13 females) were included in this study. MD-CT scans of the distal tibia were

acquired on a 128 slice Siemens Flash scanner at 120kV, 200mAs, pitch: 1, 0.3mm slice-thickness and 10cm scan-length. A Gammex phantom was used to transform CT Hounsfield units into BMD (mg/cc). Space-variant thresholding and hysteresis algorithms were applied to preserve TB connectivity for mesh generation, which was used in FEM to estimate EM. For the *in vivo* study, 30%, 45%, and 60% peels at 6-8% distal tibia were applied to generate ROIs. For the cadaveric study, the actual EM was determined using compressive mechanical testing and the ROIs for FEM were matched with the recorded location of the test volume.

The observed intra-class correlation coefficient of MD-CT-based EM from three-repeat scans of cadaveric specimens was 98.4%, and the estimates EM demonstrated a stronger linear association with the actual EM (correlation coefficient $r=0.95$) (Figure 1) than did vBMD ($r=0.89$). Analysis of pilot sample data suggested a higher mean EM for the TB of young males vs. females over the 45% peel ROI ($p=0.053$ two-sample t-test; effect size=0.82) (Table 1). Height differences explained most of the EM difference, as EM showed a strong positive association with height in IBDS participants, with a mean increase in EM of 292MPa for every 5cm increase in height ($p<0.001$ for height in a simple regression model) at the 45% peel. Sex was not statistically significant in models that included height.

Together with advanced image processing algorithms, FEM is applicable to MD-CT imaging for determining the EM of human TB. MD-CT-based computed EM is reproducible and strongly associated with actual bone strength. Our preliminary finding that the male-female difference in TB EM may be largely due to height differences requires confirmation in a larger sample.

This study was funded by NIH grants: R01-AR054439, R01-DE012101, and UL1-TR044206.

Genetic Variability in Fracture Healing Under Phosphate Deficiency. Amira Hussein*, Alexander Wulff¹, Heather Matheny¹, Brenna Hogue¹, Kyle Lybrand¹, Anthony DeGiacomo¹, Louis Gerstenfeld¹, Elise Morgan². ¹Orthopaedic Surgery, Boston University School of Medicine, USA, ²Mechanical Engineering, Boston University, USA

Introduction: Phosphate deficiency leads to osteomalacia in adults and affects many systemic and local physiological processes, including fracture healing. This study's goal was to determine how the genetic variability that controls the structural and biomechanical phenotypes of bone interacts with phosphate deficiency to affect fracture healing. **Methods:** Closed, stabilized fractures were generated in the femora of three strains [A/J (AJ), C57BL/6J (B6), and C3H/HeJ (C3)] of male 8- to 12-week-old mice. Phosphate deficiency (Pi) was initiated 2 days prior to fracture and was maintained for 17 days, after which a normal diet was resumed. Control groups were given a normal diet throughout. Fracture calluses were harvested at post-operative days 14, 21, 35, and 42 ($n=12$ per time-point/strain/diet). Micro-computed tomography (μ CT) was used to evaluate the structural and material properties of the calluses. Mechanical properties of the calluses were assessed by torsion testing. Outcomes were compared among strains, between diets, and among time-points using three-factor analyses of variance with Tukey *post hoc* tests. **Results:** μ CT evaluations showed that Pi calluses had lower volume fraction (BV/TV), bone mineral density (BMD) and tissue mineral density (TMD) than control calluses ($p<0.0001$) (Table 1). Yet, Pi calluses had higher strength (maximum torque), toughness (work to failure), and ductility (twist to failure), and lower rigidity, compared to control calluses ($p<0.0015$). Although neither callus strength nor toughness was dependent on the interaction between diet and strain ($p>0.174$), an effect of diet was seen in some strains at some time-points ($p<0.0068$): both toughness and strength were higher in

C3 Pi vs. C3 control calluses at day 35; and toughness was higher, and callus rigidity lower, in B6 Pi vs. B6 control calluses at day 14. Discussion: The results indicate that phosphate deficiency affects the strength and mineralization of calluses at different stages of healing depending on the strain of mice. Despite Pi-induced reductions in callus volume fraction and mineral density, callus strength and toughness were higher with Pi. These data suggest that an overall compensatory response to the early phosphate deficiency occurs during the later stages of bone formation when phosphate was replenished in the diet. This compensation was most pronounced in the C3 strain, which heals through more osteogenic versus chondrogenic mechanisms.

MO0028

Glucose-dependent insulinotropic polypeptide (GIP) is required for an optimal bone strength and quality. Benoît Gobron¹, Béatrice Bouvard¹, Satoko Kuwahara², Sheng Zhang³, Norio Harada², Burton Wice³, Nobuya Inagaki², Erick Legrand¹, Daniel Chappard¹, Guillaume Mabiliau¹. ¹GEROM-LHEA, LUNAM University, France, ²Department of Diabetes, Endocrinology & Nutrition, Graduate School of Medicine, Kyoto University, Japan, ³Department of Internal Medicine, Washington University School of Medicine, USA

After a meal ingestion, gut hormones are secreted in the blood stream and induce a response in cells expressing gut hormone receptors. A role for the glucose-dependent insulinotropic polypeptide receptor (GIPr) in controlling bone strength and quality has previously been reported. GIPr KO animals presented with higher trabecular bone mass and reduction. Nevertheless tissue mineral density and extent of collagen cross-linking were altered in trabecular and cortical bone. However, a second animal model of GIPr deletion exists in which the opposite bone phenotype has been reported. The

aims of the present study were to decipher the role of GIP in bone physiology by using an animal model of GIP deletion (GIP-GFP KI) and animals deprived in GIP-producing cells (GIP-DT). Eight GIP-GFP KI and GIP-DT mice (16-week old) were age- and sex-matched with eight wild-type (WT) littermates. Trabecular bone microarchitecture was studied by high resolution microCT in long bones. Osteoclast and osteoblast activities were assessed in undecalcified bone sections. Bone strength was investigated at the organ level by three-point bending and at the tissue level by nanoindentation. The composition of the matrix was assessed with quantitative electron backscattering imaging and Fourier transform infrared microspectroscopy. Non-parametric Mann-Whitney U-test was used to compare differences between groups. As compared with control mice, GIP-GFP KI animals exhibited significant reductions in BV/TV (-22%), trabecular number (-19%) and higher values for trabecular separation (14%). GIP-GFP KI mice had a higher bone remodelling with significant higher values for Oc.S/BS and BFR/BS. These modifications of trabecular microarchitecture were not seen in GIP-DT animals, lacking K-cell-produced gut hormone, including GIP. Furthermore, bone strength at the organ level presented with a 10% reduction in stiffness in GIP-GFP KI mice that was not mirrored in GIP-DT animals. Bone strength at the tissue level was altered in GIP-GFP KI animals with a significant drop in ultimate load. These results support a role for the GIP/GIPr pathway in controlling bone strength and quality. However, these data also suggest that GIP-DT animal have a compensatory mechanism to maintain bone quality in the absence of GIP, that will require further investigation. This might open a new therapeutical approach to prevent fragility fracture.

MO0029

HIV infection is associated with reduced bone material properties independently of bone mineral density. Robert Güerri-Fernández¹, Daniel Prieto-Alhambra², Judit Villar-García¹, Xavier Nogués³, Leonardo Mellibovsky⁴, Ana Guelar⁵, Natalia Garcia-Giral⁶, Anna March¹, Maria Rodríguez-Sanz⁷, Juan Pablo Horcajada⁵, Hernando Knobel⁵, Adolfo Díez-Pérez⁴. ¹Infectious Diseases. Hospital del Mar., Spain, ²NIHR Clinician Scientist NDORMS, University of Oxford, United Kingdom, ³Internal Medicine. Hospital del Mar, Spain, ⁴Internal Medicine. Hospital del Mar., Spain, ⁵Infectious Diseases. Hospital del Mar, Spain, ⁶URFOA. IMIM, Spain, ⁷URFOA. IMIM, Spain

Introduction: Both HIV infection and anti-retroviral therapies are associated with an increased risk of fragility fracture, partially independent of BMD changes. Bone microindentation allows to measure in vivo the mechanical properties of bone at a tissue level. Resulting measurements (BMSi = Bone Material Strength index) have been shown to correlate better than BMD with fracture risk in several studies. We aimed to study the association between treatment-naïve HIV infection and BMSi.

Methods: A group of treatment naïve HIV-infected patients were compared to HIV infection-free controls. Measurements: Bone mineral density (DXA Hologic QDR4500SL), high sensitivity CRP, 25-hydroxy-Vitamin D, bone turnover (PINP, bone-specific alkaline phosphatase, C-telopeptide), and BMSi (Osteoprobe, Active Life Sci). Characteristics of the infection were recorded in the HIV participants. Multivariable linear regression modelling was used to compare groups adjusted for age, sex, body mass index, BMD, vitamin D, and CRP levels.

Results: A total of 49 HIV patients (37 men, 75.5%) and 33 controls (21 men, 63.6%) were analyzed. HIV patients had been diagnosed for a median of 1.56 years; their mean (SD) CD4 nadir concentration was 501.6/mm³ (368.1) and viral load 230,524 copies (694,936). HIV-infected participants presented a significantly reduced BMSi compared to controls (85.034 vs 90.995, p < 0.001), which stood for multivariable adjustment (adjusted beta -5.87 [95%CI -8.63 to -3.10]; p < 0.001). Conversely, no differences were observed in BMD (at any of the studied sites) nor in bone formation or resorption markers.

Conclusions: HIV infection has direct bone toxicity independently of antiretroviral treatment, patient characteristics, and systemic inflammation markers. Bone microindentation identifies a bone material strength deterioration that occurs in the early stages of HIV infection, not detectable by either densitometry or bone turnover markers.

Impaired Bone Material Properties are associated with increased fracture risk and severity of vertebral fractures in osteoporosis. Erik Fink Eriksen^{*1}, Daysi Duarte Sosa². ¹Dept. of Clinical Endocrinology, Morbid Obesity & Preventive Medicine, Oslo University Hospital, Norway, ²Dept. of Endocrinology, Morbid Obesity & Preventive Medicine, Oslo University Hospital, Norway

Bone mass, bone architecture and bone material properties are the principal determinants of bone strength. In this study we tested how bone material properties relate to overall risk of fracture and severity of vertebral fractures in osteoporosis.

Bone material strength of the thick cortex of the anterior tibia was assessed using a bioindentation device (Osteo Probe III, ActiveLife Scientific, Santa Barbara, CA) in 40 controls and 72 patients with postmenopausal osteoporosis, (23 cases with hip fracture, 29 cases with vertebral fracture and 23 patients with non-vertebral non-hip fracture). The penetration into bone (indentation distance increase) measured by the device was standardized towards a calibration phantom made from methylmethacrylate yielding a Bone Material Strength Index (BMSi). Bone mineral density (BMD) was measured by dual x-ray absorptiometry at the hip and spine and vertebral fracture severity was determined by semi-quantitative (SQ) grading of compression fractures on lateral X-rays from the DXA-scanner. Bone turnover markers were measured using commercially available assays.

BMSi was found to be significantly lower in subjects with osteoporotic fractures than in controls (77 ± 6.1 vs 71.2 ± 6.1 $p < 0.001$) and each incremental decrease of one unit in BMSi was associated with increased risk of fracture, after adjustment for age, height and weight (OR 4.45, 95% CI 1.07, 19.21 $p = 0.04$). Moreover, a significant negative correlation was observed for BMSi on vertebral fracture severity ($r^2 = 0.14$, $p = 0.012$), which remained significant after adjusting for age and lumbar spine BMD ($r^2 = 0.19$, $p = 0.008$). Fracture cases exhibited higher PINP- and CTX-levels and lower BMD at the total hip than controls ($p = 0.03$, $p = 0.01$ and $p < 0.05$, respectively). Regression analysis revealed that BMSi did not vary with BMD, age, or markers of bone turnover.

Conclusion: Bone material strength constitutes an independent risk factor for osteoporotic fractures and also determines severity of vertebral fractures. Moreover, BMSi does not vary with age, BMD or bone turnover.

MO0031

Is it time to say goodbye to SMI? Michael Doube¹, Phil Salmon^{*2}, Ava Tivesten³. ¹Royal Veterinary College, United Kingdom, ²Bruker-microCT, Belgium, ³Sahlgrenska Institute

Osteoporotic deterioration of trabecular bone involves a transition from plate-like to rod-like architecture. The structure model index (SMI) measures convex curvature and has long been used to quantify this transition. But it has a significant shortcoming: it is confounded by porosity. Both porosity and high percent volume result in extensive concave curvature, whose existence is ignored in the standard narrative of the shape-dependence of SMI. Traditionally SMI ranges from 0 (plate) to 3 (rod); however in real bone samples negative SMI routinely arises from high trabecular BV/TV or from porosity. To improve upon SMI two alternatives are presented.

The first is the Ellipsoid Factor (EF), a development of the 3D local thickness algorithm, but with fitted ellipsoids in place of spheres [1]. The ellipsoid has freedom to assume a range of shapes from oblate (flat disc shaped, $EF = -1$) to prolate (long javelin shaped, $EF = 1$). EF ranges from -1 (ideal plate) to +1 (ideal rod). The EF algorithm calculates both a mean value of EF and a 3D spatial map of local EF values.

The second alternative to SMI is a simpler parameter; the unplate index (uPi) which is the ratio of the trabecular direct thickness measured in 3D by sphere-fitting, $Th(d)$, to that calculated from the plate model ($2BV/BS$). Thus $uPi = Th(d) \times BS/2BV$. For an ideal plate $uPi = 1$ and with departure from plate shape the value increases above 1.

MicroCT morphometric data of rat femoral trabecular bone from an OVX study into efficacy of sex steroids [2] is reanalysed to compare values of SMI, EF and uPi. This study is a case where high BV/TV from anabolic drug treatment resulted in negative SMI. The unplate index uPi followed both trabecular SMI and BV/TV in showing weaker than sham amelioration of OVX osteopenia from administered testosterone (DHT) and stronger than sham architecture in both estradiol (E2) and E2 + DHT treatment groups, with the strongest response in the latter, combined treatment. The EF results however depart from this pattern in that, while E2 gives a stronger response than DHT, the E2 + DHT group gives the weakest, not strongest, reversal of OVX changes. Both EF and uPi are free of the problem of out-of-range values, unlike SMI. Also unlike SMI, both uPi and especially EF have nonlinear regression with BV/TV indicating that they bring new information beyond BV/TV.

Pore Network Architecture Determines Cortical Bone Elasticity During Growth and Aging. Yohann Bala^{*1}, Emmanuelle Lefèvre², Jean-Paul Roux¹, Cécile Baron², Philippe Lasaygues³, Martine Pithieux², Valérie Kaftandjian⁴, Hélène Follet⁵. ¹INSERM U1033, Université de Lyon, France, ²Aix-Marseille Université, CNRS, ISM UMR 7287, 13288 Marseille Cedex 09, France / APHM, Hôpital Sainte Marguerite, IML, Marseille Cedex 09, France, France, ³Laboratory of Mechanics & Acoustics, UPR CNRS 7051, Aix-Marseille University, Centrale Marseille, 13009 Marseille, France, France, ⁴Laboratoire Vibrations Acoustique, INSA Lyon, Campus LyonTech la Doua, 69621 Villeurbanne Cedex, France, France, ⁵INSERM UMR 1033, Université de Lyon, France

Cortical porosity is a major determinant of bone strength. Haversian and Volkmann's canals are 'seen' as pores in 2D cross-section but fashion a dynamic network of interconnected channels in 3D, a quantifiable footprint of intracortical remodeling. Given the changes in bone remodeling across life, we hypothesized that the 3D architecture of the cortical pore network is age-dependent and influences its stiffness. Cubes of cortical bone of 2 mm side-length harvested in the distal 1/3 of the fibula in 13 growing children (9M, 4F, mean age \pm SD: 12.4 yrs) and 16 adults (7M, 9F, 74.12 yrs) were imaged using desktop micro-CT (8 μ m isotropic voxel size). Pores were segmented as a solid to assess pore volume fraction (Po.V/TV, %), number (Po.N, 1/mm), diameter (Po.Dm, μ m), separation (Po.Sp, μ m) and connectivity ConnD, 1/mm³). Compression (C33) and shear (C66) elastic coefficients were derived by assessing waves velocity using ultrasonic measurements. Spearman correlation coefficients (r) are reported when statistical significance reached ($p < 0.05$). Pore volume fraction (Po.V/TV) did not differ between growing children and adults groups but originated from different architectural pattern (Figure). Relative to children, adults had 46% higher Po.N, 17% lower Po.Sp, 250% higher ConnD, 14% and 13% higher compressive (C33) and shear (C66) stiffness, respectively (All $p < 0.02$). In growing children, age was associated with a decrease in Po.V/TV ($r^2 = -0.6$) due to decreasing Po.N ($r^2 = -0.5$), Po.Dm ($r^2 = -0.4$) and increasing Po.Sp ($r^2 = 0.6$). C33 and C66 were inversely correlated with Po.V/TV, Po.N and Po.Dm (r ranging from -0.56 to -0.82), none of the correlations remained significant after adjustment for Po.V/TV contribution. Among adults, age was associated with higher Po.V/TV ($r^2 = 0.7$) originating from an increase in Po.N ($r^2 = 0.8$), Po.Dm ($r^2 = 0.5$) and a decrease in Po.Sp ($r^2 = -0.8$). C33 was inversely correlated with Po.V/TV ($r^2 = -0.6$), Po.N ($r^2 = -0.6$) and positively with Po.Sp ($r^2 = 0.7$). Po.Sp remained correlated with C33 after accounting for Po.V/TV contribution ($r^2 = 0.6$). No correlation was found between C66, Po.V/TV or pore network architecture. We infer that changes in intracortical remodeling across life alter the distribution, size and connectedness of the channels forming cortical porosity. These alterations in pore network architecture participate in compressive stiffness impairments with aging, independently of the age-related increase in porosity.

Precision Assessment of Biomechanical Testing of the Distal Radius in Cynomolgus Monkeys. Gabrielle Boyd, Aurore Varela^{*}, Susan Y. Smith. Charles River Laboratories, Canada

Biomechanical strength testing of bones, considered the ultimate test of bone quality, is a key end-point in the safety testing and efficacy evaluation of test compounds in nonclinical studies. In humans, distal radius fractures are an early and sensitive marker of skeletal fragility and represent a high risk for subsequent spine or hip fracture. The purpose of this study was to assess the adequate procedures to obtain appropriate precision for biomechanical testing of the distal radius in Cynomolgus monkeys.

Twenty radii were collected from female Cynomolgus monkeys aged 5 to 9 years old. A disc with plano-parallel ends was prepared from the distal metaphysis region, 6 mm distal from the styloid process. Densitometry and morphology parameters were measured by HR-pQCT (Xtreme-CT II, Scanco Medical) for the prepared specimens, and height was measured by caliper (5.60 \pm 0.05 mm). All discs underwent axial compression using a MTS MiniBionix Testing System (model 358.02C). The load was applied on the distal surface at a rate of 20 mm/min. Load and displacement data were collected using TestSuite with TWE software version 1.1, along with derived biomechanical parameters.

Results for the compression test were: peak load 1267-2517 N, CV 17%; stiffness 9451-19693 N/mm, CV 25%; yield load 1177-2410 N, CV 18%; area under the curve at peak load (AUC) 243-584 N-mm, CV 22%. Results for the respective intrinsic parameters normalized for specimen size were: apparent strength 30-58 MPa, CV 17%; modulus 856-2276 MPa, CV 24%; yield stress 24-54 MPa, CV 17%; toughness 0.9-2.2 MPa, CV 30%.

It was noted that peak load, yield load, apparent strength and yield stress were the least variable. Linear regression analysis showed a positive relationship between HR-pQCT area BMC and peak load: $r=0.7413$. With respect to precision, these results were similar to tests performed for vertebral body compression, confirming that the current procedures used for specimen preparation and compression testing of the distal radius were adequate. Compression testing of the distal radius in addition to established procedures to assess strength at the spine and proximal femur (hip) will be important to provide a comprehensive assessment of the effects of drug treatment on biomechanical strength in nonclinical studies.

QCT Intra- and Inter-Scanner Precision In Estimation Of Proximal Femur Strength. SERENA BONARETTI¹, JULIO CARBALLIDO-GAMIO², JOYCE KEYAK³, ISRA SAEED⁴, LIFENG YU⁵, MICHAEL BRUESEWITZ⁵, ANDREW J. BURGHARDT², SUNDEEP KHOSLA⁶, THOMAS F. LANG². ¹University of California, San Francisco, USA, ²Musculoskeletal Quantitative Imaging Research Group, Department of Radiology & Biomedical Imaging, University of California, San Francisco, CA, USA, ³University of California, Irvine, Irvine, CA, USA, ⁴Musculoskeletal Quantitative Imaging Research Group, Department of Radiology & Biomedical Imaging, University of California, San Francisco, CA, USA, ⁵Division of Medical Physics, Department of Radiology, College of Medicine, Mayo Clinic, Rochester, MN, USA, ⁶Division of Endocrinology, Metabolism & Nutrition, Department of Internal Medicine, College of Medicine, Mayo Clinic, Rochester, MN, USA

Quantitative Computed Tomography (QCT) is increasingly used to assess proximal femur strength in epidemiologic and drug studies using finite element analysis (FEA). Bone material properties are derived from image intensities, which strongly depend on QCT scanners. Inter-scanner differences are critical in multicenter studies where multiple scanners are used, and in longitudinal studies where scanner upgrades or substitutions frequently occur. Inter-scanner corrections can be applied to reduce inter-scanner variability to intra-scanner precision. However, standardized scanner cross-calibration procedures are still an open challenge. The aim of this study was to compare single scanner precision to inter-scanner reproducibility for FEA calculations of proximal femur strength.

We scanned proximal femurs of 60 subjects at UCSF and 60 subjects at Mayo Clinic using QCT. At each site, we scanned 30 subjects on the same scanner for intra-scanner precision measurements (scan/rescan with subject repositioning), and 30 subjects on two different scanners for inter-scanner precision measurements. We processed images automatically, using a novel pipeline constituted of segmentation¹, image calibration and creation of FE mesh with QCT-based mechanical properties and boundary conditions. We computed FEA for stance and posterolateral fall loading conditions, both for intra-scanner and inter-scanner precision measurements.

Intra-scanner precision was in the range 2.26-4.41% for stance and fall configurations (Table1). Although the mean values for the subject on the different scanners were not significantly different, inter-scanner variability was more than two-fold greater than intra-scanner precision error.

In this study we found that inter-scanner precision errors of bone strength for stance and fall conditions were considerably higher than intra-scanner precision errors. We are currently working on reducing inter-scanner precision errors to intra-scanner precision errors using scanner cross-calibration corrections. We will calculate corrections using a novel anthropomorphic hip phantom, which contains a calibration hip to calculate inter-scanner corrections, and a test hip to test the corrections². Corrections will be applied to bone mineral density, from which mechanical properties derive, and will take into account body size.

MO0035

Significant Alterations in Gene Expression Within the Wnt Pathway Contribute to the Natural Variation in Bone Mechanical Function. Stephen Schlecht^{1*}, Lauren Smith¹, Erin Bigelow¹, Yueqin Yang², Amber Cathey¹, Bonnie Nolan¹, Eugene Manley¹, Melissa Ramcharan¹, Maureen Devlin³, Joseph Nadeau⁴, Karl Jepsen¹. ¹University of Michigan, USA, ²Tsinghua University, China, ³Department of Anthropology, USA, ⁴Pacific Northwest Research Institute, USA

Targeted perturbations within the Wnt pathway identified genes that alter bone strength and thus contribute to mechanical homeostasis. However, it remains unclear how genes and their interactions within the Wnt pathway contribute to normal bone mechanical function. We tested the hypothesis that two inbred mouse strains (*A/J*, C57BL/6J (B6)) that achieve similar whole bone mechanical function, albeit via different morphological and compositional traits (Fig.1), will show significant differences in gene expression. *A/J* and B6 mice have slender (narrow) and robust (wide) femora, respectively, similar to the natural variation seen in humans.

cDNA from femoral diaphyses of 4 week old male B6 (n=18) and *A/J* (n=18) mice was analyzed using a TaqManTM gene array of 87 osteogenic genes. Several genes were differentially expressed (> 2-fold) between the two strains, including *SOST* and several *BMPs*. We then examined the Wnt pathway using a TaqManTM gene array of 46 involved genes, testing for differential gene expression between male *A/J* and B6 femurs at critical ages in long bone growth (n=18/strain/age). The array showed that 25%, 17%, 61%, 69%, and 78% of the genes were significantly differentially expressed at 2, 4, 6, 8, and 12 weeks of age, respectively. Importantly, *SOST* was upregulated 1.7-7.6 fold in *A/J* across all ages, with *SOSTDC1*, *DKK1*, and *DKK2* also upregulated in *A/J* for all but one age. *A/J* femurs had significantly lower total cross-sectional area (29-40%) and cortical area (10-19%) than B6 at most ages (Fig 1), suggesting the increased *SOST* expression may contribute to these morphological differences. Finally, femora from *A/J* females increased in cortical area with exercise compared to controls (GLM ANOVA; p=0.04), whereas B6 femora became more slender with exercise (p=0.0004), confirming a differential response to increased loading.

The differential gene expression provided evidence that the Wnt pathway, in particular *SOST*, is involved in bone homeostasis, as expected. However, we showed that the relative expression of many genes in the Wnt pathway differ significantly between two normal inbred mouse strains that achieve similar bone strength but in different ways. Further work testing for differences in gene networks using RNAseq will provide context to how the Wnt pathway is being differentially regulated in these strains. Additional studies will test if this model is clinically meaningful by testing for a differential response to *SOST* inhibition.

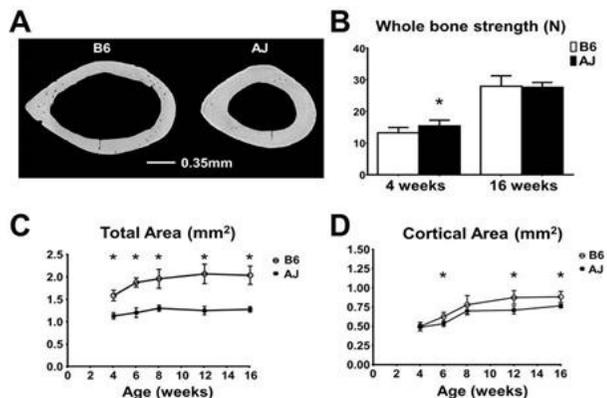

Figure 1. Phenotypic differences between B6 (wide) and AJ (narrow). A) Typical mid-diaphyseal cross sections of both strains at 16 weeks of age, nanoCT images at 1.5µm voxel size. B) Whole bone strength derived from 4-point bending of both strains at 4 and 16 weeks of age. Morphological traits C) total cross sectional area and D) cortical area for B6 and AJ at 4, 8, 12 and 16 weeks of age, measurements derived from nanoCT images at 1µm voxel size. AJ has significantly lower total cross sectional area throughout the time sequence and tends to also have lower cortical area after 4 weeks of age. * signifies $p < 0.01$.

MO0036

The Effect of Age on Cortical Bone Crack Initiation and Crack Growth Toughness. Travis Eliason¹, Todd Bredbenner¹, Lorena Havill², Daniel Nicoletta¹. ¹Southwest Research Institute, USA, ²Texas Biomedical Research Institute, USA

Humans experience an age-related increase in the risk of skeletal fractures due to changes in a variety of bone properties. Of particularly high interest is the change in the fracture toughness of bone and its resistance to crack initiation and propagation. In order to compare the fracture toughness of cortical bone, fracture toughness arch-shaped tension specimens (ASTM E399) were machined from the femoral shaft of 10 young (< 15 years) and 10 old (>22 years) female baboons. Specimen geometries were chosen for each animal to minimize the amount of machining needed to match the prescribed ASTM standard geometry. Specimens were loaded in tension under a Keyence digital optical microscope using a custom microscopy test frame to directly measure force vs crack length. The stress intensity factor K was calculated from the geometry, force, and crack length measures according to the ASTM standard and used to approximate the K-resistance (K vs. change in crack length) curves for each animal. Crack initiation toughness and the R curve slope were determined from the least squares linear regression of K given change in crack length. One way analysis of variance was used to compare crack initiation toughness and slope between old and young animals. Both crack initiation toughness and R curve slope were significantly different between the old and young animals (p-values of .048 and .0396 respectively). Older animals had both lower crack initiation toughness (4504 vs .5892 MPa (m)^{1/2}) and a lower R curve slope (2.216 vs 3.218 MPa(m)^{1/2}/mm). These results show that the femoral cortical bone has experience fundamental material changes during the aging process which results in a lower resistance to fracture. In ongoing work we are characterizing these bones with a comprehensive suite of bone traits to investigate the combinations of traits which lead to strong vs weak bones along with the associated age and sex effects.

Tumor necrosis factor negative regulation on the bone mineral density and trabecular bone architecture texture in chickens. Lixian Liu¹, Hua Rong¹, Qihua Li¹, Dahai Gu¹, Zhiqiang Xu¹, Tengfei Dou¹, Ying Huang¹, Limei Huang¹, Hongyong Zhang², Marinus F.W.te Pas³, Changrong Ge¹, Junjing Jia⁴. ¹Yunnan Provincial Key Laboratory of Animal Nutrition & Feed Technology, Yunnan Agricultural University, China, ²Department of Medicine, University of California at Davis Medical Center Sacramento, USA, ³ Animal Breeding & Genetics Centre, Wageningen UR Livestock Science, Wageningen, Netherlands, ⁴Faculty of Animal Science & Technology, Yunnan Agricultural University, Peoples republic of china

The bone mineral density (BMD) and strength are most important economical traits for poultry production. It has been caused huge economic losses in poultry industry due to bone defects, osteoporosis, rickets and other bone diseases. Tumor necrosis factor- α (TNF- α) is a key cytokine regulator of bone and mediates inflammatory bone loss. In our previous studies, we found that slow growing small chicken with 1.2 kg of adult body weight (Daweishan mini chicken) showed higher bone strength and association with lower expression of TNF- α mRNA in tibia bone,

compare to slow growing large chicken with 2.5 kg of adult body weight (Wuding chicken) and fast growing large avian broilers. TNF- α may plays important role effect on the BMD and trabecular bone architecture in chicken. The objective of this study was to investigate the effect of expression of TNF- α mRNA on the BMD and trabecular bone architecture. A total of 180 1-day-old chicks from Daweishan mini chickens, Wuding chicken and avian broiler were fed in an environmentally controlled room. All chickens from 1-21 days were fed a starter diet, older chickens received a full diet. The chickens had free access to feed and water. Twenty chickens from each breed were scarified at 4, 8 and 12 weeks and samples from cartilage and distal tibia were taken to detect the expression of TNF- α mRNA. The femur and tibia in each time point were used to scan mineral density and trabecular bone microarchitecture by using MicroCT, and then to determine the mechanical properties via by 3-point bending test.

Results: Daweishan mini chickens showed the highest femur and tibia bone strength ($P < 0.01$); BMD, BV/TV, trabecular thickness (Tb Th) and number (Tb N) ($P < 0.05$) while converse case were observed in broilers that showed the lowest these parameters and with the highest trabecular space (Tb Sp) among the thress breed in all time points. It is interesting to find that broilers showed the highest expression of TNF- α mRNA in cartilage and distal tibia in all time points while converse case were observed in mini chickens ($P < 0.05$).

In conclusion, TNF- α gene expression is negative association with femur and tibia bone strength, BMD and trabecular score in chickens. Validation of CT-based Assessment of Bone Mineralization and Heterogeneity. Maleeha Mashiatulla*, Ryan D. Ross, D. Rick Sumner, Rush Medical University, USA

A number of studies indicate the importance of bone quality for bone strength. Bone quality covers a wide range of parameters, including matrix mineralization and geometry. Micro-computed tomography (μ CT) has been extensively used to quantify bone geometry, but recently tissue mineral density (TMD) has been reported, which has been validated with ash density. TMD has not been validated against backscatter scanning electron microscopy (bSEM), which has the advantage of anatomic specificity. The aim of the present study was to validate μ CT-based TMD assessment against bSEM and to explore if mineralization heterogeneity can also be evaluated by μ CT, analogous to the bone mineral density distribution (BMDD) assessed in bSEM.

Phantoms between 0-1860mgHA/cm³ were used for calibration and to select scanner settings. One set of phantoms was prepared for bSEM and a second set was used for μ CT imaging. Results with μ CT (70kVp, 200 μ A, 2 μ m voxel size and 1500ms integration time; Scanco μ CT50) were strongly correlated with bSEM-derived mineralization levels ($R^2=0.99$, $p < 0.001$). A cohort of animal samples ($n=16$) were obtained from several species and assessed with both μ CT and bSEM. The mean TMD from μ CT was strongly correlated with the mean effective atomic number obtained with bSEM (Fig.1, $R^2=0.81$; $p < 0.001$).

To determine if μ CT can also be used to measure BMDD, TMD frequency distributions were analyzed to measure the full width at half maximum (FWHM-mineralization heterogeneity) and the lower 5% and upper 5% cutoffs for the frequency distribution. Significant correlations were found for the upper 5% cutoff ($R^2=0.57$; $p < 0.001$) and the lower 5% cutoff ($R^2=0.34$, $p=0.01$). However, no correlation was found for FWHM ($R^2=0.01$; $p=0.66$). Since porosity is a potential confounding factor, pore number, diameter and area fraction were determined using bSEM sample images. The μ CT FWHM measurements were weakly correlated with mean pore diameter ($R^2=0.07$, $p=0.039$), %pore area ($R^2=0.25$, $p=0.032$) and total number of pores ($R^2=0.29$, $p=0.031$). None of the pore characteristics were correlated with bSEM-based FWHM.

In this study, we have shown that μ CT can be utilized to accurately measure mean mineralization of bone with anatomic specificity. Although some of the BMDD characteristics can be measured with μ CT, it is likely that porosity may be a confounding variable. Further investigation is needed to determine if mineralization heterogeneity can be accurately assessed by μ CT.

Correlation of mean mineralization of different animal species measured by bSEM and μ CT, $R^2=0.81$

Hindlimb Suspension Plus Immobilization Exaggerates Sarcopenia but not Osteopenia. Toni Speacht^{*1}, Andrew Krause¹, Jennifer Steiner², Charles Lang³, Henry Donahue⁴. ¹Division of Musculoskeletal Sciences, Department of Orthopaedics & Rehabilitation, Penn State College of Medicine, USA, ²Department of Cellular & Molecular Physiology, Penn State College of Medicine, USA, ³Department of Cellular & Molecular Physiology, Department of Surgery, Penn State College of Medicine, USA, ⁴Division of Musculoskeletal Sciences, Department of Orthopaedics & Rehabilitation, Department of Cellular & Molecular Physiology, Penn State College of Medicine, USA

Astronauts in space experience a unique environment that causes both bone and muscle loss. However the interaction between these two tissues and how osteopenia and sarcopenia affect each other is unclear. We used a hindlimb suspension (HLS) model to study the effects of microgravity experienced by astronauts during space travel. This model is also appropriate to study the effects of age-related muscle and bone loss, including osteoporosis, as the mechanisms of loss are similar. To explore the relationship between bone and muscle, we examined the hypothesis that exaggerating unloading-induced muscle loss via HLS + casting, will also exaggerate unloading-induced bone loss.

Twenty C57Bl/6J mice (5m, male) were exposed to HLS with one limb unrestrained (HLS) and one limb casted (HLS+Cast), or maintained as ground controls (GC) for 2 weeks (2 groups, n=10/group). Mice were subjected to baseline and endpoint microCT scans to assess bone micro-architectural changes. Quadriceps and gastrocnemius muscles were excised, weighed, and assessed for protein synthesis and protein degradation.

Gastrocnemius and quadriceps weight was decreased 10% in HLS limbs and 20% in HLS+Cast mice compared to GC ($p<0.05$). The rate of in vivo protein synthesis was decreased in both HLS and HLS+Cast groups compared to GC ($p<0.05$), however, HLS+Cast limbs had a 15% increase in protein synthesis compared to the HLS limbs ($p<0.05$). Measurements of mTOR signaling (S6K1 and 4E-BP1 phosphorylation) correlated with our in vivo protein synthesis measurements. We also evaluated markers for protein degradation. There was no difference in ubiquitin-E3 ligases (Atrogin-1 and MuRF1) mRNA between any groups. There was, however, an increase in autophagy associated proteins LC3-II/I, Atg7, and Atg5-12 in the HLS+Cast limb compared to both HLS and GC ($p<0.05$). Bone volume/total volume (BV/TV) decreased significantly in HLS and HLS+Cast limbs compared to GC mice ($p<0.01$), however, unlike muscle, there was no difference in HLS and HLS+Cast limbs, suggesting a disconnect between bone and muscle loss.

Our data suggest that casting exacerbates the muscle loss attributed to unloading and the mechanism of this response includes activation of the autophagy degradation pathway. Surprisingly, casting did not cause an exacerbation of bone loss, suggesting that muscle and bone loss, in response to unloading, are uncoupled. Thus, countermeasures to prevent muscle loss will not necessarily affect bone loss.

Effect of HLS and HLS+Casting for 2 weeks on gastrocnemius mass (A) and tibia trabecular BV/TV (B)

Pre-Treatment with Bisphosphonates Mitigates Bone Loss at the Tibia Metaphysis and Femoral Neck During Subsequent Hindlimb Unloading and Recovery. Jessica Brezicha^{*1}, Scott Lenfest², Jennifer Kosniowski², Coleman Leach¹, Jeremy Black¹, Susan Bloomfield¹, Matthew Allen³, Harry Hogan¹. ¹Texas A&M University, USA, ²Texas A&M, USA, ³Indiana University School of Medicine, USA

Disuse during long-duration space flight is a potent down-regulator of bone mass and density. We have used the rat hindlimb unloading (HU) model previously to

demonstrate that bisphosphonates (BPs) given during HU can mitigate negative effects of simulated microgravity. In this study, we compared two BPs, alendronate (ALN) and risedronate (RIS), given prior to HU on bone properties during HU and a recovery period. Since ALN has a higher binding affinity than RIS, we hypothesized that ALN would protect bone more than RIS.

Adult Sprague-Dawley male rats (6 mo.) were assigned by initial body weight and cancellous vBMD to 1 of 4 groups: AC (aging control), HU, ALN+HU, and RIS+HU. ALN (2.4 μ g/kg) and RIS (1.2 μ g/kg) were administered 3x/wk for a 28d pre-treatment period prior to HU. After 28d of HU, animals returned to normal weight bearing for 56d of recovery. *In vivo* peripheral quantitative computed tomography (pQCT) scans were made of the proximal tibia metaphysis (PTM) at baseline (BL) and every 28d. Femurs were collected from a subset of animals at the end of HU and from the remaining animals at the end of recovery. *Ex vivo* pQCT scans were made of the femoral neck (FN), and then the FN was mechanical tested to failure.

Disuse caused significant total BMC loss (-9%) at the PTM vs. AC after 28d HU, and this was prevented by pre-treatment with either RIS or ALN. PTM cancellous BMC was higher vs. AC (+38% for ALN, $p<0.05$; and +22% RIS, n.s.), and cancellous vBMD was significantly higher for both BPs (+30% for ALN, +25% for RIS). After the full 56d recovery, results were similar, with cancellous BMC significantly higher for both BPs (+58% for ALN, +37% for RIS) vs. AC and cancellous vBMD also higher for both (+39% for ALN, +32% for RIS). At the FN, both BPs were protective after HU, with cancellous vBMD higher than HU (+6% for ALN, +12% for RIS) and HU lower than AC (-12%). There were no differences after 56d recovery. FN fracture force was higher for ALN (+28%) and RIS (+32%) vs. HU at 28d, with no differences for either BP vs. AC.

In conclusion, beneficial effects of BP pre-treatment not only mitigated losses during a period of disuse but also enhanced cancellous bone properties during recovery at the PTM. Protective effects at the FN were less dramatic (lower %) for densitometric variables but similar in magnitude for mechanical properties. Contrary to our hypothesis, there were no major differences between ALN and RIS effects.

Age Matters: Correlating Age with Spectroscopic Markers of Fragility Risk. Adele Boskey^{*1}, Lyudmila Spevak¹, Elizabeth Boskey², Robert Recker³. ¹Hospital for Special Surgery, USA, ²Boston University, USA, ³Creighton University, USA

Bone mineral density (BMD) is routinely used to predict fragility fracture risk. However women with equivalent BMDs may show a different fracture incidence due to differences in "bone quality". Bone quality refers to architecture, morphology, extent of mineralization, mineral crystal properties and collagen structure. All but architecture and morphology can be determined by Fourier transform infrared spectroscopic imaging (FTIRI). In a previously published random population of otherwise healthy women with and without fractures (Gourion-Arsiquaud et al, 2009), increased collagen maturity and crystal size in both cortical and cancellous bone within iliac crest bone biopsies were associated with risk of fragility fracture. In a larger population of iliac crest bone biopsies from women with and without fragility fractures, paired by age and BMD (Boskey et al, 2015), collagen maturity was no longer predictive, implying that this variable might be a biological mechanism or marker for patient age related fracture risk. Knowing that bone matrix composition varies with age (Cleland & Vasishth, 2015) and that risk of fragility fracture also increases with age (Ensrud, 2013), we queried whether enzymatic cross-links measured by FTIRI in these earlier reports was age dependent. Linear-regression (Prism 3.03) was used to determine whether collagen maturity and other FTIRI variables were correlated with age at the time of biopsy, analyzing cortical and cancellous variables separately, in those patients from the first study for which age was known (n=31), all patients from the second study (n=120) and the combined studies (n=151). There was a significant positive correlation (Figure 1) between cancellous collagen maturity and age ($r^2=0.88$) in all data sets, and between crystallinity and age in the fracture group alone ($r^2=0.66$). This suggests that some of the fracture risk associated with aging may be related to age-related changes in crystallinity, but that collagen maturity is likely a marker for age-related changes in bone rather than directly associated with excess fracture risk.

Global Phosphorylation of Bone Matrix and Bone Fragility. Grazyna Sroga*, Deepak Vashishth, Rensselaer Polytechnic Institute, USA

It has been proposed that posttranslational modifications (PTMs) of bone matrix proteins play a significant role in controlling biomineralization [1]. Despite years of studies, the precise roles of different matrix phosphoproteins in the context of their levels of phosphorylation remain elusive.

Mechanically tested specimens (18) from male and female cadavers (age range 19 to 97) cadavers were used to isolate bone matrix proteins using methods published previously [2]. Detection of protein phosphorylation was based on the addition of the pIMAGO reagent (Tymora Analytical, West Lafayette, IN). The pIMAGO is the water-soluble nanopolymer that attaches only to phosphoproteins. This nanopolymer contains biotin groups that allow enzyme-linked spectrophotometric detection using a microtiter plate reader. The normalized values of triplicate assays were then averaged and tested for correlation with fracture toughness of bone using crack propagation test [2].

The level of global protein phosphorylation in human posterior cortex bone was inversely related to the age ($p < 0.001$, $R^2 = 0.46$) and was on average about 1.5-fold lower in the tenth than the third decade of human life. Positive and highly correlated relationship between phosphorylation of bone matrix measured “in bulk” and propagation toughness of bone was observed ($R^2 = 0.26$, $p < 0.03$).

To our knowledge, this is the first study on the relationship between the global bone matrix phosphorylation levels, age and bone quality. Further studies should be conducted to investigate the role of phosphorylation in bone fracture.

MO0043

Hip Fracture Risk during Simulated Falls: Influence of Pelvis Impact Angle and Hip Muscle Forces. Woochol Joseph Choi*¹, Stephen Robinovitch², ¹Chapman University, USA, ²Simon Fraser University, Canada

Over 90% of hip fractures in older adults are caused by falls (Grisso et al., 1991). Risk for hip fracture depends on bone strength, and on the impact force and stress applied to the proximal femur during the fall (Bouxsein et al., 2007). In the current study, we used a mechanical model to examine how peak stresses at the femoral neck during simulated falls are affected by (1) the angle of the pelvis at impact, and (2) the forces in the muscles spanning the hip. We also examined how pelvis impact angle influences the protective benefit of wearable hip protectors. Using the SFU hip impact simulator (Choi et al., 2015), we measured 3D forces at the femoral neck under various levels of gluteus maximus and medius muscle forces, and pelvis impact angles. Hip abductor muscle forces were set to either 300 or 700 N. Seven impact configurations of the pelvis were examined, ranging in 5 deg increments between -15 degrees and +15 degrees (Figure 1). Measures were conducted with no hip protector, and two commercially available protectors (HipSaver and SafeHip). Outcome variables (Figure 2) included peak values at the femoral neck of: (a) axial

force, (b) shear force, (c) bending moment, (d) shear stress, (e) compressive stress and (f) tensile stress, and (g) percent attenuation in peak compressive stress provided by hip protectors. ANOVA was used to test whether each outcome variables associated with our testing conditions at $\alpha = 0.05$. All of our outcome variables were associated with pelvis impact angle ($p < 0.0005$), hip abductor muscle force ($p < 0.018$) (Table 1), and padding device ($p < 0.0005$). On average, peak compressive and tensile stresses decreased 27% and 68%, respectively, when the pelvis impact angle changed from 15° posterior to 15° anterior, and were 8% and 73% lower, respectively, in the 700 N than 300 N muscle force condition when the pelvis impact angle was zero. Furthermore, the force attenuation provided by hip protectors peaked between zero and 10° anterior, and declined rapidly for posterior impacts (Figure 3). Our results indicate that activation of the hip abductors is protective (caused a reduction in bending moment, and peak compressive and tensile stress) at zero degree and anterior impact angles, and dangerous (caused an increase in bending moment and peak stresses) for posterior impact angles (Figure 4). Furthermore, the protective benefit of common hip padding devices depends strongly on pelvis impact configuration during falls.

Optimizing Pulsed Electromagnetic Field (PEMF) Signals to Reduce Bone Loss in the Ovariectomized (OVX) Rat. Caroline Androjina^{*1}, Erik I. Waldorff², Nianli Zhang², James T. Ryaby², Maciej Z. Zborowski³, Ronald J. Midura³. ¹Lerner Research Institute/Cleveland Clinic, USA, ²Orthofix Inc., USA, ³Cleveland Clinic, USA

PEMF treatments have been shown to exhibit anabolic effects on bone tissue specifically by enhancing the metabolic activities of osteoblastic cells. However the efficacy to significantly block bone loss has been shown to be variable and it is unclear what parameters may result in an optimal PEMF dosage regimen for osteoporosis treatment. This study focused on signal slew rate (SR) variations of a commercially available FDA approved PEMF waveform (PhysioStimU, Orthofix, Lewesville, TX). We hypothesized that exposure to PEMF at higher SRs, and thus higher energy dosage, would more effectively reduce trabecular bone losses in osteoporotic rats. In this study 6-7 month-old OVX female Sprague-Dawley rats underwent 4 weeks (wks) of estrogen-depletion to achieve a state of menopausal bone loss. Five groups were followed (n = 10/group): CON (OVX control, no PEMF); ALN (alendronate); PS10 (PEMF SR 10 T/s, PhysioStim); PS100 (PEMF SR 100 T/s) and PS300 (PEMF SR 300 T/s). All treatments began 4 wks after OVX surgery for a period of 6 wks. ALN treated animals received sc injections of ALN, 3 days/wk (10 µg/kg BW per wk). All PEMF-treated rats received daily 3-h whole body treatments, 7-days per week. Using in vivo microCT imaging (20 µm) at 3 time-points (baseline, 4-wks post-OVX and 10-wks post-OVX) trabecular (proximal tibia) bone volume fraction (BV/TV), bone mineral content, and bone mineral density were examined. Injections of Alizarin Red and Calcein were done at 8 and 10-wks post-OVX, respectively, for end-point dynamic histomorphometry assessment of endosteal cortical bone formation rates (BFR) at the proximal tibia. Results (Fig. 1) show that treatment with the PS10 and PS300 do not mitigate trabecular bone losses, while treatment with the PS100 is trending towards a sizeable mitigation of OVX bone loss. BFR in the PS100 and PS300 groups were comparable to that of the ALN group, and both of these treatments showed BFR roughly 1/3 of that shown for the CON group (Fig. 2). In contrast, BFR for the PS10 were significantly different from the ALN group, and found to be comparable to the CON group. It appears that PEMFs of various SRs exhibit a variable range of biological effects on trabecular bone loss in osteoporotic rats. Interestingly, treatment with the PS100 partially mitigated trabecular loss supporting the rationale that PEMF treatment merits further investigation as a possible alternate treatment modality for the mitigation of osteoporotic bone loss.

Low-Impact Multi-Directional Mechanical Loading Using a Fine-Wire Climbing Substrate Enhances Mechanical Properties of the Mouse Femur. Jason Organ^{*1}, Benjamin Vickery¹, Jeffery Joll¹, Kelly Biro¹, Craig Byron², Joseph Wallace³, Matthew Allen¹. ¹Indiana University School of Medicine, USA, ²Mercer University, USA, ³Indiana University-Purdue University at Indianapolis, USA

High-impact exercise (running/jumping) during childhood has been shown to be a potent osteogenic stimulus to augment the growing skeleton. However, physical activity of this nature is associated with an increased incidence of skeletal fracture, and therefore may not be an appropriate recommendation for children with already elevated risk of fracture. Multi-directional off-axis loading events, having low magnitude forces, can elicit osteogenic responses and therefore may represent a potential alternative to high-impact exercise for improving skeletal mechanical properties. We examined the effect of low-impact, multi-directional mechanical loading using a novel fine-wire climbing exercise regimen. We raised 19 weanling female C57BL/6 mice to skeletal maturity (4 months) in custom enclosures that prevent (control) or require (experimental) manual and pedal grasping while balancing and climbing above fine wire substrates. At sacrifice, we measured whole body bone density (DEXA) and performed geometric/architectural (μ CT) and mechanical (4-pt bending) analyses of the femur. Body mass was similar between groups, although experimental mice were significantly leaner (-34% fat mass). Bone mineral density and bone mineral content were similar between the groups. Femoral midshaft polar moment of inertia, cortical area, and cortical thickness were also similar between groups, but experimental mice had significantly lower BV/TV (-24.1%) of the distal femur as a result of having significantly lower trabecular number (-27%). Experimental mouse femora experienced significantly higher ultimate force (+17%), post yield displacement (+67%) and post yield work (+82%) prior to failure

than controls, while stiffness was non-significantly higher (+22%). Calculation of material properties showed that experimental mouse femora were non-significantly tougher (+33%) and experienced non-significantly lower strain to yield (-28%) than controls. These data suggest that the low-impact, multi-directional mechanical loading model improve whole bone mechanical properties by affecting aspects of the material. Future work will focus on understanding the specific aspects of the material-level properties that are responsible for these positive changes.

MO0046

Structural and Mechanical Improvements to Bone are Strain Dependent in a Targeted Tibial Loading Model of Young Female C57BL/6 Mice. Alycia Berman^{*1}, Creasy Clauser², Caitlin Wunderlin², Max Hammond³, Joseph Wallace⁴. ¹Indiana University - Purdue University Indianapolis, USA, ²Indiana University Purdue University Indianapolis, USA, ³Purdue University, USA, ⁴Indiana University Purdue University Indianapolis (IUPUI), USA

The targeted tibial loading murine model has been used extensively to assess the adaption of bone to external loading. However, most studies only explore alterations in bone morphology. Doing so provides useful information as to the adaptive response, but does not consider the broader functional implications of those changes. For example, analysis of bone architecture only measures bone quantity, even though bone quality also plays an integral role in overall bone integrity. For that reason, we studied the morphological and the mechanical adaption of bone to three levels of strain using the targeted tibial loading model. The right tibiae of female C57BL/6 mice (8 week old) were compressively loaded to one of three strain levels (1700 ue, 2050 ue, and 2400 ue as determined by a strain calibration), while the contralateral limb served as a non-loaded control. Mice were loaded for 3 days, followed by 1 day of rest, repeated 3 times over a 12 day period. Each day of loading consisted of 4 cycles of compression at 2 Hz, followed by 3 seconds of rest. This block (load then rest) was repeated 55 times, yielding a total of 220 cycles of compression per day. Two days following the last loading cycle, mice were euthanized and the tibiae were harvested for analysis. Ex vivo analyses consisted of micro-computed tomography to assess cortical and cancellous bone architecture, and 4-point bending to assess structural and tissue level mechanical integrity. Results indicated that loading improved bone architecture in a dose-dependent manner. At the lowest strain level (1700 ue), loading had little effect on bone morphology or mechanical integrity. In contrast, significant changes in bone architecture of the mid-strain group (2050 ue) indicated a formation response in both cortical and cancellous regions (Figure 1 and 2). In addition, significantly increased structural and tissue level strength and energy dissipation indicated improved mechanical integrity (figure 3). The highest strain group (2400 ue) also showed an increased formation response, but to the point of woven bone formation in half of the animals. These results indicate that loading to 2050 ue provided the greatest improvement in bone architecture and mechanical function, while not inducing a woven bone response. Future work will use these results to explore mechanical stimulation as a therapeutic means to recover bone functional quality in diseased mouse models.

A 7-Year School-Based Exercise Intervention Improves Musculoskeletal Traits in Both Genders and Reduces in Girls with Each Year with the Program the Fracture Risk. Jesper Fritz¹, Björn Rosengren², Magnus Dencker², Caroline Karlsson², Magnus Karlsson². ¹Skane University Hospital, Sweden, ²Clinical & Molecular Osteoporosis Research Unit, Departments of Orthopedics & Clinical Sciences, Lund University, Sweden

Purpose: Short-term childhood physical activity programs seem to improve musculoskeletal development but it is unclear if they continue to be beneficial in puberty and more importantly, decrease the fracture risk. **Methods:** In a prospective cluster randomized controlled trial (RCT) we increased school physical education (PE) to 200 minutes per week in one school as intervention and closely monitored 72 girls and 100 boys from mean age 7 to mean age 14 years. 45 girls and 47 boys, in three other schools continued with the Swedish standard of 60 PE minutes per week. They were followed in the same manner and were thus used as controls. Before study start and after 7 years we measured bone mineral content (BMC), bone mineral density (BMD) by DXA and muscle strength by a computerized dynamometer (Biodex[®]). At follow-up we also measured tibia with pQCT. In all 3534 children who in the four schools were included in the program (1339 in the intervention and 2195 in the control group) we registered incident fractures and estimated fracture incidences and risk ratios (RR). Data are presented as mean differences (95% CI). **Results:** Girls in the intervention group gained more total spine BMD [+0.04 g/cm² (+0.01, +0.08)] and

knee flexion strength [+6.2 Nm (+1.6, +10.7)] than control girls. They also had a greater tibial cortical thickness [+0.1 mm (+0.0, +0.3)] at follow-up. Boys in the intervention group gained more knee extension [+7.3 Nm (+0.4, +14.2)] and knee flexion strength [+7.4 Nm (+2.3, +12.4)] than control boys. In girls there was also a statistically significant inverse relationship between years with extra PE and the RR of fracture [$r = -0.86$; 95% CI -0.98 to -0.23] not evident in boys ($r = -0.64$ [95% CI -0.93 to +0.26]). **Conclusion:** A 7-year pediatric school-based moderate exercise intervention program enhances bone mass, muscle strength and reduces the fracture risk in girls and enhances the gain in muscle strength in boys. 74% of the variance in the diminished fracture risk during the study period could in the girls be explained by the intervention.

Peri-menarcheal Upper Extremity Bone Loading Index Reflects Post-menarcheal DXA Outcomes. Jodi Dowthwaite^{*1}, Kristen Dunsmore², Paula Rosenbaum³, Carol Sames³, Tamara Scerpella⁴. ¹SUNY Upstate Medical University, Syracuse University, USA, ²SUNY Upstate Medical University, USA, ³SUNY Upstate Medical University, USA, ⁴University of Wisconsin, USA

Purpose: Mechanical loading is believed to provide a potent osteogenic stimulus during growth. However, the extent to which different organized physical activities (sports) promote site-specific osteogenesis has not been determined. The current analysis refined and tested a novel sport-specific bone loading index for the non-dominant upper extremity in 2 samples of post-menarcheal girls with detailed records of sport exposure for 3 years prior to the focal DXA scans.

Methods: Cohort A was recruited between 1998 and 2003 (n=55); Cohort B was recruited between 2008 and 2011 (n=48). For inclusion in analyses, subjects provided whole body and radius DXA scans at 1.0-2.6 years post-menarche, with semi-annual sport records for 36 months prior. DXA outcomes were Area, bone mineral content (BMC) and areal bone mineral density (aBMD) for the non-dominant distal radius (1/3, ultradistal) and Arm regions of interest, as well as Arm non-bone lean mass (nbFFM). The bone loading index is based on sport-specific loading factors as follows: velocity (non-loaded, static load, non/low/high impact), magnitude (load mass), frequency (impulses per session) and non-dominant arm loading (non/low/high). Sport-specific bone loading indices were multiplied by 3-year cumulative exposure hours to yield 3 year total BLI (totBLI). Separate regression analyses were performed for Cohorts A&B, with years post-menarche, height, whole body nbFFM and totBLI as independent variables and bone outcomes as dependent variables. Squared semi-partial correlation coefficients (SSPCCs) were evaluated as metrics of explanatory value.

Results: After accounting for years post-menarche, height and nbFFM, totBLI explained 7%-34% of variance for all outcomes ($p < 0.05$), except Arm Area. In comparison, nbFFM explained 6%-31% of variance for all outcomes ($p < 0.05$), except 1/3 aBMD (Cohorts A&B), UD Area (A). Comparing the 2 Cohorts, totBLI SSPCCs were within 10% of each other for BMC (1/3, UD, arm), arm aBMD and arm nbFFM.

Conclusions: Peri-menarcheal 3-year bone loading index was significantly correlated with post-menarcheal arm lean mass and all bone outcomes except non-dominant arm Area, demonstrating similar explanatory value to that of whole body lean mass. These results support the consistent utility of the BLI algorithm as an index of site- and sport-specific loading for the upper extremity.

Restoring Standing Height: Yet Another Benefit of Exercise for Osteoporosis. Belinda Beck^{*}, Benjamin Weeks, Amy Harding, Sean Horan, Steven Watson. Griffith University, Australia

Purpose: The utility of exercise for improving or maintaining bone mass is well-recognized. The ability of exercise to maintain or restore lost stature however has rarely been reported. Such a finding would have considerable clinical significance in light of the known relationships between stature, function and quality of life. We hypothesized a targeted heavy progressive resistance training program would increase back muscle strength and prevent loss of height in postmenopausal women with low bone mass.

Methods: Fifty postmenopausal women (66.3 ± 5.1 y) with low bone mass (FN or LS t-score: ≥ 1) who undertook twice weekly progressive heavy resistance training (EX) or a very low intensity home exercise program (CON) for 8 months were tested for height, LS BMD, WB lean mass (DXA, XR-800, Norland) and back extensor strength (BES) at baseline and follow-up. Between-group difference in change in height over time was examined by repeated measures ANOVA. Multiple regression analysis was used to determine the degree to which baseline values and change in BES, lean mass and LS BMD predicted variance in change in height.

Results: Change in height over the 8 month period differed significantly between groups (CON, -0.41 ± 0.28 vs EX, 0.60 ± 0.27 cm, $P = 0.001$). Change in BES ($R^2 = 0.637$, $P = 0.032$) and change in WB lean mass ($R^2 = 0.310$, $P = 0.039$) together accounted for almost three quarters of the variance in change in height ($R^2 = 0.707$, $P = 0.038$). The correlation of change in LS BMD with change in height approached significance ($r = 0.518$, $P = 0.058$), but did not contribute significantly to the regression model, $P = 0.074$.

Conclusion: Heavy progressive resistance training induced a mean net benefit of 1 cm in stature over the course of an 8 month training program in comparison with very lightly exercising controls. The clear relationship of changes in back extensor strength and lean mass to changes in height suggest heavy resistance training is a powerful therapy for the maintenance or restoration of height in postmenopausal women.

Sclerostin Serum Level Immediate Variation After Physical Activity in Young Females. Marie-Eva Pickering¹, Marie Simon², Karim Chikh³, Marie Christine Carlier³, Cyrille Confavreux^{*4}. ¹Université de Lyon-INSERM UMR1033-Hospices Civils de Lyon, France, ²Hospices Civils de Lyon, France, ³Université de Lyon - Department of Biochemistry, Hospices Civils de Lyon, France, ⁴Université de Lyon-INSERM U1033- Department of Rheumatology Hospices Civils de Lyon, France

Objectives: Osteoporosis is characterized by low bone mass and poor bone quality leading to a reduction in bone strength and an increase risk of fracture. Osteoporosis prevention is of major interest for public health. In addition to vitamin D supplementation, prevention relies on regular loading physical activity such as a 30mn daily walk to favor bone formation. Wnt pathway is the main anabolic pathway in osteoblasts. It is regulated by sclerostin which is secreted by osteocytes, a bone cell harboring mechanoreceptors. Thus we assayed sclerostin serum level variation after physical activity. Patients and methods: After ethical comity approval and sample size calculation, we recruited young healthy female volunteers with a body mass index (BMI) between 18 and 25 kg/m². Participants practicing more than 90 mn physical activity per week or having any cardiac medical history or any chronic diseases were excluded. We submitted participants to a 45mn run on a treadmill. After 5 mn warm-up, participants ran at the established speed of 7.5 km/h. Blood withdrawal was performed before and 5mn after the end of physical activity. Sclerostin was assessed using ELISA kit (Teco médical®). Results: We enrolled 23 young females and all completed the whole protocol. Mean age of participants was 22 ± 1.5 years with a mean BMI of 21.9 ± 2.4 kg/m². Mean strength of participants, assessed by a dynamometer, was 35.2 ± 5.7 kg. Mean vitamin D serum level was 75 ± 18 nmol/L. Sclerostin serum level significantly increased by 44.6 ± 26.4% (mean gain) after physical activity with 290 ± 90 ng/L at rest and 410 ± 130 ng/L after activity (p<0.001). CTX variations were not significant and bone specific alkaline phosphatase variations remained below the CV (8.1%) of the method. Conclusion: We observed a sharp increase of serum sclerostin levels immediately after physical activity in a homogenous group of young healthy females. Our study shows a high reactivity of osteocytes in response to physical activity.

MO0051

Vitamin C and E supplementation reduces the beneficial skeletal effects of strength training in elderly men. Astrid Kamilla Stunes^{*1}, Unni Syversen², Sveinung Berntsen³, Göran Paulsen⁴, Tonje H. Stea³, Ken J. Hetlelid³, Hilde Lohne-Seiler³, Thomas Bjørnsen³, Glenn Haugeberg⁵. ¹Norwegian University of Science & Technology, Norway, ²Department of Cancer Research & Molecular Medicine, Norwegian University of Science & Technology, (NTNU), Trondheim, Norway & Department of Endocrinology, St Olav's University Hospital, Trondheim, Norway, ³Department of Public Health, Sport & Nutrition, University of Agder, Norway, ⁴Department of Physical Performance, Norwegian School of Sport Sciences, Oslo, Norway & Norwegian Olympic Sport Center, Oslo, Norway, ⁵Department of Rheumatology, Hospital of Southern Norway Trust, Kristiansand, Norway & Department of Neuroscience, Division of Rheumatology, Norwegian University of Science & Technology (NTNU), Trondheim, Norway, Norway

Resistance training and impact-loading activities are considered beneficial for maintaining bone mass and preventing osteoporosis in elderly men. The musculoskeletal effects of dietary intake of high doses of antioxidants, such as vitamin C and E, have been disputed. We wanted to study possible additive effects of strength training and supplements with antioxidants on bone health.

The skeletal effects of vitamin C and E were examined in a double-blinded randomized placebo-controlled study during a 12 weeks supervised strength training program in healthy, elderly men. All participants followed an undulating training program: 2/wk 8-10RM (1 min inter-set rest periods), 1/wk between 3-5RM (2 min rest) and 13-15RM (45 sec rest). The load was weekly adjusted, and the volume increased progressively. The control group (CTR), (N=17, 67 ± 5 years old) received daily placebo pills, and the antioxidant group (AO), (N=16, 70 ± 7 years old) received 1000 mg vitamin C and 235 mg vitamin E daily. Fasting blood samples were drawn for analyses of bone turnover and sclerostin. BMD and lean mass at whole body and BMD at hip and lumbar spine (L1-L4) were measured by DXA, and muscle strength was assessed by one repetition maximum (1RM), at baseline and post-intervention.

After the intervention significant increases were observed in total lean mass and muscle strength in both the CTR and AO groups. Both groups displayed significantly increased total hip BMD, while whole body and femoral neck BMD remained unchanged. The CTR group had a significant increase in L1-L4 BMD when compared to the AO group. A significant decrease in serum sclerostin levels in the CTR group compared to the AO group was also observed. The serum levels of the bone formation markers PINP and osteocalcin were significantly increased in both groups, while the bone resorption marker CTX remained unchanged. Data (mean±SD) are presented in the table below.

In conclusion, 12 weeks of supervised strength training increased total hip BMD and serum bone formation markers in elderly men. The CTR group also displayed an increased BMD at the lumbar spine and a decrease in serum sclerostin, indicating a favoring of bone formation. This was not observed in the AO group, indicating a blunting of some of the positive effects of strength training. High doses of vitamin C and E during strength training have no beneficial or probably negative skeletal effects in healthy, elderly men.

Adenine based mouse model of juvenile chronic kidney disease: preliminary bone and mineral findings. Oleh Akchuric^{*1}, Sara Gardenghi², Paraskevi Rea Oikonomidou², Adele Boskey³, Stefano Rivella². ¹Cornell University, USA, ²Weill Cornell Medical College, USA, ³Hospital for Special Surgery, USA

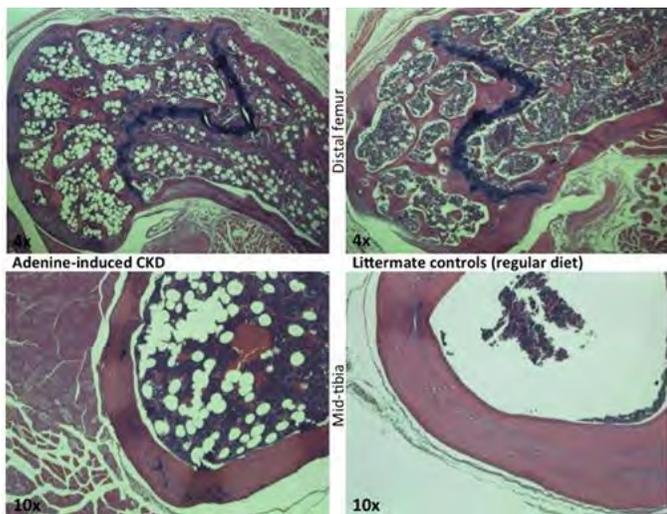

Chronic kidney disease (CKD) in children has a number of differences from CKD in adults, such as development of growth failure. However, no convenient mouse model is available to address numerous knowledge gaps related to pediatric CKD, such as, for example, the role of CKD mineral and bone disease in growth retardation.

High adenine diet has been shown to induce CKD in adult mice. The purpose of this study was to test whether 0.2% adenine diet would also induce CKD in growing mice resembling CKD in children, including CKD - mineral and bone disease and growth delay.

C57Bl6 mice were started on 0.2% adenine diet (Harlan) at weaning (3 weeks) and sacrificed in 8 weeks. Littermate controls were fed a regular diet. Weekly measurements of nose-to-tip-of-tail length were used for tracking linear growth.

Adenine fed juvenile mice had statistically significant elevation of BUN (87.0 vs. 29.5 mg/dL in controls), creatinine (0.57 vs. 0.19 mg/dL) and phosphorus (14.6 mg/dL vs. 5.3 mg/dL) at sacrifice. Adenine fed mice had slower rate of weight gain compared with controls and by 3 weeks they stopped gaining and / or started to loose weight. Linear growth was also significantly slower in adenine fed mice. At sacrifice, adenine fed mice had about 40% deficit in body weight and 10-15% deficit in body length, as compared with controls (both differences are statistically significant). In addition, adenine fed mice developed anemia, increased neutrophil count and relative lymphopenia. Bone histology revealed extensive marrow adiposity and cortical thinning in adenine fed mice (figure).

In conclusion, this study demonstrated for the first time that 0.2% adenine diet reliably induces CKD-related growth failure and cachexia in juvenile mice, resembling those seen in children with CKD. Adenine induced CKD in juvenile mice is also characterized by distinct changes of bone histology. Our ongoing experiments are directed towards further characterization of the bone and mineral phenotype and eliciting the mechanisms of the described findings, as well as utilizing this model to characterize the contribution of disordered phosphorus homeostasis to growth delay in pediatric CKD.

Low Bone Mineral Density and Fractures are Prevalent in Children with Spinal Muscular Atrophy. Halley Wasserman*, Lindsey Hornung, Peggy Stenger, Meilan Rutter, Brenda Wong, Irina Rybalsky, Jane Khoury, Heidi Kalkwarf. Cincinnati Children's Hospital Medical Center, USA

Background: Spinal Muscular Atrophy (SMA), an autosomal recessive disease of the spinal motor neurons, results in varying degrees of hypotonic immobility. Lack of weight-bearing activity and low muscle mass lead to poor bone accrual. Prior reports demonstrate an increased risk of fracture and a trend toward low bone mineral density (BMD). However, no studies report the prevalence of fractures or low BMD (Z-score ≤ -2.0) by SMA subtype, low BMD of the lateral distal femur (an important fracture location in non-ambulatory children), nor the prevalence of osteoporosis according to 2013 ISCD criteria, in this population. **Methods:** A retrospective chart review was conducted of 86 patients, ages 12 months to 25 years, with confirmed diagnosis of SMA, seen at our institution between January 2005 and January 2015 (Table 1). Lumbar spine (LS), total body (TB), and lateral distal femur (LDF) DXA scans (Hologic 4500) were obtained as part of routine clinical care, and patients' initial DXA scans results were reported for this study. All DXA scans were reviewed for image quality. Fracture history was reported at annual clinic visits and confirmed when possible by review of radiographs. Cumulative fracture frequencies from patients' last encounters were reported for this study. Kruskal Wallis, Chi-square and Fisher's exact tests were utilized to compare groups.

Results: Median age at initial SMA visit was 1.8 years, but differed by SMA subtype. DXA data were available on 69% of the sample: of these, 90% had a BMD Z-score ≤ -2.0 SD at time of first DXA. In those with missing DXA data, 63% of patients were <3 years of age at time of last encounter. BMD of all sites was lower with worsening SMA severity. Fractures occurred in 36% of patients with the femur being the most common location (25 of 53 total fractures). Median age at first fracture was significantly younger with worsening SMA severity. 13% of patients had multiple fractures.

Conclusion: Low BMD is highly prevalent in SMA patients at the time of first DXA. Fracture frequency is also high with a predominance of femur fractures in all subtypes. However, few patients met ISCD diagnostic criteria for osteoporosis. Our data suggests poor bone health is a significant concern for SMA patients, but may be underestimated using the 2013 ISCD criteria for diagnosis of osteoporosis in children.

Bone Robusticity in Two Distinct Skeletal Dysplasias: an Evaluation of the Second Metacarpal, a Surrogate for Bone Strength. Josephine Marino¹, Karl Jepsen², Erin Carter³, Cathleen Raggio^{*4}. ¹Hospital for Special Surgery, USA, ²Department of Orthopaedic Surgery, University of Michigan, USA, ³Kathryn O. & Alan C. Greenberg Center for Skeletal Dysplasias, Hospital for Special Surgery, USA, ⁴Pediatric Orthopaedics, Hospital for Special Surgery, USA

Radiographs of the second metacarpal are used to assess bone strength development in pediatric populations. Children with achondroplasia and osteogenesis imperfecta (OI) have known differences in bone strength. Details of how bone strength develops and compares within these populations to unaffected children are lacking. A data set for patients with achondroplasia and OI was established.

A retrospective IRB-approved review of bone-age films (n=67; 1-11 films/patient) from patients (5mos to 16yrs+3mos old) with achondroplasia (6 males; 10 females) or OI (9 males; 11 females) was conducted. A sample of modern controls (diagnosis: leg-length discrepancy) matched historical measurements from Bolton-Brush collection (6mos-16yrs). Metacarpal length (Le) was measured from the proximal end to the most distal ossified end along the midshaft axis. Outer and inner diameters were measured at 50% and 60% of the length, averaged, and used to calculate total cross-sectional area (Tt.Ar) and cortical area (Ct.Ar) using a circular approximation. To adjust for differences in body size, we compared robustness (Tt.Ar/Le) and relative cortical area (RCA=Ct.Ar/Tt.Ar) among groups.

Achondroplasia patients tend to have both robusticity and RCA values above the most robust Bolton-Brush tertile (Fig. A). This robust phenotype was consistent with the reduced longitudinal growth seen in achondroplasia patients. Increased RCA values were unexpected and may indicate deregulated mass-accumulation. In contrast, OI patients followed the Bolton-Brush pattern of decreased robusticity and increased RCA, but not the distribution. OI patients all fell in the most slender tertile (Fig. B). No sexual dimorphism was noted in this study (Fig. C).

The lack of sexual dimorphism in the dysplasia populations is in contrast to that reported in the unaffected population. We suggest that the underlying dysplasia overrides the sex-specific effects on bone strength development. The contribution of the specific mutation is unknown and needs to be further studied.

Decreased Vertebral Dimensions and Increased Spine Flexibility in Girls And Patients With Adolescent Idiopathic Scoliosis. Tishya Wren¹, Skorn Ponrartana², Carissa Fisher¹, Patricia Aggabao¹, Vicente Gilsanz¹. ¹Children's Hospital Los Angeles, USA, ²Children's Hospital Los Angeles, USA

Adolescent idiopathic scoliosis (AIS) affects girls more than boys and has an unknown etiology. We hypothesized that AIS is promoted by decreased vertebral size and increased spine flexibility, which would accentuate differential loading of the vertebrae during bending. MRI and CT were used to measure vertebral height, anterior-posterior and lateral width, and cross-sectional area of the L1, L2, and L3 vertebrae and height of the inferior intervertebral discs (IVD) in 80 adolescents (61 girls, 19 boys) with AIS and 229 adolescents (122 girls, 107 boys) without spinal deformity ages 10-15 years. Maximum rotation of each vertebral body was estimated from the ratio of IVD height to vertebral width using a simple biomechanical model. Two-way ANOVA was used to examine the effects of sex and scoliosis on outcome measures. Boys had greater height, weight, and BMI than girls (all $p \leq 0.03$), but scoliosis did not affect these measures (all $p > 0.2$ for scoliosis, $p > 0.1$ for interaction). All vertebral cross-sectional dimensions were significantly smaller for females compared with males (all $p < 0.0001$) and for adolescents with AIS compared with controls (all $p < 0.0001$) at all vertebral levels examined. In many cases, there was also a significant interaction between sex and scoliosis reflecting a larger difference between AIS and controls in boys than in girls. Vertebral height was larger in controls (all $p \leq 0.003$), but IVD height was larger in AIS (all $p < 0.0001$) with no significant differences due to sex (all $p > 0.06$). Consequently, predicted spine motion was significantly greater for females and adolescents with AIS (all $p < 0.0001$). The increased spine flexibility would increase asymmetric loading on the vertebrae during anterior and lateral bending, promoting differential longitudinal growth. Growth would be accelerated on the convex side of the curve by increased tensile stresses and inhibited on the concave side by increased compressive stresses, leading to vertebral wedging. Decreased vertebral size and increased flexibility may therefore help to explain the greater prevalence of AIS in females. If these relationships can be confirmed in future prospective longitudinal studies, multi-planar imaging of vertebral morphology may contribute to improved prognosis for adolescents with early AIS and development of treatments to prevent AIS progression.

Side-to-side Differences in Bone Strength and Microstructure in Children and Adolescents with a Distal Radius Fracture. Mikko Maatta¹, Heather Macdonald², Douglas Race², Lindsay Nettlefold², Kishore Mulpuri³, Heather McKay². ¹University of British Columbia, Canada, ²Centre for Hip Health & Mobility, Canada, ³British Columbia Children's Hospital, Canada

We recently reported⁽¹⁾ associations between impaired bone strength, microstructure and forearm fractures (Fx) in children and adolescents. Here we aimed to determine if similar bone strength deficits were apparent on the contralateral non-fractured (NF) limb.

Participants were 173 youth with a recent distal radius Fx [61 girls, 112 boys (12.1 ± 1.8y)]. We assessed bone strength and microstructure of the distal radius (7%

site) on both the Fx and NF arm using high-resolution pQCT (Scanco Medical). The average time between injury and the HR-pQCT scan was 2.6 ± 0.9 mo. We excluded 40 participants due to motion during scan acquisition, previous distal radius Fx, Fx due to high energy trauma or missing trauma degree. We also excluded 63 participants for whom a Fx line was visible throughout the region of interest (ROI), which resulted in a final sample of 70 [26 girls, 44 boys (11.8 ± 1.8y)]. In cases where the Fx was visible in part of the ROI (n=46), we excluded slices (48 ± 17) with a visible Fx line. We assessed total area (Tt.Ar) and bone mineral density (Tt.BMD), trabecular bone volume ratio (BV/TV), trabecular thickness (Tb.Th) and number (Tb.N), cortical area (Ct.Ar), BMD (Ct.BMD), thickness (Ct.Th) and porosity (Ct.Po), and used finite element analysis to estimate bone strength (failure load and ultimate stress). We calculated the mean difference (95% confidence intervals) in bone outcomes between the Fx and NF arms, adjusting for hand dominance and used paired samples *t*-tests to estimate statistical significance.

40% of fractures occurred on dominant arm. We found higher Tt.Ar on the Fx radius compared with the NF radius (250.8 vs. 236.3 mm²; mean difference 14.5 (95% CI 8.5-20.5) mm²). Compared with the NF radius, Fx radii also showed higher Ct.Po (4.8 vs. 4.0%; 0.8 (0.5-1.1)%), smaller Ct.Th (0.47 vs. 0.49 mm; 0.03 (0.01-0.04) mm) and Ct.Ar (25.7 vs. 27.4 mm², 1.7 (0.8-2.6) mm²) and lower Ct.BMD (504.4 vs. 539.9 mgHA/cm³; 35.4 (24.9-46.0) mg HA/cm³, $p < 0.01$ for all). Fx radii had higher BV/TV (0.155 vs. 0.145; 0.010 (0.002-0.017)) and higher Tb.Th (0.070 vs. 0.067 mm; 0.003 (0.001-0.006) mm) than NF radii ($p < 0.02$). Bone strength did not differ between sides.

Deficits in cortical bone structure and BMD were only apparent on the Fx limb and thus may predispose growing bone to Fx. Greater bone volume and thicker trabeculae in the trabecular compartment may compensate for these cortical bone deficits.

Underdevelopment in trabecular bone microarchitecture is dictated by level of motor function in children with cerebral palsy. Christopher Modlesky¹, Harshvardhan Singh¹, Daniel Whitney¹, Freeman Miller². ¹University of Delaware, USA, ²Nemours AI duPont Hospital for Children, USA

Nonambulatory children with cerebral palsy (CP) have a severely underdeveloped trabecular bone microarchitecture; however, whether children with milder forms of the disorder have a similar profile or whether the degree of underdevelopment is related to the degree of motor function has not been determined. Nonambulatory children (n = 13) and ambulatory children (n = 13) with spastic CP and typically developing children (n = 50) between 5 and 13 years of age participated in the study. Twenty six axial magnetic resonance images (175 x 175 x 700 μm³) of the distal femur were collected from the more affected limb in children with CP and the nondominant limb in controls. Measures of trabecular bone microarchitecture [apparent trabecular bone volume to total volume (appBV/TV), trabecular number (appTb.N), trabecular thickness (appTb.Th) and trabecular separation (appTb.Sp)] were estimated using the 20 most central images and custom software (Interactive Data Language, Boulder, CO). Level of gross motor function was assessed using the gross motor function classification system (GMFCS) with levels I and II representing children able to ambulate independently, and levels III to V representing children unable to ambulate independently. Compared to controls, nonambulatory and ambulatory children with CP had lower appBV/TV by 28% (Cohen's d (d) = 2.4, $p < 0.001$) and 11% (d = 1.0, $p = 0.007$), lower appTb.N by 18% (d = 2.5, $p < 0.001$) and 9% (d = 1.3, $p = 0.001$), and higher appTb.Sp by 31% (d = 2.6, $p < 0.001$) and 15% (d = 1.2, $p = 0.004$), respectively. Additionally, compared to controls, nonambulatory children with CP had lower appTb.Th by 11% (d = 1.6, $p < 0.001$). GMFCS was negatively correlated with appBV/TV, appTb.N, and appTb.Th ($r = -0.45$ to -0.56 , $p < 0.05$) in children with CP; on the other hand, GMFCS was positively related to appTb.Sp ($r = 0.48$, $p = 0.014$). The findings suggest that the degree of underdevelopment in trabecular bone microarchitecture in children CP is dictated by the level of compromise in motor function. Although the degree of underdevelopment in ambulatory children with milder forms of CP is not as large as that observed in nonambulatory children with more severe forms of CP, it is substantial with measures of trabecular bone microarchitecture deviating from control values by ≥ 1 SD. Treatments that enhance the development of trabecular bone microarchitecture in children with CP, irrespective of motor function, are needed.

Denosumab treatment of severe disuse osteoporosis in a boy with Werdnig-Hoffmann disease. Stepan Kutilek^{*}. Klatovy Hospital, Czech republic

Denosumab is a fully human recombinant monoclonal antibody to the receptor activator of nuclear factor-κB ligand (RANKL). In postmenopausal osteoporotic women subcutaneous denosumab administration every 6 months increases bone mineral density (BMD) at the lumbar spine, total hip, and/or femoral neck, and significantly reduces markers of bone turnover, thus reducing the risk of vertebral, nonvertebral, and hip fractures. There are only scarce data about denosumab treatment in children and adolescents.

Case report: 14-year old boy presented with severe disuse osteoporosis due to muscular atrophy in Werdnig-Hoffmann disease.(SMA type 2). The boy was wheelchair-bound with muscle weakness, severe joint contractures, quadraparesis, kyphoskoliosis, difficult swallowing and had recurrent respiratory infections. In the past 6 months he experienced 2 low-energy trauma fractures of the right femur and left tibia. L1-L4 BMD was low: 0.406 g/cm²(-6.2 SD Z-score;DXA Lunar). Serum levels of Ca, P, ALP and PTH were normal. Osteoporosis treatment was clearly indicated, however intravenous bisphosphonates were out of question due to history of convulsions triggered by fever including low-grade fever. Neither oral bisphosphonates could be used due to difficult swallowing and risk of consequent oesophageal ulceration. Therefore, denosumab treatment (60 mg s.c.) was started with the patients and parents consent. He also received 1000 mg calcium/day and 1000 IU cholecalciferol/day p.o. The denosumab injection was well tolerated and there were no adverse reactions. Six months later upon check-up his L1-L4 BMD increased by 19% to 0.485 g/cm² (Z-score -5.8 SD). S-Ca, P, ALP and PTH were normal. Unfortunately the same day he fell from the wheelchair and broke his right femur. This fracture could be attributed to the high-energy trauma mechanism and still very low BMD. He received his second denosumab injection one month later (i.e on month 7), without any complications. Third denosumab injection was scheduled 6 months later. Prior to the planned visit and third injection, the boy died from respiratory failure due to pneumonia. This should be considered as not related to the denosumab treatment, as respiratory failure is a frequent cause of death in patients with WHD. Conclusion: One dose of s.c. denosumab significantly increased BMD in a child with severe disuse osteoporosis. Denosumab might present a suitable treatment option in children with bone fragility.

MO0059

Improved Functional Mobility with Asfotase alfa Treatment in Childhood Hypophosphatasia. Katherine L Madson¹, Dawn Phillips², Cheryl Rockman-Greenberg³, Amy Reeves¹, Kenji P Fujita⁴, Scott Moseley⁴, David Thompson⁴, Michael P Whyte¹. ¹Shriners Hospital for Children, USA, ²University of North Carolina Division of Physical Therapy, USA, ³University of Manitoba, Canada, ⁴Alexion Pharmaceuticals, USA

Purpose. Hypophosphatasia (HPP) is the rare inborn-error-of-metabolism caused by loss-of-function mutation(s) within the gene that encodes the tissue nonspecific isoenzyme of alkaline phosphatase (TNSALP) gene. The biochemical hallmark is hypophosphatasemia (low serum alkaline phosphatase activity). Children with HPP may experience compromised physical function, including gait impairments, secondary to skeletal deformities and muscle weakness. We report significant gait improvements in children with HPP treated with asfotase alfa, an investigational, bone-targeted human TNSALP replacement, compared with untreated historical control (HC) patients (pts).

Methods. Videos of basic mobility of treated and HC pts ages 5–15 years were assessed using the 12-point Modified Performance-Oriented Mobility Assessment – Gait subscale (MPOMA-G; 12=no impairment.) The MPOMA-G, an adaptation of the POMA-G, provides improved sensitivity for HPP-related impairments. Results were compared between pts participating in a Phase II, open-label, ongoing study of asfotase alfa¹ (n=8) and those in a HC gait substudy² (n=6) from a retrospective natural history study of pts matched for age and HPP severity. Enrollment criteria for these analyses included: onset of HPP symptoms from age ≥6 months, HPP-related skeletal abnormalities, and ≥2 gait assessments between 5 and 15 years of age. Rate of change per year was calculated as MPOMA-G change from Baseline (BL) to Last Assessment (LA) divided by intervening time. For treated pts with a pre-treatment video (n=5), rates of change (Pre-treatment to BL assessment) were compared with untreated rates.

Results. Group ages were not significantly different at BL or LA (Table 1). BL characteristics were also generally similar. All pts showed deficits in gait as assessed by MPOMA-G at BL (Table 1). Treated pts had a significantly greater rate of improvement in MPOMA-G scores compared to HC (p=0.03), and a greater absolute increase in MPOMA-G score from BL. Of note, gait had deteriorated prior to BL in pts who later received asfotase alfa (Table 1). Significance was retained in sensitivity analyses controlling for assessment interval and BL gait score.

Conclusion. Children with impaired gait due to HPP demonstrated clinically significant improvement in functional mobility when treated with asfotase alfa compared to both pretreatment history and historical controls.

Treating Low Bone Mass with Calcium and Vitamin D Supplementation in Girls with Adolescent Idiopathic Scoliosis (AIS) – A Randomized Double-blinded Placebo-controlled Trial. Tsz Ping Lam¹, Benjamin Hon Kei Yip¹, Echo Ka Ling Tsang¹, Fiona Wai Ping Yu¹, Kenneth Kin Wah To², Yuk Wai Lee¹, Kwong Man Lee³, Bobby Kin Wah Ng¹, Jack Chun Yiu Cheng¹. ¹Department of Orthopaedics & Traumatology, The Chinese University of Hong Kong, Hong kong, ²School of Pharmacy, The Chinese University of Hong Kong, Hong kong, ³Lee Hysan Clinical Research Laboratories, The Chinese University of Hong Kong, Hong kong

Purposes AIS is a prevalent three-dimensional spinal deformity associated with low bone mass which has been reported to be a significant prognostic factor for curve progression in AIS. If left untreated, low bone mass in AIS could persist into adulthood thus leading to subsequent health problems. This study aimed at evaluating the therapeutic effect of oral calcium plus Vit-D supplementation for low bone mass in skeletally immature AIS girls. **Methods** This was a randomized double-blinded placebo-controlled trial recruiting AIS girls (11-14 years old, Tanner < IV) with BMD Z-scores <0 and Cobb angle >15°. 330 subjects were randomly allocated to Group1 (placebo), Group2 (600mg Calcium + 400 IU Vit-D3/day) and Group3 (600mg Calcium + 800 IU Vit-D3/day). The study period was two years. At baseline (T0) and 24-month (T1) time-point, aBMD and BMC at bilateral femoral necks were measured with Dual-Energy X-ray Absorptiometry (DXA); and serum 25(OH)Vit-D level was measured with liquid chromatography tandem mass spectrometry. Intention-to-Treat principle was followed. ANOVA and Generalized Estimating Equations were used for analyses. Results The baseline data at T0 are shown in Table 1. The corresponding mean % increases at T1 are shown in Table 2. The gain in right and left aBMD and BMC were significantly greater in the treatment group than the placebo group (Table 2) **Conclusions** The results provided strong evidences that treatment with 600mg calcium + 400/800 IU Vit-D3 was effective for treating low bone mass in AIS subjects having Z-score <0. Given the suboptimal 25(OH)Vit-D levels detected in this study and the association between AIS and low bone mass, Vit-D status and bone mineral density should be assessed and be followed as indicated by calcium+Vit-D supplementation for all AIS subjects.

EPO Attenuation of Bone Formation Is Mediated by the Plexin B1-Sema4D Pathway. Sahar Hiram-Bab¹, Tamar Liron¹, Namit Deshet-Unger¹, Moshe Mittelman¹, Max Gassmann², Martina Rauner³, Ben Wielockx⁴, Drorit Neumann¹, Yankel Gabet¹. ¹Tel Aviv University, Israel, ²Institute of Veterinary Physiology, Vetsuisse Faculty, & Zurich Center for Integrative Human Physiology (ZIHP), University of Zurich, Switzerland, ³Department of Medicine III, Dresden University Medical Center, Germany, ⁴Institute of Clinical Chemistry and Laboratory Medicine, Department of Clinical Pathobiochemistry, University of Technology, Dresden, Germany

In addition to the pivotal erythropoietic role of erythropoietin (EPO), recent publications underline EPO's non-erythropoietic functions, occurring *via* non-erythroid cells. We recently reported on the dramatic effect of EPO on bone metabolism. High EPO levels were associated with reduced bone formation (number and activity of osteoblasts) and increased bone resorption. While EPO's catabolic effect is attributable - at least in part - to EPO receptor (EPO-R) signaling in preosteoclasts, the effect on bone formation remains elusive. Here we tested whether EPO-R signaling acts directly on osteoblasts and/or indirectly via non-osteoblastic cells to suppress bone formation. Previous studies, including our own, showed that EPO administration at high doses on isolated osteoblasts resulted in no response (1 to 10 U/ml) or in enhanced osteogenesis (>50 U/ml). We therefore tested lower doses of EPO *in vitro*. Doses between 1 and 10 mU/ml EPO inhibited mineralization of primary osteoblasts, in line with the *in vivo* observation, thus demonstrating a direct effect of EPO-R signaling in these cells. We then tested whether EPO-R signaling renders the osteoblasts more sensitive to inhibitory signals from other cells. The Plexin B1-Sema4D axis is one of the few identified osteoblasts' inhibiting pathways involving osteoclast-to-osteoblast communication. Expression levels of Plexin B1, the osteoblastic receptor of Sema4D, were increased in total bone marrow (BM) RNA from EPO-injected mice as well as in EPO-treated (1 to 10 mU/ml, versus vehicle) isolated primary osteoblasts. To test indirect mechanisms, we also examined BM total mRNA expression of Sema4D. In EPO-treated mice as well as in constitutively EPO-overexpressing Tg6 animals, high levels of EPO were associated with a ~2-fold increase in Sema4D expression. Moreover, EPO administration (10 U/ml) in differentiating preosteoclasts in cultures (treated with RANKL and M-CSF), induced a 1.4-fold increase in Sema4D transcript levels. Here we present a dual direct and indirect pathway of EPO action in bone cells in the inhibition of bone formation. These findings support the notion that EPO-R signaling in both osteoblasts and osteoclasts affects bone turnover via direct effects as well as through the regulation of paracrine signals.

MO0063

Bone Marrow Blood Vessel Ossification is Present in 1-month-old Fischer-344 rats and Coincides with Altered Bone and Hematological Parameters in Advanced Age. Sophie Guderian¹, Mary Ann McLane², Rhonda Prisby³. ¹The University of Delaware, USA, ²The University of Delaware Department of Medical Laboratory Sciences, USA, ³The University of Delaware Bone & Microcirculation Lab, USA

Advanced age corresponds with reduced bone mass and blood flow, diminished hematopoiesis, vascular rarefaction, and augmented marrow adiposity and ischemia (Prisby et al., 2007; Burkhardt et al., 1987; Kita et al., 1987). Further, we discovered ossification of bone marrow blood vessels (BMBV) in 6- and 24-month old rats (Prisby, 2014). Since, bone marrow is the site for erythrocyte and lymphocyte production and blood cells access the peripheral circulation via blood vessels, we sought to assess whether ossification coincides with age-related declines in red and white blood cell count. We kinetically examined the development and progression of BMBV ossification and hematological parameters as a function of advancing age. Left femora and whole blood samples were collected from young (1 mon; n=4), middle-aged (12 mon; n=5) and aged (24 mon; n=6) male Fischer-344 rats. Bone microarchitecture (BV/TV, %; Tb.N, /mm²; Tb.Th, μ m & Tb.Sp, μ m) in distal femora and ossified vessel volume (OsVV) in femoral shafts were assessed by μ CT (Scanco Medical). Density (g/cm³) and SMI were compared between bone and ossified vessels. Complete blood counts were determined with a Coulter[®] AcT diffTM Analyzer (Beckman Coulter). Body mass (p<0.05) increased with age. BV/TV was higher in middle-aged (25.9 \pm 1.1%) vs. young (17.4 \pm 0.26%) and aged (13.9 \pm 1.6%) rats, resulting from an augmented Tb.N and Tb.Th. Tb.Sp was greater (p<0.05) in young (2098 \pm 203 μ m) vs. middle-aged (237 \pm 9 μ m) and aged (463 \pm 42 μ m) rats. OsVV increased (p<0.05) across the lifespan (young, 0.075 \pm 0.02%; middle-aged, 0.57 \pm 0.18% and aged, 2.00 \pm 0.41%) and coincided with SMI values indicative of cylindrical (range: 3.0-4.0) vs. plate-like shapes of middle-aged (range: 0.7-1.2) and aged (range: 0.9-2.1) trabecular bone. Bone was denser

MO0061

Bone marrow niche crippled by obesity is dependent on potent bone marrow HSC transplants for repopulation. Divya Krishnamoorthy¹, Benjamin J. Adler², Tee Pamon², Jayant Srinivas Sankaran², Danielle M. Frechette³, Clinton T. Rubin². ¹SUNY Stony Brook University, USA, ²Stony Brook University, USA, ³Stony Brook, USA

Obesity is associated with systemic complications that are realized not only in the skeleton but also within bone marrow (BM) niches. Understanding obesity driven disruptions to BM hematopoietic (HSC) and mesenchymal stem cell fate can help elucidate the mechanisms by which musculoskeletal and immune systems are compromised by adipose invasion into the BM. Using a high-fat diet model of obesity, *in vivo* HSC function was first analyzed by their ability to repopulate a system following bone marrow transplantation (BMT). 6w old male B6 mice were pre-fattened with either a 60% fat (HF, n=5) or 10% fat (RD, n=5) diet for 7w in order to establish an obese or lean phenotype, respectively. Mice were lethally irradiated (6+6 Gy), rescued by BMT consisting of equal doses of enriched cd45.1 tagged HSCs (LSK⁺). Control animals (n=6) were on a lean diet, received no irradiation and saline BMT. By 1w post-irradiation, RD and HF mice lost 8 & 12% of body weight, respectively. However, while RD recovered their weights by 8w, HF had not reestablished body weight by 16w, suggesting the extent to which obesity hinders the rate of tissue recovery. Interestingly, flow cytometric analysis showed that HF mice had an overall increased engraftment of donor cd45.1 cells in bone marrow, peripheral blood as well as visceral fat depots compared to RD, with +149% (p=0.068), +260% (p<0.05) and +55% (p=0.08) increase. Indicating that in spite of significant bone loss that results from radiation and HF, there was successful engraftment and repopulation into multiple tissues as cd45.1 leukocytes were also quantified. Further, the contribution of donor cd45.1 cells to total BM leukocytes in HF was +53% (p>0.05) greater than those contributed by recipient non cd45.1 cells, while there was an opposite trend of -211% (p<0.05) fewer donor cell contribution in RD mice. From these finding we hypothesize that HF recipient BM HSC stores were either more sensitive to radiation than those in RD, or more severely compromised by the HF diet thus repopulation of the immune system was more dependent on the donor cd45.1 HSCs. In conclusion, the results from this competitive repopulation assay, where a pre-established marrow niche was competing with potent donor HSCs, may be indicative of a failing marrow in HF where donor cd45.1 HSCs proved to be dominant and more relevant to recovery. In effect, skeletal deterioration following HF maybe

($p < 0.05$) but similar to the densities of ossified vessels at all ages. Red blood cell (RBC; $8.0 \pm 0.1 \times 10^6/\mu\text{L}$ vs. $6.2 \pm 0.1 \times 10^6/\mu\text{L}$ & $6.6 \pm 0.9 \times 10^6/\mu\text{L}$), hemoglobin (Hgb; $14.1 \pm 0.3 \text{ g/dL}$ vs. $11.8 \pm 0.3 \text{ g/dL}$ & $12.7 \pm 0.8 \text{ g/dL}$) and hematocrit (Hct; $41.5 \pm 0.7\%$ vs. $35.7 \pm 0.8\%$ & $37.6 \pm 2.0\%$) were higher in middle-aged vs. young and aged rats, respectively. Percent lymphocyte (%LY) declined with age (young, $84 \pm 2\%$; middle-aged, $77 \pm 2\%$ & aged, $60 \pm 2\%$) and was negatively correlated ($r^2 = -0.81$, $p = 0.00$) with OsVV. Ossified vessels were prevalent as early as 1 month and OsVV progressively worsened with advancing age. This vascular pathology coincided with reduced bone mass, RBC, Hgb, Hct and %LY from 12- to 24-months.

MO0064

Bone marrow mesenchymal stem cells are recruited towards expansion of fat depots, a migration accelerated by high fat diet and disrupted by mechanical signals. Danielle Frechette*, Divya Krishnamoorthy, Vihitaben Patel, Meilin Chan, Clinton Rubin. Stony Brook University, USA

Obesity, an expanding epidemic, involves significant adipose accumulation that may depend in part on the recruitment of mesenchymal stem cells (MSC) from bone marrow (BM). Using GFP+ cell tracking, we hypothesized that high fat diet would enhance the migration of bone marrow cells to extra-BM fat depots, while low intensity vibration (LIV) would interrupt this fate by biasing differentiation towards forming higher order tissues such as bone. Following (6+6) Gy of ^{137}Cs γ -irradiation, 8w male C57BL/6 mice received intravenous GFP+ bone marrow transplants (BMT). Irradiated mice were fed a 45% high fat (HD, $n=20$) or 10% regular (RD, $n=20$) diet for 10w. Age-matched controls were sham irradiated and given saline injections (AC, $n=10$). At 2w, 50% of mice from each diet group were vibrated (RDV, HDV) (0.25g, 90Hz) for 30min/d and 5d/w. FACS quantification of MSC (Sca1+/C-Kit+/CD44+/CD90.2+/CD105+) was performed from either pooled BM of femur and tibia or epididymal fat pad. After 10w, transplanted bone marrow cells (GFP+) were detected in the fat pads of all BMT groups (between 26-30% of total fat cell population excluding adipocytes), demonstrating that bone marrow cells contribute to formation of extra-BM fat depots and/or function. Further, transplanted MSC proportions were higher in only HD compared to AC (+51.5%, $p < 0.05$), showing acceleration of MSC fate to extra-BM tissues due to diet. The proportion of total transplanted bone marrow cells in the epididymal fat pad was higher in both HD and HDV groups compared RD (+55%, +60%, respectively; $p < 0.05$) despite no differences in visceral fat pad weights, likely due to an increase in adipose inflammation. In the BM cavity, MSC proportions were decreased in LIV compared to AC (RDV: -24%, $p \leq 0.05$; HDV: -27%; $p = 0.07$) while non-vibrated groups did not see similar declines. Differentiation markers of fat (PPAR γ) and bone (Runx2) showed no differences in the BM, suggesting the noted changes with LIV may be due to stem cell migration or differentiation at an earlier time point. Together, these data demonstrate that bone marrow cells contribute to extra-BM fat depots and possibly the fat pad inflammatory response, while high fat diet specifically accelerates BM MSC recruitment to abdominal fat depots.

Alternative activation of macrophages by IL-10 promotes efferocytosis of osteoblasts. Megan Michalski*, Amy Koh, Hernan Roca, Laurie McCauley. University of Michigan School of Dentistry, USA

Macrophages play a key role in the inflammatory and resolution phases of wound healing and promote intramembranous bone healing in animal models of osseous injury. Apoptotic cells are increased in the early phases of wound healing and are engulfed by alternatively activated (M2) macrophages, a process termed efferocytosis. The role of efferocytosis during the process of osseous wound healing has not been examined. The objective of this study was to define the role of macrophages in clearing apoptotic bone cells. Bone marrow macrophages harvested from 4-8wk C57BL/6, IL-10KO or BALB/c mice were differentiated *in vitro* with M-CSF for 6-7d and treated with rIL-10 (0.1-100ng/mL) or vehicle for 24h. Bone marrow stromal cells (BMSCs) harvested from 4-8wk C57BL/6 mice or MC3T3-E1 (subclone 4, MC4) pre-osteoblastic cells were grown to confluency, stained with cell tracking dye, and apoptosis (ap) induced with UV light. Macrophages were incubated with apBMSCs or apMC4 cells for 0.5-6.0hrs. Efferocytosis was assessed via fluorescence-activated cell sorting (FACS) for cells exhibiting double-positive immunofluorescence for F4/80 and cell tracker, reflecting internalized apBMSCs within macrophages. Double positive gates were confirmed using ImageStream analysis and IDEAS software for imaging of gated populations. Bone marrow macrophages treated with rIL-10 (10ng/mL; 24h) were analyzed for the M2 phenotype via double positive staining for F4/80 and CD206 (mannose receptor). FACS analysis showed a significant increase in double-positive immunofluorescent cells in cultures pre-treated with 1-100ng/mL rIL-10 compared to vehicle, with 10ng/mL showing the largest increase ($p < 0.01$). The greatest change in efferocytosis between vehicle and treatment groups was apparent at 0.5-1hr of co-culture. Additionally, IL-10 promoted alternatively activated macrophages, detected by increased CD206-antibody staining ($p < 0.01$). Efferocytosis of MC4 cells by IL-10KO vs. BALB/c macrophages was not different, and both displayed increased efferocytosis and M2 polarization with IL-10 treatment ($p < 0.05$). Efferocytosis of apoptotic bone cells by macrophages is enhanced with IL-10 treatment and M2 polarization. Upregulation of IL-10 in bone may enhance effective clearing of apoptotic bone cells and other debris in an osseous wound environment, promoting optimal healing.

MO0066

A Novel Sequestosome-1 / p62-ZZ Domain Inhibitor Prevents Gfi1-Mediated Epigenetic Suppression of Runx2 in Myeloma Exposed Preosteoblasts. Rebecca Silbermann*¹, Juraj Adamik², Dan Zhou³, Xiang-Qun Xie², Noriyoshi Kurihara³, Deborah Galson², G. David Roodman³. ¹Indiana University School of Medicine, USA, ²University of Pittsburgh, USA, ³Indiana University, USA

Myeloma bone disease (MMBD) is a paradigm for uncoupled bone remodeling, with increased bone destruction and persistent osteoblast (OB) suppression in the absence of MM cells. As the mechanisms mediating long term OB suppression in MMBD are unclear, we hypothesized that MM cells induce epigenetic changes to the Runx2 promoter, the key regulator of OB differentiation, in bone marrow stromal cells (BMSC), which are preOB. We found that the transcriptional repressor Gfi1 directly binds and recruits the chromatin corepressor HDAC1 to Runx2 in MM exposed preOB, reducing euchromatin marks such as H3K9ac. Importantly, this reduction persists in the absence of MM cells, suggesting these epigenetic changes result in long term OB suppression.

We recently showed that p62 (sequestosome-1) in BMSC is a platform for the formation of signaling complexes critical to MMBD and that XRK3F2, an inhibitor of the p62-ZZ domain, induced new bone formation in mice with established MMBD, but did not affect bones without MM. Interestingly, osteoclasts were noted in the new bone, suggesting that XRK3F2 restores coupled bone remodeling in the presence of MM. These data suggest that p62 is critical to the persistent OB suppression of MMBD. We hypothesized that XRK3F2 prevents Gfi1-induced epigenetic suppression of Runx2 and showed that XRK3F2 blunted MM cell induction of Gfi1 expression and Runx2 repression in preOB. We then performed ChIP analyses of MM exposed preOB treated with XRK3F2 and found that XRK3F2 decreases both MM induced Gfi1 occupancy and prevents the decrease of H3K9ac at the Runx2 promoter, consistent with a lack of Runx2 mRNA suppression. As we found that TNF α is a major suppressor of OB in MMBD that reduces Runx2 levels and induces Gfi1 in preOBs, we compared the epigenetic changes at Runx2 induced by TNF α to those in MM exposed preOB and found them similar. To determine how XRK3F2 alters MM effects on OB, we tested if XRK3F2 blocked TNF α -induced signaling or changed TNF α production in the MM marrow microenvironment. XRK3F2 blocked TNF α -induced NF κ B signaling in preOB and in MM cells. Interestingly, adding XRK3F2 to cocultures of MM cells with murine BMSC blunted the upregulation of TNF α observed in both MM and BMSCs after coculture, but did not alter TNF α production in cocultures of p62^{-/-} BMSC and MM cells. These results suggest that targeting the p62-ZZ domain in MMBD may restore coupled bone remodeling in MM.

Etoposide directs apoptosis and myeloid driven cell clearance with net negative impacts on bone. Amy Koh*, Megan Michalski, Benjamin Sinder, James Rhee, Laurie McCauley. University of Michigan, USA

Chemotherapy is widely used for the treatment of various cancers and has often been attributed for negative effects in bone. Etoposide, is a chemotherapy which targets rapidly dividing cells, inducing them to undergo apoptosis. While tumor cells are the intended target, normal cells are affected as well. The aim of this study was to determine the impact of etoposide on bone and the bone marrow microenvironment. Sixteen week old female C57B6 mice were injected i.p. with etoposide (20mg/kg) or vehicle in two different regimes: 1) daily for 5d or 9d, or 2) daily for 5d then 3x/wk for 6wks. Skeletal phenotyping, flow cytometry, serum bone markers, and marrow gene expression were analyzed. After 5 days of treatment, etoposide significantly reduced RBC and WBC populations, reducing neutrophil, lymphocyte and monocyte numbers by 50% and increasing platelet numbers. In the bone marrow, etoposide increased early apoptotic cells (AnnexinV⁺PI⁻), Lin⁻CD29⁺sca1⁺ (mesenchymal stem cells, MSCs) and CD45⁺ leukocytes. Myeloid CD11b⁺, and phagocyte CD68⁺ cells in combination with the expression of MER (an apoptotic bridge receptor tyrosine kinase) were also increased. Etoposide had noted bone effects as early as 9 days resulting in a significant decrease in tibial bone area (via histomorphometry) and femoral bone volume (via microCT). In the longer treatment regime, flow cytometry of the bone marrow cellular population revealed increased CD68⁺, monocyte Gr1⁺, CD11b⁺, F4/80⁺, CD45⁺ and MSCs. MicroCT and histomorphometry revealed etoposide decreased tibial bone volume and bone area, with decreases in both trabecular thickness and cortical bone volume. Serum TRAcP5b was increased with etoposide, while PINP levels were unchanged. Functionally, flow cytometry revealed that CD68⁺ cells in the bone marrow were significantly increased and were significantly more effective at phagocytosing carboxylated beads which suggested instigation of the cell clearance program. Gene expression studies revealed that etoposide increased CCL2 (MCP-1) expression in the bone marrow which could explain the increased myeloid cell population and the bone resorptive phenotype. These data indicate that induction of apoptosis via the chemotherapeutic agent etoposide skews normal bone marrow in favor of monocyte/macrophage populations as well as MSCs, yet ultimately has deleterious effects on bone.

MO0068

Osteocytes are an Important Mediator of Bone Pain in Myeloma. Masahiro Hiasa*¹, Tatsuo Okui², Yuki Nagata², Yohance M Allette³, Matthew S Ripsch³, Jesús Delgado-Calle⁴, Teresita Bellido⁴, G David Roodman², Lilian Plotkin⁴, Fletcher White³, Toshiyuki Yoneda². ¹Indiana University School of Medicine, USA, ²Department of Medicine, Hematology Oncology, Indiana University School of Medicine, USA, ³Department of Anesthesia, Paul & Carole Stark Neurosciences Research Institute, USA, ⁴Department Anatomy & Cell Biology, Indiana University School of Medicine, USA

Bone pain is one of the most prevalent and devastating complications of multiple myeloma (MM). Although the mechanisms of MM-associated bone pain (MABP) remain unclear, complex interactions between cancer cells and bone cells in the bone microenvironment are likely critical to the pathophysiology of MABP. Several studies have reported that calcitonin gene-related peptide-positive (CGRP+) sensory neurons (SN) deeply innervate mineralized bone where numerous osteocytes (OCy) reside and develop cell-cell networks, suggesting that OCy and SN may interact. We propose that these interactions occur and play an important role in the pathophysiology of MABP. To test this hypothesis, we examined whether OCy and SN fibers are in physical contact in bone, and if they could exchange small molecules via these connections. We found that CGRP+ SN fibers in bone were in direct physical contact with OCy, predominantly via connexin 43 (Cx43) on OCy. Further, co-culture of MLO-A5 osteocytic cells with F11 SN cells demonstrated that F11 cells contacted with dendritic processes of MLO-A5 cells by extending their neurites and exchanged small soluble molecules with MLO-A5 cells, as determined by transfer of permeable dye calcein. Using Ca²⁺ influx imaging assays, we also found that co-culture with MLO-A5 cells enhanced F11 cell excitation induced by acid (pH 6.5), which, we showed, corresponds to the acidic microenvironment developed in MM-bearing bone. Importantly, addition of GAP27, a selective inhibitor of Cx43, or knockdown of Cx43 in MLO-A5 cells abolished the enhanced F11 cell excitation seen in the co-culture. To confirm that blocking Cx43 also affected bone pain in vivo, mice injected intratibially with human MM JN3 cells were treated with GAP27 and assessed for MABP by measuring tactile hypersensitivity and thermal hyperalgesia in JN3-bearing tibiae and expression of p-ERK, a molecular marker of pain, in the dorsal root ganglia. We found marked suppression of MABP and p-ERK in mice treated with GAP27 compared with vehicle-treated control mice. These data demonstrate that OCy and SN are in intimate physical contact in mineralized bone, and that they exchange small molecules via Cx43 gap junctions or hemi-channels to induce SN excitation that results in severe MABP. These results further suggest that targeting Cx43-mediated OCy-CGRP+ SN fiber contacts may provide a new potent approach for treating the devastating bone pain seen in patients with MM.

Curcumin promoting osteosarcoma cell death by activating miR-125a/ ERRA/ ROS pathway. Peng Chen*¹, Haibing Wang², Junjian Wang³, Wei He². ¹First School of Clinical Medicine of Guangzhou University of Chinese Medicine, USA, ²First Affiliated Hospital of Guangzhou University of Chinese Medicine, China, ³Cancer Center, UC Davis, USA

Curcumin (CUR) shows valuable therapeutic potential against a variety of cancers. However, the molecular mechanism underlying antitumor remains unclear. By RNA sequence profiling, we found that curcumin effectively suppressed ERRA and its target gene expression. Employing ERRA ectopic stable cell line, we found that ERRA overexpression blocked CUR-induced cell death through down-regulating CUR induced ROS production, and ERRA silencing sensitized osteosarcoma cells to CUR-induced cell death. Furthermore, our results also revealed that CUR suppressed ERRA expression through enhancing miR-125a level. In conclusion, our results revealed a novel mechanism for CUR induced cell death, which involves tumor cell killing via activating miR-125a/ ERRA/ROS pathway and provide further support for targeting ERRA only or combine with CUR in the potential cancer therapy.

Enhanced sensitivity of bone seeking breast cancer cells to Metformin by targeting Runx2-IGF-1R β and AMPK-Erk pathway. Manish Tandon*, Ahmad Othman, Zujian Chen, Jitesh Pratap. Rush University Medical Center, USA

The breast cancer metastasis is a major cause of skeletal-related events and patient mortality due to lack of effective targeting strategies against tumor survival in bones. The breast cancer cells preferentially survive in hypoxic and growth factor rich bone microenvironment, however, the underlying molecular mechanisms are not clear. Here we show that bone-derived breast cancer cells can be sensitized to Metformin by targeting Runx2-related transcription factor (Runx2) regulatory network. Since Runx2 regulates osteoblast differentiation, growth factor and metabolic signaling, mammary gland morphogenesis, invasive properties and cell survival during stressful conditions, we investigated its role in invasive breast cancer survival in bones. We performed systemic inoculation of control or Runx2 knockdown invasive MDA-MB-231 cells in NOD/SCID mice, and compared parental and bone-derived variants for phenotypic and molecular alterations. Both control and Runx2 knockdown cells showed tumor growth in bone coupled with osteolysis. Notably, the Runx2 knockdown cells showed early (0-2 weeks) delay but late (4-6 weeks) aggressive metastatic outgrowth in bones suggesting Runx2-dependent bi-phasic response and reprogramming of survival pathways. The late-stage tumor growth and bone loss in Runx2 knockdown cells associated with increased IGF-1-induced pIGF-1R β and pAkt signaling. Interestingly, glucose uptake and glycolysis were reduced in the Runx2 knockdown cells due to reduced extracellular-regulated protein kinase (Erk1/2) activity leading to the activation of AMP activated protein kinase (AMPK), the sensor of cellular metabolism. Therefore, we tested if Runx2 expression alters the sensitivity towards pharmacological compounds targeting IGF-1R β , AMPK and Erk1/2 signaling pathway. The Runx2 knockdown increased the sensitivity towards both Erk1/2 inhibition and AMPK activation by PD184161 and Metformin, respectively. The growth inhibitory effects were increased in bone-derived Runx2 knockdown cells compared to controls as indicated by cellular rounding, cytoskeletal condensation and reduced metabolism. In addition to increased pAMPK levels, p70S6K were significantly downregulated in Metformin treated Runx2 knockdown cells. Collectively, our results reveal a critical link between de-regulated energy metabolism and cell survival via Runx2, AMPK-Erk1/2 and IGF-1R β -Akt signaling crosstalk, and support repositioning Metformin treatment for breast cancer bone metastasis.

P38 MAPK regulates the Wnt-inhibitor Dickkopf-1 in osteolytic prostate cancer cells. Andrew Browne¹, Andy Göbel¹, Martina Rauner¹, Lorenz Hofbauer¹, Tilman Rachner^{*2}. ¹Technische Universität Dresden, Department of Medicine III, Germany, ²University Hospital Dresden, Germany

Prostate cancer (PCa) is the most common cancer in men above 50 years of age with a predilection to metastasize to bone in advanced stages.

The Wnt-inhibitor Dickkopf-1 (DKK-1) has been described to be highly expressed in bone metastasizing cancers and is thought to inhibit osteoblast function thereby enhancing the osteolytic process. P38 MAPK (p38) activity is also dysregulated in patients with advanced stages of cancer and has previously been shown to regulate DKK-1 in multiple myeloma. This study aimed to clarify the regulatory function of DKK-1 by p38 in PCa.

DKK-1 was barely expressed in MDA-Pca2b and C4-2B cell lines which are known to induce osteoblastic and mixed lesions in vivo respectively. In contrast, the osteolytic PC3 cells had a high level of DKK-1 expression as measured by qPCR and by ELISA (p<0.005). Treatment of the osteoblastic cell line C2C12 with supernatants

of PC3 cells, but not MDA-PCa2b supernatants, led to a significant suppression of Wnt3a inducible osteoblastic markers including alkaline phosphatase and osteopontin. This inhibition could be reversed by adding a neutralizing DKK-1 antibody or by knocking down DKK-1 expression in PC3 cells using siRNA. The expression and secretion of DKK-1 was significantly decreased by the p38 inhibitors LY2228820 and SB202190 ($p < 0.001$). Vice versa, treatment of PC3 cells with anisomycin, which activates the MAPK pathway, increased DKK-1 ($p < 0.01$). Knockdown of p38 in PC3 cells using siRNA further confirmed the link between p38 and DKK-1 expression ($p < 0.001$).

Assessment of DKK-1 expression and p38 isoforms (MAPK11, MAPK12 and MAPK14) in prostate cancer samples using a cDNA array containing samples from 48 patients revealed an increased DKK-1 expression in prostate cancer compared to benign tissue and a significant positive correlation between DKK-1 and MAPK11 and MAPK14.

These results indicate that DKK-1 is regulated by p38 in osteolytic PCa cells. Future investigations may strengthen the role of both DKK-1 and p38 activity as novel therapeutic targets in PCa-induced osteolytic bone lesions.

Runx2 is associated with poor survival in dogs with malignant mammary tumors. Kristi Milley*¹, Eman Saad², Syu Mi Sam², Barbara Bacci³, Judith Nimmo⁴, Samantha Richardson², Janine Danks⁵. ¹RMIT University, Australia, ²School of Medical Sciences, RMIT University, Australia, ³School of Veterinary Science, The University of Melbourne, Australia, ⁴Australian Specialised Animal Pathology Laboratories, Australia, ⁵School of Medical Science, RMIT University, Australia

Runx2 is a master-regulator of bone development and is essential for osteoblast differentiation. Recent data has outlined a potential role for Runx2 in breast cancer development. The loss of Runx2 expression, in transgenic mouse models, resulted in increased tumor latency and increased overall survival. As canine mammary tumors (CMTs) are a good natural model for human breast cancer, our aim was to evaluate the potential of Runx2 as a prognostic marker using these companion animals. Samples were prospectively collected by the Australian Veterinary Cancer BioBank and follow-up data on recurrence and survival was collected until death. Runx2 was localized in benign (n=21) and malignant (n=69) CMTs as well as in adjacent normal mammary tissue (n=37) by immunohistochemistry. In addition, malignant samples were also subtyped using a five antibody panel (ER, HER2, p63, CK5 and Vimentin). Finally, Runx2 gene expression was quantified in both normal and CMT samples from animals which had corresponding RNA-stabilized frozen tissue available. Runx2 protein was localized in the nuclei of 92% of normal mammary samples, 81% of benign CMTs and 78% malignant CMTs. A subset of Runx2 positive malignant CMTs (15/54) demonstrated significantly stronger staining compared to normal samples. This increased Runx2 staining was associated with poor survival ($p < 0.0001$). The median survival of dogs with increased Runx2 was only 258 days compared to 724 days for Runx2 negative tumours. Runx2 was not associated with a specific subtype but was more common in basal-like and HER2+ subtypes. Our study is the first to demonstrate and link the presence of Runx2 in CMTs to survival. Overall, our results support the potential use of Runx2 as a prognostic marker for breast cancer.

CD44 and RUNX2 Peptides Prevents Osteoclastogenesis by Suppressing RANKL Expression in Prostate Cancer PC3 cells. Meenakshi Chellaiiah*¹, Aditi Gupta². ¹University of MarylandDental School, Us, ²University of Maryland, USA

Background: Pathological skeletal fractures develop in prostate cancer patients as a result of bone loss induced by androgen deprivation therapy and bone metastases. In this regard, bone-resorbing osteoclasts are essential in mediating bone loss induced by metastatic prostate cancer cells homing to the skeleton. Therefore, there is a critical need for novel pharmacotherapeutic approaches to control this debilitating disease. We have previously demonstrated that prostate cancer cells secrete receptor activator of NF- κ B ligand (RANKL), a protein essential for osteoclast differentiation and activation. The objective of our study is to inhibit the expression and function of RANKL in metastatic prostate cancer cells.

Results: We used prostate cancer cells lines derived from a variety of anatomic metastases. We found a significant increase in the expression of CD44, a cell surface receptor in prostate cancer cells derived from human bone metastases (PC3) as compared with those derived from brain (DU 145) or lymph node (LNCaP) metastases. CD44 expression is very negligible or not observed in LNCaP cells. We find that RUNX2 and Smad 5 are involved in the regulation of expression of RANKL. CD44 and α v β 3 signaling pathways support RANKL expression by phosphorylation of RUNX2 and Smad 5 proteins, respectively. RUNX2-Smad 5 complex formation and intranuclear targeting of RUNX2 are functionally required for this process. An inhibitor to integrin α v and siRNA to CD44 attenuated the expression of RANKL in PC3 cells. Immunohistochemistry analysis of tissue microarray sections containing primary prostatic tumor (grade2-4) detected pre-

dominant localization of RUNX2 and phosphorylated Smad 5 in the nuclei. Small molecular weight peptides to CD44 and RUNX2 have the potential to block localization of RUNX2 in nuclei and RANKL expression/secretion. As a consequence of these peptide-based approaches, conditioned media from these cells failed to support osteoclast formation in vitro.

Conclusions/Future Perspectives: We found that CD44 and RUNX2 peptides have the potential to block RANKL expression by PC3 cells. Studies are under way to test for the efficacy of these peptides in the inhibition of metastasis to bone and subsequently bone loss by osteoclast differentiation in animal models. We envision that peptide-based therapeutics will greatly impact cancer treatment in the near future. Ultimately, these peptides could be useful for the development of novel therapies for the treatment of prostate cancer bone metastases (Supported by NIH-NIAMS 5 R01 AR066044-02).

TRAIL is not a proapoptotic but rather anti-apoptotic mediator for osteoclasts to stimulate their differentiation and survival. Hirofumi Tenshin*¹, Jumpei Teramachi², Asuka Oda³, Ryota Amachi¹, Masahiro Hiasa⁴, Keiichiro Watanabe¹, Shingen Nakamura³, Hirokazu Miki⁵, Itsuro Endo³, Eiji Tanaka¹, Toshio Matsumoto⁶, Masahiro Abe³. ¹Department of Orthodontics & Dentofacial Orthopedics, Institute of Biomedical Sciences, Tokushima University Graduate School, Japan, ²Department of Histology & Oral Histology, Institute of Biomedical Sciences, Tokushima University Graduate School, Japan, ³Department of hematology, endocrinology & metabolism, Institute of Biomedical Sciences, Tokushima University Graduate School, Japan, ⁴Department of Biomaterials & Bioengineering, Institute of Biomedical Sciences, Tokushima University Graduate School, Japan, ⁵Division of Transfusion Medicine & Cell Therapy, Tokushima University Hospital, Japan, ⁶Fujii Memorial Institute of Medical Sciences, Tokushima University, Japan

Myeloma (MM) cells preferentially reside in the bone marrow, and develop extensive osteolytic lesions. TNF-related apoptosis-inducing ligand (TRAIL) selectively induces apoptosis in various cancers including MM. Although TRAIL agonists are considered as an attractive anti-MM agent, the impact of TRAIL-mediated immunotherapy on osteoclast (OC) formation and function is unclear. The present study was undertaken to clarify the role of TRAIL-mediated signaling in OC differentiation and survival. RANK ligand time-dependently induced the expression of death receptor5 (DR5), a TRAIL receptor in mice, along with NFATc1 and cathepsin K in mouse RAW264.7 preosteoclastic cells or bone marrow cells during their osteoclastogenesis. Treatment with rTRAIL promptly induced RANK in a dose-dependent manner at 10 to 500 ng/ml to facilitate RANK ligand-mediated expression of c-fos, NFATc1 and DC-STAMP and osteoclastogenesis in RAW264.7 cells. Although DR5 expression was up-regulated in mature osteoclasts, treatment with rTRAIL at concentrations up to 500 ng/ml neither induced apoptotic cell death with caspase8 cleavage nor impaired actin ring formation in them, while rTRAIL at concentrations as low as 10 ng/ml was able to induce cell death in a portion of MM cell lines, including MM.1S. Interestingly, rTRAIL induced the degradation of I κ B α in RAW264.7 cells and OCs, suggesting deflection of DR-mediated signaling towards activation of the NF- κ B pathway while sparing the extrinsic caspase-dependent apoptotic pathway. We also found increase of TGF-beta-activated kinase-1 (TAK-1), an up-stream mediator of the NF- κ B pathway, during osteoclastogenesis. The TAK-1 inhibitor LLZ1640-2 abrogated the NF- κ B activation by rTRAIL in OCs, and impaired RANK ligand-mediated osteoclastogenesis, and triggered cell death in OCs in the presence of rTRAIL, suggesting a role of TAK-1 in the NF- κ B activation and survival by rTRAIL in OCs. Collectively, these results demonstrate that osteoclastic lineage cells efficaciously utilize TRAIL for their differentiation and activation, and that TAK-1 may play a critical role in skewing DR-mediated signaling to be anti-apoptotic but not pro-apoptotic in OCs. Caution on bone resorption should be taken in TRAIL-mediated immunotherapy especially for cancers with enhanced bone resorption such as MM.

$\alpha_v\beta_3$ -Fumagillin-prodrug Nanoparticles and Zoledronic Acid Additively Reduce Tumor Angiogenesis Through Differential Effects on Endothelial and Myeloid Cells. Alison Esser¹, Anne Schmieder¹, Michael Ross¹, Jingyu Xiang¹, Xinming Su¹, Grace Cui¹, Huiving Zhang¹, Xiaoxia Yang¹, John S. Allen¹, Chidananda Mudalagiriappa¹, Samual Wickline¹, Rebecca Aft¹, Dipanjan Pan², Gregory Lanza¹, Kathy Weilbaecher¹.
¹Washington University in St. Louis, USA, ²University of Illinois at Urbana-Champaign, USA

Innate and acquired resistance to VEGF targeted therapies is a significant problem of angiogenesis blockade for breast cancer. Effective treatments require novel non-cancer resistant strategies. This project elucidated the potential of a dual-therapy anti-angiogenic approach using $\alpha_v\beta_3$ -targeted fumagillin nanoparticles in combination with zoledronic acid. Zoledronic acid (ZA), a long acting osteoclast and macrophage inhibitor used in breast cancer patients, has anti-angiogenic properties in mouse tumors through an unknown mechanism. In a cohort of breast cancer patients receiving chemotherapy, ZA treatment decreased vascularity (CD31) relative to those without ZA ($p < 0.05$). ZA improved survival in those patients with pre-chemotherapy gene expression profiles indicative of high levels of inflammatory macrophages (CD163+) and VEGF. *In vitro*, ZA reduced macrophage viability ($p < 0.05$) without effects on endothelial cell viability or tube formation. Fumagillin (Fum), a methionine aminopeptidase-2 inhibitor, elicits anti-angiogenesis via neoendothelial apoptosis rather than by VEGF suppression. Fumagillin-prodrug (Fum-PD), a photochemically stable drug form, alone and incorporated into $\alpha_v\beta_3$ -targeted nanoparticles (NP) reduced ($p < 0.05$) endothelial cell viability and tube formation, but did not have an impact on macrophage viability. Rabbits with popliteal Vx2 tumors were given serial control, ZA, $\alpha_v\beta_3$ -Fum-PD NP, or ZA plus $\alpha_v\beta_3$ -Fum-PD NP treatment to assess the benefit of dual complementary anti-angiogenesis therapy. On day 17, tumor MR neovascular molecular imaging revealed that Fum-PD NP alone and with ZA decreased ($p < 0.05$) angiogenesis, while ZA alone did not. Microscopically, tumor vascularity (CD31) was reduced ($p < 0.05$) by both ZA and Fum-PD NP independently and further decreased ($p < 0.05$) by the dual-therapy. These data suggest a complementary role for ZA and $\alpha_v\beta_3$ -Fum-PD NPs to accelerate anti-angiogenesis benefits in aggressive tumors characterized by increased angiogenesis and inflammatory macrophages.

The purpose of this study was to elucidate the potential of a dual-therapy anti-angiogenic approach using $\alpha_v\beta_3$ -targeted fumagillin nanoparticles in combination with zoledronic acid.

MO0077

A high-throughput screening identified flucinolone acetonide as a potent synergistic factor of TGF- β 3-mediated chondrogenesis of BMSCs for articular surface repair. Emilio Hara^{*1}, Takuo Kuboki², ¹Department of Oral Rehabilitation & Regenerative Medicine, Graduate School of Medicine, Dentistry & Pharmaceutical Sciences, Japan

In this study, we performed a high-throughput screening of 640 FDA-approved drugs for compounds that can enhance chondrogenesis and interact synergistically with major growth factors (TGF- β , BMP) regulating chondrogenesis. We found that the combination of flucinolone acetonide (FA) and TGF- β 3 strongly potentiated chondrogenic differentiation of human bone marrow-derived mesenchymal stem cells (hBMSCs). In contrast, FA repressed BMP-2-mediated chondrogenesis of hBMSCs. In a newly-generated full-thickness articular cartilage defect model in knee joints of immunocompromised mice, transplantation of FA/TGF- β 3-treated hBMSCs could clearly regenerate the articular surface. However, cartilage repair could not be observed in groups that received hBMSCs treated with other glucocorticoids (dexamethasone (DEX) and triamcinolone acetonide (TA)) in association with TGF- β 3. Analysis of intracellular pathways revealed that FA enhanced TGF- β 3-induced phosphorylation of Smad2 and Smad3. Additionally, we performed a pathway array and found that FA activates mTORC1/AKT pathway. Chemical inhibition of mTORC1 with rapamycin substantially suppressed FA effect. Furthermore, activation of glucocorticoid receptor (GR) was evidently highly with FA and TA, but to a less extent with DEX. Since glucocorticoids are known to bind to GR, inhibition assays with rapamycin also suppressed FA effect, suggesting that FA action involves binding to GR. In summary, these results show a unique ability of FA to strongly enhance TGF- β 3-associated chondrogenesis, and suggest that FA/TGF- β 3 may be used as major inducers of chondrogenesis of stem cells to improve clinical outcomes for cartilage regeneration.

MO0078

Involvement of Core binding factor β in maintenance of the articular cartilage through interaction with Runx. Xiangguo Che^{*}, Clara Yongjoo Park, Na-Rae Park, Yu-Ra Choi, Da-In Yeo, Je-Yong Choi. Kyungpook National University, School of Medicine, South Korea

The function of core binding factor β (Cbfb), a partner protein of the Runx family transcription factor, has not been determined in articular cartilage. To explore the *in vivo* function of Cbfb in articular cartilage, we generated articular cartilage-specific Cbfb-deleted mice (Cbfb^{Δac/Δac}) by crossing Gdf5 promoter-driven Cre mice with Cbfb floxed mice. Osteoarthritis (OA) was induced through destabilization of the medial meniscus (DMM) surgery in 12 week-old mice. At 8 weeks, OA phenotypes were exacerbated in Cbfb^{Δac/Δac} mice compared to wild type mice. Type II collagen and Runx1 decreased and MMP13 increased in Cbfb^{Δac/Δac} OA mice compared to wild type OA mice. In addition, sham Cbfb^{Δac/Δac} mice had less Runx1 and type II collagen, and more MMP13 than wild type sham mice, though no difference was detected in joint and skeletal tissue formation. Cbfb^{Δac/Δac} mice naturally acquired phenotypes similar to mild OA from 8 months of age in which Runx1 and type II collagen diminished and MMP13 increased. Messenger RNA levels of early chondrogenic markers, including *Aggrecan* and *Col2*, decreased and late chondrogenic markers, such as *collagen X*, *Vegf* and *Mmp13*, increased in Cbfb^{Δac/Δac} mice compared to wild type mice at 1 year. Rescue of Cbfb in Cbfb-deficient primary articular chondrocytes increased Runx1 and decreased MMP13 expression. The formation of a Runx1/Cbfb complex, stabilizing Runx1 from proteosomal degradation, was detected in primary cultured articular chondrocytes as well as in ATDC5 cells *in vitro*.

Collectively, these results indicate that Cbfb is required for Runx1 stability as a partner protein in articular cartilage and that the formation of the Cbfb-Runx1 complex plays an essential role in maintaining articular cartilage integrity.

MO0079

Long-Acting Parathyroid Hormone Analog as a Therapy for Osteoarthritis in mice. Tomoyuki Watanabe^{*}, Thomas Gardella, Tatsuya Kobayashi, Braden Corbin, Monica Reves, Henry Kronenberg, John Potts. Massachusetts General Hospital, USA

The parathyroid hormone receptor-1 (PTH1R) plays a key role in regulating the proliferation and differentiation of chondrocytes in growth plate cartilage, but its role in regulating chondrocytes in articular cartilage is less well understood. Evidence suggesting that the PTH1R plays a role in maintaining the integrity of articular cartilage is provided by a recent study showing that the receptor is up-regulated in articular chondrocytes in patients with osteoarthritis (OA), as well as in rodents with surgically induced OA. Indeed, this same study showed that articular cartilage degeneration in mice with surgically induced OA can be inhibited by daily injection with PTH (1-34). We have recently developed a new high affinity, long-acting PTH analog, called LA-PTH, as a potential PTH1R-based therapeutic, and assess it here for the capacity to inhibit OA development in mice with surgical destabilization of the medial meniscus (DMM). Sham or DMM surgery was performed on the right knee of wild-type mice (C57/BL6, female, 11-weeks old), and the mice were then treated by subcutaneous injection with either vehicle, PTH (1-34) at 10 nmol/kg, or LA-PTH at 2 nmol/kg, for eight weeks at five days per week. We used LA-PTH at a five-fold lower dose versus PTH(1-34) to avoid risk of excessive bone turnover and hypercalcemia that can occur with this long-acting PTH ligand. At the end of the eight-week treatment, right knee joints were isolated and processed for histopathology. Safranin-O-stained sections were scored according to the OARSI (Osteoarthritis Research Society International) Histopathology Initiatives. In addition, the left distal femurs (non-DMM) were isolated and processed for micro-computed tomography (micro-CT) analysis of bone-mineral density (BMD).

At the end of the study, basal blood calcium levels were normal in all animal groups. Micro-CT results showed that both PTH (1-34) and LA-PTH induced modest increases in BMD in the distal femur region. The OARSI scoring results showed that articular cartilage degeneration was reduced significantly ($P < 0.05$) in both the PTH (1-34)- and LA-PTH-treated groups, as compared to the vehicle-treated group. Thus, LA-PTH, even at a five-fold lower dose, was at least as effective as PTH (1-34) in preventing OA progression in DMM mice. These results support the hypothesis that the PTH1R is a valid target for OA therapy, and that long-acting PTH analogs might provide improved efficacy.

Mechanical responsive miR-365 contributes to osteoarthritis development. Xu Yang^{*1}, Yuanhe Wang¹, Yingjie Guan², Qian Chen², Kang Sun¹.
¹Affiliated Hospital of Medical College of Qingdao University, China, ²Alpert Medical School of Brown University, USA

Purpose: Joint tissues are exquisitely sensitive to their mechanical environment. Mechanical overload is an important pathogenic factor to osteoarthritis, which is the major cause of traumatic osteoarthritis (OA). We aim to characterize the role of

mechanical responsive miR-365 in OA development by using human articular chondrocytes, animal model and OA patients. Methods: Human articular chondrocytes isolated from cartilage were seeded into 3D collagen sponges and subjected to cyclic loading. Surgically induced OA model in rats was created by anterior cruciate ligament transection and medial meniscal tear with approval from institutional animal care and use committee. Human articular cartilages were aseptically obtained from OA patients at the time of total knee replacement which have been approved by the institutional human research committee. The OA patients were divided into primary arthritis group and traumatic arthritis group according to their clinical, radiographic feature and history of trauma. The control cartilage was harvested from normal looking cartilage in non-weight bearing area from same patient. Total RNA was extracted then reverse transcribed and analyzed for expression of collagen type 2(Col2) and MMP13 by real-time PCR. miR - 365 expression level was determined by using TaqMan miRNA assay. Results: The expression of miR-365 in OA chondrocytes was significantly higher than the control as well as up-regulated in surgically induced OA cartilage compared with sham control. Overexpression of miR-365 in chondrocytes significantly reduced the mRNA level of Col2 and up-regulated MMP13. Furthermore, miR-365 expression was also significantly up-regulated by treatment with pro-inflammatory cytokine IL-1 β . Moreover, In OA patients, the miR-365 expression levels of lesion area were significantly higher than the non-lesion control both in primary osteoarthritis group as well as traumatic osteoarthritis group. Conclusions: miR-365 expression is induced by both biophysical and biochemical factors in human articular chondrocytes which constitute one of the key factors of osteoarthritic cartilage destruction. miR-365 inhibitor may be one of mechanosensitive chondroprotective molecule and a novel target in preventing cartilage degeneration.

P34HB film promote cell adhesion and proliferation in vitro and cartilage repair in vivo. Na Fu^{*1}, Yunfeng Lin². ¹Sichuan University, Peoples republic of china, ²Sichuan University, China

A. Objective The management of chondral defects is a challenging topic of current actuality for scientists and surgeons, and resultantly has an important impact on human costs. For several centuries after its first observation, this problem has not yet found a satisfactory and definitive answer. Cartilage tissue engineering, which involves novel natural scaffolds, has emerged as a promising strategy for cartilage regeneration and repair. In our previous study, the results had indicated that P34HB was a good material for tissue engineering. Therefore, in the present study, in order to further mimic the native ECM microenvironment of articular cartilage and improve the biomechanical strength of scaffold microarchitecture, P34HB film were fabricated and characterized. B. Materials and Methods In the study, the bioplastic poly(3-hydroxybutyrate-co-4-hydroxybutyrate) (P34HB) film was first fabricated. The characteristics of P34HB film were tested by using SEM and AFM, and the contact and mechanical properties of P34HB film were all tested. Cell morphologies on P34HB film were obtained by SEM and fluorescence microscopy after cell seeding. The tests of cell adhesion and proliferation on P34HB film were conducted by the MTT and CCK-8 assay, respectively. Furthermore, the full cartilage defects in rats were created and P34HB films were implanted to evaluate the healing effects within 8 weeks. C. Results By AFM, contact angle and tension test, we found P34HB film suitable for implantation for cartilage defect as a relatively favorable natural biomaterial, especially for its intrinsic hydrophilicity. RASCs seeded and green fluorescent mASCs 1 day, 3 days, 5 days and 7 days P34HB film SEM showed apparent morphological and quantity differences. Through the observation of the SEM, fluorescence microscopy we could only draw that the ASCs grow well in the P34HB film. The MTT and CCK-8 results showed that, after 3 day, the rASCs on the P34HB film had a significantly higher proliferation rate than on the petri dish group (up to ~ 81%). P34HB has been shown to have a wide range of physical properties ranging from high crystalline to elastic character depending on mol (%) of 4HB monomer. The samples from the repair sites of cartilage defects at 4 and 8 week post-surgery were evaluated by HE, Toluidine Blue O, Alcian blue and type-II collagen stains. Among the implant groups, the interfaces at 4 week were more distinct compared with those at 8 week post-surgery. At 4 week, the layers of P34HB film were clearly shown, but the newly formed tissue (NT) was gradually covered at the top of cartilage defect indentation. At this time, the original tissue (OT), newly formed tissue (NT), and P34HB film (F) were all clearly observed at the site of cartilage defects. At 8 week, a better repaired new-formed tissue gradually covered the P34HB film to form integral cartilage-like tissue. D. Conclusion In the study, the P34HB film was fabricated and the mechanical properties were characterized. The adipose-derived stem cells (ASCs) were seeded onto the films to evaluate their abilities of adhesion, and proliferation. It was found that cells seeded onto the films had better abilities of adhesion, and proliferation in vitro. Next the full thickness cartilage defects were created at the site of the femoropatellar groove of rat knee and the P34HB film scaffold were immediately implanted. After 8 weeks post-surgery, a new cartilage-like tissue was formed at the site of defects. By evaluation from histological staining to immunohistochemistry, a better integration between native tissues and scaffolds were confirmed. These results demonstrated that P34HB film scaffold has a great potential in the field of tissue engineering and may lead to better repair of cartilage defect.

Protein Malnutrition affects cartilage quality and could contribute to osteoarthritis development. CEDRIC LAVET^{*1}, Patrick AMMANN². ¹Division of Bone Diseases, Switzerland, ²Division of Bone Diseases, Department of Internal Medicine Specialties, Geneva University Hospital & Faculty of Medicine., Switzerland

IGF-I is a major anabolic agent for cartilage homeostasis. Protein malnutrition results in major alteration of the somatotrophic axis as well as IGF-I local production and thus may contribute to osteoarthritis (OA) development. Such malnutrition could also be implicated in subchondral bone (SB) alterations described in early OA. We hypothesizes that protein malnutrition could alter cartilage metabolism and predispose to OA.

To address this question, 9 months old rats were pair fed a normal or an isocaloric low protein diet (LP, 2.5% casein) for 2 months (n=6/group). Contrast enhanced computed tomography (Hexabrix) of distal femur allowed to assess cortical and trabecular SB architecture, thickness of hyaline and calcified cartilage as well as an estimation of hyaline cartilage proteoglycan (PG) density. Since early OA is characterized by PG loss and collagen network disorganization which could alter cartilage biomechanical properties we set up a novel bio-indentation technique to assess hyaline cartilage material level properties. Indentation tests corresponding to 35-40% of hyaline cartilage thickness were performed with an accuracy of 8%.

Systemic IGF-I was 18% decreased in LP group (p<.001). Hyaline cartilage biomechanical properties (force, elastic modulus and working energy) were respectively decreased by 47, 58 and 41% (p<.01) in the medial condyle of the LP group as well as SB cortical thickness (-12%, p<.05). These parameters remained unaltered in the lateral condyle. Trabecular SB mass was 10% decreased (p<.01) in LP. Medial and lateral hyaline cartilage thicknesses tended to decrease by 8-10% but not significantly without alterations of PG density, thickness of calcified cartilage and SB cortical density in LP group.

We identified alteration of hyaline cartilage biomechanical properties and SB cortical thickening at the most frequently affected condyle in OA (ie. medial condyle) as well as trabecular SB deterioration with only mild alteration of hyaline and

calcified cartilage. Since these parameters have been documented in early OA, alteration of the somatotrophic axis by LP could predispose to OA. In the medial condyle, cortical SB alteration could alter pattern of joint loads distribution and initiate OA. However, crosstalk between modulated cellular activities in LP SB and cartilage and/or alteration of the cartilage collagen synthesis could also onset OA. Since protein malnutrition is frequent in elderly this mechanism could be relevant in human.

Delayed bone fracture healing in mice due to the knockout of CaSR gene in chondrocytes. Zhiqiang Cheng^{*1}, Alfred Li², fuqing song², Hanson Ho², dolores shoback², Chia-ling Tu², wenhan chang². ¹University of California, San Francisco, USA, ²Department of Veterans Affairs Medical Center, NCIRE, University of California, San Francisco, CA, USA., USA

Bone fracture repair recapitulates key steps of endochondral bone formation. Studies of mice with extracellular calcium-sensing receptor (CaSR) gene knockout (KO) targeted specifically to chondrocytes confirmed non-redundant roles of the receptor in mediating terminal differentiation and mineralizing functions of chondrocyte, and growth delay in the mice. We now investigate the role of chondrocyte CaSR in modulating bone fracture healing by studying the repair of unfixed tibial mid-shaft fractures (created by 3-point bending) in 3-month-old Tamoxifen-inducible cartilage-specific CaSR KO (Tam-CartCaSR-KO) mice and control (Cont) littermates. Calluses were analyzed at day 10 and 28 post-fracture by histomorphometry and uCT. At day 10 post-fracture, the sizes of Tam-CartCaSR-KO calluses were significantly (p<0.05) increased by >54% when compared to Cont, as indicated by the increased tissue/callus volume (TV) by micro-computed tomography (uCT) analyses. Ablation of the CaSR gene in the cartilage of the Tam-CartCaSR-KO callus was confirmed after by genomic DNA analyses. Changes in callus size were accompanied by a 12% increase (p>0.05) in cartilage fraction (cartilage volume over TV, CV/TV) in the Tam-CartCaSR-KO calluses, as determined by von Kossa and Safranin O staining and histomorphometry. However, the ratio of mineralized cartilage volume (MCV) over CV (MCV/CV) was reduced by 38% (p<0.01) in Tam-CartCaSR-KO calluses vs Cont, indicating a delay in chondrocyte terminal differentiation and/or reduced mineralizing function. At day 28 post-fracture and in the osteogenic phase of fracture repair, TVs of Tam-CartCaSR-KO and Cont calluses were not different. However, the Tam-CartCaSR-KO calluses showed smaller bone fraction (BV/TV) by >13% (p<0.05) mainly due to decreased trabecular thickness by 21% (p<0.05) and lower bone mineral density (BMD) in the Tam-CartCaSR-KO calluses (p<0.05), as determined by histomorphometry and µCT, respectively. Our data indicate a critical role for the CaSR in promoting terminal differentiation of chondrocyte and subsequent osteogenic activity in the fracture calluses and present a novel molecular target for fracture repair.

Estrogen via Estrogen Receptor α Promotes Mandibular Condylar Chondrogenesis. Jennifer Robinson^{*1}, Jing Chen¹, Manshan Xu¹, Thomas Choi¹, Kenneth Korach², Helen H. Lu¹, Sunil Wadhwa¹. ¹Columbia University, USA, ²National Institutes of Health, USA

Purpose: Temporomandibular joint pain afflicts approximately 10% of the population. Of those affected, 30-50% experience degeneration-related diseases of the joint (TMJ-DD). Among TMJ-DD patients, the majority are women 44-65 years of age. These clinical statistics suggest the role of female sex hormones, namely loss of estrogen, in TMJ degeneration. The biological effects of estradiol are predominantly mediated by the nuclear estrogen receptors (ERs) ER α and ER β . Previously, we have illustrated the role of estrogen through ER β in inhibiting cell proliferation and estrogen independent of ER β in mediating mandibular condylar chondrogenesis. Thus, the role of estrogen through ER α on the condylar cartilage is necessary to determine the mechanism of estrogen signaling in TMJ growth and degeneration. This work details the phenotypic characterization of the condylar cartilage of 49-day old ER α KO mice.

Methods: Breeding pairs of heterozygous C57Bl/6 ER α KO +/- mice were obtained from Dr. Ken Korach. Genotyping utilizing PCR methods was done to identify homozygous female KO (n=6 for each analysis technique) and WT (n=6) mice for evaluation. Mice were euthanized at 49 days and condyles extracted for analysis. Sections were stained with hematoxylin/eosin to assess cell and matrix structure and Safranin O to observe glycosaminoglycan content. Histomorphometry was conducted to determine cartilage thickness and cell numbers. Cell proliferation was measured by BrdU labelling and quantification.

Results: No significant difference in cartilage thickness, cell numbers, or proliferation was found in the ER α KO mice compared to age-matched WT controls. A significant decrease in Safranin O-positive matrix thickness was observed in the ER α KO condylar cartilage compared to WT.

Conclusions: We have previously found that estradiol treatment caused increased chondrogenesis in both WT and ER β KO mice. In this study, despite having reported increased endogenous estradiol levels, the ER α KO mice had decreased Safranin O staining compared to age- and gender-matched WT mice. Together these results

suggest a role of ER α in mediating mandibular condylar chondrogenesis warranting further investigation.

Halofuginone Attenuates Osteoarthritis by Inhibition of TGF- β activity and H-type Vessel Formation in Subchondral Bone. Zhuang Cui^{*1}, Janet Crane¹, Hui Xie¹, Xin Jin¹, Gehua Zhen¹, Changjun Li¹, Liang Xie¹, Long Wang¹, Qin Bian¹, Tao Qiu¹, Mei Wan¹, Sheng Ding², Bin Yu³, Xu Cao¹. ¹Johns Hopkins University School of Medicine, USA, ²University of California, San Francisco, USA, ³Nanfeng Hospital, Southern Medical University, China

Osteoarthritis (OA) is the most common degenerative joint disease and major cause of physical disability. Abnormal vascular congestion in subchondral bone has long been recognized as a pathologic feature of OA. A specific subtype of vessels, termed H-type vessels as defined by high co-staining for CD31 and endomucin (CD31hiEmcnhi), have been identified in the murine skeletal system to couple angiogenesis and osteogenesis. Our recent study demonstrated that the formation of subchondral bone "osteoid islet" induced by aberrant TGF- β signaling promotes OA development. In the present study, we investigated whether the increased vessels along with "osteoid islet" during the onset of OA were H-type vessels; and whether a small molecule isolated from ancient Chinese herb Chang Shan, halofuginone (HF), could attenuate OA development by inhibition of TGF- β signaling and the formation of H-type vessels. We found that HF, delivered either systemically or locally, effectively attenuates OA progression in an anterior cruciate ligament transaction (ACLT) rodent model. HF protected articular cartilage from degeneration by normalizing subchondral bone microarchitecture and prevented proteoglycan loss and calcification of articular cartilage relative to vehicle-treated ACLT control mice. HF reduced levels of collagen X and matrix metalloproteinase-13, increased expression of lubricin and resulted in substantially lower OARSI scores for cartilage degradation. In parallel, HF normalized subchondral bone microarchitecture defined by reduced subchondral bone tissue volume (TV), lower trabecular pattern factor (Tb.pf) and increased thickness of subchondral bone plate (SBP) relative to vehicle-treated ACLT controls. Furthermore, we found the underlying molecular mechanisms for the protective effect of HF on the articular cartilage rely on the inhibition of TGF- β signaling by reducing the Th17-induced TGF- β release and directly suppressing TGF- β -dependent Smad2/3 signaling in MSC/osteoprogenitor cells, as well as the attenuation of H-type vessel formation along the "osteoid islet" in subchondral bone. Therefore, halofuginone attenuates OA progression and is a potential therapeutic agent for OA.

A bioactive perlecan/HSPG2 IV-3 subdomain promotes chondrocyte condensation. Jerahme Martinez^{*}, Mary C. Farach-Carson, Brian Grindel, Jose Olmos. Rice University, USA

Perlecan/HSPG2, a large heparan sulfate proteoglycan (HSPG), is instrumental in the development and maintenance of musculoskeletal tissue including cartilage and bone. Perlecan is deposited within the pericellular matrix (PCM) of chondrocytes and turns over at the chondro-osseous junction (COJ) of developing long bones. A reduction in perlecan secretion is associated with chondrodysplasia with widespread musculoskeletal and joint defects, including the disruption of epiphyseal cartilage and bone. This work sought to elucidate novel signaling roles of perlecan and to identify cell surface receptors that initiate perlecan signaling during development. To examine the core protein of perlecan exclusively, we produced purified recombinant fragments of perlecan and tested bioactivity in a chondrogenic cell line, ATDC5. Our findings showed that a subfragment (IV-3) within domain IV of perlecan has anti-adhesive properties and promotes cell-cell adhesion and chondrocyte clustering. Furthermore, the perlecan induced cell cluster phenotype is significantly enhanced when domain IV-3 is partially unfolded by mild heating into an intermediate conformation. We tested a mutant IV-3 fragment, harboring a single residue change that is associated with the human skeletal disorder Schwartz-Jampel syndrome, and found that cell clustering activity was reduced. Through solid phase binding assays we found that perlecan domain IV-3 binds to various cell adhesion molecules (CAMs) expressed by cartilage and bone cells. We believe the ectodomains of these CAMs serve as binding partners of perlecan and initiate signal transduction associated with chondrocyte clustering. Preliminary results indicate that both FAK and Src activation are involved in the perlecan IV-3 induced phenotype. Together, these results point to a key role for perlecan in chondrocyte condensation in the developing growth plate, which is disrupted in certain chondrodysplasias.

Regulation of Chondrocyte Differentiation by miR-483. Britta Anderson^{*}, Audrey McAlinden. Washington University in St. Louis, Department of Orthopaedic Surgery, USA

Purpose: MicroRNAs (miRNAs) are important regulators of diverse cellular processes and regulate multiple genes simultaneously, typically resulting in destabilization of target mRNAs and suppression of protein synthesis. To gain insight into miRNA-mediated regulation during chondrogenesis, we recently described miRNA expression patterns in precursor, differentiated, and hypertrophic chondrocytes during human embryonic cartilage development. Among those differentially-expressed miRNAs, we discovered miR-483 to be more highly expressed in precursor and differentiated chondrocytes. We hypothesize a potential pro-chondrogenic role for miR-483. To address this, we aim to determine the effects of miR-483 on stem cell chondrogenic differentiation and whether co-regulation with its host gene, IGF2, is important.

Methods: Human bone marrow mesenchymal stem cells (BM-MSCs - Lonza) were transduced with lentivirus overexpressing miR-483 or a non-silencing (NS) control miRNA. BM-MSCs (passage 3) were seeded in Transwell inserts and cultured as three-dimensional discs for 28 days in chondrogenic medium containing 10 ng/mL TGF- β 3. RNA from two discs was pooled at each time point for gene expression analysis by TaqMan miRNA assay, SYBR Green qRT-PCR, or TaqMan gene expression quantitative RT-PCR arrays (Life Technologies).

Results: During BM-MSC chondrogenesis, miR-483-5p and miR-483-3p increase as differentiation proceeds and are upregulated approximately 30-fold by day 14. A similar trend was observed for IGF2 (~100-fold increase by day 14). Stable overexpression of miR-483 did not affect IGF2 expression during differentiation, but it did result in increased chondrogenic gene expression compared to NS control cultures. Examination of several signaling pathways known to regulate chondrogenesis revealed increased TGF β 3 and IGF1 mRNA levels and upregulation of the Wnt antagonists DKK2, SFRP1, and SFRP2, as well as the Wnt pathway transcriptional mediator LEM1 at day 4 of differentiation.

Conclusions: miR-483 promotes chondrogenesis in the BM-MSC model of differentiation, possibly by exaggerating responses to the pro-chondrogenic growth factors TGF- β 3 and IGF1 and/or by altering Wnt signaling. miR-483 does not appear to participate in a feedback loop with its host gene, IGF2 in this system. Further studies will decipher the apparent pro-anabolic effects of miR-483 in chondroprogenitor cells as well as in primary human chondrocytes.

Disclosures: Britta Anderson, None.

MO0088

Bone density and strength are significantly compromised in the db/db mouse model of diabetes. Rana Samadfam^{*1}, Erik C. Rocheford², Joe Cornicelli², Gabrielle Boyd¹, Susan Y. Smith¹. ¹Charles River Laboratories, Canada, ²Charles River Laboratories, USA

Cardiovascular disease, renal impairment, neuropathy, inflammation, ocular changes and impaired wound healing are well recognized complications of diabetes, sometimes even in the presence of reasonably well-controlled blood glucose. Recently osteoporosis and increased fracture risk have also been added to this long list. To complicate matters, some therapies that provide good glycemic control have adverse effects on the skeletal system, further compromising already fragile bones in diabetic patients.

db/db mice are commonly used for diabetes research. The goal of this work was to first investigate the skeletal integrity of this model. In addition, as PPAR gamma agonists reportedly decreases bone mass, our other objective was to assess the effects of pioglitazone (PIO) on bone density and strength in a disease model. The diabetes status in db/db mice were characterized by fasted glucose levels and by oral glucose tolerance test (OGTT). Body weight and soft tissue composition were performed prior to necropsy. At necropsy, bones were collected from db/db mice following 1 month of treatment. Wild type littermates (same age group) were used as controls. Collected femurs were scanned using pQCT and BMC, BMD and bone geometry parameters were obtained at the metaphysis and diaphysis sites. Femur bone strength was measured using three point bending. Marked increases in body weight were noted for db/db mice compared to controls. These increases were for the most part attributed to marked increases in fat tissue. Marked increases in OGTT and glucose levels were noted for db/db mice compared to controls, confirming the diabetic status of the db/db mice. The bone evaluations revealed that db/db mice have smaller bones with lower bone density and reduced bone strength compared to wild type controls. Pioglitazone slightly increased the body weight associated with slight increases in fat. Pioglitazone treatment partially corrected the changes in OGTT and glucose levels and showed no effect on bone density or bone strength in this model. The bone density and bone strength data from db/db mice were in line with the reported data in clinic for diabetic patients. In addition, the lack of effect on bone for PIO highlights the importance of the model selection in safety studies to monitor for diabetic complications.

MO0089

Disruption of Glucocorticoid Signaling in Osteoblasts Prevents Diet-induced Obesity and Metabolic Dysregulation. Sarah Kim^{*1}, Holger Henneicke², Sylvia Gasparini², Lee Thai², Markus Seibel³, Hong Zhou². ¹ANZAC Research Institute, Australia, ²Bone Research Program, ANZAC Research Institute, The University of Sydney, Australia, ³Department of Endocrinology & Metabolism, Concord Hospital, The University of Sydney, Australia

Hypercaloric diets are causally associated with obesity and diabetes. Increased glucocorticoid action has been described as a central feature of metabolic dysregulation. Since osteoblasts are involved in the regulation of overall energy balance, this study aims to examine the contribution of glucocorticoid action in osteoblasts to whole-body energy metabolism during high-calorie feeding.

To this end, we utilized a transgenic (tg) mouse model in which glucocorticoid signaling has been selectively disrupted in osteoblasts and osteocytes via targeted overexpression of the glucocorticoid-inactivating enzyme, 11 β -hydroxysteroid dehydrogenase type 2. Seven-week-old male tg mice and their wild type (WT) littermates (n=6-15/group) were fed *ad libitum* a control diet (13.8kJ/g total energy (TE), 14% TE as fat, 26% TE as protein) or a high-calorie, high-fat (HC-HF) diet (16.3kJ/g TE, 43% TE as fat, 26% TE as protein) for 18 weeks. To delineate the effects of high caloric intake and high fat intake, a high-calorie, normal-fat (HC-NF) diet group was also included (16.3kJ/g TE, 14% TE as fat, 26% TE as protein). Body weight and composition, insulin sensitivity and glucose tolerance, as well as serum osteocalcin (OCN) levels were measured.

High-calorie feeding, regardless of dietary fat composition resulted in significantly increased fat mass in WT mice compared to mice fed the control diet (HC-NF: +88%, p<0.01, HC-HF: +73%, p<0.01, Fig 1A). Furthermore, WT mice fed either high-calorie diet exhibited elevated fasting glucose levels and reduced insulin sensitivity, with HC-HF mice displaying pronounced insulin resistance (Fig 1B). Correspondingly, WT mice fed the HC-HF diet showed marked glucose intolerance (Fig 1D). Interestingly, tg mice on high-calorie diets were not only protected from excessive fat accrual (HC-NF: +5%, HC-HF: +35%, Fig 1A) but also revealed healthy insulin sensitivity and glucose tolerance (Fig 1C&E). While serum OCN levels were reduced in WT HC-NF mice relative to WT control mice, they remained unchanged in WT HC-HF, despite marked obesity and glucose intolerance. Moreover, there was no difference in OCN levels of tg mice on either diet.

We conclude that glucocorticoid signaling in osteoblasts and osteocytes plays a central role in the pathogenesis of diet-induced obesity and impaired glucose tolerance through an OCN-independent mechanism.

Effect of Hydrogenated Coconut Oil High Fat Diet on Bone Mass in Streptozotocin-induced Type 1 Diabetic Mice. Adriana Carvalho^{*1}, Katherine Motyl², Francisco De Paula¹, Clifford Rosen². ¹University of Sao Paulo, Brazil, ²Maine Medical Center Research Institute (MMCRI), USA

Bone loss is a well described feature of type 1 diabetes mellitus (T1DM) and bone marrow adipose tissue (BMAT) has been investigated as a biomarker of bone health may play a key role. We hypothesized that nutritional status has a major protective

effect on T1DM bone mass. This study aims to evaluate the effect of high-fat diet (HFD) on bone mass and BMAT in streptozotocin (STZ)-induced T1DM mice. Eight week-old male C57BL/6J mice were submitted to a 5-day STZ (50mg/kg) or vehicle IP injections (0.1M citrate buffer pH 4.5). Mice were considered diabetic when glucose levels were > 300 mg/dL. Mice were then fed with HFD (58% kcal from fat: hydrogenated coconut oil) or low-fat diet (LFD) (11% kcal from fat) for 6 weeks after diabetes confirmation. Mice were placed in 4 different groups: STZ-HFD group (n=10), STZ-LFD group (n=8), Vehicle-HFD group (n=7), and Vehicle-LFD (n=7). Bone mass was measured by DXA (baseline, 2 weeks after baseline, and endpoint) and also by micro-computed tomography (μ CT) at endpoint. Energy expenditure (EE), food and water consumption were also measured at the end of the study. There were no differences in BMD or body composition between groups at baseline (p>0.05). STZ mice exhibited a significant fat mass loss 2 weeks after baseline (p<0.05) but there was no change in BMD (p>0.05) at this time point. STZ-HFD mice tended to have less weight loss when compared to STZ-LFD group. At the endpoint, all STZ mice presented with a significantly lower femur BMD regardless of the diet treatment. However, non-fasting glucose levels in STZ-HFD mice were lower than STZ-LFD (447 \pm 36 vs >600 mg/dL, respectively). Yet, STZ-HFD mice exhibited a lower EE when compared to STZ-LFD and Vehicle-HFD. STZ-LFD mice had marked diabetic symptoms such as polydipsia, polyphagia, and ketoacidosis condition (respiratory quotient = 0.61) and these symptoms were ameliorated in STZ-HFD mice. Our preliminary μ CT data showed a lower BV/TV in both STZ groups but also that STZ-HFD (n=3) tended to have higher BV/TV and Tb.N and a lower Tb.Sp compared to STZ-LFD (n=3) mice. Thus, although coconut oil HFD did not have an effect on diabetic BMD, preliminary μ CT indicates that it did shield against trabecular bone loss. Ongoing studies are investigating the role of HFD and nutritional status in bone marrow adipose tissue in this diabetes mouse model.

Glucose Fluctuations in Diabetes Have Targeted Effects on the Osteocyte *In Vitro* and *In Vivo*. Donna Pacicca^{*1}, Tammy Brown¹, Josh Wirtz¹, Karen Kover¹, Yun Yan¹, Dara Watkins¹, Pei Tong¹, Lynda Bonewald². ¹Children's Mercy Hospital, USA, ²University of Missouri - Kansas City, USA

Diabetic patients have increased fracture risk, but the effect of glucose fluctuation on bone cells has not been well-studied. We have previously shown few effects of high and low glucose on osteoblast function, but dramatic effects on sclerostin production in osteocytes. In this study we compared these *in vitro* data with *in vivo* results using the streptozotocin (STZ)-induced diabetic rat model. We hypothesized that elevated glucose and increased glucose variation would result in increased SOST/sclerostin expression in osteocytes and increased circulating serum sclerostin. Male Sprague-Dawley rats were divided into diabetic (n=8) and control groups (n=8). Diabetic animals were given one dose of STZ (70 mg/kg), resulting in elevated blood glucose within 2 days and were subsequently treated with insulin via osmotic pumps. We recorded blood glucose measurements. At 8 weeks, serum samples were taken and long bones harvested for qPCR and osteocyte isolation. Isolated rat osteocytes were cultured under 5.5mM and 25mM glucose conditions. SOST qPCR was performed on whole bone and cultured osteocytes. Sclerostin protein ELISA was performed on serum samples and culture media.

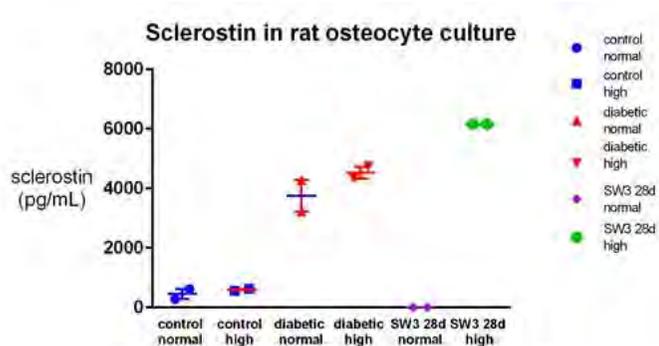

Glucose variability and maximum glucose were significantly increased in the diabetic vs. control animals (670/796 vs. 102/142 mg/dL). Relative SOST expression was increased 4 fold in the long bones of diabetic animals, with no difference in osteocalcin. SOST and sclerostin were elevated in cultured osteocytes from diabetic animals compared to normal regardless of whether cultured in normal or high glucose. These levels (60+ fold increase) were comparable to response of the IDG-SW3 osteocyte cell to high glucose. However, serum sclerostin from the rats was decreased in diabetics (300 pg/ml vs. 450 pg/ml controls). Diabetic rats express higher levels of SOST in bone, correlating with both high glucose levels and increased variability. Cultured osteocytes from diabetic animals continue to express higher levels of SOST and sclerostin in culture even under normal glucose, showing retention of the *in vivo* phenotype. Despite this, the diabetic animals have lower serum sclerostin, which may reflect retention of sclerostin in bone matrix. These data suggest that high glucose and glucose variability have a detrimental effect on bone through a dramatic increase in sclerostin production by osteocytes. Local elevation in sclerostin may be responsible for increased fractures in diabetics.

Metformin Increases Bone Mass, Reduces Adipocyte Size and Significantly Changes Circulating Metabolites in B6 Mice Only During States of Energy Excess. [Michaela Reagan](#)¹, [Michele Moschetta](#)², [Yawara Kawano](#)², [Mark Horowitz](#)³, [Karla Salem](#)², [Mary Bouxsein](#)⁴, [Daisy Huynh](#)², [Juliette Bouyssou](#)², [Aldo Roccaro](#)², [Clifford Rosen](#)⁵, [Irene Ghobrial](#)². ¹Dana-Farber Cancer Institute/ Harvard Medical School, Us, ²Dana-Farber Cancer Institute, USA, ³Yale University, USA, ⁴Beth Israel Deaconess Medical Center, USA, ⁵Maine Medical Center Research Institute, USA

Patients with type 2 diabetes mellitus (T2DM) have an increased risk of fracture, despite normal BMD. Factors contributing to increased fracture risk in T2DM are not well understood. Metformin (*met*) is the most frequently prescribed treatment for T2DM. In retrospective studies of T2DM patients, *met* has variable effects on BMD and a very modest reduction in fractures. However, its effects on bone mass and adipocytes are not well defined, and differential effects of *met* in obese vs normal weight patients are unknown. We hypothesized that *met* would have both local and systemic actions that positively affect bone mass in obese, pre-diabetic mice. Hence we performed an analysis of diet by drug interactions in female B6 mice. Female B6 mice fed a high fat diet (HFD:60% fat) or low fat diet (LFD:4% fat) for 16 weeks were then administered *met* (300 mg/kg per day in drinking water) or no *met*, for 6.5 weeks. Bone structure was measured by μ CT, circulating metabolomics by LC-MS, inguinal (iWAT) and visceral adipocyte (VAT) size by histology, and marrow adiposity by

histology and osmium μ CT. HFD alone had no effect on trabecular or cortical bone, but HFD mice with *met* had higher trabecular BV/TV, greater trabecular thickness and lower SMI than LFD+*met* (drug x diet interaction, $p=0.02$). Cortical thickness and BV/TV were higher in HFD+ *met* mice vs LFD+*met* mice ($p<0.05$). *Met* significantly improved glucose uptake ($p=0.04$) in the HFD group. Although *met* had no significant effect on weight, it significantly reduced marrow adiposity in the HFD+*met* vs HFD groups ($p=0.01$). Adipocyte size was significantly greater in HFD vs LFD mice in VAT and iWAT, and HFD vs HFD+*met* in iWAT but not VAT ($p=0.0036$). Many metabolites were significantly different between groups. Interestingly, a HFD, independent of *met*, induced a profound suppression in serum shikimate, a metabolite only produced by gut microbiome. *Met* significantly suppressed the microbial metabolite citraconic acid, but only in HFDs. Serine, associated with glycolysis, and 3 other metabolites were increased in HFD, independent of metformin. In summary, *met*'s positive effects on bone may depend on the degree of substrate availability (e.g. fatty acids). Drug and diet-induced changes in the gut microbiome, quantified with sequencing, may also impact bone mass and contribute to the skeletal effects of *met* in T2D. In conclusion, effects of *met* on bone and other tissues may be different in obese vs normal weight individuals.

Arachidonic Acid Reduces Bone Mass Without Influencing Visceral Adiposity in Growing Obese Rats. [Ivy Mak](#)^{*}, [Krystyna Wang](#), [Paula Lavery](#), [Sherry Agellon](#), [Hope Weiler](#). McGill University, Canada

Visceral (VAT) and subcutaneous (SAT) adipose tissues exert differential effects on bone density. Long-chain polyunsaturated fatty acids such as arachidonic acid (AA, C20:4 n6) modulate bone mass and adiposity. AA is elevated in obesity and fatty marrow; whether AA status affects the two fat compartments and bone growth in obrogenic states is not clear. This study aims to determine the effect of AA on bone and adipose mass acquisition in diet-induced obesity during growth. Male Sprague-Dawley rats $n=42$, 4 wk, 89.8 ± 1.1 g) were randomized to one of the following diets: CTRL, high-fat (HFD, 16.7% fat w/w), HFD + AA (1% w/w) for 6 wk. Body composition and bone mass were measured by *in vivo* micro-computed tomography (μ CT, Aloka LCT-200) at baseline and end-point. VAT and SAT were quantified from CT scans of the abdominal region (L3–5). Fatty acid composition was measured in red blood cells (RBC) using gas chromatography. Group differences were tested by repeated-measures 2-way ANOVA with post-hoc Tukey's HSD and relationships assessed by a general linear model. No differences in body weight, bone parameters, body composition or RBC fatty acids were observed at baseline. High fat feeding led to 28-45% lower RBC α -linolenic acid (ALA, C18:3 n3) incorporation; whereas reductions in linoleic acid (LA, C18:2 n6, -38%), eicosapentaenoic acid (EPA, C20:5 n3, -70%) and docosahexaenoic acid (DHA, C22:6 n3, -70%) was observed in HFD + AA only. HFD + AA had significantly lower bone mineral content of the whole body and L2-4, along with lower lumbar bone volume relative to HFD and CTRL (Table 1). Despite greater % total fat and body weight gain in HFD + AA ($504 \pm 12\%$) vs HFD ($495 \pm 13\%$) and CTRL ($484 \pm 11\%$), addition of AA in the diet did not lead to greater gains in abdominal fat mass, VAT or % VAT than high-fat feeding alone (Table 2). In addition, RBC ALA status negatively related to total abdominal fat mass ($\beta=-85.3 \pm 35.5$, $p=0.02$) and % VAT ($\beta=-45.1 \pm 21.1$, $p=0.04$), while an inverse relationship between LA and % VAT ($\beta=0.5 \pm 0.3$, $p=0.04$) was observed. RBC AA, EPA and DHA were not related with abdominal adiposity. These results suggest potential adverse effects of elevated AA status on bone in obese states is independent of the influence on regional fat distribution, and could be mediated indirectly through influencing the balance of other fatty acids that share common metabolic pathways.

Exercise diminishes obesity-associated Marrow Fat as quantified by Magnetic Resonance Imaging (MRI). Maya Styner¹, Martin Styner², Gabriel Pagnotti³, Xin Wu⁴, Buer Sen⁴, Gunes Uzer⁵, Zhihui Xie⁴, Mark Horowitz⁶, Clinton Rubin³, Janet Rubin⁴. ¹University of North Carolina, Chapel Hill, School of Medicine, USA, ²Departments of Computer Science & Psychiatry, University of North Carolina at Chapel Hill, USA, ³Department of Biomedical Engineering, State University of New York, Stony Brook, NY, USA, ⁴Department of Medicine, University of North Carolina at Chapel Hill, USA, ⁵University of North Carolina at Chapel Hill, USA, ⁶Department of Orthopedics & Rehabilitation, Yale University, New Haven, CT, USA

The effect of marrow adipose tissue (MAT) on bone remains poorly understood. Using a μ CT measure of osmium to visualize and quantify MAT, we found that 6 wk of high fat diet (HFD) increased MAT prior to attaining obesity. Here we asked whether MAT would respond to running exercise in the setting of diet-induced obesity (DIO). 4-wk old female C57BL/6 mice were fed low fat diet (LFD) or HFD. After 12 wk, mice were divided into control (LFD, DIO) or exercise groups (LFD-E, DIO-E) with voluntary running wheels (n=7/group). Running distances were equivalent in LFD and DIO mice. After 3 wks running, total body fat mass was double in DIO compared to DIO-E (p<0.05). Lean mass was also higher in DIO vs. LFD (p<0.01). Respiratory quotients were lower in DIO (p<0.01) suggesting use of fat energy. After 6 wks running, mice were significantly heavier in DIO vs LFD (p<0.001). Femoral MAT (osmium- μ CT) and μ CT tibial bone quantity were assessed^{1,2}. To increase reproducibility and prepare for future *in-vivo* studies, femoral MAT was also assessed via 9.4 Tesla MR resulting in fat and water intensity normalized image maps. Total femur MAT (osmium volume/femoral volume) was 6.2 ± 2.8 in LFD, 4.7 ± 2.1 in LFD-E, 9.0 ± 4.2 in DIO and 4.7 ± 2.9 in DIO-E (p<0.05 for an exercise). MAT quantified by MRI (fat signal/femoral volume) was 2.5 ± 1.1 in LFD, 1.2 ± 0.8 in LFD-E, 3.3 ± 1.5 in DIO and 0.5 ± 0.4 in DIO-E (p<0.001 for exercise, p<0.01 for DIO vs. DIO-E). Pearson correlation coefficient showed an appropriate correlation of MAT quantification between osmium- μ CT and MRI of 0.65 (95% CI 0.31-0.84, p-value=0.0012). Obese mice had similar relative amount of MAT to the controls, likely due to increased femoral volume in DIO (14% higher in DIO compared to LFD, p<0.01). Trabecular BV/TV increased with exercise by 20% in both LFD and DIO groups, p<0.001. DIO did not affect BV/TV or cortical parameters. In conclusion, MAT normalized to femoral volume as assessed by either osmium- μ CT or MRI was significantly attenuated by exercise in obese mice as well as mice on LFD. Both measures are relativized to bone volume, which as DIO mice have increased femoral volume, shows MAT is increased in DIO. In summary, diet and exercise effect on bone quantity and marrow fat are maintained in the setting of obesity. In addition, we present a quantitative MRI image tool, which should allow longitudinal study of MAT during behavioral, pharmacologic and genetic modification.

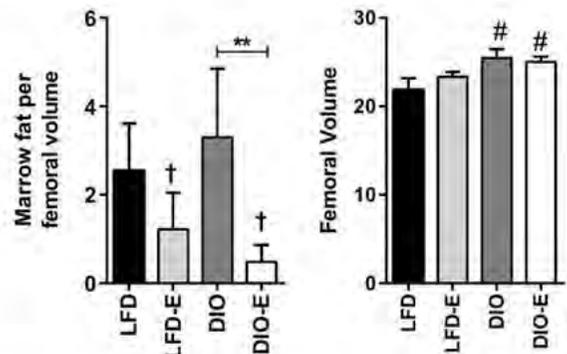

Figure 1. Volumetric MRI fat quantification normalized to total femoral volume. Obese or lean C57BL/6 +/- exercise for 6 weeks. # Denotes a significant effect due to diet by 2-way ANOVA. † Denotes a significant effect due to exercise by 2-way ANOVA.

Bone Marrow Adipose Tissue (BMAT) in Short Bowel Syndrome (SBS).

Francisco Jose De Paula^{*1}, Luciana Parreiras-e-Silva², Jessica Bonella², Iana Araújo², Carlos Salmon³, Júlio Marchini², Vivian Suen², Marcello Nogueira-Barbosa², Jorge Elias Jr.². ¹School of Medicine of Ribeirão Preto - USP, Brazil, ²Ribeirão Preto Medical School, USP, Brazil, ³Faculty of Philosophy, Sciences & Arts of Ribeirão Preto, USP, Brazil

Introduction: The SBS is a complex disease marked by severe impairment in nutrient absorption consequent to extensive bowel resection. The initial hallmark of this disease is loss of gut function leading to malnutrition. No previous study evaluated the role of adipose tissue distribution, particularly BMAT, in bone mass of patients with SBS.

Objective: Investigate the influence of BMAT, visceral adipose tissue (VAT) and intrahepatic lipids (IHL) in bone mass in SBS.

Material and Methods: The study comprised 12 controls (8M and 4F) and 13 patients with SBS (7M and 6F). Nuclear magnetic resonance (NMR) was used to assess BMAT in L3 (1H spectroscopy), VAT and IHL. We also assessed biochemical parameters in serum: calcium, phosphorus, alkaline phosphatase (AP), 25-OHD, PTH and IGF-1.

Results: The mean time of SBS diagnosis was 5.8±3.0 years. There was no difference between the groups in age (C=57±11 vs SBS=55.4±12 years), height, weight (C=65±6.7 vs SBS=56.5±14.7 Kg) and BMI (C=24±1.6 vs SBS=21±5 Kg/m²). Unexpectedly, only 30.7% of the SBS group was underweight, while 46.1% had normal IMC and 23.2% were overweight. The SBS group showed serum levels of albumin (C=4.4±0.2 vs SBS=3.7±0.6 g/dL;p<0.005) and calcium (C=9.8±0.4 vs SBS=9±0.7 mg/dL;p<0.01) lower and AP (C=180±50 vs SBS=313±137 U/L;p<0.01) higher than the C group. The T-score in 1/3 radius (C=-1.4±1.3 vs SBS=-2.2±0.7) and in total hip (C=0.8±0.8 vs SBS=-1.7±1.3) were lower in SBS group;p<0.05. There was no difference in BMAT between groups (C=34.6±10.8 vs SBS=36.8±12.1%). It should be highlighted that the patient with lowest BMI (10.2 Kg/m²) also had the lowest BMAT (19.1%). The amount of fat in the subcutaneous (C=21,382±6,004 vs SBS=7,104±4,210 mm²) and VAT (C=8,646±4,226 vs SBS=3,197±2,678 mm²) was lower in SBS group; p<0.05, whereas the IHL (C=3.2±2.6 vs SBS=13±11%; p<0.05) was higher in SBS group. BMD of total hip was positively correlated with body weight in SBS group (r=0.59;p<0.05). There was no correlation between lumbar spine BMD and BMAT.

Conclusion: Our results support previous studies showing the detrimental effects of SBS on the skeleton. In addition the present study shows that BMAT is not increased in SBS, suggesting that bone loss mechanisms in these patients differ from other conditions associated with weight loss, namely anorexia nervosa. These results encourage further studies about the effects of incretins and central nervous system in the modulation of bone remodeling.

Disclosures: Francisco Jose De Paula, None.

Receptor 4 (TLR4), increase pro-inflammatory mediators and contribute to the development of OA. TREM2, paired with DAP12, inhibits TLR-induced cytokine responses in macrophages and therefore may provide protection from high-fat diet induced OA. Our in vitro studies show that palmitic and lauric acid induce dose and time-dependent ERK and NF κ B activation as well as tumor necrosis factor- α (TNF α) production in WT macrophages. DAP12 KO macrophages have increased ERK and NF κ B activation and TNF α production indicating that DAP12 negatively regulates FFA-induced responses in macrophages, while TLR4 KO macrophages show no TNF- α production in response to FFA stimulation. We hypothesize that high fat diet-induced OA is partly mediated by dysregulation of innate immune responses to FFA leading to increased pro-inflammatory cytokines driving abnormal cellular responses within joints resulting in OA. To test our hypothesis, WT, DAP12 KO and TLR4 KO mice were placed on high fat (HF) or control diet (Con) for 12 weeks and knee joints collected for histological OA analysis and gene expression analysis. All three groups of mice gained significant fat mass on high fat diet (60% fat). HF diet induced significant glucose intolerance in WT and TLR4 KO mice but minimal glucose intolerance was seen in DAP12 KO mice. HF diet lead to the development of more osteophytes in medial and lateral compartments of knee in DAP12 KO mice compared to WT and TLR4 KO mice. Histological analysis of knee joints and qPCR results from joint specific domains including the subchondral bone, subchondral bone marrow, long bone marrow, infrapatellar fat pads are being processed. Results from these studies will provide new insight into the role of innate immunoreceptor regulation of high fat diet induced inflammation and osteoarthritis.

MO0097

Male, But Not Female, *Trpm8*^{-/-} Mice Have Impaired Core Temperature Regulation, Altered Body Composition, and Low Bone Mass With Age. Katherine Motyl^{1*}, Daniel Brooks², Mary Bouxsein², Clifford Rosen¹. ¹Maine Medical Center Research Institute, USA, ²Beth Israel Deaconess Medical Center, Harvard Medical School, USA

TRPM8 (the transient receptor potential cation channel, subfamily M, member 8) is expressed in several tissues and is the principal detector of environmental cold. TRPM8 activation in brown adipose tissue (BAT) can induce UCP-1 dependent thermogenesis. With age, BAT function declines concomitantly with loss of bone. We hypothesized that TRPM8 was involved in the co-regulation of bone mass and temperature during aging. At 52 weeks, male C57BL/6J mice with a global deletion of TRPM8 (*Trpm8*^{-/-}) had significantly reduced core temperature (T), total body mass, fat mass and fat-free mass compared to male wildtype littermates (+/+). Although female *Trpm8*^{-/-} mice had reduced body mass and fat mass, they did not have significantly altered lean mass or core T compared to +/+ females. The absence of TRPM8 also significantly reduced total body bone mineral density (BMD, $p=0.02$), content (BMC, $p<0.001$), and femur length ($p=0.003$) in male *Trpm8*^{-/-} mice. However, female *Trpm8*^{-/-} mice had no difference in BMD, BMC or femur length compared to +/+. Despite the differences in BMD and BMC in male mice, μ CT revealed no significant differences in trabecular bone parameters in the femur of *Trpm8*^{-/-} male or female mice compared to +/+. However, total area (bone + marrow) and marrow area at the cortical midshaft were both reduced in male *Trpm8*^{-/-}, consistent with reduced femur length and body weight. When challenged at 18°C and 4°C, male *Trpm8*^{-/-} mouse core T decreased significantly compared to +/+ mice at the same environmental temperatures, while female mice had no genotype-specific alterations in core T. Both +/+ and *Trpm8*^{-/-} mice lost bone similarly after 3 weeks at 4°C (male mice lost trabecular bone and female mice lost cortical bone). To summarize, male *Trpm8*^{-/-} mice, which have impaired temperature regulation, also have reduced BMD and growth during the first year of life. Surprisingly, female *Trpm8*^{-/-} mice had normal thermoregulation and bone parameters, despite reduced body mass. Investigations are underway to determine (1) the cell-specific role of TRPM8 in the skeleton and in thermoregulation and (2) the mechanism of compensation for loss of TRPM8 in female mice, which could be through other thermosensitive TRP channels. In conclusion, these findings support the concept that functional brown fat and normal temperature homeostasis is necessary for bone acquisition and maintenance and demonstrate that TRPM8 is a critical regulator of these processes in male mice.

Aromatic Amino Acids Restore the Impaired Anabolic Effect to PTH Associated With A Low Protein Diet. Mona El Refaey, Mark Hamrick, Ke-Hong Ding, Qing Zhong, William Hill, Xing-ming Shi, Mohammed Elsalanty, Nicole Howie, Monte Hunter, Meghan McGee-Lawrence, Jianrui Xu, Wendy Bollag, Carlos Isales*. Georgia Regents University, USA

Aging is associated with a gradual loss of bone mass. Anabolic agents such as parathyroid hormone (PTH) are commonly used to reduce fracture risk. However, it has recently been reported that PTH therapy is not effective in increasing bone mass in 6 month-old female rats on a low protein diet (Ammann P, et al. *Endocrinology* 2015). We previously reported that addition of aromatic amino acids to a low protein diet for eight weeks in aged (approximately 2-year-old) C57BL/6 mice prevented the bone loss

associated with low protein diets. The aromatic amino acids supplemented were tyrosine, tryptophan and phenylalanine equivalent to that of an 18% diet. The dietary benefits of aromatic amino acids on bone mineral density was not observed at time points earlier than eight weeks. Further, we had also previously shown that the bone mass of C57BL/6 mice peaks around 12 months, followed by a subsequent marked decline in bone mass and density by 24 months of age. We wished to study whether the loss of PTH anabolic effects were also seen in 24-month-old male mice on a low protein diet as well as what impact the addition of aromatic amino acids to the diet had on PTH effects. Twenty four-month-old, male C57BL/6 mice were divided into one of five treatment groups; 18% protein diet (normal protein diet); 8% protein diet (low protein diet); 8% protein diet + aromatic amino acids, 8% protein diet + PTH (20 μ g/kg) or 8% protein diet + aromatic amino acids + PTH (20 μ g/kg) for 4 wks. Bone densitometry and micro-CT analyses demonstrated bone loss with the low protein diet, which was not prevented by either the addition of PTH or aromatic amino acids. However the combination of both PTH + aromatic amino acids completely prevented any bone loss associated with a low protein diet. Bone mineralization is associated with the generation of reactive oxygen species while aromatic amino acids are natural antioxidants. Measurement of oxidized amino acids (kynurenine) in the bone marrow of these mice demonstrated a large and significant drop of oxidation products in those mice fed the diet enriched in aromatic amino acids. Thus, these data demonstrate that specific amino acid supplements can restore PTH's anabolic effects on bone in the setting of a low protein diet and we propose that part of the beneficial effects on bone mass might be through changes in the levels of reactive oxygen species.

Dietary restriction of methionine affects bone structure differently in young male and female mice. Jason Plummer¹, Frantz Perodin¹, Mark Horowitz², David Orentreich¹, Julie Hens^{1*}. ¹Orentreich Foundation for the Advancement of Science, USA, ²Yale Medical School, USA

Dietary methionine (met) restriction (MR) increases longevity and improves healthspan, by reducing adiposity and improving insulin sensitivity in rodent models. We placed young male (3 wk) and female (8 wk) C57BL/6J mice on MR to assess effects on bone structure, growth, and formation. Mice were fed diets containing 0.86% or 0.12% met for 5 weeks. Fasting blood plasma was analyzed for metabolic and bone-related biomarkers. Tibiae were analyzed by histology and histomorphometry, while femurs were analyzed by micro-CT and biomechanically using 4-point bending. Marrow fat was measured by osmium staining with micro-CT. MR mice had reduced plasma glucose and insulin, while FGF21 increased; FGF23 increased only in males. Plasma levels of osteocalcin and osteoprotegerin were unaffected, but sclerostin and procollagen I intact N-terminal decreased. Female mice were more resistant to MR effects on bone than younger males. In cortical bone, μ CT analysis showed significant decreases in Bone Tissue Density (BTD) (CF: 971 ± 28 mg HA/cm³ vs. MR: 929 ± 34 mg HA/cm³) and Apparent Density (CF: 895 ± 31 mg HA/cm³ vs. MR: 845 ± 33 mg HA/cm³) in males, but increased BTD in females (CF: 1020 ± 24 mg HA/cm³ vs. MR: 1035 ± 31 mg HA/cm³). In trabecular bone, males had decreased BTD, bone surface, trabecula and bone volume, and trabecular thickness (CF: 0.033 ± 0.008 mm vs. MR: 0.027 ± 0.0012 mm), while in females only trabecular thickness decreased (CF: 0.039 ± 0.0046 mm vs. MR: 0.035 ± 0.0033 mm). Histomorphometry confirmed reduced trabecular thickness. Bone formation rate (BFR/BV) and index for bone remodeling (DLS/BS) increased in MR males, but in females BFR/BV and SLS/BS were decreased and DLS/BS was not different between CF and MR. Biomechanical testing showed in both MR females and males bones were significantly less stiff and had reduced maximum load and total work, suggesting greater fragility. Reduced expression of RUNX2, DMP1, and osteocalcin occurred in bone marrow from MR mice. MR induced bone marrow fat accretion in both sexes, antithetical to the reduced fat depots seen throughout the body. These results suggest that MR alters bone remodeling and apposition differently in young male and female mice. MR reduction of RUNX2 may alter osteoblast function and lower sclerostin levels may change anabolic activity of osteocytes. Therefore, use of dietary MR to promote improved healthspan should be limited to adults, who appear to be more refractory to MR effects on bone.

Down-regulation of Sirtuin type 1 (Sirt 1) expression in bone marrow of anorexia nervosa mouse model: potential involvement in osteoporotic phenotype. OLFA GHALI^{1*}, DAMIEN LETERME², ANNE RESONET², SEVERINE DELPLACE², PIERRE MARCHANDISE², FLORE MIELLOT², PIERRE HARDOUIN², CHRISTOPHE CHAUVEAU². ¹Laboratory of bone diseases inflammatory (PMOI) EA 4490, France, ²PMOI-EA 4490, France

Background: Osteoblasts and adipocytes share a common mesenchymal stem cell (MSC) origin. Marrow adipocyte accumulation observed in osteoporosis is caused by a shift in MSCs commitment from osteogenic to adipogenic pathway. Sirt1 is implicated in the regulation of osteoblast/adipocyte differentiation. Its activation by resveratrol increases osteoblastogenesis and reduces adipogenesis in vitro. At present, no study focused on the link between sirt1 and osteoporosis related to Anorexia

Nervosa (AN). Thus the aim of this work is to determine if sirt1 alterations could be linked to bone loss observed in AN. Methods: A mouse model mimicking numerous consequences of severe AN (SBA) was used to obtain female mice with significant bone alterations [Zgheib S et al. Plos One 2014]. Determination of the effect of sirt1 on osteoblastic/adipogenic differentiation was performed in the co-differentiation medium [Ghali O et al. BMC cell Biol 2015] after treatment of bone marrow stromal cells (BMSCs) from control (CT) and SBA mice with resveratrol and sirtinol, an activator and an inhibitor of sirt1 respectively. Bone marrow adipocytes number and microarchitecture were performed by histological and μ CT analysis respectively. Results: After 48 h of adhesion, BMSCs of SBA mice presented a decrease of 80% and 50% in mRNA expression of sirt1 and runx2 respectively and an increase of 50% in PPAR γ 2 expression. BMSCs from SBA mice showed earlier and higher adipogenic capacities than those from CT mice in the co-differentiation medium while osteoblast functions were decreased. Interestingly, partial correction of sirt1 expression by resveratrol in BMSCs from SBA mice induced an increase in early osteoblastic markers expression (Runx2, ALP and Osterix/SP7) but failed to enhance osteocalcin expression. Accordingly, high adipocyte number/mm² of tibias of SBA mice was also accompanied by a decrease in cortical and trabecular parameters. Conclusion and Perspective: These data demonstrate for the first time that down-regulation of sirt1 in BMSCs of SBA mice is associated with a rise in adipogenesis and a decrease in osteoblastogenesis which may partly explain its involvement in osteoporosis related to AN. This study will be completed by analyzing the effects of sirt1 on bone marrow adiposity and microarchitecture on sirt1 transgenic mice and organotypic culture of tibias treated with sirtinol and resveratrol for 10 days.

LCN2 knock out mice have an unexpected osteopenic phenotype. Association with altered energy metabolism. Nadia Rucci*¹, Mattia Capulli², Sara Gemini-Piperni², Antonio Maurizi², Anna Teti². ¹University of L'Aquila, Italy, ²Department of Biotechnological & Applied Clinical Sciences, University of L'Aquila, Italy

Lipocalin 2 (LCN2) is an adipokine that carries out a variety of functions in different organs. We previously demonstrated that increased LCN2 expression impairs osteoblast differentiation and enhances bone resorption in response to bone mechanical unloading. To in-depth characterize the role of LCN2 in bone metabolism, we investigated the bone phenotype of LCN2 knock out (LCN2KO) mice. Unexpectedly, microCT analysis revealed 40% less bone volume/total volume in LCN2KO mice compared to WT littermates ($p=0.02$, Student's t test), paralleled by 50% and 21% lower trabecular number ($p=0.02$) and thickness ($p=0.019$), respectively, and 20% higher trabecular separation ($p=0.053$). Consistently, histomorphometry showed 43% lower osteoblast surface/bone surface ($p=0.045$), while osteoclast parameters were unremarkable. Despite this overt in vivo osteoblast deficiency, LCN2 expression in WT osteoblasts was almost undetectable and osteoblast primary cultures from calvariae of 7 day-old WT and LCN2KO mice revealed no difference in alkaline phosphatase activity and nodule mineralization, suggesting that the osteopenic phenotype in LCN2KO mice was not osteoblast autonomous. Of note, LCN2KO mice presented with higher body weight and gonadal fat weight compared to WT mice. Therefore, we hypothesized that the low bone mass in LCN2KO mice was due to an altered energy metabolism. Accordingly, we observed significant lower levels of fasted glucose (60.58 \pm 7.48 vs 83.10 \pm 18.9, $p=0.008$) and higher levels of insulin (3.67 \pm 0.7 vs 2.25 \pm 0.7, ng/ml, $p=0.036$) in LCN2KO mouse sera compared to WT. Furthermore, the insulin tolerance test (ITT) showed normal response, confirmed by the glucose tolerance test (GTT) that revealed 20% lower glycaemia ($P=0.003$, area under the curve test) in LCN2KO mice. These results suggest that the sensitivity of peripheral tissues to insulin was normal. However, the mRNA expression of the insulin receptor (InsR) in LCN2KO osteoblasts was 30% lower compared to WT, indicating that there was an osteoblast-specific insulin resistance in the LCN2KO mice. Consequently, the InsR signal was impaired in LCN2KO osteoblasts, as demonstrated by the reduced transcriptional expression of the InsR downstream gene, osteocalcin. In conclusion, our data underscore a systemic role of LCN2 in bone homeostasis and point to this adipokine as an important linker between bone and energy metabolism.

Thermoneutral Housing Prevents Premature Age-Related Cancellous Bone Loss in Mice. Urszula T. Iwaniec*¹, Kenneth Philbrick¹, Carmen Wong¹, Dawn Olson¹, Arianna Kahler-Quesada¹, Adam Branscum¹, Russell Turner². ¹Oregon State University, USA, ²Oregon State University, USA

Mice housed at room temperature exhibit age-related cancellous bone loss prior to achieving peak bone mass at approximately 4 months of age. Sympathetic-mediated non-shivering thermogenesis is induced in mice housed at room temperature as an adaptive response to cold stress. Increased sympathetic tone has been implicated as having a negative influence on the skeleton. The purpose of this study was to assess the efficacy of thermoneutral housing (temperature range where the basal rate of energy production is at equilibrium with heat loss) in preventing premature cancellous bone loss in mice. Female C57BL/6J (B6) mice were housed at room temperature

(22 \pm 3 \circ C) or at thermoneutral (32 \pm 3 \circ C) from 2 to 4 months of age. Cancellous bone was evaluated by microcomputed tomography and histomorphometry. Mice housed at room temperature exhibited dramatic cancellous bone loss from the distal femur metaphysis and lesser bone loss from other skeletal sites, whereas cancellous bone volume fraction in thermoneutral-housed mice, depending on the skeletal site, either remained the same or increased. This phenomenon was not limited to B6 mice because C3H/He mice housed at room temperature also exhibited lower cancellous bone volume fraction than mice housed at thermoneutral. The sparing effect of thermoneutral housing on cancellous bone in B6 mice was associated with increased bone marrow adiposity and higher rates of bone formation. Mice housed at room temperature consumed more food but did not differ in weight from mice housed at thermoneutral. However, the room temperature-housed mice had lower abdominal white adipose tissue mass and lower serum leptin levels. Gene profiling revealed that housing temperature had a major effect on expression of osteogenic genes in tibia. Specifically, room temperature-housed mice had lower expression levels of genes for bone matrix proteins (type I collagen and osteocalcin) and genes associated with BMP signaling (BMPs, BMP receptors and SMADs). Our findings support the conclusion that mild cold stress has a major negative impact on cancellous bone mass in mice and that early onset cancellous bone loss in this species is due, in part, to cold adaptation. The findings also suggest that studies using mice as a preclinical model to investigate interactions between energy homeostasis and bone or the etiology of age-related bone loss need to account for confounding species differences in thermoregulation and energy metabolism.

MO0103

Fkbp10 deletion in osteoblast and joint tissues leads respectively to qualitative but not quantitative defects in bone, and a postnatal contracture phenotype seen in Bruck syndrome. Caressa Lietman*¹, Zhechao Ruan¹, Ingo Grafe¹, Elda Munivez¹, Yuqing Chen¹, Hao Ding², Xiaohong Bi², Catherine Ambrose², Nadia Fratzl-Zelman³, Paul Roschger³, MaryAnn Weis⁴, David Eyre⁴, Deborah Krakow⁵, Brendan Lee¹. ¹Baylor College of Medicine, USA, ²University of Texas Health Science Center at Houston, USA, ³Ludwig Boltzmann Institute of Osteology, Austria, ⁴University of Washington, USA, ⁵University of California at Los Angeles, USA

Osteogenesis Imperfecta (OI) is the most commonly inherited form of brittle bone disease and displays a spectrum of clinical severity from mild (OI type I) to severe early lethality (OI type II). Mutations in FKBP5 Binding Protein 10 (*FKBP10*), encoding the FKBP65 protein, causes a recessive form of OI and Bruck Syndrome, the latter being characterized by congenital joint contractures in addition to the low bone mass. We have shown that *Fkbp10* expression is limited to bone, tendon and ligaments in postnatal tissues. Furthermore, in both patients and *Fkbp10* knockout mice, collagen telopeptide crosslinking has been shown to be dramatically reduced. To further characterize the tissue specific contribution of *Fkbp10* to bone and joint tissues, we conditionally ablated FKBP65 in *Fkbp10*^{fl/fl} mice using the osteoblast specific *Coll1a1* 2.3kb Cre and Scleraxis Cre. Using μ CT, histomorphometry and quantitative backscattered electron imaging, we find only minimal alterations in the quantity of bone and no differences in bone matrix mineralization in this model. However, mass spectroscopy of bone collagen demonstrated reduction of telopeptide collagen crosslinking. Furthermore, collagen and matrix components are altered as shown by Raman spectroscopy, and mutant bone is weaker and less stiff than that from wild type littermates on 3-point bending experiments. Taken together, these data suggest that the reduction of collagen crosslinking through *Fkbp10* ablation in osteoblasts leads to qualitative, rather than quantitative changes in the skeleton. Similarly, loss of *Fkbp10* in presumptive tendons and ligaments led to a progressive contracture phenotype in mutant mice, evidenced through radiography, histology, and biomechanical testing. As such, this model represents the first one characterized by postnatal joint contractures. Together, loss of *Fkbp10* leads to altered collagen crosslinking that leads to qualitative defect in bone, tendon, and ligaments.

Gnas Inactivation Adversely Affects Cortical Bone Quality by Altering Osteoclast and Osteocyte Activity During Bone Remodeling. Girish Ramaswamy*¹, Hyunsoo Kim, Deyu Zhang, Yongwon Choi, Frederick Kaplan, Robert Pignolo, Eileen Shore. University of Pennsylvania, USA

The *GNAS* gene encodes multiple transcripts, including the α -subunit of the stimulatory G-protein ($G_{\alpha s}$) of adenylyl cyclase, and shows genomic imprinting, with paternal but not maternal *GNAS* inactivation associated with Progressive Osseous Heteroplasia, a rare disorder of extraskelatal (heterotopic) ossification. We previously showed that paternal *Gnas* inactivation enhances osteoblastogenesis and inhibits adipogenesis. This study examined whether heterozygous *Gnas* inactivation also enhances bone formation during skeletal development and bone remodeling.

Trabecular BV/TV and architecture were unaffected in both *PatGnas*^{+/-} and *MatGnas*^{+/-} mice at all ages. However, compared to WT, 2-week-old *PatGnas*^{+/-} and *MatGnas*^{+/-} mice showed cortical BV/TV reduced by 15% and cortical thickness by

20% by μ CT. At 3 and 9 months of age when bone remodeling occurs, *PatGnas*^{+/-} showed persistent reductions in BV/TV and cortical thickness, while *MatGnas*^{+/-} were similar to WT. Cortical porosity was elevated by ~10% in *PatGnas*^{+/-} mice at all ages. Femurs from *PatGnas*^{+/-} mice were weaker by >25% by 3-pt bending at all ages while *MatGnas*^{+/-} femurs had reduced strength only at 2 weeks of age, consistent with μ CT data.

TRAP staining revealed dramatically increased numbers of multinucleated endosteal osteoclasts in 9-month-old *PatGnas*^{+/-} but not in *MatGnas*^{+/-} mice. Differentiation of bone marrow macrophages (BMM) from *PatGnas*^{+/-} mice formed more multinucleated osteoclasts and increased TRAP activity compared to WT BMMs indicating that $G_{\alpha s}$ regulates osteoclast differentiation. In addition, cortical bone from 9-month-old *PatGnas*^{+/-} mice showed higher fraction of TRAP+ osteocytes and elevated *Acp5*, *Sost* and *Pthrp* mRNA levels by qPCR. Osteoblast number and mineral apposition rate were similar between 2-week-old WT and *PatGnas*^{+/-} mice supporting that changes in bone formation did not contribute to the cortical bone defects.

Overall our results indicate that paternal inheritance of *Gnas* inactivation in mice adversely affects cortical bone quality by altering osteoclast and osteocyte activity during bone remodeling. Studies are ongoing to investigate the effects of $G_{\alpha s}$ mutation on osteoclast progenitors and signaling mechanisms driving the differential effects between *PatGnas*^{+/-} and *MatGnas*^{+/-} mice. Thus *Gnas* regulates multiple cell types within the normal skeleton and extraskeletal tissues in age and inheritance dependent manner to impact skeletal development and heterotopic ossification.

An Optimized In Vivo Chemical Screening Regimen For Osteoactive Compound Discovery in the Regenerating Zebrafish Tail Fin. Adrian Monstad-Rios*, Ronald Kwon. University of Washington, USA

Though *in vivo* chemical screens represent a powerful strategy for bone pathway discovery, such screens are largely inaccessible in traditional animal models. In this project, we seek to utilize the regenerating zebrafish tail fin, a rapid, genetically tractable, and optically transparent model of intramembranous ossification, for osteoactive compound discovery. Given that adult zebrafish require a relatively large water volume for housing, this makes chemical screening costly due to the large compound quantities necessary to achieve an active concentration in the water. To overcome this hurdle, we previously developed a 3D printed screening system that enabled rapid, efficient, and cost-effective chemical administration in adult zebrafish [1]. Further, we demonstrated its potential to detect clinically-relevant inhibitors of bone formation during tail fin regeneration. In this study, our objective was to define optimal dosing and imaging regimens to maximize chemical screening efficiency. Zebrafish were subjected to 50% tail fin amputation and dosed each day for 1 hr/day. Fin area was measured periodically following amputation. We computed the coefficient of variation (COV) of fin regrowth at different days post amputation (dpa). Analysis revealed decreasing COV with time, with values plateauing by 8 dpa. The COV was not decreased when area of regrowth was normalized by pre-amputation area. Administration of 10, 50, and 100 μ M cyclopamine for 8 days resulted in a characteristic dose-response curve in percent regrowth (0 μ M:50.2%, 10 μ M:53.5%, 50 μ M:24.8%, 100 μ M:17.2%), demonstrating the fidelity of our system. Previously, we found that administration of dorsomorphin (an inhibitor of type I BMP receptors and AMPK currently in therapeutic development) impaired mineralizing activity during fin regeneration as indicated by decreased calcein labeling [1]. To examine the potential to measure mineralization using label-free methods, we imaged bone ray birefringence in dorsomorphin-treated fish using Rotopol microscopy [2]. We observed a 20.2% decrease in birefringence in dorsomorphin-treated animals relative to vehicle controls, suggesting the utility of this approach. Collectively, this study develops optimized parameters for efficient chemical screening during zebrafish fin regeneration, an essential step towards *in vivo* osteoactive compound discovery in this system.

Cause of Abnormal Bone Mineralization in X-Linked Hypophosphatemia. Baozhi Yuan*¹, Abigail Radcliff², Ryley Zastrow³, Ying Liu⁴, Jian Feng⁵, Robert Blank⁶, Marc Drezner⁷. ¹Department of Medicine, University of Wisconsin-Madison & GRECC, William S. Middleton Memorial Veterans Hospital, USA, ²Department of Medicine, University of Wisconsin-Madison & GRECC, William S. Middleton Veterans Hospital, USA, ³University of Wisconsin-Madison, USA, ⁴Baylor College of Dentistry, Texas A&M Health Science Center, USA, ⁵Baylor College of Dentistry, Texas A&M Health Science Center, USA, ⁶Medical College of Wisconsin & Clement J Zablocki Veterans Administration Hospital, USA, ⁷University of Wisconsin, USA

Loss of function PHEX mutations lead to increased serum FGF-23, which underlies the biochemical abnormalities in patients with X linked hypophosphatemic rickets (XLH) and *hyp* mice: renal phosphate (P) wasting and hypophosphatemia. Whether abnormal bone mineralization is due to direct effects of FGF-23 and/or hypophosphatemia is less certain. To explore the cause of osteomalacia, we compared the phenotype of *hyp*-mice to that in mice with *Phex* deletion in osteoblasts (*Ocn-Cre-Phex*^{Afloxly}) and in osteocytes (*Dmp1-Cre-Phex*^{Afloxly}). Although *Ocn-Cre-Phex*^{Afloxly}- and *Dmp1-Cre-Phex*^{Afloxly}-mice had biochemistries no different from *hyp*-mice, the mineralization defect in *Dmp1-Cre-Phex*^{Afloxly}-mice was mild compared to severe osteomalacia present in *Ocn-Cre-Phex*^{Afloxly}- and *hyp*-mice. Moreover, while treatment with high P diet normalized serum P in each model, osteomalacia persisted in *hyp*-mice, but normal bone mineralization ensued in *Dmp1-Cre-Phex*^{Afloxly}-mice (mineral apposition rate 1.4 ± 0.2 vs 3.1 ± 0.4 μ m/day). Thus the mild mineralization defect in *Dmp1-Cre-Phex*^{Afloxly}-mice is a P dependent abnormality, whereas the profound osteomalacia in *Ocn-Cre-Phex*^{Afloxly}- and *hyp*-mice is due to hypophosphatemia and an additional unidentified factor(s). In this regard, we found that *hyp*-mouse bone exhibited decreased *Dkk1* mRNA expression (0.35 ± 0.2 vs 1.2 ± 0.4 relative expression [re], $p < 0.05$) and an increase in β -catenin mRNA (6.6 ± 0.5 vs 1.4 ± 0.7 re, $p < 0.0001$), whereas *Dmp1-Cre-Phex*^{Afloxly}-mouse bone had normal *Dkk1* and β -catenin mRNA levels. In parallel experiments, we observed that constitutively expressed β -catenin in osteoblasts results in osteomalacia. Thus, we compared treatment of *hyp*-mice with Hexa-D-Arginine (D6R), a curative therapy for the osteomalacia, vs saline control. Five weeks of D6R (1.5 μ M/kg/day, ip) increased serum P in *hyp*-mice (6.2 ± 0.1 vs 3.2 ± 0.2 mg/dl, $p < 0.001$) to levels no different from D6R treated normals (6.8 ± 0.3). D6R also significantly increased *Dkk1* mRNA in *hyp*-mouse bone (2.3 ± 1.0 vs 0.31 ± 0.2 re, $p < 0.05$) to levels greater than in D6R treated normals and decreased β -catenin mRNA (4.4 ± 0.7 vs 2.0 ± 0.3 re, $p < 0.05$) to levels no different than in D6R treated normals. The *Dkk1* change occurred due to normalization of miRNA-217 (6.6 ± 0.5 vs 1.4 ± 0.7 re, $p < 0.001$). Our data indicate that osteomalacia in *hyp*-mice results from both hypophosphatemia and increased bone β -catenin, indicating successful treatment of XLH requires normalization of both abnormalities.

Collaborative cross Mice in a GWA Study Reveal New Candidate Genes for Bone Microarchitecture. Roei Levy*¹, Richard Mott², Fuad Iraqi¹, Yankel Gabet¹. ¹Tel Aviv University, Israel, ²Oxford University, United Kingdom

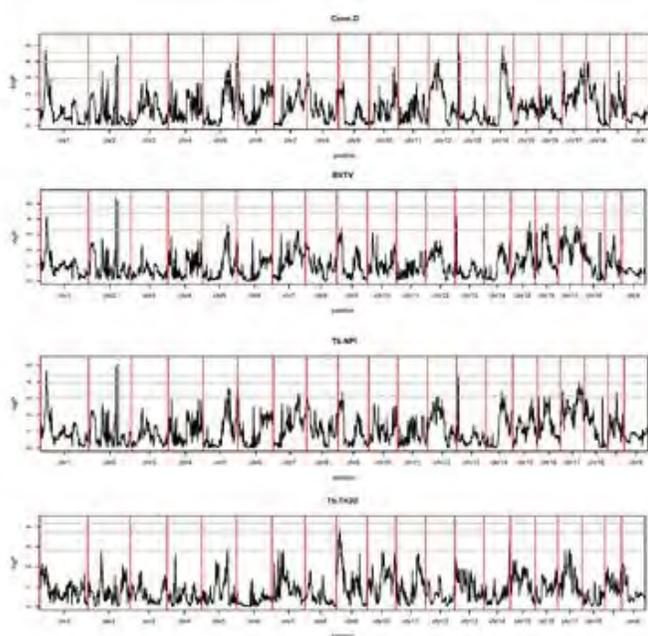

Purpose To identify new causative genetic determinants of bone microarchitecture.

Background The microstructure of trabecular bone is a composite trait governed by a complex interaction of multiple genetic determinants. Comprehensive mapping of their full expression spectra can drastically improve our ability to predict the risk of osteoporosis and other bone pathologies. The inclusion of the widely-varied collaborative cross (CC) - the latest recombinantly inbred mouse reference panel - in GWA studies enables reproducible experiments at a resolution of one mega base-pairs and below, with a relatively small cohort size. Here we utilized 30 CC lines (160 individuals in total) of both genders to perform a detailed haplotype mapping across 170K genome-wide SNPs. Samples were collected over a period of two years that spanned a near-complete seasonal cycle. Femurs were scanned at a resolution of 10 μ m to morphometrically analyze the trabecular bone compartment in the distal femur. We carried out our bioinformatics analyses on the trabecular bone volume fraction (BV/TV), trabecular number (Tb.N), trabecular thickness (Tb.Th), and trabecular connectivity density (Conn.D). Thorough refinement of the initial haplotype scan was done by merging the full genomic sequence of the CC founders to pinpoint specific genes.

Results With heritability of 0.7-0.8 for the morphometric parameters we noted a cardinal ($P < 0.01$) sex-specific effect in all but Tb.Th. Our haplotype scan yielded three QTL; BV/TV, Tb.N and Conn.D yielded one at chromosome 2 ($-\log P > 5$; $CI_{95} = 4.4$) and another at chromosome 1 ($-\log P > 4.7$; $CI_{95} = 4.5$) while Conn.D has contributed an extra QTL at chromosome 14 ($-\log P > 4.9$; $CI_{95} = 4.5$). Using eight-way merge analysis we located two adjacent genes, namely *AVP* and *OXT*, near the peak of the first QTL. *AVP* encodes for vasopressin and *OXT* encodes for a precursor of oxytocin. Recent articles attributed a role for both vasopressin and oxytocin in bone biology. However, to the best of our knowledge, genome-wide significance has not yet been demonstrated for either gene. The third QTL yielded *Lrch2*, which was previously found to be associated with knee osteoarthritis. Lastly, the candidate genes

for Conn.D are *C4bp* and *Zp3r* for which a role in bone biology has yet to be documented.

Conclusion These data demonstrate for the first time genome-wide significant association between OXT and AVP and trabecular microstructural parameters, which support previously reported experimental observations. In addition, these data validate our approach and its ability to reveal new determinants of bone microarchitecture.

Development of a database and web portal for murine models of skeletal variation. Caibin Zhang¹, Pujan Joshi², Seung-Hyun Hong², Cheryl Ackert-Bicknell³, John Sundberg⁴, Douglas Adams¹, Dong-Guk Shin², David Rowe^{*1}. ¹University of Connecticut Health Center, USA, ²University of Connecticut, USA, ³University of Rochester, USA, ⁴The Jackson Laboratory, USA

The mouse genetics community has built a number of modeling systems for identifying genetic loci that contribute to phenotypic variation in every organ system. The mouse knock out project (KOMP) produces lines with inactivation of genes in a C57BL/6NJ background. In contrast, the diversity outbred population (DO) is a random distribution of genetic segments from 8 inbred mouse lines. These populations demonstrate extreme phenotypic variation that can be associated with strain specific SNPs. Additional inbred lines derived from the 8 same strains provide a stable phenotype are called the collaborative cross (CC) lines. The essential element for using these tools is the ability to perform high throughput, digital and objective phenotyping such that the data can be retrieved and linked to genomic data through web-accessible databases.

We have developed a μ CT screening \rightarrow histomorphometric pipeline that is being used to study unselected KOMP lines, DO populations and CC lines. Here we introduce a website (bonebase.org) that is an evolving effort to present this information. The site is populated with measurements from an internal database that captures all the data streams, calculates statistics and flags measures that exceed the control values. The flagged items are grouped into biological categories (bone architecture, cellular activity) to provide an overview of analysis. The database also distinguishes if the abnormality is present in both genders and within appendicular and axial bone to identify dimorphic phenotypes.

From the bonebase.org website, the user selects which type of model system to be queried (KOMP, DO, CC, investigator initiated). The list of lines is presented and indicates which lines contain information that was flagged. The next level (analysis) lists all the biological categories in which an abnormality was found and whether it had any dimorphic properties. The next (summary) level presents the group means for each measurement within each biological category and it is followed by the individual mouse values for each measurement (detail level). The final level presents the images of the μ CT and histology from which the measurements were made. All of these features can be found by searches and have been marked with terms listed in the Mouse Phenotype Ontology database. We welcome suggestions and contributions to what we hope will become a common resource for the skeletal biology community.

MicroCT-Based Barcoding Reveals Novel High Bone Mass Mutations in Zebrafish. Philippe Huber, Jane Lee, Claire Watson, Marjorie Thompson, Sarah McMenamin, David Parichy, Ronald Kwon^{*}. University of Washington, USA

Zebrafish have emerged as an indispensable system for human disease modeling due to their genetic tractability, optical properties, and amenability to in vivo screening. However, their use as a model for bone biomedical research has been hindered by the lack of quantitative strategies for skeletal imaging in zebrafish, as well as the unknown degree to which zebrafish and mammalian bone physiologies are regulated by similar genetic and cellular networks. In this project, our goal was to 1) develop a microCT-based platform for systems-level bone phenotyping in adult zebrafish, and 2) identify coordinated patterns of altered bone mass/mineralization following mutagenesis. For this, we integrated whole-body (21 μ m resolution) microCT scanning in multiple fish with a custom image processing pipeline to compute 288 different measures (24 vertebral bodies x 3 vertebral elements x 4 quantities per fish) of axial bone morphology and mineralization in a process we call "skeletal barcoding" (Fig 1A). Using this pipeline, we barcoded zebrafish mutants previously isolated from genetic screens (Fig 1B), and identified two mutants with abnormal skeletal phenotypes: *puma* and *opallus* (which harbors a mutation in thyroid stimulating hormone receptor (*tshr*) identical to a human mutation causing constitutive TSHR activity and hyperthyroidism [1]) exhibited significantly elevated TMD across all centra (Fig 1C). *puma* (which harbors a mutation in the alpha tubulin gene *tuba8/3a* [2]) exhibited increased volume in anterior haemal arch/rib elements only (Fig 1D), suggesting the potential to detect both global and regional shifts in mass/mineral accrual. In humans, hyperthyroidism is associated with low BMD [3], whereas TSHR gain-of-function has been associated with high BMD [4]. Thus, this study suggests the potential for the zebrafish skeleton to predict a complex phenotype integrating competing influences at both systemic (hyperthyroidism) and local (e.g., Tshr activity in bone cells) levels. Together, this study develops quantitative technologies for bone imaging in zebrafish, advances novel approaches to systems-level bone phenotyping, and provides new evidence supporting the translational value of zebrafish as a model of human genetic bone disorders.

Mutations in *Lrp5* Improve Bone Properties and Osteoblast Function In Mice with Osteogenesis Imperfecta. Christina Jacobsen^{*1}, Erin Spiller², Kyung-Eun Lim³, Alexander Robling³, Matthew Warman⁴. ¹Boston Children's Hospital/Harvard Medical School, USA, ²Keck School of Medicine, University of Southern California, USA, ³Indiana University, USA, ⁴Boston Children's Hospital, Harvard University School of Medicine, Howard Hughes Medical Institute, USA

Heterozygous missense mutations in the cell surface receptor, low-density lipoprotein receptor-related protein 5 (LRP5) increase bone mass and strength in humans and mice. Osteogenesis Imperfecta (OI), a disorder most frequently caused by mutations in Type I collagen, is characterized by increased skeletal fragility which can lead to deformity, pain and disability. Therapies are needed that can reduce fractures and improve bone health in patients with OI. Our previous work demonstrated that increased LRP5 signaling from either a high bone mass (HBM) mutation or a monoclonal antibody targeting an inhibitor of LRP5 improves bone density and strength in a mouse model of moderate OI by increasing the amount of type I collagen incorporated into the bone matrix.

We mated mice with a dominant *Lrp5* HBM-causing knockin allele to a mouse model of severe OI (*Colla1⁴⁸⁰*) that carries a mutation causing retention of type I collagen in the ER and subsequent osteoblast apoptosis. We analyzed bone density at 12 weeks of age by DEXA and measured the number of long bone fractures by Faxitron. As expected, offspring with OI alone have lower bone density and more fractures than wild-type siblings. Compared to siblings with OI alone, siblings with OI and a HBM allele have significantly increased bone density ($p < 0.05$). More importantly, more fractures were seen in the mice with OI alone (9/14) than the mice with OI and a HBM allele (2/13). This suggests that *Lrp5* HBM mutations improve bone properties even in a mouse model of OI with compromised collagen secretion.

To further determine the effects of *Lrp5* HBM mutations on collagen secretion in osteoblasts, we examined osteoblasts from femurs of 3-week old mice with both a moderately severe OI allele (*Colla2^{6610C}*) and a *Lrp5* HBM allele as well as siblings with an OI allele alone by electron microscopy ($n = 3$ per genotype). The mice with an OI allele alone had disordered, swollen ER. The appearance of the ER improved in mice with both an OI allele and a *Lrp5* HBM allele, suggesting that the HBM allele may improve mutant type I collagen processing and/or secretion in osteoblasts.

These results indicate that therapies targeting the LRP5 pathway may improve bone properties in mice with OI even if the causative mutation affects collagen production by osteoblasts. This suggests that most human patients with OI may benefit from these therapies, even if their mutation affects collagen processing and/or secretion.

MO0111

Osteogenesis Imperfecta Causes Splenomegaly and Elevated Osteoclast Progenitor Numbers in OIM Mice. Brya Matthews^{*1}, Emilie Roeder¹, Mara O'Brien¹, Danka Grcevic², Ivo Kalajzic¹. ¹University of Connecticut Health Center, USA, ²University of Zagreb, Croatia

Osteogenesis imperfecta (OI) is caused by insufficient or improper type I collagen synthesis, and is characterized by bone fragility. However, in children with severe OI and a number of mouse models of OI, high bone turnover is observed with elevated osteoclast numbers. While this phenotype is likely to be influenced by osteoblast dysfunction, *in vitro* studies suggest that there is also a defect in the osteoclast compartment. Therefore, in this study we sought to evaluate osteoclast progenitor (OCP) numbers and their differentiation potential in the well-characterized OIM mouse model.

OIM mice and their wild-type (WT) sex-matched littermates were analyzed at 7-9 weeks of age. Peripheral blood was collected, whole spleens were weighed, then processed, and bone marrow was flushed from the tibias and femurs. Identification of OCPs was achieved using established antibody cocktails for flow cytometry. Mice were processed individually and at least 4 animals per group were including in each experiment.

Serum CTx levels are 5-6x WT levels in both male and female OIM animals indicating elevated resorption, consistent with previous results showing increased osteoclast surface. OIM mice consistently showed lower bodyweight than WT controls. OIM mice had enlarged spleens, and therefore higher spleen cell numbers up to at least 13 weeks of age, particularly when corrected for bodyweight. OCPs in peripheral tissues like spleen reside in the lymphocyte(CD3/B220/NK1.1)CD11b^{hi} fraction. Male OIM mice showed a significantly higher proportion (50-100% increase) of CD11b^{hi}CD115⁺ cells, and CD11b^{hi}CD115⁺Ly6C^{hi} cells, which have been shown to be most enriched for OCPs. Similar trends were seen in females, although these did not reach significance. Unsorted OIM spleen cells formed around 2.5x more osteoclasts in culture, however, we did not observe changes in osteoclast differentiation from sorted CD11b^{hi} progenitors. We did not find any consistent changes in OCP fractions in peripheral blood, and have been unable to identify consistent changes in bone marrow OCP frequencies or their differentiation.

In conclusion, young adult OIM mice show enlarged spleens and increased numbers of spleen-resident OCPs suggesting a systemic effect of the disease on the hematopoietic system.

Identification of the mutations in the prostaglandin transporter gene, *SLCO2A1* and clinical characterization in Korean patients with pachydermoperiostosis. Sihoon Lee^{*1}, So Young Park², Yumie Rhee³. ¹Gachon University School of Medicine, South Korea, ²Cheil General Hospital, South Korea, ³Yonsei University College of Medicine, South Korea

Objective: Pachydermoperiostosis (PDP), or primary hypertrophic osteoarthropathy, is a rare genetic disease affecting both skin and bones. Both autosomal dominant with incomplete penetrance and recessive inheritance of PDP have previously been confirmed. Recently, hydroxyprostaglandin dehydrogenase (HPGD) and solute carrier organic anion transporter family member 2A1 (*SLCO2A1*) were reported to be pathogenic genes responsible for PDP. Both genes are involved in the PGE2 degradation. We aimed to identify responsible genes for PDP and the clinical features in Korean patients with PDP.

Methods: We studied six affected individuals and their available healthy family members from three unrelated Korean families with PDP. The *SLCO2A1* and HPGD genes were screened and analyzed.

Results: We identified two different *SLCO2A1* mutations in the PDP patients from two unrelated families; homozygous for c.940+1G>A and compound heterozygous for c.940+1G>A and p.Arg603* (c.1807C>T). In a third family, we found a novel heterozygous mutation in the *SLCO2A1* gene at nucleotide 302 causing a substitution of the amino acid isoleucine to serine at codon 101 (p.Ile101Ser) in affected individuals. Genetic analyses of the PDP patients showed no abnormality in HPGD gene. Mutated patients displayed characteristic phenotypes of PDP with various degrees of pachydermia and bone abnormality.

Conclusion: Our study further supports the role of mutations in *SLCO2A1* gene in the pathogenesis of PDP and could provide extended clues to the genotype-phenotype relations of PDP.

Supported by the Basic Science Research Program, National Research Foundation of Korea (NRF-2013R1A1A1A05005629 to S.L.).

Mild bone phenotype in a young adult man with homozygous p.Val667Met mutation in LRP5 gene: the culprit gene. Corinne Collet^{*1}, Agnes Ostertag², Thomas Funck-Brentano³, Jean-Louis Laplanche¹, Marie-Christine de Vernejoul³, Martine Cohen-Solal⁴. ¹Department of biochemistry & Genetics, hospital Lariboisiere, France, ²Inserm U1132, hospital Lariboisiere, France, ³Inserm U1132 & university Paris 7, hospital Lariboisiere, France, ⁴Centre Viggo Petersen, France

Purpose: Osteoporosis is characterized by low bone mineral density (BMD) and susceptibility to fracture. Genetic determinants are major factors of low bone mass with a high heritability. Polymorphisms in fifty genes have been reported to be associated with osteoporosis. Among them, LRP5 mutation has been described in osteoporosis pseudoglioma (OPGG), a rare recessive disease characterized by severe osteoporosis with fractures in infancy associated with a congenital blindness. Moreover, heterozygous mutations of p.Val667Met in LRP5 are associated with idiopathic osteoporosis and risk of fractures in young adults. Interestingly, this mutation is classified as a conflict variant in databases and described as a polymorphism with heterozygous frequency of 1-4% according to the analysed ethnic population.

Method: This study was performed to investigate the prevalence of LRP5 heterozygous mutations of p.Val667Met in a young adult idiopathic osteoporosis cohort.

Results: Among the 60 patients with T-score below 2.5 SD, 14 displayed heterozygous mutations and one carried the p.Val667Met variant at homozygous level. The patient was 35 year-old, had a T-score of -3.2 SD and a mild vertebral deformity, but no ophthalmologic signs. No mutation was found in other genes such as SOST. The mild phenotype revealed at mid-age raised the question of the severity of bone signs in the first description and that OPGG cannot be attributed to homozygous p.Val667Met alone. This observation suggests that another LRP5 variant or another gene was could have been responsible for OPGG.

Conclusion: This report showed that homozygous mutation in p.Val667Met LRP5 variant does not fully explain the OPGG phenotype and suggest the need to investigate mutations of other genes in severe osteoporosis.

MO0114

Identification of Novel BMD Associated Genes Using Integrated Genome-Wide Analyses Employing DNA Methylations and Transcript Levels in Bone Biopsies from Postmenopausal Women. Sjur Reppe^{*1}, Tonje G. Lien², Ole K. Olstad³, Vigdis T. Gautvik⁴, Ingrid K. Glad², Kaare M. Gautvik⁵. ¹Oslo University Hospital, Ullevaal, Norway, ²Department of Mathematics, University of Oslo, Norway, ³Oslo University Hospital, Department of Medical Biochemistry, Norway, ⁴University of Oslo, Institute of Basic Medical Sciences, Norway, ⁵Lovisenber Diakonale Hospital, Norway

While 60-80% of the BMD variation has been shown to be heritable, genome wide analyses have so far been able to explain only a fraction. This study attempts to dissect information from global transcription and DNA methylation analyses obtained from bone biopsies of postmenopausal women of varying BMD to identify novel BMD associated genes using the statistical method weighted lasso.

Eighty trans-iliacal bone biopsies, containing cortical and trabecular bone have been collected, and bone DNA and RNA have been isolated from the same samples. For RNA expression analysis HG-U133 plus 2.0 chips (Affymetrix) were used, and for DNA methylation analysis we used the Infinium HumanMethylation450 BeadChip, with about 17 CpG sites per gene region present in the promoter, 5'UTR, first exon, gene body, and 3'UTR.

We use the statistical method lasso, which is based on multiple linear regression, but contains a penalty part to reduce the number of influencing variables/covariates. In a weighted lasso approach we reduce the penalty part for methylations that are highly associated to one or more transcript levels. Thus, the methylation sites

which best explain BMD and are highly associated with gene expression will be slightly favored, while methylations with no association to gene expression will be weighted down. The output of lasso is a short list of DNA methylations that together explain a large part of BMD variation.

The R package glmnet is used to fit the weighted lasso, and use of weighted lasso leads to a 17% reduction in the prediction error as compared to un-weighted Lasso. Using this method, methylations in 22 genes are selected, including COL11A2, PCDH9, MKL1, SPI1 and ALDH3B1. For 14 of these, the degree of methylation is inversely correlated to BMD. Functional analysis of the 22 genes using DAVID Bioinformatics Resources 6.7 and applying 5% FDR, results in enrichment favoring: "collagen fibril organization", "alternative splicing" and "splice variant". Our novel statistical approach to map DNA methylations which correlate to BMD and favors methylations associated with gene expression shows the presence of mitochondrial, muscle and bone related genes, of which most have previously not been associated with BMD. The 22 methylations explain 62% of the variation in BMD, while a set of 22 randomly chosen methylations explain on average 22%, indicating that DNA methylation contribute significantly to BMD variation in postmenopausal women.

MO0115

Osteoblasts from Type V OI patients demonstrate gain-of-function for mineralization despite decreased COL1A1 expression. ADI REICH*¹, Alison Bae², Aileen Barnes², Wayne Cabral², Aleksander Hinek³, Jennifer Stimec⁴, Suvmil Hill⁵, David Chitavat⁶, Joan Marini². ¹NIH, USA, ²Bone & Extracellular Matrix Branch, NICHD, NIH, USA, ³Physiology & Experimental Medicine Program, Heart Center, Hospital for Sick Children, University of Toronto, Canada, ⁴Division of Diagnostic Imaging, Department of Pediatrics, Hospital for Sick Children, University of Toronto, Canada, ⁵Diagnostic Radiology Department, NIH Clinical Center, NIH, USA, ⁶The Prenatal Diagnosis & Medical Genetics Program, Department of Obstetrics & Gynecology, Mount Sinai Hospital, University of Toronto, Canada

Osteogenesis imperfecta (OI) is a genetically heterogeneous disorder characterized by bone fragility. Most cases result from dominant mutations in type I collagen, while recessive OI is caused by defects in genes whose products interact with type I collagen. Type V OI has dominant inheritance, with characteristic skeletal findings including ossification of the forearm interosseous membrane, radiodense metaphyseal bands, propensity for hyperplastic callus formation, and mesh-like lamellation on bone histology. It is caused by a unique heterozygous mutation in *IFITM5* (c.-14C>T), which encodes BRIL, a transmembrane protein expressed in osteoblasts. The mutation generates a start codon in the 5'-UTR, adding five residues to the BRIL N-terminus. However, the mechanism of type V OI and its relationship with type I collagen is unknown. We identified 8 patients with the *IFITM5* (c.-14C>T) mutation. Using cultured primary osteoblasts from patients with type V OI, we verified that *IFITM5* expression and BRIL protein level were comparable to control during osteoblast differentiation. Type V OI osteoblast function was most consistent with a gain-of-function mutation. Both early (*ALPL* and *IBSP*) and late (osteopontin and osteocalcin) markers of osteoblast differentiation are increased in type V OI osteoblasts; as are *SERPINF1* expression and PEDF secretion during differentiation. *SOST*, a marker of mature osteocytes, was also increased, although in-vitro mineralization by type V OI osteoblast was increased on alizarin red stain compared to control. In contrast, *RANKL/OPG* ratio was decreased due to increased *OPG* expression. This result supports prior histomorphometry reports on type V OI patients, who do not have high turnover bone. In addition, *COL1A1* is not activated in type V OI osteoblasts, which have less than half the level of *COL1A1* transcripts found in control in mid to late differentiation, with concomitantly decreased collagen protein secretion. Decreased secreted type I collagen underlies decreased crosslinked collagen in matrix, and altered appearance of fibrils deposited in culture. The increased mineralization and advanced differentiation of type V OI osteoblasts likely underlie the overactive tissue calcification and hypertrophic callus formation seen in affected individuals and demonstrates that type V OI has a gain-of-function mechanism. Decreased type I collagen expression, secretion and matrix incorporation establish type V OI as a collagen-related defect

MO0116

The Role of Wnt10b in Antiresorptive Therapy for Ovariectomy-Induced Osteoporotic Rats. Jia-Fwu Shyu*¹, Hung-Shu Ma², Jung-Tzu Cheng², Tzu-Hui Chu², Wei-Yu Chen², Yen-Nien Ting². ¹National Defense Medical Center, Taiwan, ²Department of Biology & Anatomy, National Defense Medical Center, Taiwan

Osteoporosis is characterized by a marked decrease in bone mineral density and strength, resulting in fragility fractures associated with high morbidity and mortality. Uncoupling antiresorptives, such as calcitonin, odanacatib, and saracatinib, are better drugs because they inhibit osteoclast bone resorbing activity while maintaining the communication between osteoclasts and osteoblasts that promotes bone formation.

Our recent results indicated that calcitonin inhibited bisphosphonate-induced osteoclast apoptosis and combined usage of calcitonin and bisphosphonate increases its efficacy in a rat model of osteoporosis. This suggests that different kinds of antiresorptives may induce different bone formation-stimulating osteoclast-derived factors (clastokines). Wnt10b is a recent identified clastokine and potential novel therapeutic target of postmenopausal osteoporosis. The role of Wnt ligands involved in skeletal physiology and disease is not fully understood yet. We hypothesize that uncoupling antiresorptive increase bone formation by inducing Wnt10b expression in osteoclasts. Bone marrow hematopoietic mononuclear cells were isolated from femur and tibia of Sprague-Dawley rats. They were induced into osteoclasts by M-CSF and RANKL treatments. In these cells, calcitonin induced a decrease of TRAP stain-positive reaction. However, ELISA analysis showed increase of Wnt10b expression in supernatant collected from the calcitonin-treated osteoclasts. Pretreatment of Wnt10b secretion inhibitor, C-59, blocked the increase of Wnt10b induced by calcitonin. Western blot analysis showed increase of Wnt10b in the calcitonin-treated osteoclasts. Culture of osteoblasts isolated from neonatal rat calvarias with the calcitonin-treated osteoclasts supernatant showed increase of mineralization as indicated by alizarin red staining. In vivo, microCT analysis showed calcitonin and alendronate treatment recover bone loss in ovariectomized rats. In these animals, immunohistochemistry showed calcitonin increases level of Wnt10b in femur as compared to saline- and alendronate-treated groups. In conclusion, the present study provides more information of calcitonin on the molecular level of bone remodeling which will help in future potential therapeutic studies on postmenopausal osteoporosis.

MO0117

Effects of genetic ablation of parathyroid hormone on the induction of FGF23 by dietary phosphate. Sherrri-Ann Burnett-Bowie*, Marie Demay. Massachusetts General Hospital, USA

Both parathyroid hormone (PTH) and fibroblast growth factor 23 (FGF23) increase in response to a dietary phosphate load in humans and mice. Because PTH promotes production of 1,25-dihydroxyvitamin D, a known inducer of FGF23 expression, it is not known whether PTH induces FGF23 directly or indirectly through its actions on 1,25-dihydroxyvitamin D or circulating calcium levels.

To determine if PTH is required for induction of FGF23 in response to dietary phosphate loading, male and female PTH-knockout (*PTHKO*) mice and their wildtype (*WT*) littermates were weaned onto chow d18 and transitioned to a 0.6% calcium, 1.25% phosphate diet d28 with terminal bleeding on d35. To determine the contributions of PTH to basal FGF23 levels, *WT* and *PTHKO* littermates were treated with the calcimimetic R568 at 10 mcg/g (Amgen, Inc) from d28 to 35 while being maintained on standard chow (1.0% calcium and 0.4% phosphate). FGF23 was measured using the Immotopics C-terminal assay.

Chow fed *PTHKO* mice were hypocalcemic and hyperphosphatemic d28 as compared with *WT* littermates. Despite this hyperphosphatemia, *PTHKO* mice had significantly lower circulating FGF23 levels than *WT* littermates. In response to 7 days of dietary phosphate loading, (d28- 35) circulating FGF23 increased significantly, in both the *PTHKO* mice and *WT* littermates, suggesting that PTH is not required for the induction of FGF23 by a dietary phosphate load. Ionized calcium decreased with dietary phosphate loading in the *PTHKO* mice, but not in *WT* littermates. Administration of R568 to chow-fed *PTHKO* and *WT* littermates from d28-35 decreased circulating ionized calcium and increased circulating FGF23 levels, though there was no difference in these levels between *WT* and *PTH gene* ablated mice.

Thus, PTH is not required to maintain basal circulating FGF23 levels, nor is PTH required for induction of FGF23 in response to dietary phosphate loading. The induction of FGF23 observed with the administration of a calcimimetic suggests that the parathyroid or renal calcium sensor may be involved in the regulation of circulating FGF23.

MO0118

Phosphate Regulates Production and Post-Translational Modification of FGF23. Yuichi Takashi*¹, Yuka Kinoshita², Nobuaki Ito³, Michiko Hori³, Manabu Taguchi³, Seiji Fukumoto¹. ¹Fujii Memorial Institute of Medical Sciences, Tokushima University, Japan, ²Division of Nephrology & Endocrinology, The University of Tokyo Hospital, Jordan, ³Division of Nephrology & Endocrinology, The University of Tokyo Hospital, Japan

Purpose: Hormonal function is regulated not only by the production but also by post-translational modification. Fibroblast growth factor 23 (FGF23) is a hormone produced by bone. FGF23 affects serum phosphate levels by suppressing the expression of sodium-phosphate co-transporters in the proximal tubules. In addition, FGF23 suppresses the production of 1,25-dihydroxyvitamin D and decreases intestinal phosphate absorption. A part of FGF23 protein is cleaved into inactive fragments. It was previously shown that O-glycosylation of FGF23 protein by GalNac-T3, a gene product of *GALNT3*, inhibits this cleavage. However, the regulatory mechanisms of this processing remain to be clarified. Methods: Human *FGF23* was overexpressed in UMR106 cells and the processing of FGF23 protein was analyzed by Western blotting of conditioned media using an antibody recognizing C-

terminal portion of FGF23. We also analyzed the expression of *Fgf23* and *Galnt3* by real-time PCR. Results: Western blotting detected both intact full-length and C-terminal fragment of FGF23. Increase of extracellular phosphate enhanced *Fgf23* expression and also increased full-length / C-terminal fragment ratio of FGF23 protein indicating that phosphate prevented the processing of FGF23 protein. Extracellular phosphate also enhanced *Galnt3* expression. Overexpression of both *FGF23* and *GALNT3* in UMR106 cells increased full-length / C-terminal fragment ratio of FGF23 protein in the conditioned media compared to cells with *FGF23* alone. Conclusions: It is well known that the increase of calcium concentration inhibits parathyroid hormone (PTH) production and enhances PTH degradation in parathyroid glands. In this study, the increase of extracellular phosphate not only promoted *Fgf23* production but also inhibited the cleavage of FGF23 protein possibly through enhancing expression of *Galnt3* (Fig.). Therefore, the activity of FGF23 is regulated by both its production and post-translational processing. These results confirm that FGF23 functions as a phosphotropic hormone.

Calorie restriction changes bone metabolism by a pathway both GH-IGF-1 axis and others in rat. Seichiro Shimauchi^{1*}, Masato Tomita¹, Isao Shimokawa², Makoto Osaki¹. ¹Department of Orthopaedic Surgery, Graduate School of Biomedical Sciences, Nagasaki University, Japan, ²Investigative Pathology, Graduate School of Biomedical Sciences, Nagasaki University, Japan

Objective: Previous studies elucidated the effect of caloric restriction on life extension in different kinds of experimental animal; however, the effect on bone metabolism has not been sufficiently clarified. Growth hormone-insulin-like growth factor (GH-IGF-1) axis, greatly associated with the effect of caloric restriction on life extension, may have an effect on bone metabolism. In this study, we investigated the effect of caloric restriction on bone metabolism and the role of GH-IGF-1 axis by comparing the bone metabolism of calorie-restricted rats with that of GH-suppressed rats.

Methods: We divided male Wistar rats into a WT AL group (wild-type, fed *ad libitum* from 6 weeks old) and WT CR group (wild-type, fed a calorie-restricted diet [30%]) and sacrificed them at the age of 10 months. Similarly, GH-antisense transgenic (Tg) rats, the first filial hybrid rats fed *ad libitum* (F1 AL) until the age of 10 months, were sacrificed. Their femurs and blood were collected. While bone microstructural analysis of the femurs was conducted by micro CT, IGF-1 and bone metabolism markers were measured in blood; thereby, we compared the differences among the groups.

Results: The body weight was significantly higher in the WT AL group than WT CR and F1 AL groups, and was the second highest in the WT CR group. Blood IGF-1 level was significantly higher in the WT AL group than F1 AL groups, but there were no significant differences in blood IGF-1 level between WT AL and WT CR groups. On bone microstructural measurement by micro CT, the bone density (bone volume over total volume [BV/TV]) was significantly higher in the WT AL group than WT CR ($P < 0.05$). There were no significant differences in BV/TV between WT AL and F1 AL groups, but values were lower in the F1 group. No significant differences were observed in bone alkaline phosphatase, a type of osteogenic marker, among the groups.

Discussion: From the results of this study, the effect of caloric restriction on bone metabolism is likely to be due to GH-IGF-1 axis, but it is suggested that there is another pathway other than GH-IGF-1.

MO0120

Diphtheria Toxin- and GFP-PTX-based mouse models of acquired hypoparathyroidism and treatment with a long-acting parathyroid hormone analog. Ruiye Bi^{1*}, Tomoyuki Watanabe¹, Yi Fan², Thomas Gardella¹, Michael Mannstadt¹. ¹Massachusetts general hospital, USA, ²Harvard School of Dental Medicine, USA

Background: Hypoparathyroidism (HP) is caused by inadequate levels of PTH and is characterized by hypocalcemia, hyperphosphatemia, and low bone turnover. The most common form of HP is post-surgical, caused by damage or removal of the parathyroid glands during neck surgery. Treatment with oral calcium and active vitamin D can lead to hypercalciuria and renal complications. More effective therapies are needed, but development of these requires reliable animal models.

Methods: PTHcre-iDTR mouse were generated by crossing mice carrying an inducible diphtheria toxin receptor (iDTR) allele with mice carrying a PTH-Cre allele, such that DTR is expressed specifically in the parathyroid glands. Parathyroid cells can thus be selectively destroyed by injecting mice with diphtheria toxin (DT). GFP-PTX mice were generated using mice that specifically express GFP in the parathyroid glands, such that surgical removal of the glands is greatly facilitated by the localized green fluorescence.

Results: Optimizing the dosing regimen of DT in PTHcre-iDTR mice revealed that two repetitive injections of DT at 5ug/kg, i.p. yielded the greatest reductions in serum PTH and blood Ca^{++} levels, as compared to vehicle injections (PTH = 251 ± 83 vs. 580 ± 53 pg/mL; Ca^{++} = 1.12 ± 0.03 vs. 1.26 ± 0.06 mmol/L; $p < 0.05$; $n=8$). More pronounced reductions in serum PTH and blood Ca^{++} levels were observed in the GFP-PTX mice (PTH = 32 ± 21 pg/mL; Ca^{++} = 1.05 ± 0.05 mmol/L measured 3 days after PTX surgery).

We then evaluated the efficacy of a long-acting PTH analog, LA-PTH, in correcting the hypoparathyroidism in these two mouse models. In each model, a single s.c. injection of LA-PTH (10 nmol/kg) elevated blood Ca^{++} to approximately the normal range, and the calcemic effects persisted for up to ~48 hours. In contrast, a single injection of PTH(1-34) at a five-fold higher dose (50 nmol/kg) elevated blood Ca^{++} levels for no longer than 6 hours. Importantly, LA-PTH did not increase urinary calcium excretion.

Conclusions: We present two new mouse models of acquired hypoparathyroidism: a PTHcre-iDTR mouse, which eliminates the need for surgery, and a GFP-PTX mouse, which greatly facilitates parathyroid surgery and provides for a more severe HP phenotype. The utility of these models is highlighted by the rescue effects observed with a long-acting PTH analog.

Effects of Abaloparatide on the Expression of Bone Resorption- and Formation-related Factors in Osteoblastic Cells; a Comparison with Teriparatide. Akito Makino^{*}, Hideko Takagi, Hiroyuki Sugiyama, Tsunefumi Kobayashi, Yoshinori Kasahara. Teijin Institute for Bio-Medical Research, Teijin Pharma Limited, Japan

Abaloparatide (ABL), a novel synthetic analog of human parathyroid hormone-related peptide, is currently under clinical development for severe osteoporosis in United States, Europe and Japan. In these clinical studies, the intermittent administration of ABL showed robust increase in bone mineral density (BMD) while its calcemic effect was limited as compared with teriparatide (TPD). Analysis of bone turnover markers suggested that both ABL and TPD increased bone formation and resorption, but bone resorption by ABL was lower than that by TPD.

In this study, to address the difference in the mechanism of action of ABL and TPD, effects on the expression of bone formation- and resorption-related factors were examined in human osteoblastic cell line, SaOS. Cells were treated with ABL or TPD transiently by mimicking clinical dosing regimen. Then, the expression of RANKL and M-CSF as bone resorption-related factors, and SOST and DKK1 as bone formation-related factors was measured by quantitative PCR and ELISA. ABL and TPD increased RANKL and M-CSF mRNA expression level, but these effects were rapidly reversed after removal of ABL from the culture media, while those in TPD-treated cells were sustained. Similarly, increased expression of M-CSF declined more rapidly after removal of ABL than TPD.

Next, to assess the influence on bone formation, expression of Wnt signaling inhibitors, SOST and DKK1, were measured. Cells were differentiated into post-osteoblast/pre-osteocyte state where the higher expression levels of SOST and DKK1 were confirmed. Both ABL and TPD suppressed the expression of SOST and DKK1. These effects continued after removal of the compounds and no difference was seen between ABL and TPD, suggesting comparable efficacy of ABL and TPD on Wnt-mediated bone formation.

These results suggest that ABL stimulates bone resorption less than TPD, while bone formation is similarly enhanced. The difference between ABL and TPD obtained in this study strongly supports the results of the clinical studies. ABL has a more potent effect on BMD increase and lower risk of hypercalcemia based on the preferable balance of bone formation to bone resorption as compared with TPD.

The Calcium-Sensing Receptor Supports the Growth and Survival of Breast Cancer Cells By Stimulating Parathyroid Hormone-related Protein Production in Calcium Rich Environments. Wonnam Kim*, Pamela Dann, Karena Swan, John Wysolmerski. Yale School of Medicine, USA

Bone metastases from breast cancer cause pain, hypercalcemia, pathologic fractures and, ultimately, death. In order for breast cancer cells to grow in the bone microenvironment, they must adapt to high levels of extracellular calcium. Cells respond to extracellular calcium by activating the calcium-sensing receptor (CaSR), a G protein-coupled receptor that binds and signals in response to calcium and other cations. The CaSR is expressed in many breast cancer cell lines and its expression has been shown to be higher in bone metastases than in primary tumors in patients. Therefore, we studied the role of the CaSR in breast cancer cell behavior. First, we identified that activation of the CaSR with high extracellular calcium stimulated proliferation in human BT474 breast cancer cells. Knocking down expression of the CaSR inhibited proliferation in response to extracellular calcium. BT474 cells treated with the CaSR antagonist, NPS2143, showed decreased proliferation in a dose dependent manner. Activation of the CaSR also increased the production of parathyroid hormone-related protein (PTHrP). Since PTHrP has been reported to increase proliferation in some breast cancer cell lines, we also knocked down PTHrP expression in BT474 cells, which reduced proliferation in response to increasing doses of calcium. The proliferation was not mediated by PTH receptor signaling but by nuclear translocation of PTHrP, which inhibited the cell cycle inhibitor p27. Knocking down either the CaSR or PTHrP, or treatment with NPS2143 also dramatically induced apoptosis in response to increasing doses of extracellular calcium. Apoptosis was mediated through the nuclear translocation of apoptosis-inducing factor (AIF). In order to determine whether these findings were relevant in vivo, we knocked out the CaSR in breast tumors in MMTV-PyMT transgenic mice. These mice showed decreased tumor PTHrP expression, slower tumor growth and prolonged survival. CaSR knockout tumors showed lower rates of BrdU incorporation and increased p27 levels. However, at normal calcium levels, rates of apoptosis were negligible in both knockout and control tumors. These data suggest that the CaSR promotes the survival and proliferation of breast cancer cells under calcium-rich conditions such as those found in the bone microenvironment, and that PTHrP acts as an important mediator of these effects.

Cyp11a1 Expression In Bone Is Associated With Aromatase Inhibitor-Related Bone Loss. MARIA RODRIGUEZ SANZ*¹, NATALIA GARCIA-GIRALT¹, DANIEL PRIETO-ALHAMBRA², SONIA SERVITJA³, SUSANA BALCELLS⁴, ROSANGELA PECORELLI⁵, ADOLFO DÍEZ-PÉREZ⁵, DANIEL GRINBERG⁴, IGNASI TUSQUETS³, XAVIER NOGUES⁵. ¹IMIM (Hospital del Mar Research Institute), Red Temática de Investigación Cooperativa en Envejecimiento y Fragilidad (RETICEF), ISCIII, Barcelona, Spain., Spain, ²Nuffield Department of Orthopaedics, Rheumatology & Musculoskeletal Sciences, Oxford. NIHR Musculoskeletal Biomedical Research Unit, University of Oxford, Oxford, UK., United Kingdom, ³Medical Oncology Department, Hospital del Mar, Universitat Autònoma de Barcelona, IMIM (Hospital del Mar Research Institute), Barcelona, Spain., Spain, ⁴Departament de Genètica, Universitat de Barcelona, IBUB, Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), ISCIII, Barcelona, Spain., Spain, ⁵Internal Medicine Department, Hospital del Mar, Universitat Autònoma de Barcelona, Barcelona, Spain., Spain

Aromatase inhibitors (AIs) used as adjuvant therapy in postmenopausal women with hormone receptor-positive breast cancer cause diverse musculoskeletal side effects that include bone loss and its associated fracture. The present study aimed to determine the genetic basis for the bone loss variability observed among women receiving AI treatment. B-ABLE is a prospective cohort of 531 women recruited at the time they initiate AI therapy in a bone metabolism unit. Bisphosphonate users were excluded, and finally 391 patients were selected for these analyses. SNPs in candidate genes involved in vitamin D and estrogen hormone-response pathways (CYP11A1, CYP17A1, HSD3B2, HSD17B3, CYP19A1, CYP2C19, CYP2C9, ESR1, DHCR7, GC, CYP2R1, CYP27B1, VDR and CYP24A1) were genotyped for association analysis with AI-related bone loss (AIBL). Multivariate linear regression was used to test their association with relative lumbar spine (LS) and femoral neck (FN) BMD loss after 1 and 2 years of follow-up. All models were adjusted for age, body mass index, previous tamoxifen and chemotherapy. Further, potential confounding for baseline 25(OH)-VITD concentrations and AI used was assessed. Next, CYP11A1 and expression in human fresh bone tissue and primary osteoblasts was assessed by RT-PCR. Western blot was used to detect the human cholesterol side-chain cleavage enzyme (encoded by CYP11A1 gene) in osteoblasts. After 2 years on AI treatment, 80.3% and 61.6% patients suffered a significant bone loss at lumbar spine (LS) and femoral neck (FN), respectively. In contrast, up to one third (19.6% LS, 38.6% FN) showed no decline or even increased bone density. After multiple testing correction, 3 tag-SNPs (rs4077581, rs11632698 and rs900798) located in the gene CYP11A1 were

significantly associated ($p < 0.005$) with FN AIBL at 2 years of treatment. CYP11A1 and CYP17A1 mRNA were detected in primary osteoblasts and total bone tissue. Both common isoforms of cholesterol side-chain cleavage enzyme were identified in osteoblasts. In conclusion, the genetic association of CYP11A1 gene with AIBL and its expression in bone tissue reveals a potential local function of this enzyme in bone metabolism regulation, offering a new vision of the steroidogenic ability of this tissue and new understanding of aromatase inhibitor-induced bone loss.

Disclosures: MARIA RODRIGUEZ SANZ, None.

MO0124

Enzalutamide Reduces the Bone Mass in the Axial but not the Appendicular Skeleton in Male Mice. Jianyao Wu*¹, Sofia Movérare-Skrtic¹, Anna E Börjesson¹, Marie K Lagerquist², Klara Sjögren¹, Sara H Windahl¹, Antti Koskela³, Louise Grahne², Ulrika Islander², Anna S Wilhelmson⁴, Åsa Tivesten⁴, Juha Tuukkanen³, Claes Ohlsson¹. ¹Centre for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, ²Centre for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, ³Department of Anatomy & Cell Biology, Medical Research Center, University of Oulu, Finland, ⁴The Wallenberg Laboratory for Cardiovascular & Metabolic Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden

Testosterone is a crucial regulator of the male skeleton and its skeletal effects are at least partly mediated via estrogen receptors as a result of aromatization of testosterone into estradiol. In addition, lifelong global androgen receptor (AR) inactivation results in reduced bone mass in both the axial and appendicular skeleton of male mice. In the present study, the role of the AR for adult bone metabolism was evaluated by means of the drug enzalutamide, which is a new efficient and specific AR antagonist used in the treatment of prostate cancer patients.

Nine-week-old male mice were treated with 10 mg/kg/day, 30 mg/kg/day, or 100 mg/kg/day of enzalutamide for 21 days or were surgically castrated and compared with vehicle-treated gonadal-intact mice.

Enzalutamide treatment markedly reduced the weights of the seminal vesicles and the levator ani muscle, confirming an AR antagonistic effect of enzalutamide. Although orchidectomy (orx) substantially reduced the cortical bone thickness and trabecular bone volume fraction (BV/TV) in the appendicular skeleton, these parameters were unaffected by enzalutamide. In contrast, both enzalutamide and orx reduced the trabecular bone mass in the axial skeleton as revealed by reduced lumbar spine areal bone mineral density (enzalutamide 100 mg/kg/day $-10.1 \pm 1.1\%$; orx $-7.7 \pm 0.9\%$, $p < 0.001$) and trabecular BV/TV in L₅ vertebrae (enzalutamide 100 mg/kg/day $-11.8 \pm 1.9\%$; orx $-20.5 \pm 2.7\%$, $p < 0.001$) compared with vehicle-treated gonadal intact mice. A compression test of the L₅ vertebrae revealed that the mechanical strength in the axial skeleton was significantly reduced by enzalutamide treatment (maximal load at failure, $-15.3 \pm 3.5\%$; $p < 0.01$). The effects of enzalutamide in the axial skeleton were associated with a high bone turnover supported by elevated serum levels of the bone resorption marker C-terminal collagen cross-links ($+40.7 \pm 8.4\%$; $p < 0.01$) and the bone formation marker osteocalcin ($+55.0 \pm 10.1\%$; $p < 0.01$) as well as increased bone formation rate as measured by dynamic histomorphometry in the L₄ vertebrae.

In conclusion, enzalutamide reduces the bone mass in the axial but not the appendicular skeleton in male mice. Castration, affecting both estrogenic and androgenic pathways, increases the risk of both vertebral and non-vertebral fractures while our findings suggest that anti-androgen monotherapy with enzalutamide may increase vertebral but not non-vertebral fracture risk.

Estrogen and Androgen Differentially regulate RUNX2: Genome-wide analysis with implications to gender-dependent control of bone formation and resorption. Anthony Martin¹, Jiali Yu¹, Jian Xiong¹, Jie Ji¹, Anna Börjesson², Sara Windahl², Paul Kostenuik³, Yankel Gabel⁴, Nyam-Osor Chimgé¹, Dustin Schones⁵, Claes Ohlsson², Baruch Frenkel^{*1}. ¹University of Southern California, USA, ²Gothenburg University, Sweden, ³Phylon Pharma Services, USA, ⁴Tel Aviv University, Israel, ⁵City of Hope, USA

The master transcription factor RUNX2 promotes both osteoblast differentiation and osteoblast-driven osteoclastogenesis. Receptors for steroid hormones, including estrogens and the androgens, physically interact with RUNX2 and generally attenuate stimulation of its target genes. Loss of these interactions may therefore contribute to increased bone turnover upon loss of sex steroids. To investigate the RUNX2-related regulatory gene network mediating skeletal effects of estradiol (E2) and dihydrotestosterone (DHT), we employed the NeMCO/Rx2dox primary culture system, in which doxycycline (dox) induces premature RUNX2 expression in Newborn Mouse Calvarial Osteoblasts. As expected, dox induced, and both E2 and DHT counteracted, expression of osteoblast marker genes (e.g., *Ibsp*, *Sparc*). Additionally, RUNX2 induced, and sex steroids antagonized osteoclastogenic genes (e.g., *Ltc4s*), as well as association of RANKL with the osteoblast membrane, likely contributing to

osteoblast-driven osteoclastogenesis and the anti-resorptive properties of sex steroids, respectively. Because loss of sex steroids increases bone resorption more than it increases bone formation, we hypothesized that it has differential effects on the activity of RUNX2 upon different target genes. Furthermore, because the bone-sparing effects of androgens go beyond those mediated through aromatization to estrogens, we also hypothesized that the locus-specific hormonal responses of RUNX2 target genes differ between estrogens and androgens. To test these hypotheses, we compared the influence of E2 and DHT on RUNX2-driven gene expression in NeMCO/Rx2dox cells using microarray hybridization. Whereas both sex hormones generally attenuated RUNX2-driven expression of its target genes, each of E2 and DHT displayed locus-specific interactions. Thus, the magnitude of attenuation varied considerably among RUNX2 target genes. Furthermore, exceptional gene sets were defined, which were resistant to steroid-mediated RUNX2 attenuation, and these gene sets varied considerably between E2 and DHT. Finally, we identified genes displaying uncommon additive and even synergistic interactions between RUNX2 and sex steroids, and again these gene differed considerably between E2 and DHT. In summary, RUNX2 may play a pivotal role in the skeletal response to loss of sex steroids. First, the general upregulation of RUNX2-driven transcription may contribute to increased bone turnover. Second, locus-specific effects of estrogens and androgens may contribute to shifting the balance between bone resorption and bone formation towards the former. Third, differential modulation of the responses to RUNX2 by androgens versus estrogens may contribute to gender differences in adult bone metabolism.

High-fat diet can elicit diverse effects on bone in relation with different sex hormone status. Shinya Tanaka¹, Takuto Tsuchiya², Akinori Sakai³, Hiroshi Odd¹. ¹Saitama Medical University, Japan, ²University of Occupational & Environmental Health, Japan, ³University of Occupational & Environmental Health, Japan

(Background and Objective) High-fat diets also decreased bone volume, what we clearly demonstrated in our recent study using male mice given high-fat diet due to increases in bone resorption and decreases of bone formation. On the other hand, weight losses in women are one of independent risk factors of osteoporotic fracture. Thus high-calorie diet can elicit diverse effects on bone in relation with different sex hormone status. The objective of this study is to clarify the difference of effects of high-fat diet on bone between ovariectomized (OVX) mice and sham operated female mice.

(Materials and Methods) Seven weeks old, female, C57BL/6J mice were purchased and subjected to 4 groups, sham operated mice given standard chow (SS), OVX mice given standard chow (OS), sham operated mice given high-fat diet (SH), and OVX mice given high-fat (OH). After 1 week of acclimatization, mice were operated sham or OVX, and were given standard or high-fat diets from 8 weeks age to 20 weeks age. At 6 and 12 weeks of experiment, bone mineral density (BMD) in the lumbar spine and the femur of mice were detected under anesthesia. At the end of experiment, mice were sacrificed and the left tibia was harvested for bone histomorphometry.

(Results) Decreases in BMD were observed in the lumbar spine of OVX mice and what was more apparent in OH mice, while the lumbar BMD did not decrease in SH mice. In the femur, although decreases in BMD was not observed OS mice or SH mice, while decreased in BMD in OH mice was apparent. Increasing in bone volume (BV/TV) were observed in SH mice insignificantly, while decreased of BV/TV were observed in OH mice significantly. Although mineralizing surface (MS/BS) and bone formation rate (BFR/BS) increased insignificantly in SH mice compared with SS mice, MS/BS and BFR/BS in OH mice decreased compared with OS mice insignificantly. (-Conclusion) High-fat diet increases in bone formation and in bone volume in sham operated mice, but facilitates decreases of bone formation and of bone volume in ovariectomized mice.

MO0127

Broader Transcriptional Activity of Vitamin D Receptor (VDR) in the Absence of 1,25-dihydroxyvitamin D in Human Cells. Bruno Ferraz-de-Souza¹, Pedro L F Costa², Eduardo C Teodoro², Maria L Katayama³, Maria A K Folgueira³, Monica M Franca². ¹Univ of Sao Paulo School of Medicine (FMUSP), Brazil, ²Endocrinology/LIM-18, Univ of Sao Paulo School of Medicine, Brazil, ³Oncology/LIM-24, Univ of Sao Paulo School of Medicine, Brazil

The vitamin D receptor (VDR) is expressed in several cell types beyond those involved in vitamin D-mediated mineral homeostasis, prompting the investigation of its actions in general human health. VDR activation by 1,25-dihydroxyvitamin D (1,25D) leads to transcriptional regulation of numerous targets, and the unliganded VDR is believed to mainly silence target gene transcription. Understanding human VDR actions in the absence of 1,25D may shed light on the transcriptional outcome of 1,25D dosage variation and the molecular consequences of vitamin D insufficiency.

We have established skin fibroblast cultures from a patient bearing a severe homozygous p.Arg30* VDR mutation (MUT), leading to ablation of VDR expression, and from a healthy control individual (CO). Absence of VDR expression

and resistance to 1,25D in MUT cells were confirmed by immunoblotting and RTPCR. Total RNA was extracted from MUT and CO cells after 24-h treatment with vehicle or 10 nM 1,25D, and global gene expression was analyzed with Affymetrix Human Gene 2.0 ST arrays. A Benjamini-Hochberg $p < 0.05$ was set for significance. For subsets of targets, relative gene expression was confirmed by TaqMan qRT-PCR and direct VDR binding to DNA was confirmed by chromatin immunoprecipitation.

In CO fibroblasts with intact VDR, expression of 1,161 target genes was regulated by 1,25D. Confirming the extreme insensitivity of MUT cells, 1,25D treatment led to differential expression of 2 genes only. Surprisingly, 4,051 genes were differentially expressed in CO and MUT cells treated with vehicle, reflecting basal VDR regulation. A bioinformatics approach was undertaken to correct for putative genetic background variability, rendering the identification of 2,164 genes regulated by VDR in the absence of 1,25D (71% up-, 29% down-regulated). Of these, 268 genes were also 1,25D targets, and an antagonistic effect in absence vs presence of ligand was seen. Strikingly, 194 genes (73%) were basally upregulated by VDR and downregulated by 1,25D stimulus. In conclusion, we report broader transcriptional output induced by VDR in the absence of 1,25D in human fibroblasts. Approximately a quarter of 1,25D targets in these cells are also basally regulated by VDR. Furthermore, an antagonistic transcriptional activity of the VDR is seen in basal vs 1,25D-activated states, mainly in the form of basal upregulation and ligand-induced downregulation of target genes, challenging the current paradigm for VDR activity.

Disclosures: Bruno Ferraz-de-Souza, None.

MO0128

CKD induces intrinsic alterations in osteoblast response to 1,25D. Renata Pereira¹, Nadine Khouzam¹, Richard Bowen¹, Earl Freymiller², Isidro Salusky¹, Katherine Wesseling-Perry³. ¹David Geffen School of Medicine at UCLA, USA, ²School of Dentistry, UCLA, USA, ³UCLA Medical Center, USA

Chronic kidney disease (CKD) increases expression of osteocyte-specific regulators of bone metabolism, including FGF23. 1,25D is used to control bone turnover in children with CKD but increases osteocytic FGF23 expression. We have demonstrated that primary osteoblasts obtained from patients with CKD have altered proliferation and mineralization characteristics, suggesting CKD-mediated intrinsic changes to osteoblast biology. The direct effect of 1,25D and FGF23 on osteoblast maturation and mineralization in the context of CKD remains unknown. Thus, primary human osteoblasts from 3 healthy controls, 3 pediatric dialysis patients with low bone turnover (adynamic bone) and 3 pediatric patients with high bone turnover (2°HPT) were cultured under pro-mineralizing conditions consisting of 10mM β -glycerolphosphate and 100 μ g/ml ascorbic acid in the presence of 1,25D at 1, 10, and 100 nM. After 2, 3, and 4 weeks of growth, cells were washed, fixed with 10% formalin, and stained with 2% Alizarin Red S. Mineral content was assessed by measuring absorption of acetic acid-extracted Alizarin Red S dye (at 405 nm) normalized by live cell concentration (as assessed by absorption (at 570 nm) of methanol-extracted Crystal Violet staining obtained from parallel cultures. 1,25D treatment decreased proliferation and increased mineralization; however, high concentrations were required in CKD cells, suggesting osteoblast resistance to 1,25D in CKD. (Figure 1)

To assess whether FGF23 modifies the effects of CKD and 1,25D on osteoblast maturation and mineralization, cells from 3 healthy controls and 3 pediatric CKD patients with normal rates of bone turnover were induced to mineralize by culturing for 2 weeks under pro-mineralizing conditions (as above). 1,25D (10nM) and/or FGF23 (10 nM) were then added to the media for an additional 2 weeks. Mineralized nodule formation was compared to cells from the same individuals grown for 4 weeks in the presence of 1,25D, FGF23, or both. 1,25D alone increased mineralization in control and CKD cells already entering a mineralized state while the addition of FGF23 to 1,25D increased mineralization in CKD but not in control cells already starting to mineralize. By contrast, the addition of FGF23 and 1,25D before the onset of mineralization inhibited mineralization in control, although not in CKD, cells, suggesting an interaction between the effects of 1,25D, FGF23, and CKD in osteoblast maturation and mineralization. (Figure 2)

between D2 and D3 mice ($193 \text{ pg/ml} \pm 9.0$ vs. $196 \text{ pg/ml} \pm 6.2$) at wk 8. Using two-way ANOVA to assess the impact of diet independent of sex, bone histomorphometric analysis showed that wk8 mice fed D2 only had significantly higher values for osteoclast surface/bone surface (Oc.S/BS), eroded surface/bone surface ES/BS), and mineral apposition rate (MAR) compared to D3 mice. By Mann-Whitney, osteoblast surface/bone surface (Ob.S/BS) was higher in wk 8 female but not wk 8 males. At wk16, D2 animals had significantly higher bone volume/total volume (BV/TV) and trabecular number (Tr.N) compared to D3 mice. Differences in bone phenotype were observed despite D2 fed mice reaching similar serum 25D levels and lower 1,25D levels compared to D3 fed animals. This suggests that D2 is less well bound to DBP, with the resulting higher levels of free 25D2 relative to 25D3 promoting differential effects on bone.

Examination of VDR/RXR/DRIP205 interaction, intranuclear kinetic and DNA binding in ras-transformed keratinocytes and its implication for designing optimal vitamin D therapy in cancer. Sylvester Jusu^{*1}, John Presley², Richard Kremer³. ¹Royal Victoria Hospital, Canada, ²McGill University, Canada, ³Supervisor, Canada

We previously reported that the malignant human keratinocyte HPK1Aras cell line is resistant to the growth inhibitory action of $1, 25(\text{OH})_2\text{D}_3$, compared to its normal counterpart immortalized HPK1A cells. We further demonstrated that this resistance was due to phosphorylation of the vitamin D receptor (VDR) heterodimeric partner, human retinoid X receptor alpha (hRXR α) on a critical amino acid, serine 260 located in close spatial proximity to regions of coactivators and corepressors interactions. We next demonstrated that subcellular localization of the hRXR α was impaired in HPK1Aras cells but could be restored using either the MAPK inhibitor UO126 or a non-phosphorylatable mutant of hRXR α (hRXR α ala260 mutant). In order to examine further the mechanisms of $1, 25(\text{OH})_2\text{D}_3$ resistance we looked at VDR/RXR and DRIP 205(a critical coactivator required for downstream signaling of $1, 25(\text{OH})_2\text{D}_3$) interactions, intranuclear kinetic in live cells and DNA binding in fixed cells using FRET (Fluorescence Resonance Energy Transfer), FLIP (Fluorescence Loss In Photobleaching), FRAP (Fluorescence Recovery After Photobleaching) and Hoechst staining. We used VDR-GFP, hRXR α wt-GFP, hRXR α mutant-GFP, VDR-mCherry, hRXR α wt-mCherry, hRXR α mutant-mCherry and DRIP205-GFP fluorescent receptors transfected into either HPK1A or HPK1A ras cells and treated with $1, 25(\text{OH})_2\text{D}_3$, 9-cis-Retinoic Acid or vehicle in the presence or absence of UO126.

Using FRET we showed that $1, 25(\text{OH})_2\text{D}_3$ addition increases their interaction in HPK1A cell but only in HPK1Aras cells treated with either UO126 or transfected with the hRXR α mutant. Furthermore, we demonstrated using FLIP that the half time of dissociation of hRXR α in the nucleus and residence time of the receptor within the nuclear compartments are significantly increased in HPK1Aras cells transfected with the non-phosphorylatable hRXR α mutant or treated with the MAPK inhibitor UO126.

Finally we demonstrated with Hoechst staining impaired VDR/ hRXR α /DRIP205 complex binding to chromatin in HPK1A-ras cells that was restored with UO126 treatment or transfection of the hRXR α mutant.

In summary we have demonstrated using highly specific intra-cellular tagging methods in live cells important alterations of the vitamin D signaling system in cancer cells in which the ras-raf-MAP kinase system is activated suggesting that specific inhibition of this commonly activated pathway could be targeted therapeutically to enhance vitamin D efficacy.

Gender Differences in Vitamin D Metabolism in MSCs from Pre-Pubertal Subjects. Julie Glowacki^{*1}, Brian Ruggiero¹, Kristina Christoph¹, Bonnie Padwa². ¹Brigham & Women's Hospital, USA, ²Boston Children's Hospital, USA

Vitamin D is crucial for mineral homeostasis and contributes to bone metabolism by inducing osteoblast differentiation of marrow stromal cells (MSCs). We recently reported that MSCs from adults demonstrate 1α -hydroxylase activity *in vitro* and express vitamin D-related genes; this raises a possible autocrine/paracrine role for D activation in pre-osteoblasts. Because nothing is known about vitamin D metabolism in MSCs from children, we tested the hypotheses that pre-pubertal MSCs have 1α -hydroxylase activity and express vitamin D-related genes. With IRB approval, we isolated MSCs from discarded excess iliac marrow graft from 6 male and 6 female subjects (age 8-12 yrs) undergoing alveolar cleft repair. There was a small difference in mean age (male: 10.3 yrs; female: 8.7 yrs; $p=0.01$). 1α -hydroxylation of substrate $25(\text{OH})\text{D}$ ($1 \mu\text{M}$, 24hr) was measured by ELISA for $1\alpha, 25(\text{OH})_2\text{D}$. RT-PCR was used for expression of D-related genes. Pediatric MSCs showed 1α -hydroxylase enzyme activity *in vitro* (68.7 - $160.3 \text{ fmol/mg protein/hr}$). There was constitutive expression of D receptor (VDR) and D-hydroxylases ($1\alpha/\text{CYP27B1}$, CYP27A1 , CYP2R1 , and CYP24A1). The constitutive expression of $1\alpha/\text{CYP27B1}$ paralleled the level of 1α -hydroxylase enzyme activity. There was 2.6-fold greater expression of $1\alpha/\text{CYP27B1}$ in

Differential Effects of Vitamin D2 vs. Vitamin D3 on Bone are Associated with Variations in Free 25-Hydroxyvitamin D. Rene Chun^{*1}, Renata Pereira², Tonnie Huijs³, Leon Swinkels³, Ivan Hernandez⁴, Rui Zhou⁵, Nancy Liu⁵, John Adams⁵, Martin Hewison⁴. ¹Dept of Orthopaedic Surgery, UCLA-Orthopaedic Hospital Research Center, Us, ²Dept of Pediatric Nephrology, David Geffen School of Medicine at UCLA, USA, ³Future Diagnostics, Netherlands, ⁴Centre for Endocrinology, Diabetes & Metabolism, The University of Birmingham, United Kingdom, ⁵Dept of Orthopaedic Surgery, UCLA-Orthopaedic Hospital Research Center, USA

Pro-hormone 25-hydroxyvitamin D (25D) circulates bound primarily to the serum vitamin D binding protein (DBP). For some target tissues DBP facilitates receptor-mediated uptake of 25D by cells, but 25D may also access target cells in a free, non-DBP-bound, form. To assess the importance of 'free' versus DBP-bound 25D for bone health, we compared the effects of vitamin D2 (D2) and vitamin D3 (D3) diets in mice. Both forms of vitamin D show similar 25-hydroxylation (to 25D2 and 25D3 respectively), but the 25D3 metabolite shows higher binding affinity for DBP than 25D2, so that free 25D may be higher for D2 relative to D3. Male and female mice were placed on diets containing equal amounts (1000 IU/kg) of D2 or D3 beginning at wk3 of age. At wk8 of age mice fed D2 diet had only 25D2 in circulation ($26.6 \text{ ng/ml} \pm 1.9$), and mice fed D3 mice had only 25D3 ($28.3 \text{ ng/ml} \pm 2.0$). Similar results were obtained at wk16 ($33.3 \text{ ng/ml} \pm 4.4$ for 25D2 vs. $31.7 \text{ ng/ml} \pm 2.1$ for 25D3). D2 fed mice had significantly ($p<0.05$) lower total $1, 25(\text{OH})_2\text{D}$ compared to D3 diet at both wk8 ($44.5 \text{ pg/ml} \pm 6.4$ vs. $62.4 \text{ pg/ml} \pm 11.6$) and wk16 ($78.4 \text{ pg/ml} \pm 12.6$ vs. $95.5 \text{ pg/ml} \pm 11.6$). By contrast, measured 'free' 25D was significantly ($p<0.001$) higher in D2 animals at wk8 ($16.8 \text{ pg/ml} \pm 0.65$ vs. $8.4 \text{ pg/ml} \pm 0.63$) and wk16 ($17.4 \text{ pg/ml} \pm 0.43$ vs. $8.4 \text{ pg/ml} \pm 0.44$). There was no significant difference in serum PTH

MSCs from boys compared with girls ($p=0.04$) and 3.5-fold greater expression of CYP24A1 in boys compared with girls ($p<0.0001$). There was 2.4-fold greater expression of ER α in MSCs from prepubertal boys than girls ($p<0.02$). *In vitro* treatment of female prepubertal MSCs with 10 nM 25(OH)D upregulated 1 α /CYP27B1 (4.8-fold), VDR (6.4-fold), and ER α (4.4-fold); and 10 nM 17 β -estradiol upregulated 1 α /CYP27B1 (5-fold) and CYP24A1, as well as VDR (2.6-fold), ER α (2.0-fold), and ER β , with no change in CYP27A1 or CYP2R1. These data show ranges of 1 α -hydroxylase activity and D-related genes in pre-pubertal hMSCs. The unexpected pre-pubertal gender differences in D metabolism in MSCs, not found for adults, suggest a possible metabolic insufficiency in prepubertal girls. Expression and regulation of vitamin D related genes in pre-pubertal hMSCs reinforce an autocrine/paracrine role for vitamin D in hMSCs. Finding striking gender differences in D-related genes in MSCs from prepubertal subjects adds insight to the metabolic environment of bone and presents a research approach for investigating and optimizing pediatric bone health.

Mouse and Human Bacterial Artificial Chromosomes Encoding the CYP24A1 Loci Rescue the Ability of Cyp24a1 Null Mice to Catabolize 25-Hydroxyvitamin D₃ to 24,25-Dihydroxyvitamin D₃ and 25-Hydroxyvitamin D₃-26,23-Lactone. Alex Carlson^{*1}, Martin Kaufmann², Rene St-Arnaud³, Glenville Jones², J. Wesley Pike¹. ¹University of Wisconsin-Madison, USA, ²Queen's University, Canada, ³McGill University, Canada

Serum 25-hydroxyvitamin D₃ and 1,25-dihydroxyvitamin D₃ (1,25(OH)₂D₃) levels are maintained in part through CYP24A1 activity. Produced in the kidney, CYP24A1 expression is also found in all cellular targets of vitamin D action and is rapidly upregulated in response to 1,25(OH)₂D₃. Traditional approaches and more recent ChIP-seq analyses have identified 1,25(OH)₂D₃-inducible vitamin D receptor binding to both the promoter proximal region of CYP24A1 and to a cluster of elements downstream as well. Analyses of cell lines with stably integrated recombinant mouse and human BAC clones spanning the CYP24A1 loci and containing luciferase reporters within the 3' UTRs of each gene have shown that these constructs recapitulate the expression profile of endogenous CYP24A1 and that both the proximal and distal enhancer elements are involved in CYP24A1 regulation. To study this regulation further, we utilized these two mouse and human constructs as transgenes in mice. Two strains for each transgene were selected for their high basal, yet 1,25(OH)₂D₃-inducible renal luciferase activity as well as for inducible activity in other 1,25(OH)₂D₃ target tissues such as intestine, but not liver or muscle. Importantly, when crossed into a Cyp24a1 null background, both transgenes rescued the 24,25(OH)₂D₃ deficiency seen in the absence of Cyp24a1, producing somewhat higher levels of the metabolite than in wildtype mice. Interestingly, while 24,25(OH)₂D₃ was produced from both transgenes, the mouse version made significantly higher levels of the 25-hydroxyvitamin D₃-26,23-lactone than in human, supporting previous studies suggesting that utilization of this pathway is more prevalent in mice. Finally, examination of transgene expression revealed that all strains of mice expressed lower basal levels of renal CYP24A1 than seen for endogenous Cyp24a1. Coincident with this finding, the higher levels of circulating 24,25(OH)₂D₃ suggest either that the enzyme produced is incapable of fully catabolizing 24,25(OH)₂D₃ to water soluble products or that post transcriptional regulation of Cyp24a1 enzyme activity exists independently of low transcript production. Our current studies demonstrate that both mouse and human CYP24A1 gene loci are similarly expressed and regulated by 1,25(OH)₂D₃ in mice and are capable of rescuing the Cyp24a1 null phenotype. Nevertheless, these two transgenes continue to display both similar and unique features consistent with the species from which they were obtained.

MO0133

Optimization of an Elisa for the Direct Measurement of Free 25OH Vitamin D. Nicolas Heuereux^{*1}, Leon Swinkels², Fabienne Mathieu¹, Tonnie Huijs², Ernst Lindhout², Gregg Mayer², Mike Martens². ¹DIAsource Immunoassays, Belgium, ²Future Diagnostics Solutions, Netherlands

The objective of this project was to optimize and characterize a simple immunoassay for the quantification of free 25-hydroxyvitamin D (25OH Vit D). Recent studies suggest that the concentration and genotype of Vitamin D binding protein (DBP) are important factors that determine the bioavailability of 25OH Vit D in blood. It has been suggested that measurement of free, non-protein bound 25OH Vit D in serum, may provide more relevant diagnostic information than the measurement of total 25OH Vit D, for instance in critically ill patients, statin treated patients, chronic kidney disease, liver failure, bladder cancer, pregnant women, or in hemodialysis patients. Following the first laboratory evaluation phase, a two-step enzyme-linked immunosorbent assay (ELISA) was optimized for the quantification of free 25OH Vit D assay. Modifications were made in the protocol for the coating of the monoclonal anti-25OH Vit D in the microtiter plates as well as in the formulation of the sample diluent and of the biotinylated Vitamin D conjugate. The optimized assay was validated against the first version of the assay and the calibration and sample values remained equivalent. The following performances were obtained: the calibrator

range was 0.2-35 pg/ml. The LoB was 1.9 pg/ml; the LoD was 2.8 pg/ml. Total assay precision was 10.2% at 6.0 pg/ml, 7.6% at 10.9 pg/ml and 5.5% at 24.9 pg/ml. The cross-reactivity of the antibody towards 25OH Vitamin D₂ was 77% and the influence of interfering hemoglobin, bilirubin and triglycerides was also verified. Finally the shelf life of the assay was extended to over one year when stored at 2-8°C. The evaluation of plasma samples and of the stability of free 25OH Vit D in serum samples stored at room temperature and at 2-8°C were also performed. The assay was recently compared to the calculation method for the determination of free 25OH Vit D levels in clinical populations and showed better results, i.e. in relationship with iPTH. (J.B. Schwartz, J. Clin. Endocrinol. Metab. 2014). The assay was optimized so that it reproducibly determines the level of free 25OH Vit D in human serum or plasma samples. The assay can be used as a valuable tool in studies to establish the clinical relevance of free 25OH Vit D.

RNA- and ChIP-sequencing Analyses Identify Gene Networks Modulated by 1,25-Dihydroxyvitamin D₃ in Mouse Intestine and Directly Regulated by the Hormone-activated Vitamin D Receptor. Seong Min Lee^{*}, Mark Meyer, Nancy Benkusky, Lori Plum, Hector DeLuca, J. Wesley Pike. University of Wisconsin-Madison, USA

The vitamin D receptor (VDR) is a nuclear factor that mediates the process of mineral regulation by 1,25-dihydroxyvitamin D₃ (1,25(OH)₂D₃) through actions in intestine, kidney and bone. In the intestine, various genetic deletion studies suggest that calcium absorption is a prerequisite for normal calcium/phosphorus homeostasis. To understand the gene networks modulated by the 1,25(OH)₂D₃/VDR system in the intestine, we have identified through RNA-sequencing analysis a subset of 45 genes that are regulated by 1,25(OH)₂D₃ in duodena of Cyp27b1 null mice under both hypocalcemic and normocalcemic conditions. This gene network includes previously identified calcium regulators such as Trpv6, Atp2b1, S100g and Cldn2. Importantly, 1,25(OH)₂D₃-responsive genes were similarly regulated by 1,25(OH)₂D₃ in the duodena of wildtype mice, and many were expressed in more distal portions of the intestinal track as well. To explore the molecular mechanisms associated with the regulation of 1,25(OH)₂D₃ target genes, we performed in vivo ChIP-sequencing analysis using intestinal epithelial cells obtained from the proximal small intestine of vehicle- or 1,25(OH)₂D₃-treated vitamin D sufficient wildtype mice to identify VDR binding sites. The results reveal a striking VDR cistrome in the absence of added 1,25(OH)₂D₃ and a dramatic increase in VDR binding sites following treatment with 1,25(OH)₂D₃. VDR action was confirmed at sites previously identified as regulatory for Cyp24a1, Trpv6 and Pllim2 and newly identified for genes such as S100g, Atp2b1, Pllim2 and Slc37a2 known to be VDR targets. Further bioinformatic analysis of the ChIP-sequencing data revealed that VDR binding sites were located predominantly within intronic and intergenic regions that contained a high frequency of classic VDREs which were associated with adjacent motifs for HNF4 and GATA4. Most importantly, almost all of the 1,25(OH)₂D₃ regulated genes that were identified by RNA-sequencing analysis and linked to calcium absorption and metabolism contained VDR binding activity within their loci. In conclusion, we have identified a gene network that is regulated directly by 1,25(OH)₂D₃ in a spatially-dependent manner throughout the intestinal track through enhancers that are occupied by the VDR in both vitamin D sufficient and 1,25(OH)₂D₃ treated mice. These studies provide a foundation for understanding the molecular mechanisms of target gene regulation and calcium absorption by 1,25(OH)₂D₃ in the intestine.

Up-regulation of CYP24A1 splicing variants (CYP24A1-SV) expression is associated with vitamin D metabolic abnormality in insulin deficient diabetes mellitus. Hironori Yamamoto^{*1}, Mari Tajiri², Otoki Nakahashi², Mariko Ishiguro³, Eiji Takeda², Yutaka Taketani². ¹University of Jin-ai, Japan, ²University of Tokushima, Japan, ³Jin-ai University, Japan

Decrease of blood vitamin D concentration has been reported in patients with type 1 and 2 diabetes. However, the molecular reason behind this decrease is unclear. The aim of this study was to investigate the molecular mechanism of vitamin D metabolic abnormality in insulin deficient diabetes rats which were injured pancreatic beta cell by injection of streptozotocin (STZ). Sprague-Dawley rats were injected with STZ (65 mg/kg BW), and sacrificed after 9 or 29 days. Plasma activated vitamin D [1,25(OH)₂D₃], calcium and osteocalcin levels were significantly lower in STZ rats than control rats, however, there were no difference in plasma 25(OH)D₃, iFGF23 and TRAP5b levels. On the other hand, plasma levels of phosphate, iPTH and corticosterone were higher in STZ rats than control rats. Quantitative real-time PCR analysis showed that vitamin D catabolic enzyme CYP24A1 mRNA expression was significantly higher in kidney of STZ rats compared with control rats. In addition, the treatment of insulin recovered the high CYP24A1 mRNA expression levels in STZ rats. Interestingly, western blotting analysis found a strong expressed 40 kDa CYP24A1 which is differ from the reported 50-55kDa CYP24A1 in the kidney of STZ rats. And, we observed the up-regulation of CYP24A1-splicing variant (CYP24A1-SV) which lacked exon 1, 2 and N-terminal region was reported in human and chick

CYP24A1 gene in kidney of STZ rats. Finally, we confirmed the transcriptional up-regulation of endogenous CYP24A1 mRNA expression by glucocorticoid and glucocorticoid receptor in renal proximal tubular cells. These results suggest that the transcriptional up-regulation of renal CYP24A1-SV gene expression by corticosterone may cause to decrease plasma 1,25(OH)₂D level in STZ induced diabetic rats.

MO0136

A Novel Mechanically-Induced Osteocyte/Th17 Cell Signaling Mechanism.
Travis McCumber*, Kristen Drescher, Diane Cullen. Creighton University, USA

Mechanical loading of bone triggers bone formation, via osteocyte signaling. However, when mechanical loads of extreme force or repetition create tissue damage, osteocytes stimulate the remodeling of the damaged bone matrix. We have previously reported an up regulation of the pro-inflammatory cytokine GRO/KC, T cell recruiting cytokines (IL-2, MCP-1), and an increase in osteoclast number within fatigue loaded bone. This suggests a relationship between bone fatigue and the recruitment of both T cells and osteoclasts. We examined a novel, mechanically-induced signaling pathway between osteocytes and T cells, and hypothesized that repetitive fluid shear stress (FSS) would induce osteocyte production of cytokines that stimulate Th17 cell development and IL-17 and RANKL production. MLO-Y4 osteocyte-like cells were exposed to FSS (7 ± 3 dynes and 10 ± 3 dynes, at 1Hz) or Static control. The cells and medium were collected after 15, 30, 60, or 180 minutes. ELISA analysis of MLO-Y4 medium revealed greater IL-6 and TGF- β 1 in FSS versus Static groups ($p < 0.01$). IL-6 and TGF- β 1 levels were greater after 10 ± 3 dynes than 7 ± 3 dynes ($p = 0.02$ and 0.01). MLO-Y4 medium also revealed greater RANKL in Static than FSS groups ($p < 0.01$), which increased with exposure time ($p < 0.02$). Murine splenocytes were cultured in T cell growth medium and treated with FSS or Static medium for 96 hours. ELISA analysis of splenocyte culture medium revealed greater IL-17 and RANKL in cultures treated with FSS versus Static medium ($p < 0.01$). IL-17 and RANKL were greater after 10 ± 3 dynes than 7 ± 3 dynes ($p < 0.01$ and $p = 0.02$). To our knowledge these data are the first to support a novel, mechanically-induced osteocyte/Th17 cell signaling mechanism. Our data illustrates that mechanically-stimulated MLO-Y4 cells secrete cytokines (IL-6, TGF- β 1) known to induce murine Th17 cell development, and that splenocyte cultures treated with MLO-Y4 FSS medium produce Th17 cell products (IL-17, RANKL). IL-6, TGF- β 1 (MLO-Y4) and IL-17, RANKL (Th17) were expressed in a dose dependent manner with the greatest levels seen at 10 ± 3 dynes. These results suggest that greater osteocyte mechanical stress potentiates greater Th17 cell development and activity. Th17 cells, through the secretion of IL-17 and RANKL, can stimulate osteoclast formation. Future research on the osteoclast response to our osteocyte/Th 17 cell signaling model would provide a new paradigm for bone remodeling in response to mechanical stress.

MO0137

Acute Negative Feedback Autoregulation During Bone Mechanotransduction.
Leah Worton, Dewayne Threet, Brandon Ausk, Edith Gardiner, Steven Bain, Ronald Kwon, Ted Gross, Sundar Srinivasan*. University of Washington, USA

Bone tissue adapts its structure to its imposed loading environment. In theory, adaptation of bone's structure should proceed until the strain environment post adaptation approaches that prior to the imposition of external loading. In practice however, bone's anabolic response rapidly saturates, and subsequently declines to baseline within 2-4 wks despite continued loading. We estimate that bone's anabolic response (amplitude or duration) would have to be ~6-fold larger than observed in order to attain the strain-equilibrated, functionally adapted state. Given these data, we speculate that while mechanical loading activates anabolic pathways, it also activates repressive mechanisms that ultimately result in the premature cessation of the anabolic response. Here, we hypothesize that mechanical loading rapidly induces autoregulatory feedback that functions to inhibit the sustained activation of anabolic pathways. To test this hypothesis, we examined the expression of negative autoregulators of the Wnt and NFAT pathways. Briefly, the right tibiae of female C57BL6 mice ($n = 12$) underwent a single, 10-min bout of cantilever bending ($2350 \mu\text{e}$ peak strain, 50 cycles, 10-s rest). Animals ($n = 3/\text{grp}$) were sacrificed at 0, 1, 4 or 24 hrs post-loading, and the expression of Wnt and NFAT pathway autoregulators were determined via qRT-PCR at the tibia mid-shaft. We found that gene expression of a number of autoregulators of the Wnt (e.g., DKK1) and NFAT pathways (e.g., RCAN1) were elevated 2 to 5 fold (vs contralateral) immediately post-loading (i.e., 0 hr; Fig 1). Autoregulatory gene expression also followed distinct temporal patterns: a) immediate (0 hr) activation followed by a decline by 24-hrs (e.g., RCAN1, DKK2), b) late activation (peak at 4 hrs) followed by decline by 24 hrs (e.g., DYRK1A), c) sustained expression from 0 to 24 hrs (e.g., RCAN2, sFRP4), and d) oscillatory (e.g., DKK3, sFRP2). While preliminary, negative autoregulators of both NFAT and Wnt pathways were rapidly induced and displayed varied expression patterns. Given that autoregulators serve to inhibit the pathways responsible for their synthesis, sustained anabolism is not likely to be achieved via protocols that repeatedly load bone. We

propose that understanding and accounting for autoregulatory dynamics will yield novel loading strategies that robustly enhance and sustain bone's response such that a strain-equilibrated, functionally adapted state is ultimately achieved.

Fold change (FC) in NFAT and Wnt autoregulators

Application of Mechanical Vibration to Enhance Orthodontic Tooth Movement – The Science Behind It. Dawei Liu*. Marquette University School of Dentistry, USA

Objective: To review and present the current evidence on the application of mechanical vibration to enhance orthodontic tooth movement. **Materials and Methods:** Using mechanical vibration to enhance orthodontic tooth movement seems to become one of the promising new technologies in orthodontics. Although several papers have been published, the scientific evidence behind it is largely unknown. Through searching engines such as PubMed, the current literature on this topic was reviewed. With the funding support of NIDCR, the author's group has been conducting a series of experiments on this topic, using study models of animal (*in vivo*), tissue and organ culture (*ex vivo*) and cell culture (*in vitro*). In addition to the biologic effect, the role of vibration in reducing the friction in the fixed orthodontic appliance system was also investigated. These new findings were presented. **Results:** Among the very limited amount of publications on this topic, current findings are of controversy and no conclusion can be made. Using a mouse model, we applied mechanical vibration to the orthodontically moved upper 1st molars for 4 weeks. As results, the vibrated molar moved 35% faster than the control molar, with more bone resorption found on the compression side and more newly formed bone presented on the tension side. To minimize variation of the animals, we further developed a tissue (organ) culture model in which the rat mandibular slices were preloaded with an orthodontic force then subjected to vibration for 7 days. The histologic findings in this tissue model supported our findings in the animal experiment. To investigate the cellular and molecular mechanism, we subjected human PDL cells to fluid shear stress with and without vibration. Interestingly, vibration enhanced the shear stress induced decrease of OPG/RANKL (mRNA) ratio. As practically vibration imposes on orthodontic fixed appliance system, we investigated the impact of vibration on the friction in the fixed appliance system and found that vibration significantly reduces 23% of friction between the orthodontic bracket and arch wire. **Conclusion:** In summary, mechanical vibration potentially impacts both biologic and mechanic aspects of orthodontic tooth movement. However, the science behind it is still not absolutely solid, which asks for more future endeavors on this topic.

Interpretation of Gene Expression During Immobilization – Don't Miss the Boat. Jens Bay Vegger*, Annemarie Brüel, Jesper Skovhus Thomsen, Department of Biomedicine, Health, Aarhus University, Denmark

Botulinum toxin (BTX) is widely used to paralyze a rodent's hind limb in order to study immobilization induced bone loss. Many studies have characterized the BTX model, but it remains unclear how gene expression correlates to dynamic histomorphometry, microarchitecture, and biomechanical properties as a function of time.

Thirty 16-week-old C57BL/6 female mice were randomized into 6 groups: Ctrl1, BTX1, Ctrl2, BTX2, Ctrl3, and BTX3. The mice in the BTX groups were injected with 2 IU/100 g BW BTX in the right hind limb musculature. Ctrl1 and BTX1, Ctrl2 and BTX2, and Ctrl3 and BTX3 were killed after 1, 2, and 3 weeks, respectively. The analysis included RT-qPCR of the distal tibia, μ CT of the femoral mid-diaphysis, distal metaphysis and epiphysis, dynamic histomorphometry of the distal femoral metaphysis and epiphysis, and mechanical testing of the femoral mid-diaphysis and neck. BTX groups were compared with their respective Ctrl groups with a Mann-Whitney Rank Sum test and results were defined significant when $p < 0.05$.

Genes related to osteoclasts (Ctsk and Acp5) were significantly up-regulated after one (+375% and +276%) and two weeks (+437% and +318%) of immobilization, but not after three weeks. Genes related to osteoblasts (Bglap and Col1a1) were significantly down-regulated after one week (-79% and -68%), Bglap was significantly down-regulated after two weeks (-56%), while it was significantly up-regulated after three weeks (+65%). BFR/BS was significantly decreased in the first week (-29%) and significantly increased in the third week (+54%) at the distal femoral epiphysis. B.Ar of the femoral mid-diaphysis was significantly decreased after one (-4%), two (-8%), and three weeks (-15%), BV/TV was significantly decreased at the distal femoral epiphysis after one week (-33%) and at both the distal femoral epiphysis and metaphysis after two (-58% and -33%) and three weeks (-62% and -37%). Tb.Th was significantly decreased at both the distal femoral epiphysis and metaphysis after one (-28% and -24%), two (-46% and -33%), and three weeks (-42% and -29%). Bone strength was significantly decreased at the femoral neck after two weeks (-40%) and at both the femoral neck and mid-diaphysis after three weeks (-57% and -24%).

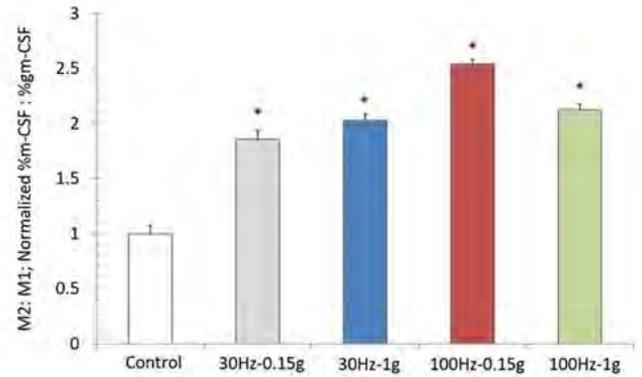

This study shows that changes in gene expression and dynamic histomorphometry takes place already during week one, whereas changes in microarchitecture and mechanical strength occur mostly during week three.

Low Intensity Vibrations Alter Macrophage Phenotype. Suphanee Pongkitwittoon¹, Eileen Weinheimer-Haus², Timothy Koh², Stefan Judex*¹. ¹Stony Brook University, USA, ²University of Illinois at Chicago, USA

Macrophages play ubiquitous roles in human physiology. Their sensitivity to mechanical signals is largely unexplored but could open up an array of opportunities from manipulating bone resorption to enhancing healing. Here, we applied low intensity vibrations (LIV) to macrophages to test their influence on cell proliferation and polarization. Two different LIV signal frequencies (30Hz or 100Hz) were combined with two acceleration magnitudes (0.15g or 1g) to generate four distinct LIV signals. Murine macrophages (J774.1) were exposed to each of the four different LIV signals for 20min per session, 2x/d. We monitored cell viability, proliferation, polarization, as well as VEGF and TGF- β gene expression. Cell viability was unaffected by LIV. Macrophage proliferation was increased significantly (1.5x-2.5x, $p < 0.05$) by each of the four LIV signals on days 1, 2, and 3. The 100Hz/0.15g was consistently the most effective signal for all three days. Flow cytometry showed that the ratio of pro-healing to inflammatory phenotypes was significantly greater (2x-2.5x, $p < 0.05$) in LIV groups than in controls, with a preference of 100Hz signals over 30Hz signals. IL-10 was up-regulated up to 2-fold with LIV ($p < 0.05$). Transcriptional levels of VEGF were 2.6x greater ($p < 0.05$) in the 100Hz/0.15g group with smaller increases for the other LIV signals. LIV also increased gene expression of TGF- β , albeit to a lesser extent, and there were no significant differences between individual LIV groups. These data demonstrate the sensitivity of macrophages to high-frequency oscillations applied at low intensities. Interestingly, LIV not only enhanced macrophage proliferation but also modulated a change in phenotype from pro-inflammatory to pro-healing macrophages. Increased VEGF expression induced by LIV may contribute towards angiogenesis and ultimately facilitate healing and survival of the pro-healing macrophages. Future studies will test whether low intensity vibrations may directly attenuate macrophage induced osteoclastogenesis and whether enhanced healing associated with LIV is driven by changes to macrophage phenotype.

Upregulation of pro-healing macrophages with four different LIV signals

“Static” Osteoblasts Placed in Contact with Osteoblasts Previously Subject to Low Intensity Vibration Increases Proliferation, Gap Junction Based Cell-to-Cell Communication and Mineralization. M. Ete Chan*, Michael Lopez, Dorothy Yuan, Clinton T. Rubin, Stony Brook University, USA

Low intensity vibration (LIV), acting as a surrogate for the mechanical components of exercise, has been shown as a potential non-invasive, non-drug treatment to improve bone quality. LIV exerts its salutary effect, in part, by promoting the anabolic response of osteoblast (OB) to form new bone. However, the mechanotransduction pathway of OB in response to LIV is unclear, or even if direct mechanical stimulation of the cell is required. In this study, we hypothesize that cell-to-cell communication via gap junction between OBs plays a role in mechanotransduction. Using a parachute assay, this study examines if proliferation and mineralization of OBs *not directly subject to* LIV could be enhanced simply by being exposed to OB previously subject to LIV. OB-like MC3T3 cells were used in this study (n=3): (1)OBs stimulated with LIV were parachuted onto recipient “static” OBs and compared to (2)static OBs placed in contact only with OBs which had received no mechanical stimulation. LIV was delivered via a vertically oscillating platform (90Hz, <1g, where $g=9.8ms^{-2}$) for 30min. While parachuted OBs were stained with a red membrane-bound dye DiI, recipient static OBs were stained with a green calcein dye which can be transferred to adjacent cells when gap junction intercellular communication (GJIC) is established. Following 24h, OBs exposed to LIV-OBs increased overall cell proliferation by 116% compared to OB in contact only to non-LIV OB ($p \leq 0.05$). Further, flow cytometry revealed that GJIC, as shown by dual colors in recipient OBs, was 73% higher in those in contact with LIV-OBs ($p \leq 0.05$), indicating that LIV promotes intercellular communication even in those cells isolated from mechanical signals. Mineralization assay showed that the OB group exposed to LIV-OBs was 16% ($p \leq 0.05$) more mineralized than control. This study demonstrated that cell-to-cell communication can be enhanced even in ‘static’ cells when in contact with cells subject to mechanical stimulation, emphasizing a ripple effect of mechanical stimulation to remote responsive cell populations. Future experiments can help elucidate what biochemical factors (e.g., nitric oxide) are being communicated through this GJIC that may foster mechanically mediated responses in bone cells, and roles of other bone marrow cell types (e.g., osteoclasts, adipocytes, mesenchymal and hematopoietic stem cells) to further expand our understanding of the working mechanism of mechanical signals to improve bone health.

Mechanobiological Modulation of Ca^{2+} Oscillations in Osteocytes of Intact Mouse Calvaria by Medium Intensity Focused Ultrasound. Minyi Hu*, Daniel Gibbons, Jian Jiao, Yi-Xian Qin, Stony Brook University, USA

Current clinical evidences have shown that mechanotransduction is critical in bone remodeling related to tissue regeneration. While the biological effect of ultrasound on bone healing has been well documented, the underlying mechanism is currently unknown. Our previous study elucidated the mechanobiological modulation of cytoskeleton and Ca^{2+} influx in *in-vitro* osteoblastic cells by short-term focused acoustic radiation force. In greater relation to physiological setting, our current study aimed to visualize and quantify Ca^{2+} oscillations of *in-situ* osteocytes in real-time response to Medium Intensity Focused Ultrasound (MIFU). All animal protocols were approved by Stony Brook University IACUC. Three-month-old Black6 mice were used to obtain fresh calvaria samples immediately after euthanasia by CO_2 inhalation. The bone samples were incubated in DMEM with 5% FBS and 1% penicillin/streptomycin til ready for Ca^{2+} fluorescent label using Fluo-8 AM (Santa

Cruz Biotechnology, Inc., Santa Cruz, CA). The stimulation pattern of MIFU with 1W (n=5), 3W (n=8), 6W (n=5), 9W (n=9) and 12W (n=7) energy powers with 2sec intervals was 10sec baseline – 30sec stimulation – 10sec post stimulation. Real-time confocal imaging (Zeiss LSM 510 META NLO Two-Photon Laser Scanning Confocal Microscope System) with 40X objective, 488-nm laser excitation, and 2 frames/sec was performed to capture the Ca²⁺ signals of the osteocyte cell bodies within each bone that was subjected to MIFU stimulation. For data analysis, the fluorescent intensity of each cell body was extracted as a function of time using the microscope software. By normalization to the baseline intensity, the percentage of response cells, number of Ca²⁺ spikes, spike magnitude, and the time to the first spike were quantified. MIFU stimulation at 6W, 9W and 12W lead to significant Ca²⁺ oscillations - 85 ± 16% (p<0.01 vs. 1W; p<0.05 vs. 3W), 80 ± 18% (p<0.01 vs. 1W; p<0.05 vs. 3W) and 84 ± 17% (p<0.01 vs. 1W; p<0.05 vs. 3W) of responsive cells, respectively. MIFU at >6W energies lead to higher number of Ca²⁺ spikes and larger spike magnitudes compared to lower energies. The initiation time to the first Ca²⁺ spike seemed to be relatively the same for all energy levels (~18sec). In conclusion, this study provided insights into the interactions between acoustic mechanical stress and *in-situ* osteocytic Ca²⁺ oscillations, which aids further exploration of the mechanosensing mechanism triggered by noninvasive acoustic radiation force.

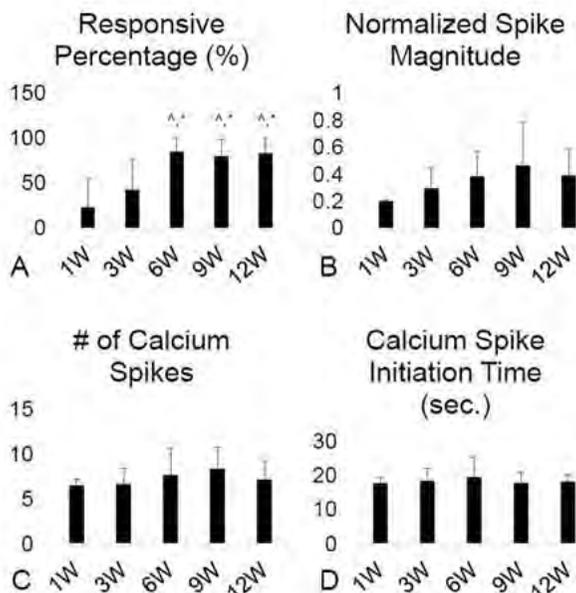

Figure 1. Responsive percentage (A), normalized spike magnitude (B), number of spikes (C), and spike initiation time (D) of osteocyte Ca²⁺ responses to MIFU at various energy powers. *p<0.01 vs. 1W; *p<0.05 vs. 3W.

Strain Derived Fluid Flow Explains Observed Alignment of New Osteons towards the Main Direction of Loading in the Compact Bone. Majid Nazemi*, James D. Johnston, David M. L. Cooper. University of Saskatchewan, Canada

Introduction: In cortical bone, basic multicellular units (BMUs) proceed by tunneling in which osteoclasts dig a resorption space that is refilled by osteoblasts, creating a new secondary osteon with a central vascular canal. Osteocytes are hypothesized to sense mechanical stimuli, including interstitial bone fluid flow caused by bone tissue strain, and coordinate BMU activities accordingly. To investigate this hypothesis, the objective of this study was to assess patterns of fluid flow around a newly forming osteon ‘breaking out’ of an existing canal using 3D biphasic poroelastic finite element (FE) modeling.

Methods: A biphasic poroelastic FE model was developed and consisted of a cylindrical space with 200µm diameter (representing BMU-created resorption space) modeled in a cube with 1000 µm side length (representing cortical bone). Required inputs for the model were adopted from literature: elastic modulus = 15.8 GPa; Poisson’s ratio = 0.33; 5% lacuno-canalicular porosity; bone bulk modulus = 17.7 GPa; fluid bulk modulus = 2.3 GPa and hydraulic permeability = 2.2 × 10⁻⁷ mm⁴/Ns. The analysis was based on an assumption of bone being fully saturated with interconnected porosity. The canal pressure was neglected against the pressure in the lacuno-canalicular porosity. A resorption space was sequentially simulated as breaking out of an existing canal wall at an initial angle of 90°, propagating straight for 200µm and then redirecting towards the longitudinal loading direction in steps of 30° (Fig 1 to 4). Fluid velocity was calculated in the cortical bone under physiologic loading conditions; mimicking a walking cycle with a peak compressive micro-strain of 1500.

Results: Lower fluid velocity was observed at the superior-inferior region of the resorption space compared to other regions, including the lateral walls at the initial breaking out phase (Fig 1 to 4). Following re-routing towards the main direction of loading, fluid velocity reduced at the resorption space tip and increased in all regions of the space’s wall except superior-anterior regions of the initial breaking out zone (Fig 1 to 4).

Conclusion: Our results support the hypothesis that reduced fluid velocity may be a stimulus for directing osteoclasts and further resorption in longitudinal directions (i.e., superior-inferior regions of the resorption space). This may explain the predominance of longitudinal osteonal canals despite many generations of remodeling activity.

MO0144

T-type Voltage-Sensitive Calcium Channels Mediate Mechanically Induced Intracellular Calcium Oscillations by Regulating Intracellular and Endoplasmic Reticulum Calcium Dynamics in Osteocytes. Genevieve Brown*, Prajesh Desai, X. Edward Guo. Columbia University, USA

Osteocytes (OCY) are highly mechanosensitive, exhibiting robust oscillations in intracellular calcium ($[Ca^{2+}]_i$) in response to mechanical stimuli, whereas osteoblasts (OB) demonstrate fewer, weaker responses. The release of Ca^{2+} from endoplasmic reticulum (ER) stores is critical to these multiple responses. Thus, the mechanisms of Ca^{2+} release and reuptake by the ER are important to OCY mechanotransduction. The differentiation of OB to OCY is characterized by many phenotypic changes, including expression of membrane Ca^{2+} channels. OB express both T- and L-type voltage-sensitive Ca^{2+} channels (VSCC), whereas L-type VSCC are barely detectable in OCY. We hypothesized that the predominant expression of T-type channels in OCY may contribute to their unique $[Ca^{2+}]_i$ patterns and further speculated that T-type VSCC in OCY may interact with ER stores.

We sought to simultaneously visualize the dynamics of Ca^{2+} in the cytosol ($[Ca^{2+}]_i$) using the calcium indicator Fura Red-AM and endoplasmic reticulum ($[Ca^{2+}]_{ER}$) by transfection with the DIER fluorescence resonance energy transfer (FRET) biosensor (Palmer 2006) within bone cells under loading. The osteocyte-like MLO-Y4 and osteoblastic MC3T3-E1 cell lines were grown to confluency, and single cells were imaged at 60x under fluid flow stimulation in the presence/absence of VSCC

inhibitors. Fluorescence emissions of YFP, CFP and Fura Red were captured separately and simultaneously using a quadview beamsplitter under single excitation. The FRET ratio was calculated on a pixel-by-pixel basis using image registration.

In OCY, elevations of $[Ca^{2+}]_i$ coincided with depression of $[Ca^{2+}]_{ER}$, with subsequent peaks occurring after recovery of $[Ca^{2+}]_{ER}$ levels (Fig 1A). Treatment with an L-type VSCC inhibitor had no effect on this behavior (Fig 1C), consistent with its lack of expression in OCY. The T-type inhibitor significantly reduced the number of $[Ca^{2+}]_i$ responses in OCY (Fig 1E, 2A) and disrupted synchrony between $[Ca^{2+}]_i$ and $[Ca^{2+}]_{ER}$ responses (Fig 2B). In OB, few $[Ca^{2+}]_i$ responses were observed in all groups (Fig 1 left, Fig 2A) and ER contribution was minimal (Fig 2B). By observing Ca^{2+} dynamics in both cytosolic and ER spaces, this study indicates that OCY generate multiple responses by an ability to refill ER stores. Our data suggests that T-type VSCC facilitate the recovery of $[Ca^{2+}]_{ER}$ in OCY to effect this behavior. We uncovered a new mechanism involving T-type VSCC underlying the unique behavior of OCY as mechanosensors.

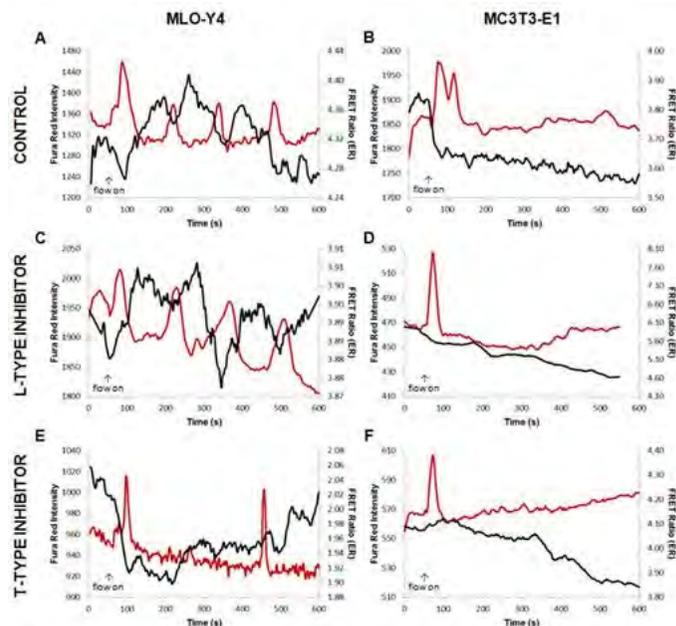

Figure 1. Simultaneous measurement of cytosolic (red) and ER (black) Ca^{2+} levels in bone cells under fluid flow. Representative time courses are shown for osteocyte-like MLO-Y4 (A) and osteoblastic MC3T3-E1 (B) control cells subjected to 35 dyne/cm² fluid flow stimulation. The effects of treatment with the L-type VSCC inhibitor nifedipine on MLO-Y4 (C) and MC3T3-E1 (D). The effects of the T-type inhibitor NNC 55-0396 on MLO-Y4 (E) and MC3T3-E1 (F).

MO0145

BIPHASIC BEHAVIOR AND SITE- AND GENDER-SPECIFICITY OF pQCT-ASSESSED “DISTRIBUTION/QUALITY” RELATIONSHIPS CONCERNING TORSION STRENGTH THROUGHOUT THE HUMAN TIBIA. Gustavo Cointry¹, Laura Nocciolino¹, Jörn Rittweger², Jose Ferretti^{*3}, Ricardo Capozza¹. ¹Centro de Estudios de Metabolismo Fosfo-Cálcico, Argentina, ²German Space Agency (DLR), Germany, ³National University of Rosario, Argentina

“Distribution/quality” (d/q) curves describe the negative, hyperbolic relationships between pQCT-assessed indicators of the efficiency of cross-sectional design concerning bending or torsion (CSMI’s, y) and of the bone tissue stiffness (cortical vBMD, vCtD, x) in long bones [Capozza *et al*, *JMNI* 2013]. The slopes and significances of d/c curves would reflect the modeling-dependent ability of bone *mechanostat* to distribute cortical tissue as an inverse function of its stiffness. We have shown that the significance of d/q relationships for *bending* of the tibia, higher in men than women, is also higher toward the midshaft than at both bone ends. This should cope with tibia bending stresses (maximal at midshaft), but not with torsion stress which can be high toward the heel, where cortical mass is the lowest throughout the bone. To search for a possible homeostatic compensation of that inadequacy, this study describes the evolution of d/q relationships calculated for *torsion* in serial slices taken at every 5% of the tibia length from heel (S5) to knee (S95) in 17/21 men/women untrained (10/12) or chronically trained (7/9) in long-distance running.

The d/q curves showed the typical hyperbolic shape from S10 to S85. The distribution of correlation coefficients r of the d/c curves throughout that tibia region was biphasic (“V”- shaped). Values were minimal at S25-S35 (-0.050 to -0.330, non-significant), increased homogeneously to maximal values toward both bone ends (up to about -0.700 at S10 and S70, all significant) and were higher by average 0.200 in men than women. The ordinates of the curves were significantly higher in men than in women ($p < 0.001$). Running tended to enhance pCSMI and reduce vCtD values (probably by increasing microdamage-induced remodeling), but it did not affect the d/c relationships. In this study, a higher r value of a d/q relationship does not indicate a higher bone strength, but just a higher efficiency of bone *mechanostat* to spatially orient the available cortical mass to resist torsion. The progressively increasing r values from S25 to the knee would have reflected what had been previously observed concerning bending, just as a parallel effect. However, the rapid distal r increase from S25 to S10 (not observed in the bending analysis), where bone section tends to be circular, would confirm the proposed homeostatic control of tibia torsion strength toward the heel as a compensation for the naturally low bone mass at that level.

MO0146

Early Stage of Osteoarthritis Development is Associated with Substantial Weakening in Cartilage Nanomechanical Properties. Wei Tong^{*1}, Basak Doyran², Qing Li³, Haoruo Jia⁴, Xianrong Zhang⁵, Ling Qin⁴, Lin Han³. ¹Perelman school of medicine, USA, ²School of Biomedical Engineering, Science & Health Systems, Drexel University, PA, United States, USA, ³School of Biomedical Engineering, Science & Health Systems, Drexel University, USA, ⁴Department of Orthopaedic Surgery, University of Pennsylvania, USA, ⁵Department of Physiology, School of Basic Medical Sciences, Wuhan University, China

Osteoarthritis (OA) is the most common degenerative joint disease in adults with no early detection method available, which is one main reason of unsatisfactory treatment up to now. Current evaluation of murine OA relies on semi-quantitative histological assay that mainly relies on structural or biochemical symptoms noticeable at intermediate or late stages. To find a sensitive and function-relevant indicator of OA, we applied atomic force microscopy (AFM)-based nanoindentation to detect mechanical changes of articular cartilage in a post-traumatic osteoarthritis murine model. To do so, we first performed destabilization of the medial meniscus (DMM) surgery on right knees and sham surgery on left knees of skeletally mature 12-week-old male C57BL/6J mice. The joints were then harvested at different time points ($n \geq 10$ /time point) for nanoindentation and histology. Each femoral condyle cartilage was indented at more than 10 locations by a borosilicate colloidal spherical tip ($R = 5 \mu\text{m}$, nominal spring constant $k = 7.4 \text{ N/m}$) with maximum indentation depth of $\sim 1 \mu\text{m}$ at $10 \mu\text{m/s}$ indentation rate. Effective indentation modulus, E_{ind} (MPa), was calculated from the loading portion of indentation force-depth curves using the Hertz model. Interestingly, E_{ind} of the medial side of femoral condyle cartilage started to decrease significantly ($61.2 \pm 2.3\%$ of sham, mean \pm SEM) at 7 days, very shortly after DMM, reached the lowest level ($27.3 \pm 2.9\%$ of sham) at 2 weeks, maintained at this low level until 8 weeks, and increased to normal value at 12 weeks. At the lateral side, E_{ind} was unchanged at 2 weeks, which is consistent with our observation that OA only develops at medial side but not lateral side in this DMM model. In contrast, there was no significant morphological change in cartilage up to 4 weeks after DMM. Mankin score increased only at 8 (7.7 ± 0.9) and 12 weeks (10.0 ± 0.5) after. Hence, this study provided direct experimental evidence that the early decrease in E_{ind} (7-14 days) of cartilage can serve as a more sensitive and functional-relevant indicator of early OA than gross-level signs measured by histology (8-12 weeks). The increase in E_{ind} in DMM femur at 12 weeks was due to a substantial loss of uncalcified cartilage, suggesting that at this stage E_{ind} of cartilage after DMM reflects the mechanical

properties of the stiffer middle/deep zone cartilage. A comprehensive understanding of nanomechanical symptoms will shed new light on the diagnosis and treatment of OA.

MO0147

IL-36 inhibits TGF- β -mediated collagen expression by suppressing nuclear localization of Smad2 and causes development of BRONJ-like lesions in mice. Sol Kim^{*1}, Reuben Kim¹, Drake Williams¹, Cindy Lee¹, Teresa Kim¹, Ki-Hyuk Shin¹, Mo Kang¹, No-Hee Park¹, Songtao Shi², Jennifer Towne³. ¹UCLA School of Dentistry, USA, ²University of Pennsylvania School of Dental Medicine, USA, ³Amgen Inc, USA

Objective: Long-term users of Bisphosphonates (BPs), anti-resorptive drugs commonly prescribed to treat bone disorders, are at higher risk of developing bisphosphonate-related osteonecrosis of the jaw (BRONJ), but the pathophysiology of BRONJ remains unclear. The purpose of this study are to identify molecular determinants of BRONJ with microarray analysis using osteomucosal tissues obtained from mice and to elucidate the role of the identified gene in vivo and in vitro.

Methods: An Affymetrix-based microarray assay was used to identify differentially regulated genes in BRONJ-like lesions in 11 week-old female C57BL/6 mice. Expression of IL-36 was validated using qRT-PCR, immunohistochemical staining and ELISA. IL-36 receptor (IL-1Rrp2) neutralizing antibody was used to inhibit the IL-36 signaling pathway in vivo, and bone necrotic lesions were evaluated using uCT scans and bone morphometric analysis. Gingival mesenchymal stromal cells (GMSCs) were isolated from the oral cavity of the mice and treated with IL-36 and TNF- β in vitro to examine expression of Col1a1, Col1a2, a-Sma using qRT-PCR, Western, and ELISA. Phosphorylation status and nuclear localization of p-Smad2 was examined using Western blots, and binding of p-Smad2 on the promoter of Col1a1 and a-Sma was determined using the CHIP assay. Nuclear localization of p-Smad2 in the presence of TGF- β and IL-36 was also examined in GMSCs isolated from IL-36 knockout mice.

Results: The Microarray analysis identified IL-36 family members among the upregulated genes. IL-36 was up-regulated both locally and systemically in a ONJ-specific manner. IL-1Rrp2 neutralizing antibody ameliorated BRONJ lesions in mice. Mechanistically, IL-36 treatment inhibited TGF- β -mediated collagen expression in GMSCs in vitro. IL-36 suppressed TGF- β -mediated nuclear localization of p-Smad2 and occupancy of Smad2 in the Col1a1 and a-Sma promoter regions. GMSCs isolated from IL-1Rrp2 KO mice nullified suppressive effect of IL-36 on nuclear localization of p-Smad2. Conclusion: IL-36 may induce BRONJ development by inhibiting wound healing processes via suppression of TGF- β -mediated collagen synthesis, suggesting that the IL-36 signaling pathway may be a potential target for managing/preventing ONJ development.

The Effects of Decellularisation on the Mechanical Properties of Bone, and Subsequent Recellularisation of the Samples. MOHD RIDUAN MOHAMAD^{*}, Philip Riches, M. Helen Grant. University of Strathclyde, United Kingdom

Regenerative medicine strategies involving decellularised extracellular matrix scaffolds are developing fast and, in particular, decellularized bone has been proposed for bone tissue engineering. This study aimed to establish decellularisation and recellularisation protocols and to measure the Young’s modulus and pore size of the decellularised trabecular bone samples. Twelve bovine cancellous proximal femur samples (7mm x 7mm x 2mm) were decellularised by six cycles of overnight incubation at 37 C using two protocols: A – 10mM Tris, 1mM EDTA, 0.1% v/v Triton X-100 and B – method A plus 0.5% w/v trypsin. Decellularisation was confirmed by the absence of DNA staining with DAPI both by detecting any DNA remaining on the bone matrix spectrofluorometrically, and by microscopic examination. Young’s modulus was determined before and after incubation through compression testing at 1 mm/s up to 400N (8.16MPa). The porosity of the bone samples before and after decellularisation was measured using a mercury porosimeter. Recellularisation using HOS cells (seeded at 5×10^5 cells per cm^2 bone) progressed for up to 3 weeks in DMEM supplemented with L-ascorbic acid, β -glycerophosphate, dexamethasone, FCS, PEST, and NEAA. Bone samples were placed onto non-adherent dishes and adherent dishes. The extent of recellularisation was compared in static and dynamic culture conditions using a roller incubator set at 15 rpm to effect dynamic conditions. DAPI staining revealed that protocol B removed all measurable DNA from the bone samples (Figure 1). Decellularisation did not affect Young’s modulus (Figure 2). Pore diameters did not differ with decellularisation and were in the ideal range for cell growth. Mean ALP activity (Figure 3A) and MTT reduction (Figure 3C) was greater on the adherent surface than on non-adherent surface albeit non-significantly. There was no significant difference between static and dynamic conditions in ALP activities between 3 and 7 days (Figure 3B). Data suggests that cells proliferated more readily when samples were placed in adherent dishes (Figure 3D). This work has established appropriate protocols to make donor bone scaffolds with appropriate porosity to allow reseeding with human bone cells. These could be used to repair bone defects in recipient patients.

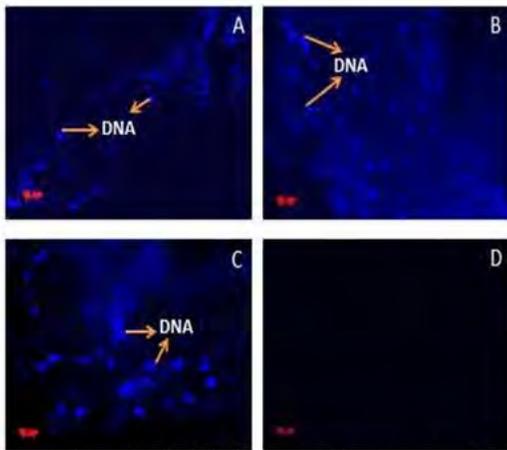

Figure 1: Bone sample tested in 0.6 nM DAPI agent A) before any treatment. B) after incubation with protocol A and B for 10 minutes. C) after overnight incubation with protocol A. D) after incubation with protocol B overnight. Protocol A – 10mM Tris, 1mM EDTA, 0.1% v/v Triton X-100; and B – method A plus 0.5% w/v trypsin. All images were taken at the surface.

Figure 1

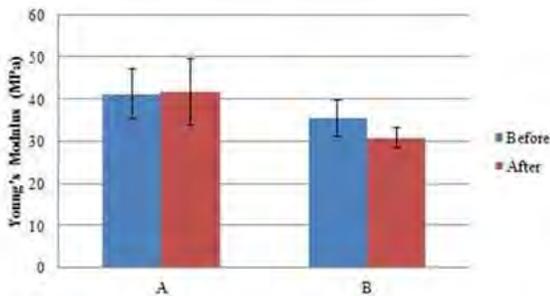

Figure 2: Young's modulus before and after six cycles of incubations with protocol A and B. A – 10mM Tris, 1mM EDTA, 0.1% v/v Triton X-100; and B – method A plus 0.5% w/v trypsin. Results are the mean ± SEM of n = 6. p > 0.05 compared with the control (ANOVA for repeated measures).

Figure 2

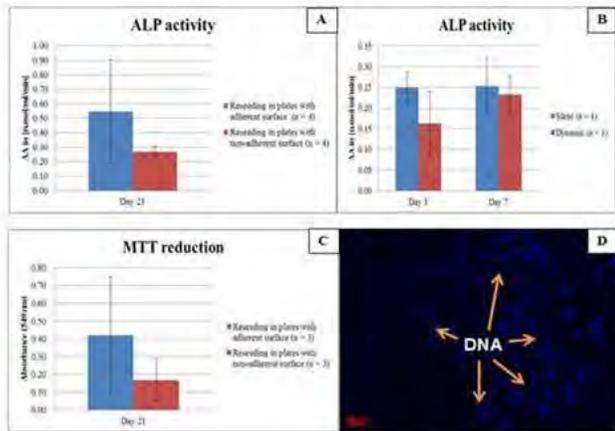

Figure 3: ALP activity of HOS cells reseeded at 5x10³ cells per cm² onto bone in A) adherent and non-adherent surface for 3 weeks, B) static and dynamic environment on day 3 and day 7. C) MTT reduction of HOS cells growing on bone seeded at 5x10³ cells per cm² in adherent and non-adherent surface for 3 weeks. Results are the mean ± SEM. p > 0.05 for all values by unpaired student's t-test. D) Bone samples were stained in 400ul of 0.6nM DAPI on bone pieces on an adherent surface after 21 days.

A Novel Vitamin D Receptor Modulator, VS-105, Improves Bone Mineral Density in an Estrogen-deficient Rat Model of Osteoporosis. J. Ruth Wu-Wong*¹, Yung-wu Chen², Jerry L. Wessale², Theresa Chen², Maysaa Oubaidin³, Phimon Atsawasuwan³. ¹University of Illinois at Chicago, USA, ²Vidasym, USA, ³University of Illinois, USA

Vitamin D is essential for bone health. Not surprisingly, vitamin D receptor modulators (VDRMs) such as calcitriol have been used as therapeutic agents for osteoporosis since 1983 in some countries outside of the US. VDRMs increase bone mineral density (BMD) and reduce the incidence of bone fracture in patients with osteoporosis. However, the fact that VDRMs are not more widely used for treating osteoporosis is in part due to the hypercalcemic side effects of current VDRMs. It is not well studied whether VDRMs at non-hypercalcemic doses have effects on bone mineral density (BMD). VS-105, a novel VDRM with an exceptionally wide therapeutic index (TI) at >50-fold (vs. TI of calcitriol at 1-fold) offers a unique opportunity for answering the aforementioned question. In this study, the effect of VS-105 on BMD was evaluated in an ovariectomized (OVX) rat model of osteoporosis. Treatment of OVX rats by VS-105 at three doses (0.1, 0.2 or 0.5 µg/kg, i.p., 3x/week, for 12 weeks, n=8-12 per group) significantly improved BMD in the L3 lumbar vertebra in a dose-dependent manner (sham: 324 ± 14 mg/cm²; OVX/vehicle: 279 ± 10 mg/cm²; VS-105 at 0.1, 0.2 and 0.5 µg/kg: 306 ± 9, 329 ± 12, and 327 ± 10 mg/cm², respectively) without affecting serum calcium (Ca). In comparison, calcitriol at 0.1 µg/kg significantly increased BMD, but it also increased serum Ca (13.8 ± 0.3 mg/dL vs. sham at 11.3 ± 0.5 mg/dL). VS-105 significantly suppressed serum PTH without affecting serum Ca at all doses tested, results attributable to its lack of effects on inducing the expression of intestinal Ca transporter genes such as Calb3 and TRPV6, and on stimulating intestinal Ca transport. VS-105 increased serum osteocalcin (a marker for osteoblast activity) in a dose-dependent manner, and reduced the expression of receptor activator of nuclear factor kappa-B ligand (RANKL) in tibia. In a mouse calvaria bone primary organ culture system, VS-105 was ~2-fold less effective than calcitriol in stimulating net Ca release from calvaria (a measurement of osteoclast activity). These results demonstrate that VS-105 is effective in improving BMD in a dose range that does not affect serum Ca in OVX rats; the improvement in BMD by VS-105 is likely attributable to increased osteoblast activity and reduced osteoclastic bone resorption, but not related to enhanced intestinal Ca absorption. The overall preclinical profile of VS-105 supports future clinical development for its use in treating osteoporosis.

MO0150

Effects of osteoporosis on the osteoinductivity of rhBMP-2 in the healing of segmental long-bone defect models. Jae Hyup Lee*¹, Hae-Ri Baek², Kyung Mee Lee², Guang Bin Zheng², Sung Joon Shin², Hee-Jong Shim². ¹Seoul National University, College of Medicine, South Korea, ²Department of Orthopedic Surgery, Seoul National University, College of Medicine, SMG-SNU Boramae Medical Center, South Korea

This study used the segmental long-bone defect model to assess the effects of osteoporosis on the formation of new bones and the osteoinductivity of recombinant human bone morphogenetic protein-2 (rhBMP-2). Seventy-two female Sprague-Dawley rats were divided into two groups: an osteoporosis group with ovariectomies and dexamethasone intramuscular injections and a sham group. When they reached 22 weeks in age, each group was further divided into two groups and a 5-mm defect was made in both fibular mid-shafts of each rat. One fibula in each rat was picked randomly and was injected with 0.05 ml of hydrogel carrier; the opposite fibula was injected with the same carrier mixed with rhBMP-2 (10 µg). After rearing for a further 5 and 9 weeks, the ratios of the lengths of the newly formed bones in the fibular defects were determined using micro-CT. The micro-CT parameters of the newly formed bones were analyzed and their undecalcified histologies were compared. The sham rhBMP-2-injected group—in all of the 5- and 9-week-kept groups—showed a significantly higher bridging bone formation ratio than the other three groups. The osteoporosis rhBMP-2-injected group showed a significantly higher ratio than both the non-rhBMP-2-injected sham hydrogel and the osteoporosis hydrogel groups. More than 50% of the ratios of the bridging bone formation in the sham rhBMP-2 group at 5 and 9 weeks were 100%, whereas the ratios of the osteoporosis rhBMP-2 group were 55.6% and 72.7% at 5 and 9 weeks, respectively. The comparison of the micro-CT parameters of the newly formed bones showed that the sham rhBMP-2 group at both 5 and 9 weeks compared with the osteoporosis rhBMP-2 group had significantly higher percentage bone volumes, trabecular thicknesses, and trabecular numbers, as well as significantly lower specific surfaces, trabecular pattern factors, and structural model indices. The histology results showed that the sham-rhBMP-2 group began forming bridging bones in the defect areas in the fifth week, and at 9 weeks, they formed trabecula and marrow spaces. However, the osteoporosis rhBMP-2 group exhibited a relatively minor level of new bone and trabecula formation. Consequently, the rhBMP-2 group showed significantly increased bone formation in the osteoporosis rat fibular defect model compared with the hydrogel group, whereas the new bone quantities, qualities, and remodeling in the osteoporosis rhBMP-2 group were less effective than those in the sham-rhBMP-2 group, signaling that osteoporosis significantly undermines rhBMP-2 osteoinductivity.

EP4 Agonist in Combination with Autograft Accelerated the Bone Fusion Time on Posterolateral Spinal Fusion in Canines. YASUTOMO NAKANISHI*, AKINA SAITOH, RYOHEI MIYATA, YUSUKE ETO, SATOSHI NISHIKAWA, HIROSHI MORI, SHINSEI FUJIMURA, KAZUYA ABE, AKIO NISHIURA, YASUO OCHI, YASUSHI HIROTA, ONO Pharmaceutical Co., LTD., Japan

In spinal fusion surgery, autografts are commonly used to obtain bone fusion. However, the successful fusion often takes quite long time and a prolonged period of bone fusion leads to potential problems with quality of life in the patients. Prostaglandin (PG) E2 receptor subtype EP4 is known to involve in an osteogenic action of PGE2. Moreover, EP4 agonist enhanced bone formation by bone morphogenic protein (BMP)-2 in vitro and in vivo. Since an autograft bone contains several growth factors including BMP-2, in this study, we investigated the effect of a small molecule, specific EP4 receptor agonist (EP4a) in combination with iliac crest autograft on posterolateral spinal fusion in canines. Eight male beagle dogs (14 - 16 months of age) underwent bilateral posterolateral lumbar spinal fusion at the fourth and fifth lumbar vertebrae (L4 and L5). After decortication of the posterior aspect of the transverse processes was performed, iliac crest bone was harvested as an autograft bone and placed on bilateral transverse processes. EP4a with gel formulation was administered at one side, and the other side was without treatment (autograft only). Fusion was evaluated by four grades fusion score (0: no osteogenesis, 3: continuous osteogenesis) every 2 or 4 weeks radiographically. Dogs were sacrificed at 8 (n=4) or 24 weeks (n=4) after the surgery, the L4-L5 vertebral segments were removed and analyzed by plain radiographs, peripheral quantitative computed tomography (pQCT) and micro (c) CT. Compared to autograft only, EP4a + autograft improved the fusion score from 4 weeks after surgery, and the score was 1.3 ± 1.0 (autograft only) and 2.8 ± 0.5 (EP4a + autograft) at 8 weeks, 2.0 ± 0.8 (autograft only) and 2.5 ± 0.7 (EP4a + autograft) at 24 weeks. EP4a + autograft significantly increased bone mass of grafted area at 8 weeks in pQCT and cCT analysis (both: $p < 0.05$ vs autograft only), and tended to increase bone mass measured by pQCT at 24 weeks ($p = 0.074$ vs autograft only). The values of bone mass in EP4a + autograft at 8 weeks was almost double compared to autograft only in pQCT and cCT. These results suggest that EP4 agonist improves the fusion score by enhancing autograft-induced new bone production. Thus, EP4 agonist is considered to shorten the time to bone fusion after spinal fusion surgery in combination with an autograft, and reduce surgery-related complications such as pseudoarthrosis.

Integrin beta 3 is required for the skeletal response to loading in mice. Nicholas Heiniger*¹, Candice Tahimic², Yongmei Wang³, Alicia Menendez³, Katherine Weilbaecher⁴, Daniel Bikle³. ¹University of California, San Francisco, USA, ²Space Biosciences Division NASA Ames Research Center, USA, ³University of California, San Francisco VA Medical Center, USA, ⁴Washington University School of Medicine, Division of Oncology, USA

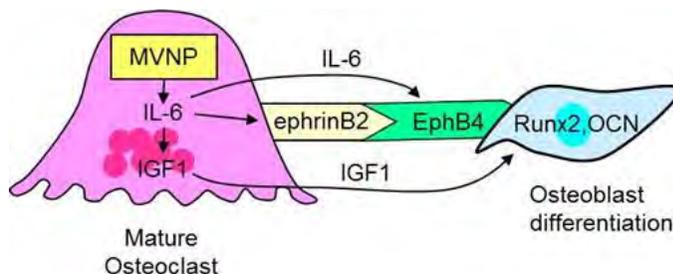

IGF1 signaling pathways are inhibited in conditions of skeletal unloading, with decreased activation of IGF1R, proliferation of bone marrow osteoprogenitor cells, and expression of α V (ITGAV) and β 3 (ITGB3) subunits of integrin in osteoblasts, associated with decreased bone formation and increased bone resorption. Applying echistatin, an inhibitor of ITGAV/ITGB3, showed similar inhibition of IGF1 signaling pathways. As neither unloading nor echistatin altered IGF1 binding to IGF1R, we hypothesized that these effects were not via interference of binding, but via a post-receptor mechanism. In further studies we observed that knock down of ITGB1 and/or ITGB3 prevented IGF1 from activating IGF1R, that ITGB3 coimmunoprecipitated with IGF1R, and that ligands for ITGB1 & ITGB3 potentiated the activation of IGF1R by IGF1. These results lead us to hypothesize that integrins such as ITGB3 are an important component of the post-receptor mechanism by which bone responds to load. We used osteocalcin-cre to selectively knock out ITGB3 from mature osteoblasts in mice. When these mice, and matched wild-type controls, were 3 months old, the femurs and tibias were harvested in 3 sets: at baseline, after 3 weeks of hind limb unloading, and after 3 weeks of hind limb unloading followed by 2 weeks of reambulation (reloading). Fourteen days prior to harvest, the mice received injections of calcein, followed 12 days later by demeclocycline. After harvest the bones were analyzed using micro-CT and histomorphometry to evaluate bone structure and formation. In males, structural parameters between ITGB3 and controls were only significantly different in trabecular number (Tb.N), bone mineral density (BV/TV), and connectivity density in unload only mice, and trabecular thickness (Tb.Th) in baseline mice, while cortical studies showed significant differences in BV/TV of reload and baseline mice, and cortical thickness of baseline mice. In females only trabecular studies revealed significant differences, seen in Tb.N of reload mice, and Tb.Th of unload only mice. Bone formation rate (BFR) and mineralizing surface (MS) of ITGB3 knockout mice were decreased compared to control after unloading followed by reloading. Further, while MS of control mice were able to recover to baseline with reloading, this did not occur in the knockout mice. These results suggest that in mice integrin β 3 is an important means through which mechanical loading is translated to osteoblast activity and bone growth.

Measles Virus Nucleocapsid Protein Increases IL-6 and IGF1 in Osteoclasts to Enhance Osteoblast Differentiation in Paget's Disease. Jumpei Teramachi¹, Yuji Inagaki¹, Khalid Mohammad², Theresa Guise², Laëtitia Michou³, Jacques P. Brown³, Jolene J. Windle⁴, Noriyoshi Kurihara^{*1}, G. David Roodman⁵. ¹Indiana University, Medicine/Hematology-Oncology, USA, ²Indiana University, Medicine/Endocrinology, USA, ³Department of Medicine, Laval University, CHU de Quebec Research Center, Canada, ⁴Human & Molecular Genetics, Virginia Commonwealth University, USA, ⁵Indiana University, Medicine/Hematology-Oncology, Roudebush VA Medical Center, USA

Paget's Disease (PD) is characterized by focal dramatic bone resorption and formation. Since treatments targeting osteoclasts (OCLs) block both pagetic bone resorption and formation, PD offers key insights into resorption/formation coupling. However, the mechanisms responsible are unclear. We reported that OCLs from 70% of PD patients express measles virus nucleocapsid protein (MVNP), and transgenic mice with MVNP targeted to OCLs (MVNP mice) develop PD-like bone lesions that are dependent on MVNP's induction of high IL-6 in OCLs. In contrast, mice with knock-in of p62P394L (p62KI mice), the most frequent mutation linked to PD, have increased bone resorption but not formation. Since PD represents the most exaggerated form of coupled bone formation, we determined expression levels of coupling factors, ephrins and their receptors, on OCLs and osteoblasts (OBs) from MVNP, p62KI/MVNP, p62KI and WT mice. Only MVNP or p62KI/MVNP, but not p62KI mice, had high ephrinB2 levels on OCLs and EphB4 on OBs compared to WT mice. We then performed a preliminary gene expression profiling study of highly purified OCLs from MVNP, p62KI and WT mice to assess if additional factors produced by MVNP expressing OCLs (MVNP-OCLs) could be involved. It showed that OCLs from MVNP but not from p62KI mice expressed elevated levels of IGF1 mRNA compared to WT mice. We further found that IL-6 increased IGF1 protein expression in MVNP-OCLs, and IL-6 and IGF1 in turn increased ephrinB2 on OCLs. IL-6 also increased EphB4 on OBs, while IGF1 enhanced OB differentiation. To confirm these results, we measured IGF1 protein levels in total bone lysates from tibia and OCLs formed from CD11b+ cells from MVNP mice and in OCLs from normals and PD patients. OCLs and bones from MVNP but not p62KI mice expressed increased levels of IGF1 compared to WT. IGF1 expression was also markedly increased in MVNP-OCLs from PD patients, but not in OCLs from a MVNP-negative patient. Immunohistochemical analysis confirmed that IGF1 expression was elevated in OCLs of MVNP mice. IGF1 was not elevated in OBs from MVNP or p62KI mice. Further, MVNP-OCLs (200k/ml) secreted 1000 pg/ml of soluble IGF1 compared to 100-200 pg/ml secreted by WT OCLs. Importantly, anti-IGF1 or anti-IGF1R blocked Runx2 and osteocalcin upregulation in OBs co-cultured with MVNP-OCLs. These results suggest that enhanced coupling factor expression and increased IGF1 production by pagetic OCLs are major contributors to the rapid bone formation in PD.

Stereological Analysis Reveals Differential Effects of Sclerostin Antibody and Parathyroid Hormone on the Osteoblast Lineage in Young Female Rats. Michael S Ominsky*¹, Danielle Brown², Gwyneth Van¹, David Cordover¹, Efrain Pacheco¹, Emily Frazier¹, Linda Cherepow¹, Marnie Higgins-Garn¹, J Ignacio Aguirre³, Thomas J Wronski³, Marina Stolina¹, Lei Zhou¹, Ian Pvrach¹, Rogely W Boyce¹. ¹Amgen Inc., USA, ²WIL Research Laboratories, USA, ³Department of Physiological Sciences, University of Florida, USA

Romosozumab, a sclerostin antibody (Scl-Ab), and parathyroid hormone (PTH) are bone-forming agents that have different modes of action on bone hypothesized to lead to quantitative differences in the osteoblast (OB) lineage at the tissue level. To compare the temporal effects of these agents on the OB lineage, 8-week-old female rats were administered vehicle (Veh), Scl-Ab (romosozumab, 3 or 50 mg/kg/week sc) or human PTH (1-34) (75 µg/kg/day sc) for 4 or 26 weeks. The high doses of Scl-Ab and PTH were also used in the respective rat lifetime studies and were the basis of these comparative assessments. At week 4, Scl-Ab effected greater increases in lumbar

vertebrae (LV) 4 cancellous bone mass compared with PTH, consistent with a higher bone formation rate (BFR/BS). In contrast to PTH, Scl-Ab did not increase osteoclastic surface. After 26 weeks, BFR/BS was similar with both agents. Using RUNX2 or nestin immunostaining, the total number of osteoprogenitor (OP) subpopulations, OBs, and lining cells was estimated across the entire LV6 body using the fractionator or proportionator stereological estimators. Density estimates referent to total bone surface, OB surface, or marrow volume were also calculated. At week 4, both Scl-Ab and PTH increased OB number, with no significant effect on OB density (Ob.N/Ob.S). After 26 weeks, in Veh-treated rats, OB surface was greatly reduced; however, total OB number was maintained, resulting in increased Ob.N/Ob.S and a reduced OB footprint (Ob.Fp; the area of bone surface covered by an OB). In contrast, in Scl-Ab-treated rats, Ob.Fp was similar to young Veh-treated rats and significantly greater than in PTH-treated rats, with fewer total OBs and a lower Ob.N/Ob.S required to provide equivalent mineralizing surface and greater mineral apposition rate (Fig.). The lower OB number at week 26 was associated with a coordinated reduction in OP number with Scl-Ab vs Veh and PTH (Fig.), with these endpoints generally positively correlated across groups and timepoints. These time-dependent reductions in subpopulations of the OB lineage may be integral to the greater attenuation of bone formation observed at the vertebra with Scl-Ab. The observation that PTH results in more OBs at the formative site, with correlative increases in progenitors compared with Scl-Ab, indicates a potentially greater stimulus for progenitor pool proliferation or differentiation with PTH, an effect that could increase carcinogenic risk in bone in the rat.

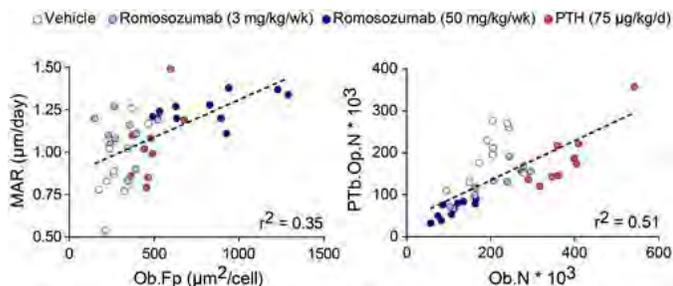

Fig. Correlations of (left) osteoblast footprint (Ob.Fp; inverse of Ob.N/Ob.S) with mineral apposition rate (MAR) and (right) osteoblast number (Ob.N) with RUNX2+ peritrabecular osteoprogenitor number (PTb.Op.N) from female rat vertebrae after treatment with vehicle, romosozumab, or parathyroid hormone (PTH) for 26 weeks.

Attenuation of antiresorptive action in withdrawal of minodronic acid for three months after treatment for twelve months in ovariectomized rats. Makoto Tanaka^{*1}, Hiroshi Mori², Kazuhito Kawabata². ¹ONO Pharmaceutical Co., Ltd., Japan, ²Discovery Research Laboratories, Ono Pharmaceutical Co., Ltd., Japan

The purpose of the study was to assess the effects of withdrawal of minodronic acid for 3 months after 12 months of treatment on bone mineral density (BMD), bone strength, bone turnover markers, histomorphometry and minodronic acid concentration in a rat ovariectomized (OVX) osteoporosis model. Female F344 rats were treated orally with minodronic acid (0.006, 0.03 and 0.15 mg/kg/day) for 12 months from the day after OVX, and necropsied on the day after the last dosing or following 3 months of withdrawal. Lumbar and femoral BMD were decreased in OVX controls. Minodronic acid dose-dependently increased lumbar and femoral BMD. Withdrawal eliminated the effect of minodronic acid on BMD loss after treatment at low dose, but not after treatment at middle and high doses. Trabecular microstructural changes, decrease of bone volume and trabecular elimination progressed during the withdrawal period in OVX controls. In minodronic acid-treated rats, trabecular thinning occurred during withdrawal after treatment at low dose, but the trabecular microstructure was maintained after treatment at middle and high doses. In a mechanical test of the femoral diaphysis in OVX controls, stiffness was decreased but maximal load was similar to that in sham rats after withdrawal. Minodronic acid increased maximal load and stiffness, but endosteal length at the femoral diaphysis decreased after withdrawal. Suppression of bone turnover by minodronic acid based on bone turnover markers and histomorphometrical indices was attenuated by withdrawal after treatment at low and middle doses, and partially after treatment at high dose. The minodronic acid concentration in the humerus decreased during withdrawal, and the half-life at middle dose was shorter than that at high dose. These results show that the antiresorptive action of minodronic acid was attenuated by 3 months withdrawal in a rat OVX model. An absence of BMD increase was only observed at a low dose, but decreases in antiresorptive activity occurred over a wide dose range. The rate of elimination of minodronic acid from bone was dependent on antiresorptive action by the minodronic acid dose.

In vivo MRI and RPI measures reveal the positive effects of raloxifene on bone properties. Mohammad Aref^{*1}, Drew Brown¹, Erin McNerny¹, Jason Organ², Chris Newman¹, Paul Territo¹, Matthew Allen¹. ¹Indiana University School of Medicine, USA, ²Indianan University School of Medicine, USA

Raloxifene affects mechanical properties of bone through both cellular and non-cellular mechanisms. Our laboratory has shown that exposure to raloxifene, both in vivo and in vitro, increases matrix bound water and this is associated with improvements in bone mechanical properties. The goal of the current work was to utilize novel in vivo methods to assess both bone hydration and mechanical properties of raloxifene-treated animals. Skeletally mature female beagle dogs (n=12/group) were treated daily for one year with oral raloxifene (RAL; 0.5 mg/kg/day) or oral saline vehicle (VEH; 1.0 mL/kg/day). All animals underwent in vivo mechanical property assessment of the tibial cortex using reference point indentation (RPI) at 6 and 12 months. One half of each group underwent MRI scans of the proximal tibia at 6 and 12 months to assess bound water. Additional MRI diffusion-weighted imaging scans at the 12-month time point were used to measure molecular diffusion of water. RAL-treated animals had significantly lower indentation distance increase (IDI), reflective of higher mechanical properties, at 6 months and a trend toward lower values at 12 months (p=0.08) compared to VEH-treated animals. Matrix bound water was significantly higher in the tibia cortex of RAL-treated animals at both time points (p < 0.05) compared to VEH-treated animals. Additional assessments at the 12-month time point reveal higher bound water in subchondral bone and lower bound water in articular cartilage of RAL-treated animals. Raloxifene significantly increased the molecular diffusion of water, after 12 months of treatment, in cortical bone, subchondral bone, and cartilage regions of interest. Taken together these results show that the positive effects of raloxifene on mechanical properties and hydration can be measured using in vivo technologies.

MO0157

Local Reduction in Iron Promotes Bone Formation and Reduces Osteoclast Mediated Resorption. Justin Drager^{*1}, Zeeshan Sheikh², Yu Ling Zhang², Abhishek Kumar², Jake Barralet², Edward Harvey². ¹McGill University, Canada, ²McGill University, Canada

Purpose: Local delivery of the widely available iron chelator, Deferoxamine (DFO) has recently been shown to augment osteogenesis through activation of Hypoxia Inducible Factor (HIF) regulated angiogenesis. HIF may also induce osteoclast differentiation and function; however mimicking this effect with chelators has shown contradicting in vitro results. We aimed to determine the effect of DFO on bone growth and graft integration in a rabbit long bone defect bridged by a calcium phosphate bone graft substitute. Additionally, we aimed to quantify its effect on osteoclast mediated graft resorption using a non-weight bearing cranial onlay model. Methods: In 6 rabbits, 3D-printed Monetite (CaHPO₄) grafts were implanted into bilateral 10mm ulnar defects. Starting on day 4 post-op, DFO (600ul/200uM) was injected into one graft every 48hrs x 6 doses, with the contralateral receiving saline. In 10 rabbits, 2 circular grafts (9mm d / 4mm thick) were fixed subperiosteally onto the cranium. Four rabbits had DFO injected into both grafts and 4 had saline. Two rabbits were injected with another chelator, 1,10-Phenanthroline (PHT). At 8 weeks, micro-CT and histology were used to assess bone growth and graft resorption. TRAP stain identified osteoclast density at the bone-graft interface. Results: Ulnar defect: New bone growth was significantly higher in the DFO group compared to the saline group (Bv/Tv: 19.6% vs 13.5%; p<0.05) (fig1) and histological analysis showed more bone integrated at the graft surface. Cranial Model: A marked decrease in graft resorption and vertical bone growth was evident in the DFO and PHT group as compared to saline controls (fig2). Osteoclast density decreased 3-fold in the chelation groups compared to controls (p<0.05). Conclusion: In the long bone model, where cellular resorption of the graft is not required for bone formation as graft dissolution is predominant, bone growth was enhanced by DFO. In the static onlay model, bone growth was actually decreased by iron chelators and this correlated to a reduction in osteoclast number and graft resorption. We propose a second mechanism in addition to HIF induced angiogenesis, by which iron chelators may function as bone anabolic agents - they may also reduce osteoclast mediated resorption by targeting iron requirements during differentiation. This previously unreported in vivo finding has exciting potential applications for implant integration, improving bone quality, and limiting bone destruction.

Odanacatib Inhibits Bone Resorption and Reverses Glucocorticoid-Induced Bone Loss in Adult Rabbits. Brenda Pennypacker¹, Peter Szczerba², Marc Washington², Maureen Pickarski², Le Duong². ¹Merck Research Laboratories, USA, ²Merck & Co., USA

Long-term glucocorticoid (GC) therapy is a common cause of secondary osteoporosis leading to an increased fracture risk. The cathepsin K inhibitor odanacatib (ODN) has been shown to effectively restore bone loss in preclinical models and in postmenopausal osteoporosis. Here, we compare efficacy of ODN versus alendronate (ALN) on bone mass and remodeling in a GC-induced osteoporosis study in rabbits in treatment mode. Adult female (7 mo.) NZW rabbits were allocated to either untreated control (CTRL) or pre-treatment with methyl-prednisolone (MP, 0.6 mg/kg IM wkly). After 3 mo., rabbits on MP were randomized by body weight and lumbar vertebral bone mineral density (LV.BMD) into 4 groups receiving: MP +Veh, MP+ALN (150µg/kg, 2x/wk), MP+ODN (1.5mg/kg/d in food), or MP+ODN (6mg/kg/d in food) for an additional 9 mo. Note, ODN 1.5mg/kg/d dosed in food provided daily drug exposures approximating the 50-mg once-wkly clinical dose. LV.BMD measurements, bone resorption marker urinary helical

peptide (uHP) and bone formation marker serum bone specific alkaline phosphatase (sBSAP) were performed at -3, baseline, 3, 6, and 9 mo. At baseline, LV.BMD in MP-pretreated rabbits decreased by 16% ($p < 0.001$), uHP elevated 3-fold ($p < 0.001$), and body weight decreased by 9% compared to rabbits not treated with MP. After 3-mo. of treatment, ODN at both doses and ALN significantly reduced uHP by 57-90% below MP+Veh (all $p < 0.001$). In addition, uHP levels remained lower in the ODN groups compared to ALN at 3 and 9 mo. uHP in the MP+Veh remained 3-4 fold higher than CTRL throughout the study ($p < 0.001$). Measurements of sBSAP were not different across all treatment groups. LV.BMD in the MP+Veh group remained 14-16% below that in CTRL at mo. 3, 6, and 9 ($p < 0.001$). ODN 6mg/kg increased LV.BMD by 16% at mo. 6 and by 20% at mo. 9 vs. MP+Veh (all $p < 0.001$). By mo.9, LV.BMD of ODN 6mg/kg was not different from CTRL. ODN 1.5mg/kg and ALN treatment gradually increased LV.BMD, achieving 12% and 10% gains respectively vs. MP+Veh by mo. 9 ($p < 0.05$). In conclusion, GC treatment accelerated bone loss accompanied with elevated bone resorption in adult rabbits. In treatment mode, ODN and ALN reversed GC-induced BMD loss similarly, with ODN achieving greater reduction of bone resorption marker than that by ALN. These results provide preclinical evidence to support the evaluation of ODN for the treatment of GC-induced osteoporosis in humans.

Osteoclast-induced TcREG limit bone loss but cannot suppress innate immune response in Serum-transfer induced arthritis. Reggie Aurora¹, Anna Cline-Smith², Elena Shashkova². ¹Saint Louis University University, USA, ²St. Louis University School of Medicine, USA

We have recently shown that osteoclast-induced FoxP3+ CD25+ CD8 T-cells (OC-iTcREG) suppress osteoclasts, effector T-cells and have an anabolic effect on bone volume in ovariectomy induced osteoporosis in mice. Here we tested these cells in a murine model of rheumatoid arthritis. We used serum-transfer induced arthritis because inflammation in this disease model is primarily through activated neutrophils and macrophages as compared to ovariectomy where proinflammatory cytokines are produced primarily by T-cells. OC-iTcREG were either induced in vivo or ex vivo induced CD8 T-cells were adoptively transferred prior to injection of arthritogenic serum. In parallel, we also used TGFβ-induced FoxP3+ CD25+ CD4 T-cells that were adoptively transferred. Our results show that while transferred OC-iTcREG limit bone and cartilage loss, they do not suppress inflammation as measured by cytokine production of cells isolated from the joint. In contrast, TREG were effectively able to suppress inflammation and limit bone loss. These results show that TcREG and TREG have overlapping yet distinct functions in vivo: while OC-iTcREG act as a buffer to limit bone loss, TREG are able to suppress the activation of the innate immune system. The implications and alternate explanations of these observations will also be discussed.

Zoledronate prevents lactation induced loss of bone strength and micro-architecture in mice. Mette Høegh Wendelboe, Jesper Skovhus Thomsen, Annemarie Brüel*. University of Aarhus, Denmark

Purpose: In rodents, lactation is associated with a considerable and very rapid bone loss, which almost completely recovers after weaning. The aim of the present study was to investigate whether the bisphosphonate Zoledronate (Zln) could inhibit bone loss during lactation. In addition, to study whether Zln interfered with recovery of bone mass after lactation has ceased. **Materials and methods:** Seventy NMRI mice, 10-weeks-old, were divided into the following groups: baseline, pregnant, lactation, lactation + Zln, recovery, recovery + Zln, and recovery control (virgin). The lactation period was 12 days, then the pups were removed, and thereafter recovery took place for 28 days. Zln, 100 µg/kg sc, was given at the day of delivery, and again 4 and 8 days after delivery. The experiment was approved by the Danish Animal Experiments Inspectorate. Mechanical testing and χ CT of femur, tibia and L4 were performed. **Results:** In L4, lactation resulted in a substantial loss of trabecular BV/TV (-40% vs. pregnant, $p < 0.001$), trabecular thickness (Tb.Th) (-29% vs. pregnant, $p < 0.001$), bone material density (-4% vs. pregnant, $p < 0.001$), and bone strength (-55% vs. pregnant, $p < 0.001$). Zln completely prevented lactation induced changes in L4: BV/TV (+10% vs. pregnant, NS), Tb.Th (+0.03% vs. pregnant, NS), bone material density (+1.2% vs. pregnant, NS), and bone strength (+11% vs. pregnant, NS). Similar results were found in the proximal tibia. Full recovery of microarchitectural and biomechanical properties was found 4 weeks after weaning. Interestingly, in the recovery group treated with Zln during the lactation period L4 had higher BV/TV (+45%, $p < 0.05$), Tb.Th (+16%, $p < 0.05$), and bone strength (+38%, $p < 0.05$) compared with recovery controls. This indicates that Zln did not interfere with the substantial anabolic response, which takes place during recovery. **Conclusion:** Zln fully prevented lactation induced loss of bone strength and microarchitecture, and did not inhibit the anabolic response taking place after weaning.

S. aureus infection causes aberrant bone healing. Brandon Romero*, Nisreen Akef, Larry Suva, Allister Loughran, Mark Smeltzer, Dana Gaddy, University of Arkansas for Medical Sciences, USA

Osteomyelitis is a serious bone infection typically caused by *Staphylococcus aureus*, the pathogenesis of which is poorly understood. The details of the cellular host responses of bone to the infection are especially lacking. We sought to determine the time course and extent of the host bone response to infection using a contemporary clinical *S. aureus* isolate (UAMS1), and measuring reactive bone formation and the temporal changes in markers of bone resorption and bone formation during the development of osteomyelitis *in vivo*. A unicortical femoral diaphyseal defect was created in 8 week old female mice that were infected with either vehicle control or UAMS1. On days 3, 7 and 14, serum was collected and infected limbs harvested and formalin fixed. As expected during healing of the unicortical bone defect, serum PINP levels increased in sham, uninfected animals across the time course of the entire bone healing response, whereas serum CTX levels were unchanged, confirming the bone formation phase of direct bone healing. In controls, the bone defect was completely healed within 14 days, whereas in UAMS1-infected bones defect healing was not observed, yet progressive and inappropriate reactive bone formation occurred over 14 days. Despite the dramatic increases in reactive bone formation in UAMS1 infected bones, serum PINP levels were diminished compared with the uninfected bones across the time course of bone healing. To determine the cellular effects of *S. aureus* products, *ex vivo* bone marrow cultures were grown toward osteoblast (OB) or osteoclast (OCL) differentiation for 4 days, and exposed to increasing concentrations (10, 25, 50%) of UAMS1 conditioned medium (CM). Cultures were then evaluated for proliferation and cytotoxicity at 24hr. UAMS1 50% CM suppressed cell survival and proliferation of OB and OCL, whereas 10 and 25% had no effect. Recruitment into the

OB lineage was unaffected by 25% CM (indicated by % AP+ CFU-AP), although exposure of cultured calvarial OBs to 25% CM significantly reduced cell survival. Thus, secreted products from a clinically relevant *S. aureus* strain has suppressive effects on the survival of OB, OCL, and their precursors, with the virulence mediated by its cytotoxic effects on more differentiated cells. Collectively, these data demonstrate that an abnormal bone response occurs in the presence of *S. aureus*, which inhibits normal bone healing, yet is not predicted by serum markers of bone turnover.

Chronic Antibiotic Treatment Causes Gender Specific Bone Loss. Jonathan Schepper*, Fraser Collins, Regina Irwin, Sandi Raetz, Nara Parameswaran, Laura McCabe, Michigan State University, USA

Chronic antibiotic therapy for recurring gastrointestinal infections significantly reduces intestinal bacteria levels. Recent studies link the intestinal microbiome and bone health. However, the effect of chronic antibiotic use on bone health is still unknown. To examine this, we treated 12-week-old healthy male and female BALB/c mice with commonly used antibiotics (1g/L ampicillin and 0.5g/L neomycin) for 4 weeks. Fecal bacterial counts were significantly decreased throughout the experiment in antibiotic treated male and female mice. MicroCT analysis of femur trabecular bone demonstrated a significant reduction in bone volume fraction (BVf) in male and a downward trend in female mice treated with antibiotics compared to gender matched controls. Interestingly the degree of bone loss was significantly greater in males compared to females (35 vs 22%). Similarly, antibiotic treated males, but not females, displayed a decrease in vertebral trabecular BVf. Consistent with the CT parameters, analysis of serum bone remodeling markers revealed significantly reduced levels of osteocalcin (osteoblast marker) and TRAP5b (osteoclast marker) in the treated males (by 50% and 12%, respectively), whereas in female mice the markers trended to decrease but were not significant. Taken together our data demonstrate that long-term antibiotic treatment could have an adverse effect on trabecular bone volume by modulating bone remodeling. The results also identify gender related differences in response to antibiotic treatment.

Effects of dietary iron and intermittent adriamycin administration on FGF23 and Fetuin A levels of C57BL/6J mice. Masanori Takaiwa*¹, Kosei Hasegawa², Hirovuki Tanaka³, Hirokazu Tsukahara². ¹Dept. of Pediatrics, Matsuyama Red Cross Hosp., Japan, ²Okayama University Graduate Department of Pediatrics, School of Medicine, Dentistry & Pharmaceutical Sciences, Japan, ³Department of Pediatrics, Okayama Saiseikai General Hospital, Japan

FGF23 plays significant role in the pathogenesis of Chronic Kidney Disease-Mineral and Bone Disorder (CKD-MBD). FGF23 shows elevation during the early CKD, and was associated with insulin resistance and cardiovascular mortality risk of CKD. Fetuin A is also related to the pathogenesis of insulin resistance, cardiovascular disease and CKD. Iron (Fe) supplementation is commonly initiated from the early CKD. Since Fe deficiency exacerbates FGF23 elevation, we created an early CKD model by intermittent administration of adriamycin (ADR) to C57BL/6J mice (C57) and examined the effect of dietary Fe on FGF23 and Fetuin A during the early CKD. Using 6 groups (2%-Fe and 2%-Fe-AN groups - fed a 2.0% Fe diet; 0.6%-Fe and 0.6%-Fe-AN groups - fed a 0.6% Fe diet and 0.02%-Fe-AN groups - fed a 0.02% Fe diet), 10-week-old male C57 were administered serine (2%-Fe, 0.6%-Fe and 0.02%-Fe) or ADR weekly (2%-Fe-AN, 0.6%-Fe-AN and 0.02%-Fe-AN) for 28 days. After treatment, Fe for 2%-Fe and 2%-Fe-AN were higher, and that of 0.02%-Fe-AN was lower than 0.6%-Fe. The kidneys of three ADR treated groups were significantly smaller in size. Although there was no statistical difference, Cr levels of ADR treated groups were higher than the groups without ADR treatment. There was no significant difference in Ca, Pi and PTH levels among all experimental groups. Oral Fe supplementation mildly suppressed intact FGF23 levels of animals without ADR treatment in dose dependent manner. Markedly this negative regulatory effect of oral Fe loading on FGF23 concentration was significantly enhanced in ADR treated groups. 0.02%-Fe-AN showed significant elevation (670 ± 134pg/ml) compared with 0.6%-Fe-AN (284 ± 10pg/ml) and 2%-Fe-AN (106 ± 10pg/ml). Oral Fe deprivation increased Fetuin A in 0.02%-Fe (149 ± 3ng/ml) compared with 0.6%-Fe (137 ± 5ng/ml) and 2%-Fe (124 ± 5pg/ml). Fetuin A was highest in 0.02%-Fe-AN (158 ± 6ng/ml) and the negative correlation between diet Fe content and Fetuin A was not observed among three ADR treated groups. The ADR treatment caused small kidney, mild increase in FGF23 without affecting Pi and PTH, serving as a reasonable early CKD model. Both FGF23 and Fetuin A levels were elevated in the Fe depleted early CKD model. Since negative regulatory effect of Fe on FGF23 was significant, it was suggested that the initiation of oral Fe during early CKD suppresses FGF23 level and has a favorable effect on progression of CKD.

Healing of large-scale bone defects in a mouse model involves hybrid cartilage/bone progenitors. Nikita Tripuraneni, Sandeep Paul, Simone Schindler, Helen Chou, Jason Hsieh, Gage Crump, Francesca Mariani*. University of Southern California, USA

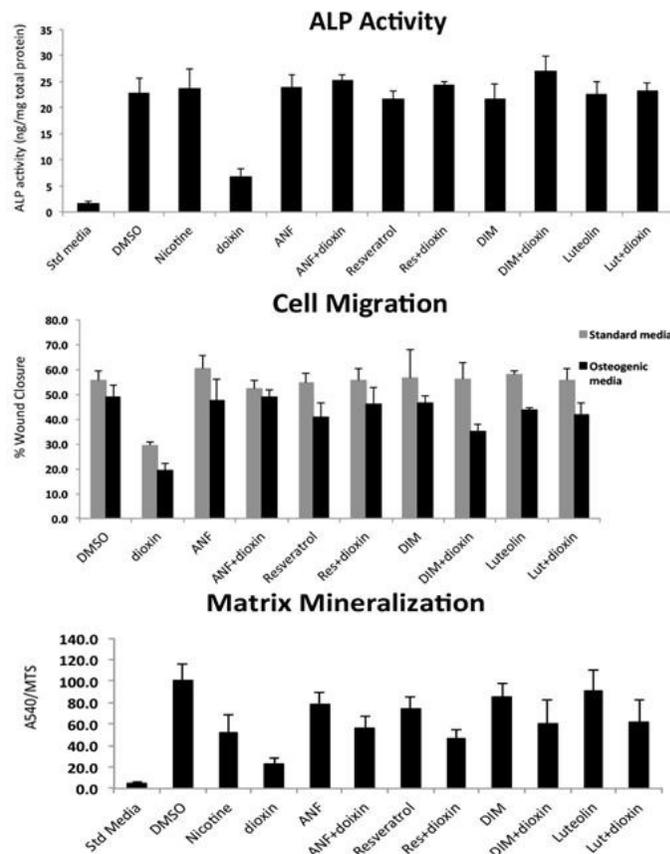

The treatment of significant bone loss remains an unresolved problem. Autogenous bone graft material is limited in supply and the biological activity of synthetic substitutes requires further refinement. Thus, new strategies stimulating the repair of large-scale bone defects are needed. We have found that, as has been anecdotally reported in humans, large resections of the adult rib of the mouse can fully repair. We believe full repair depends on skeletal progenitors emerging from the periosteum since repair fails to occur when it is removed. In addition, ectopic placement of rib periosteum into muscle supports new bone deposition. We are also testing a novel hypothesis that repair chondrocytes are distinct from growth plate chondrocytes because they have hybrid properties of both cartilage and bone cells. Our hypothesis is supported by gene expression analysis and other assays which indicate that these repair cells rapidly and actively build a stabilizing bone matrix rather than simply acting as a template for invading osteoprogenitors. Current studies in our laboratories are determining the molecular signature of these repair cells and developing ways to generate them in large numbers for augmenting repair in other parts of the skeleton.

Mechanistic insight into the adverse effects of Aryl hydrocarbon receptor activation on osteogenic differentiation. Erin Hsu*, Chawon Yun, Sean Mitchell, Abhishhek Kannan, Kevin Sonn, Sharath Bellary, Christian Park, Jonghwa Yun, Ryan Freshman, Danielle Chun, Ami Parekh, Wellington Hsu. Northwestern University, USA

Cigarette smoking is associated with increased rates of pseudarthrosis after spine fusion procedures. Numerous toxic ligands for Aryl hydrocarbon receptor are present in cigarette smoke, and recent evidence suggests that Ahr activation may inhibit osteogenic differentiation. We showed previously that activation of the Aryl hydrocarbon receptor by dioxin treatment inhibits bone regeneration and spine fusion in the rat. The purpose of this study was to elucidate downstream mechanisms of dioxin action, and to identify therapeutics that might mitigate the effects of dioxin on bone. Bone marrow stromal cells were isolated from rat femurs and tibiae and cultured under standard or osteogenic conditions. Factors that are critical to osteogenesis were evaluated after exposure to vehicle control, dioxin, Ahr antagonists, or antagonists + dioxin. Antagonists evaluated were: alpha-naphthoflavone (ANF; a synthetic antagonist), resveratrol (Res; a stilbenoid found in grapes and present in red wine), 3,3'-diindolylmethane (DIM; a flavonoid product of cruciferous vegetables), and luteolin (Lut; a flavonoid present in celery, broccoli, and other sources). We found that dioxin inhibits ALP activity, BMSC migratory capacity, and matrix mineralization. Co-treatment with each of the 4 antagonists mitigates these effects. Dioxin was also found to inhibit BMSC chemotaxis towards various chemoattractants. Co-treatment with ANF and Res generally rescued the anti-chemotactic effects of dioxin to a greater degree than DIM and Lut. RNA and protein expression studies showed that dioxin down-regulates numerous pro-osteogenic genes. Co-treatment of BMSC with Ahr antagonists prevented dioxin-induced expression changes of Col2, Col12, Phex, MMP-3, and MMP-13 proteins to varying degrees. Our results suggest that Ahr activation may play a critical role in the adverse effects of cigarette smoke on bone healing. Dietary supplementation with Ahr antagonists should be investigated as therapeutic option to combat these inhibitory effects.

The fate and distribution of autologous bone marrow mesenchymal stem cells with intra-arterial infusion in osteonecrosis of the femoral head in dogs. Hongting Jin*¹, Taotao Xu², Qiqing Chen², Chengliang Wu², Pinger Wang², Qiang Mao³, Shanxing Zhang², Jiavi Shen², Peijian Tong³. ¹Zhejiang Chinese Medical University, Peoples republic of china, ²Zhejiang Chinese Medical University, China, ³Department of Orthopaedic Surgery, The First Affiliated Hospital of Zhejiang Chinese Medical University, China

Objectives: To observe the fate and distribution of autologous bone marrow mesenchymal stem cells (MSCs) with intra-arterial infusion in treatment of osteonecrosis of the femoral head (ONFH) in dogs. **Methods:** Twelve Beagle dogs were randomly divided into two groups: MSCs group and control group. ONFH models were established by a liquid nitrogen freezing method. After three weeks, dogs in MSCs group were injected with 1 ml autologous MSCs ($5 \times 10^6 - 1 \times 10^7$ /ml) and 0.9% normal saline were used in control group. Necrotic lesions were evaluated by MRI and changes in general architecture of the femoral heads were determined by hematoxylin and eosin stain after eight weeks. The differentiation of grafted cells in the femoral heads was observed by immunofluorescence, and distribution of grafted cells in vital organs was observed through immunohistochemistry and histomorphometry. **Results:** The rate of radiological progression in MSCs group was statistically lower than that in the control group. Trabecular bone volume was increased and empty lacunae rate was decreased in MSCs group ($p < 0.05$). Most of BrdU-positive MSCs in necrotic region co-stained together with osteocalcin in MSCs group. It means that MSCs with intra-arterial infusion migrating into the necrotic field of femoral head directionally differentiated into osteoblasts and improved the necrosis of femoral head. Simultaneously, the BrdU-positive MSCs were nonuniformly distributed in vital organs and the number of BrdU-positive cells in kidney (IOD/Area = 0.050 ± 0.0013), gallbladder (IOD/Area = 0.032 ± 0.0020) and liver (IOD/Area = 0.023 ± 0.0026) were obviously higher than those in small bowel (IOD/Area = 0.005 ± 0.0009), prostate (IOD/Area = 0.005 ± 0.0006). MSCs differentiated into normal cells in corresponding organs. **Conclusions:** autologous MSCs with intra-arterial infusion may be a feasible and safe avenue for the treatment of femoral head necrosis.

α2-Antiplasmin Deficiency Protects from Bone Loss Induced in Ovariectomized Mice. Naoyuki Kawao^{*1}, Akihito Shiomi¹, Kiyotaka Okada¹, Yukinori Tamura¹, Katsumi Okumoto², Osamu Matsuo¹, Masao Akagi³, Hiroshi Kajii¹. ¹Kinki University Faculty of Medicine, Japan, ²Life Science Research Institute, Kinki University, Japan, ³Department of Orthopaedic Surgery, Kinki University Faculty of Medicine, Japan

The production of bone resorptive cytokines, such as IL-10 and TNF-α, was increased in patients with postmenopausal osteoporosis. α2-antiplasmin (α2-AP) is the primary inhibitor of plasmin in fibrinolytic system, and tissue fibrinolytic system is involved in bone metabolism and bone repair. However, its various functions other than fibrinolysis inhibition have been shown. We therefore investigated the roles of α2-AP in bone loss induced by ovariectomy using α2-AP-deficient and counterpart wild-type mice. Bone mineral density (BMD) in femur and indices of bone metabolism were analyzed at 8 weeks after ovariectomy. The levels of plasma α2-AP were elevated in wild-type mice with ovariectomy, compared to those with sham operation. Quantitative computed tomography analysis revealed that α2-AP deficiency blunted the trabecular bone loss induced by ovariectomy. α2-AP deficiency attenuated the increases in serum levels of bone-specific alkaline phosphatase, cross linked C-telopeptide of type I collagen and IL-10 induced by ovariectomy. α2-AP elevated the mRNA levels of IL-10 and TNF-α in mouse monocytic RAW 264.7 cells. Although α2-AP did not affect the mRNA levels of Runx2, Osterix, alkaline phosphatase and osteocalcin in mouse osteoblastic MC3T3-E1 cells, it attenuated RANKL-induced osteoclast formation in RAW 264.7 cells. Plasmin did not affect the mRNA levels of IL-10 and TNF-α in RAW 264.7 cells, suggesting that the effects of α2-AP on IL-10 and TNF-α in monocytes are blood fibrinolysis inhibition-independent. On the other hand, α2-AP induced the phosphorylation of ERK1/2 and p38 MAPK in RAW 264.7 cells, and PD98059, an inhibitor of ERK1/2, and SB203580, an inhibitor of p38 MAPK, antagonized IL-10 mRNA levels enhanced by α2-AP in RAW 264.7 cells, indicating that the enhancement of α2-AP on IL-10 expression in monocytes is via the activations of ERK1/2 and p38MAPK pathways. In conclusion, the present study indicates that α2-AP is involved in bone loss induced by ovariectomy through the expression of IL-10 and TNF-α from monocytes in mice.

BMP2 Regulates Both Osteogenesis and Angiogenesis. Beth Bragdon^{*1}, Thomas Cheng², Elise F. Morgan³, Ivo Kalajic⁴, Stephen E. Harris⁵, Louis C. Gerstenfeld². ¹Boston University School of Medicine Department of Orthopaedics, USA, ²Department of Orthopaedic Surgery, Boston University School of Medicine, USA, ³Department of Mechanical Engineering, Boston University College of Engineering, USA, ⁴Center for Regenerative Medicine & Skeletal Development, University of Connecticut Health Center, USA, ⁵Department of Periodontics, University of Texas Health Science Center at San Antonio, USA

Introduction: Angiogenesis is required for successful skeletal tissue repair which is highlighted during distraction ossification (DO), a procedure in which bone is regenerated by mechanical strain due to the slow lengthening of bone. Vessels formed during DO are sites where Bone Morphogenetic Protein 2 (BMP2) is predominately expressed, both in endothelial and smooth muscle cells. Although it is known that BMP2 is osteogenic and is involved with angiogenesis, it remains unclear as to

functional role that BMP2 expressed in vessels carries out in bone development as well as angiogenesis.

Methods: A transgenic mouse containing a tamoxifen inducible Cre recombinase driven by the α -SMA (Smooth Muscle Actin) promoter was crossed with a BMP2 Floxed transgenic mouse resulting in a mouse (BMP2 cKO) that upon tamoxifen treatment, BMP2 was conditionally knocked out in α -SMA positive cells. The DO surgery was performed on male mice (10-15 weeks old) and starting at post-operative day six received vehicle or tamoxifen. Distraction began at day seven and continued for 10 days resulting in a 1.5mm gain of length. The regenerating skeletal tissue within the gap and surrounding tissue was analyzed molecularly across time using RT-qPCR analysis. Bone and vessel formation was characterized with micro-CT by perfusing the vasculature with a contrasting agent followed by micro-CT scan.

Results: The expression of *BMP2* and *Id1* (Figure 1) direct targets of BMP signaling were decreased in the surrounding tissue of the BMP2 cKO. The micro-CT results suggest the BMP2 cKO has decreased bone formation, although gene expression for osteogenesis (*RUNX2* and *Osteocalcin*) was increased. Strikingly, these studies showed that the loss of BMP2 within the surrounding soft tissues led to diminished vessel formation at d31 which is supported by the expression of markers for angiogenesis, *VEGFR2*, *Pecam1*, and *Ve-Cadherin* and microCT findings (Figure 2).

Discussion: The conditional BMP2 cKO in vascular tissues decreased both osteogenesis and angiogenesis. Although osteogenic gene expression was increased in the BMP2cKO, it did not result in more mineralized tissue. Most striking was the angiogenic phenotype that occurred within the surrounding tissue where BMP2 cKO showed decreased angiogenesis. These results suggest BMP2 provides a critical mechanistic link in the morphogenetic signals that promote skeletal and vascular tissue formation.

A selective androgen receptor modulator that prevents disused muscle atrophy in rats. Kyohei Horie*, Masanobu Kanou, Kenichirou Takagi, Shinnosuke Hosoda, Hidekazu Watanabe, Motoko Hamada, Naoki Hase, Hiroimichi Sugiyama, Kei Yamana. TEIJIN PHARMA LIMITED, Japan

Muscle atrophy is caused by inactivity such as unloading and immobilization after fracture. Hip fracture is one of the most serious consequences of osteoporosis and is associated with increased mortality in older adults. Therefore, prevention of muscle atrophy after hip fracture is significant unmet medical needs and a key success factor for rehabilitation and reduction of mortality.

Selective androgen receptor modulator, SARM is one of the promising candidates for treatment of muscle atrophy due to its anabolic activity in muscle. Recently, we identified a novel non-steroidal orally available SARM, TEI-SARM2 with unique characteristics. TEI-SARM2 has strong ability to AR binding and AR-dependent transcriptional activity same as ostarine, the most advanced SARM in clinical studies. Interestingly, TEI-SARM2 showed strong activity of N/C interaction same as DHT and nandrolone (ND), a clinically available anabolic steroid while ostarine has minimal activity of it. In addition, TEI-SARM2 has longer half-life and higher AUC in blood than that of ostarine in pharmacokinetic study in rats.

To evaluate the potential values of TEI-SARM2 as a pharmaceutical candidate for muscle atrophy, we compared in vivo activity of TEI-SARM2 with ostarine and ND. In orchidectomized (ORX) rats, once-weekly oral treatment of TEI-SARM2 for 2 weeks increased muscle weight significantly stronger than ostarine and similar extent as ND. Moreover, in normal male rats, once-weekly treatment of TEI-SARM2 for 6 weeks significantly increased muscle weight same as ND treatment but did not change prostate and testis weights which were significantly reduced by ND treatment. Furthermore, in hindlimb-unloading female rats, oral treatment of TEI-SARM2 for 2 weeks almost completely prevented rapid loss of muscle weight same as ND treatment while TEI-SARM2 has no effect in ovary and uterus weights which were significantly affected by ND treatment.

In summary, TEI-SARM2 has tissue selective activity with strong anabolism in muscle and minimal adverse effects in reproductive tissues and can prevent rapid loss of unloading-induced muscle atrophy. Taken together our results suggest that TEI-SARM2 is a promising therapeutic candidate for muscle atrophy after hip fracture.

Considerations for Intramuscular Injections in Rodents. Melanie Felix*, Annie Martin, Solomon Haile, Susan Y. Smith, Charles River Laboratories, Canada

Purpose: The intramuscular route is frequently used for compound administration for nonclinical efficacy/toxicology testing, including juvenile studies. Selection of appropriate muscle to inject and tolerable limit of injection volume need careful consideration. The objective of this study was to determine the maximum volume for intramuscular injection in mice and rats at selected sites.

Method: Different volumes of diluted India ink (10%) were injected into the tibialis anterior of mouse pups weighing 1 to 7g. The outcome was assessed by visual inspection of the injection site in the live animal and following euthanasia. At the site of the India ink injection, the skin was removed and the spread of the ink within the muscle and extent of leakage outside of the muscle, were evaluated. In albino rats weighing 200-250g, different volumes of India ink and a contrast agent (Omnipaque™) were injected into the rectus femoris. Faxitron radiographs were taken immediately post, 15 minutes post and 5 hours post injection. The spread of the ink was also evaluated macroscopically.

Results: For mice weighing less than 4g, a single injection of India ink at a dose volume of ≥ 1 mL/kg caused severe swelling of the muscle and was considered unacceptable. Repeat dosing of 5 μ L in mice ≤ 4 g over 2 consecutive days, corresponding to a total dose volume of 5 mL/kg, was considered too high based on observed swelling, limb stiffness, impaired movement and abnormal posture. Two consecutive daily doses of 5 μ L in older/heavier mice of ≥ 5 g, corresponding to a dose volume of 3 mL/kg, was well tolerated. For rats, faxitron radiographs indicated that single injections of ≥ 0.20 mL resulted in leakage outside of the muscle and showed distal expansion cranially to the patella and patellar ligament. Gross observations supported these observations.

Conclusion: A single intramuscular injection in the anterior tibial muscle region at 0.5 mL/kg in mouse pups weighing 2.17 to 3.25 g did not cause any adverse local clinical observations. For mouse pups weighing at least 5g, a maximum dose volume of 3 mL/kg was considered acceptable, when administered over 2 days. For rats, a fixed volume of 0.10 mL (equal to 0.5 mL/kg) was determined as the optimal volume for injection in the rectus femoris of 200-250 g rats based on minimal spread to the neighboring muscles and limited leakage into the subcutaneous tissue.

MO0171

CRTAP, the causative protein in type VII OI, may be tethered to the ER membrane. Simone Smith*¹, Joan C. Marini². ¹National Institutes of Health, USA, ²NIH, USA

Cartilage associated protein (CRTAP) is a component of the ER-resident procollagen prolyl 3-hydroxylation complex, which also contains prolyl 3-hydroxylase 1 (P3H1) and cyclophilin B and 3-hydroxylates the $\alpha 1(I)$ Pro986 residue of types I and II collagen. The components of this complex were the first proteins shown to cause recessive OI. CRTAP is the helper protein of the complex. It shares 55% homology with the amino half of P3H1, but lacks carboxy terminal sequences harboring enzymatic activity. CRTAP deficiency causes type VII OI, with absent $\alpha 1$ Pro986 hydroxylation and over-modification of collagen α -chains. We noted hydrophobic, putative transmembrane motifs in CRTAP (Gly4-Ser32) and P3H1, but it is unknown whether components of the 3-hydroxylation complex reside at the ER membrane. We also noted 2 potential N-glycosylation sites (N⁸⁶X⁸⁷S⁸⁸, N³¹²X³¹³T³¹⁴) in CRTAP C-terminal to the hydrophobic motif. After subcellular HEPES/sucrose fractionation, CRTAP was found in ER fractions (mean 71%, range 62-88%) containing the luminal marker PDI, with a smaller but consistent portion (mean 29%, range 12-38%) co-fractionating with the ER membrane marker calnexin. P3H1, with similar putative hydrophobic domains as CRTAP, fractionated to the luminal fraction, with values similar to PDI (>90% luminal). On immunofluorescence microscopy, we observed perinuclear reticular staining of calnexin at the ER membrane, with colocalization of CRTAP; more precise localization will be performed by EM immunogold labeling. Enzymatic deglycosylation further resolved CRTAP into a smaller band consistent in size with a doubly-deglycosylated form; presence of sugars indicates the C-terminal glycosylation sites orient towards the lumen with the N-terminus towards the cytosol. In cells from a patient lacking P3H1, the residual CRTAP was detected in the ER membrane fraction. Therefore, membrane tethering of a pool of CRTAP might explain the residual CRTAP seen when its mutually stabilizing 3-hydroxylation partner, P3H1, is absent (type VIII OI), although P3H1 is totally absent when CRTAP is null. Tethering of CRTAP might improve access of the modifying complex to collagen chains during coordinated translation and folding of the collagen helix, while disruption of ER-tethering might underlie the collagen overmodification seen in types VII and VIII OI. Experiments are ongoing to obtain genetic corroboration using CRTAP constructs from which the putative transmembrane domain is deleted.

MO0172

Elucidating the Antifibrosis Effects of rPTH Therapy on Critical Defect Healing in the Murine Cranial Window Model. Longze Zhang*¹, Claire Kaiser¹, Matthew Todd², Ryan Gao¹, Xinping Zhang¹, Edward Schwarz¹.

¹Center for Musculoskeletal Research, University of Rochester Medical Center, School of Medicine & Dentistry, USA, ²Center for Musculoskeletal Research, University of Rochester Medical Center, USA

Background: Reconstruction of critical bone defects remains a major clinical challenge. To address this, we aim to elucidate the molecular and cellular differences between healing and non-healing critical defects, and assess novel interventions. Previously we found that intermittent teriparatide (rPTH) therapy facilitates structural femoral and calvarial allograft healing in mice via increased osteogenesis and decreased fibrosis, which results in significantly increase host-allograft bone union. We also discovered that rPTH significantly decreased large vessel arteriogenesis and the accumulation of mast cells in the interfacial tissue between the host and allograft bone. In the current study we utilized a chronic cranial defect window chamber model for in vivo multiphoton laser scanning microscopy (MPLSM) and longitudinal micro-CT to test the hypothesis that rPTH therapy: 1) increases small vessel (<30um) angiogenesis, and 2) decreases large vessel (>30um) arteriogenesis and mast cell numbers, to 3) significantly increase critical defect closure. To assess the direct role of mast cells on angiogenesis and bone healing, we also evaluated the effects of cromolyn sodium in our model. **Methods:** 8-week-old female C57B/6 mice received a cranial defect window, and were randomized into three groups: 1) placebo (saline), 2) rPTH treated (40cg/kg/day), and 3) cromolyn sodium (24cg/kg/day). Co-visualization of blood vessels and mast cells was achieved with i.v. administration of Texas Red-dextran and FITC-conjugated anti-Mcpt-5 antibody respectively. In vivo micro-CT and MPLSM imaging were performed every two weeks, and 3D-reconstruction of the z-stack images with Amira and Visiopharm software was used to quantify % defect closure and vascularity within the defect. We also quantified Mcpt-5+ cell numbers and determined their mean distance from large vessels (>30um) vs. small (<30um) blood vessels. **Results & Discussion:** At 4-weeks post-op the percentage of small (<30um) vs. large (>30um) vessels for the placebo group was 19.7% vs. 80.3%. rPTH therapy significantly increase small vessels to 40.4%, and decreased large vessels to 59.6% (p<0.05). Remarkably, cromolyn sodium had similar significant effects (43.1% vs. 56.9%; p<0.05). However, only rPTH significantly increased the mean % critical defect closure vs. placebo (p<0.01), which was 17.9%, 45.8% and 25.5% respectively for the 3 Groups. We also found that Mcpt-5+ cells were significantly closer to large vs. small vessels (26.9 +/- 14.6 um vs. 61 +/- 3.7 um; p < 0.05), and more Mcpt-5+ cells were found in placebo group vs. the rPTH and cromolyn treatment groups. These novel findings suggest that coupled osteogenesis and angiogenesis at the healing edge of a critical defect is opposed by arteriogenesis, mast cell accumulation and fibrosis within the defect, and that rPTH efficacy includes inhibitory effects on arteriogenesis and mast cell-induced fibrosis. However, the synergistic anabolic effects of rPTH are also required for critical defect healing, as alteration of vascularity and mast cell numbers with cromolyn is insufficient to heal critical defects.

Phosphate overload via type III Na-dependent Pi transporter deteriorates elastic fiber formation in vascular wall in Pit-1-overexpressing transgenic rats. Yasumasa Yoshino*¹, Tomoka Hasegawa², Shukei Sugita³, Eisuke Tomatsu⁴, Sahoko Sekiguchi-Ueda¹, Megumi Shibata¹, Takeo Matsumoto³, Norio Amizuka², Atsushi Suzuki¹.

¹Division of Endocrinology & Metabolism, Fujita Health University, Japan, ²Department of Developmental Biology of Hard Tissue, Division of Oral Health Science, Graduate School of Dental Medicine, Hokkaido University, Japan, ³Biomechanics Laboratory, Nagoya Institute of Technology, Japan, ⁴Division of Endocrinology & Metabolism, Fujita Health University, Japan

Phosphate (Pi) has been reported to change arterial smooth muscle cells (ASMC) to osteoblastic phenotype through the induction of type III Na-dependent Pi transporter, Pit-1. We have previously shown that extracellular Pi overload via Pit-1 induces its osteoblastic trans-differentiation, but also keeps ASMC from the terminal differentiation as mature osteoblasts, and limits the progress of further aortic calcification in Pit-1-overexpressing transgenic (TG) rats. In the present study, we investigated the role of extracellular Pi in microstructural change of arterial wall of Pit-1 TG rats. **Methods:** Aorta of TG and its wild-type littermates (WT) were obtained 8 weeks after birth. Descending aorta from both WT and TG rats were used for measurement of wall thickness and uniaxial tensile test. Breaking stress was calculated as force/(initial thickness x initial width), while breaking strain was as (length - initial length)/initial length. Elastic moduli in low and high strain regions were calculated as slopes of stress-strain relationship by fitting a linear line in each region. Structural and ultrastructural analyses were performed by using light microscopy and transmission electron microscopy (TEM). Expression of the components of connective tissue in aorta was quantified by qRT-PCR. **Results:** Aortic wall thickness in TG rats was same as that in WT. Uniaxial tensile test showed that the circumferential breaking stress in TG was significantly lower than that in WT (p<0.05), though longitudinal

breaking stress was not different. On the other hand, breaking strain in TG was same as that in WT. However, elastic moduli in TG were not different from those in WT. Ultrastructural analysis of TG rat aorta by TEM showed damaged formation of elastic fiber in aortic wall. qRT-PCR showed significant decrease of fibrillin-1 expression in aorta in TG rats. In conclusion, Pi overload via Pit-1 transporter on arterial wall weakened circumferential strength through malformation of elastic fibers including the decrease of fibrillin-1.

Variants in regulatory regions of *SREBF1*, a Lamin A interaction factor exert pleiotropic effects on BMD and lean mass in children. Carolina Medina-Gomez*¹, John P. Kemp², Eskil Kreiner-Møller³, Alessandra Chesì⁴, Denise H.M. Heppè⁵, Babette S. Zemel⁶, Klaus Bønnelykke³, Hans Bisgaard³, Vincent W.V. Jaddoe⁵, André G Uitterlinden⁷, Jon H Tobias⁸, Gustavo Duque⁹, Struan F.A. Grant⁴, David M. Evans², Fernando Rivadeneira¹⁰. ¹Erasmus Medical Center, The Netherlands, ²University of Queensland Diamantina Institute, Translational Research Institute, Brisbane, Queensland, Australia, ³Copenhagen Prospective Studies on Asthma in Childhood, Health Sciences, University of Copenhagen, Danish Pediatric Asthma Center, Copenhagen University Hospital, Gentofte, Denmark, ⁴Division of Human Genetics, Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA, ⁵The Generation R Study Group, Erasmus University Medical Center, 3015GE, Rotterdam, Netherlands, ⁶Division of GI, Hepatology, & Nutrition, Children's Hospital of Philadelphia, Philadelphia, PA 19104, USA, ⁷Department of Internal Medicine, Erasmus University Medical Center, 3015GE, Rotterdam, Netherlands, ⁸School of Clinical Sciences, University of Bristol, Bristol, United Kingdom, ⁹Musculoskeletal Ageing Research Program, Sydney Medical School Nepean, The University of Sydney., Australia, ¹⁰Department of Internal Medicine, Erasmus University Medical Center, Rotterdam, Netherlands

Background: Lean and bone mass are heritable traits with high phenotypic correlation ($\rho=0.44$), likely reflecting the underlying mechanical and biochemical interactions between tissues. **Aim:** Estimate the shared SNP-heritability (genetic correlation) of both traits in children and identify genetic determinants displaying pleiotropic effects on lean mass and bone mass accrual. **Methods:** Participants make part of three prospective birth cohorts, the Generation R Study (GenR) and the Avon Longitudinal Study of Parents and Children (ALSPAC) and the Copenhagen Studies on Asthma in Childhood (COPSAC). GenR children ($n=4,071$) born in Rotterdam, Netherlands are of multiethnic background with mean age=6.2, SD=0.37 years. ALSPAC children ($n=4,820$) born in Avon, UK had mean age=9.9, SD=0.32 years. COPSAC children ($n=273$) born in Copenhagen from asthmatic mothers had mean age=6.9, SD=0.61. Lean mass and BMD were measured with DXA (GE-Lunar iDXA/ Prodigy) and genome-wide genotyping (II 660K-III 550K) imputed to HapMap. Shared heritability estimates derived from array data of GenR were obtained using GCTA (with modified admixed-aware relatedness estimates using REAP). GWAS in GenR, ALSPAC and COPSAC were run using PLINK multivariate. Meta-analysis was performed by Fisher's method. All analyses were adjusted for age, sex, height, fat percent (and 20 genomic principal components in GenR). $P<5\times 10^{-8}$ was considered genome-wide significant. **Results:** SNP-heritability estimates were 0.31 for BMD and 0.40 for lean mass, with a genetic correlation of 0.3. The bivariate GWAS meta-analysis identified six established BMD loci with concordant effects on lean mass and BMD including: *WNT4* ($P<10^{-9}$), *GALNT3* ($P<10^{-8}$), *CPED1/WNT16* ($P<10^{-20}$), *TNFSF11* ($P<10^{-9}$), *RIN3* ($P<10^{-10}$) and *PPP6R3/LRP5* ($P<10^{-8}$). Another signal ($P<10^{-10}$) with opposite effects on lean mass and BMD mapped to the *TOM1L2/SREBF1* locus. ENCODE analyses identified enhancers for *SREBF1* in the same haplotype block. **Conclusion:** Several variants at BMD loci exert pleiotropic effects on lean mass. Bivariate analysis is a powerful method for identifying novel pleiotropic effects. *SREBF1*, an adipocyte differentiation factor, is a regulator of muscle protein synthesis regulating *MYO1D*, *MYOG* and *MEF2C* factors, which interacts with the C-terminal of *Lamin A* (*LMNA*). *LMNA* is the cause of different muscular dystrophies and has been proposed as a determinant factor in the pathogenesis and potential treatment of both sarcopenia and osteopenia.

Comparison of Hyaluronic Acid and Placebo in Patients with Knee Osteoarthritis. A Simulated Meta-Analysis Study. Abdulhafez Selim¹, Sahar Ghoname*². ¹Center for Chronic Disorders of Aging, PCOM, USA, ²Ain Shams University School of Medicine, Egypt

Although acknowledged as a conservative treatment choice for knee osteoarthritis, hyaluronic acid (HA) is still not universally embraced due to conflicting results with

respect to its efficacy in clinical studies. Several randomized clinical trials (RCTs) found significant improvement in pain after treatment as compared with the baseline, but found no significant improvement when the efficacy of HA was compared with placebo (saline). In this systematic review simulation, we compared the effects of intra-articular administration of HA with similarly administered placebo as well as, more specifically, the effects of individual HA products as compared to placebo.

A systematic review of RCTs was conducted using databases including MEDLINE, Cochrane Database of Systematic Reviews, Cochrane Clinical Trial Register, and EMBASE. Summarized data was then simulated using a Bayesian analytical approach.

Seventy-four RCTs were included in this review. Based on simulated data, HA improved pain by a mean of 79.6% (SD= 7.6%) as compared with baseline levels, while placebo improved pain by a mean of approximately 56.3% (SD= 15.6%). When HA was compared with saline, however, the difference in efficacy was only 23.3%. By testing several superiority margins (10%, 15%, 20%, and 25%), the superiority of HA performance compared to placebo could not be established beyond the 20% margin, which may not represent a clinically meaningful difference. Furthermore, when various HA products, differing in molecular weight, concentration, and volume of HA, were compared, we were not able to determine that any one brand had better efficacy than another. In addition, neither the molecular weight (MW) of the HA, its dosing, or its concentration effected efficacy outcomes. This could be explained by the wide heterogeneity of the study population as well as the high SDs that characterized the data.

This study highlighted several critical variables with potential impact on study design approaches evaluating HA effectiveness. The following variables may be considered in future studies: more objective endpoint(s), an overall success composite index (with objective as well as subjective outcomes), and the selection of more homogeneous population. Due to the limitations of this analysis (follow-up of just 3 months and the heterogeneity of the included studies), evaluation of different HA products in order to determine which product(s) as well as which MW range, concentration, and/or volume of HA are optimal in the treatment of specific population(s) of osteoarthritic patients is still needed.

Pre-operative pre-albumin: Relation to 30-day risk of complication in elective spine surgical patients. Erin Coburn*¹, Jung Yoo², Jackie Shannon², Sabina Blizzard², Lizzy Boshears², Lynn Marshall². ¹Oregon Health & Science University, USA, ²OHSU, USA

Protein malnutrition assessed by serum pre-albumin is associated with increased risk of post-operative morbidity and mortality in adult spine surgery patients. However, whether the risk of post-operative complications also varies across the range of serum pre-albumin in this patient group has not been established. We determined the association of pre-operative serum pre-albumin with 30-day risk of complication. Medical records were reviewed for adult patients age ≥ 50 years who underwent elective cervical, thoracic, thoracolumbar, or lumbar spine surgery for painful spinal degenerative conditions between June 2013 and June 2014. For the pre-operative visit just prior to surgery, we obtained serum pre-albumin level (mg/dL), serum transferrin (mg/dL), demographic factors, and health measures (such as blood pressure). Surgical information was obtained from the operative note. The primary outcome was 30-day risk of medical complication, such as deep vein thrombosis, wound problems, or infections. The relation between pre-albumin level and complications was estimated with risk ratios (RR) and 95% confidence intervals (CI) from log-binomial regression. In the final model, RRs were adjusted for transferrin, body mass index, number of levels fused, age, sex, and American Society for Anesthesiology (ASA) score, an indicator of fitness prior to surgery. During model building, factors found not to be confounders were blood pressure, previous spine surgery, and total anesthesia time. The analytic cohort included 275 adults with mean (SD) pre-albumin of 27.5 mg/dL (± 5.6 mg/dL), and median serum pre-albumin (inter-quartile range) was 27.4 (23.8, 30.8) mg/dL, and was largely within the normal range. Those in the lowest pre-albumin quartile tended to be male, heavier, have a higher ASA score, and have more levels fused compared to those in the highest quartile. The 30-day cumulative incidence of complication was 12.7% (95% CI: 10.0%-17.3%). Risk of complication was not associated with decreasing pre-albumin level. The RR per 1 mg/dl decrease in pre-albumin was 1.00 (95% CI: 0.94-1.07, p-trend=0.98). Pre-albumin below the median (vs above the median) also was not associated with risk of complications (adjusted RR=1.1, 95% CI: 0.8-1.5) (Table). Among adults undergoing surgery for degenerative spine conditions, the 30-day risk of complication was not associated with serum pre-albumin. Other biomarkers should be explored as possible risk factors for surgical complications.

Table. Risk Ratios (RR) and 95% confidence intervals (CI) of complications within 30 days among adults undergoing elective spine surgery according to pre-surgical level of pre-albumin

| Median (mg/dl) | Pre-Albumin Level | |
|--------------------------|-------------------|---------------|
| | <27.4 | ≥27.4 |
| Minimum, Maximum (mg/dl) | (12.9-27.3) | (27.4-47.9) |
| Total N | 137 | 138 |
| No. Complications (%) | 18 (13%) | 17 (12%) |
| Model | RR (95% CI) | |
| Unadjusted | 1.0 (Referent) | 0.9 (0.5-1.7) |
| *Model 1 | 1.0 | 1.1 (0.8-1.5) |
| **Model 2 | 1.0 | 1.1 (0.8-1.5) |

* Variables modeled are pre-albumin level, transferrin level, body mass index (<30 kg/m², ≥30 kg/m²) and number of levels fused (no fusion, 1 level fused, 2-3 levels fused, ≥4 levels fused)

** Variables modeled include those in model 1 plus age group (50-59 years, 60-69 years, ≥70 years), sex (female, male), and ASA score (1-2 points, 3-4 points)

Prevalence of Hand Osteoarthritis and Factors associated with Pain in Korean Farmers. Sang-Hyon Kim¹, Sang-Il Lee^{*2}, Sang-Heon Lee³, Young-Il Seo⁴, Jinseok Kim⁵, Jung Soo Song⁶. ¹Div. of Rheumatology, South Korea, ²Division of Rheumatology, Department of Internal Medicine, ²Department of Preventive Medicine, Gyeongsang National University School of Medicine, ³Clinical Research Institute, Gyeongsang National University Hospital, Jinju, Republic of Korea, South Korea, ³Division of Rheumatology, Konkuk University School of Medicine, Seoul, Republic of Korea, South Korea, ⁴Division of Rheumatology, Hallym University Medical Center, Ahnyang, Republic of Korea, South Korea, ⁵Department of Internal Medicine, Jeju National University Hospital, Jeju, Republic of Korea, South Korea, ⁶Division of Rheumatology, Department of Internal Medicine, Chung-Ang University Medical school, Seoul, Republic of Korea, South Korea

Background: A few studies investigated the prevalence of hand osteoarthritis (HOA) and associating factors of hand pain in Korean farmers. Objectives: To investigate the prevalence of HOA and to identify factors that influence hand pain among farmers in rural areas of Korea. Methods: The study was conducted from June 2013 to Dec 2014 with 700 farmers in Gyeong-nam Province of Korea. Clinical evaluation for hand joints was performed and the plain radiographs of both hands were taken. The Australian/Canadian Osteoarthritis Hand Index (AUSCAN) was used to assess pain severity of hand joints. Radiographic HOA was defined as Kellgren-Lawrence (KL) grade=2 on plain radiographs and symptomatic HOA as KL grade=2 with pain at the same joints. Presence of HOA at individual level was defined as =1 affected joint. Depressive symptoms were assessed using the Patient Health Questionnaire. Results: Participants comprised of 371 (53%) women and 329 (47%) men with mean age of 59.7±8.6 years. The mean farming duration was 30.0±14.3 years. The overall prevalence of radiographic and symptomatic HOA was 59.1%, and 13.9%, respectively. The prevalence rates of radiographic HOA for women and men were 62.3 and 55.6% (p=0.077), and symptomatic HOA for women and men were 14.8% and 12.8% (p=0.445), respectively, not significantly different. However, AUSCAN pain scores were higher in women (99.9±106.8) than men (68.0±99.9, p=0.002) among participants with radiographic HOA. Linear regression analysis showed that women and depressive symptoms were associated with AUSCAN pain scores after adjustment for radiographic severity of HOA, total numbers of affected joints, frequently repetitive hand use and pinch grip working during harvest. Conclusions: The AUSCAN pain scores were higher in women with HOA compared to men, and associated with depressive symptoms after controlling other factors. Therefore, our results show the need for depression care management in female farmers to reduce hand pain.

Disclosures: Sang-Il Lee, None.

MO0178

Ultrasound-Guided intra-articular injection of platelet-rich plasma in treating knee osteoarthritis in short-term follow-up: a prospective, randomized, controlled trial. Peijian Tong*. Zhejiang Provincial Hospital of TCM, Peoples republic of china

Purpose: To compare the clinical efficacy of platelet-rich plasma (PRP) and hyaluronic acid (HA) treatment in 2 groups of Knee osteoarthritis (KOA) patients and evaluate if the age, body mass index (BMI) and grade of gonarthrosis are associated with the outcomes on the PRP injection. Methods: A total of 100 consecutive patients were enrolled between December 2013 and November 2014. The gonarthrosis was graded according to the Kellgren-Lawrence radiographic classification. The 100 patients were randomized into 2 groups in accordance with the random

number table in a 1:1 ratio: 50 patients (50 knees) in Group A were given 3 injections of HA, and 50 patients (50 knees) in Group B received 3 injections of PRP at an interval of 3 weeks. Patients were assessed on the WOMAC, VAS and Cartilage Lesions Score (CaLS) for clinical evaluation before and after the treatment. Meanwhile we calculated the effective rate, as defined by at least 36% improvement from baseline WOMAC score at the follow-up. Results: The results had significant difference in each period (VAS: HA, P<0.01; PRP, P<0.01. WOMAC: HA, P<0.01; PRP, P<0.01) comparing with the baseline except the result at 6 months in VAS score of Group A (VAS: HA, P>0.05). The patients in Group B had better clinical outcomes than those in Group A at the 6 months follow-up (P<0.05) in Grade I, 3 months (P<0.05) and 6 months (P<0.01) in Grade II, and each period (P<0.01) as well as VAS score (P<0.05) at the 6 months follow up in Grade III. In addition, we found older patients who receives PRP injections obtained worse VAS Score and WOMAC Score at the final follow-up. In addition, we found older patients who receives PRP injections obtained worse VAS and WOMAC at 6 months' follow-up, and higher KL grade connected with lower effective rate. However, the BMI had no certain positive or negative correlation to the outcomes on the Group B. The depth and shape scores of the CaLS from different lesion location in 7 patients had no significant difference in Group B at the 6 months follow-up. As time goes on, the efficacy in both groups wore off, and the trend of recurrence rate of clinical symptom was seemingly more pronounced in Group A. Overall, the effective rate was 68% after the last treatment and 36% at the final follow-up in group A, and 84%, 60% in group B. Conclusions: The short-term efficacy of PRP injection was associated with age and level of joint degeneration. Meanwhile the PRP injection had a better clinical outcome than HA injection in providing better functional results at the final follow-up.

Efficacy and Safety of Undenatured Type II Collagen Supplement in Modulating Knee Joint Function in Osteoarthritic Subjects. James Lugo¹, Zainulabedin Saived¹, Nancy Lane^{*2}. ¹InterHealth Nutraceuticals, USA, ²University of California, USA

Background: Preclinical and clinical studies support the safety and efficacy of undenatured type II collagen (UC-II) in promoting joint comfort, mobility and flexibility in healthy as well as osteoarthritic (OA) populations. Herein we report the combined results of two recently completed, similarly designed, randomized, double-blind, placebo-controlled clinical trials in OA subjects.

Objective: To evaluate the efficacy and safety of the UC-II® supplement in comparison to placebo and glucosamine hydrochloride plus chondroitin sulfate (GC) in modulating knee joint function in OA subjects.

Methods: One hundred ninety one eligible subjects were randomized into three groups receiving a daily dose of UC-II (40 mg), GC (1500 mg G & 1200 mg C), or placebo over a 180-day period. The primary endpoint was defined as the change in total Western Ontario McMaster Universities Osteoarthritis Index (WOMAC) from baseline to day 180 for the UC-II group versus placebo. Secondary endpoints encompassed reductions in the Lequesne Functional Index (LFI), the Visual Analog Scale (VAS) for pain and the WOMAC subscales for pain, stiffness and physical function. One hundred sixty-four subjects completed the trials.

Results: At study conclusion (180 days), statistically significant reductions in the overall WOMAC score was observed in the UC-II supplemented cohort compared to placebo (p=0.0023) and GC (p=0.0404). The change in overall WOMAC score for the UC-II group resulted from statistically significant reductions in the WOMAC pain (p=0.0003 vs. placebo; p=0.0162 vs. GC), stiffness (p=0.0041 vs. placebo; p=0.0443 vs. GC) and physical function (p=0.0065 vs. placebo) subscales. The UC-II cohort also demonstrated a significant reduction in total LFI and mean VAS scores versus both placebo (p=0.0085 and 0.0021, respectively) and GC (p=0.0084 and 0.0246, respectively). No significant change in any of these clinical outcomes were observed in the GC cohort versus placebo during the study period. No major adverse events associated with supplementation were reported. Conclusions: Supplementation with UC-II was well-tolerated and led to improved knee joint function, suggesting that additional studies are warranted to better define these observations.

The Short-Term Efficacy of Denosumab in Osteoporosis in Patients with Rheumatoid Arthritis from a Japanese Multicenter Registry. Yuji Hirano^{*1}, Yasuhide Kanayama², Shinya Hirabara³, Syuji Asai⁴, Nobunori Takahashi⁴, Takavasu Ito⁵, Naoki Ishiguro⁴, Toshihisa Kojima⁴. ¹Toyohashi Municipal Hospital, Japan, ²Orthopaedic Surgery & Rheumatology, Toyota Kosei Hospital, Japan, ³Rheumatology, Toyohashi Municipal Hospital, Japan, ⁴Orthopaedic Surgery, Nagoya University Graduate School of Medicine, Japan, ⁵Ito Orthopaedic Hospital, Japan

Purpose: Osteoporosis (OP) is one of the important comorbidities in rheumatoid arthritis (RA). Pathogenesis of RA-OP is composed from multiple factors, such as hyper cytokine, concomitant drugs and disuse. Although denosumab (DMB), a fully-

human anti-RANKL antibody, is expected to be a good treatment option for RA-OP, clinical data from real-world is limited. This study investigated the effects of DMB on RA-OP from a multicenter registry data in Japan (TBCR-BONE).

Methods: 53 RA-OP cases were included. (1) %increase of bone mineral density (BMD) in lumbar spine (LSBMD) and total hip (THBMD) at 6month, (2) %change of bone turnover markers (PINP and TRACP-5b) at 6m, (3) correlation between change of BMD and change of BTM, (4) results until 12m (n=16), (5) the influence of concomitant use of biological agents (BIO) for the treatment of RA and (6) adverse events were investigated.

Results: Patients' characteristics: 50 females and 3 males. Mean age: 69.7 years old. RA duration: 14.2 years. Mean body mass index: 19.8. FRAX: 27.1%. Prednisolone use: 45.3% (mean doses: 4.3mg/day). BIO for the treatment of RA was concomitant in 34.0%. Treatment naïve of OP was 35.8%. Cases after teriparatide (TPTD) treatment were 11 cases. (1) LSBMD (g/cm²) was significantly increased from 0.825 at baseline to 0.857 at 6m (mean %increase: 3.9%). THBMD (g/cm²) was significantly increased from 0.598 at baseline to 0.611 at 6m (3.1%). (2) Both PINP and TRACP-5b were significantly decreased at 6m (41.4% and 34.8% decrease, respectively). (3) There were no significant correlation between %change of BMD at 6m and %change of BTM at 6m. (4) %increase of LSBMD was 5.1% at 6m and 6.3% at 12m. %increase of THBMD was 2.4% at 6m and 5.6% at 12m. BTMs were decreased at 6m and unchanged at 12m. (5) Baseline THBMD of BIO group was significantly low compared with that of NonBIO group. TRACP-5b of BIO group was significantly high compared with that of NonBIO group. %increase of LSBMD at 6m was 4.7% in BIO group and 3.0% in NonBIO group. %increase of THBMD at 6m was 3.4% in BIO group and 3.0% in NonBIO group. No significant differences were observed. (6) Hypocalcemia was occurred in 2 and pelvis fracture was occurred in one. Pelvis fracture was healed.

Conclusions: The short-term results of DMB in RA-OP was good especially in THBMD. This study showed that %change of BTMs were not the predictor for efficacy of DMB on BMD increase at 6m. BIO did not affect the efficacy of DMB.

MO0181

A Novel Optogenetic Approach To Elucidate Spatial Regulation Of Semaphorin-Plexin Signaling In Osteoblasts. Abhijit Deb Roy*¹, Taofei Yin², Yi Wu². ¹University of Connecticut Health Centre, USA, ²University of Connecticut Health Center, USA

Osteoclasts express Semaphorin 4D (Sema4D), a transmembrane ligand for the receptor Plexin-B1, expressed by osteoblasts. Osteoblasts and osteoclasts are spatially segregated on the bone surface *in vivo*. In mice deficient in either Sema4D or Plexin-B1, osteoclasts and osteoblasts no longer display spatial segregation and have increased cell-cell contact. Previous studies provide limited understanding of how intracellular signaling events downstream of Plexin-B1 are spatially regulated to mediate directional migration of osteoblasts. Here we developed a novel optogenetic tool, optoPlexin, to specifically activate Plexin-B1 in a ligand-independent manner, at precise subcellular locations using light.

In osteoblastic MC3T3-E1 cells, activation of optoPlexin in lamellipodial protrusions led to rapid, local recruitment of RhoGEFs, PDZ-RhoGEF and Leukemia Associated RhoGEF, necessary for RhoA activation. We observed subsequent accumulation of myosin, leading to collapse of these protrusions. Such collapse repolarized the cell to migrate away from the site of optoPlexin activation. Biosensors of Rho GTPases identified the specific induction of RhoA activity upon optoPlexin activation, which required the interaction of optoPlexin with Rnd1 or Rac1 on the membrane. Rac1/Rnd1 and RhoA are generally mutually inhibitory. However, our data demonstrate that activation of PlexinB1 converts Rac1 from an inhibitor of RhoA activity to a stimulator, initiating a rapid negative feedback loop that inhibits Rac1 at protrusions.

Local activation of optoPlexin caused local depletion and distal accumulation of beta-Pix, an activator of Rac1 and Cdc42. These distal regions of beta-Pix accumulation correlate with high Cdc42 and Rac1 activity, as well as formation of new protrusions. OptoPlexin-induced coordination among Rho GTPases was dependent on ROCK kinase activity and myosin-dependent contractility. Local perfusion of soluble Sema4D induced similar local retractions and distal protrusions in primary calvarial osteoblasts. The coordination of local suppression and distal promotion of protrusions by Plexin-B1 signaling is consistent with contact repulsion between osteoclasts and osteoblasts, which could explain their spatial segregation *in vivo*. These results revealed spatially distinct effects of Plexin-B1 signaling in regulating Rho GTPases and osteoblast migration, and highlight the utility of optogenetic approaches in studying spatiotemporal regulation of cellular signaling.

Antiarrhythmic peptide GAP-134 promote osteoblastic differentiation and function in association with upregulation of Cx43 *in vitro*. Dong Jin Chung*, Nam Hee Lee, Jin Ook Chung, Dong Hyeok Cho, Min Young Chung, Chonnam National University Medical School, South Korea

Bone-forming cells are highly coupled by gap junctions formed primarily by connexin43 (Cx43). The biological importance of Cx43 in skeletal development has been established by work in human and mouse genetics. Selective Cx43 gene deletion

in osteoblasts results in adult osteopenia, delayed osteoblast differentiation, and greatly attenuated osteoanabolic response to PTH. Recently, we demonstrated that aminobisphosphonate promote osteoblastic differentiation and function in association with upregulation of Cx43 *in vitro*. Another gap junction modulator, the antiarrhythmic peptides, stimulate gap junction communication between cardiomyocytes. Furthermore, the prototype compound had been shown to prevent deterioration of bone biomechanical properties in estrogen dependent bone loss in rats. In this study, we investigated the effect of other antiarrhythmic peptide GAP-134 on osteoblast differentiation and Cx43 expression using the cell line C2C12 and HEK293. Alkaline phosphatase (ALP) activity was increased by GAP-134 dose-dependently. When GAP-134 and 5 ng/ml of BMP2 were used in combination, ALP activity increased to a larger extent than when BMP2 was used alone. These results suggest that GAP-134 may facilitate the differentiation of osteoblasts, synergizing with BMP-2. In our previous study, co-transfection of expression vectors and luciferase-reporter constructs revealed that Runx2, Dlx5 and Osterix increased Cx43-promoter activity in a concentration-dependent manner. As the concentration of GAP-134 was increased, Cx43-promoter activity was increased by 2.5 fold. Furthermore, the combination of Dlx5 (0.5 µg) and GAP-134 up-regulated Cx43 promoter activity to a far larger extent than did Dlx5 or GAP-134 alone, suggesting an interaction between the GAP-134 and Dlx5 in activating the Cx43 promoter. These results suggest that GAP-134 promotes osteoblast differentiation and regulates Cx43 expression in C2C12 cells.

Collagens VI and XII Matrix Bridges Mediate Osteoblast Cell Communicating Networks During Bone Formation. Yayoi Izu*¹, Yoichi Ezura², Manuel Koch³, David Birk⁴, Masaki Noda⁷. ¹Tokyo Medical & Dental University, Medical Research Institute, Japan, ²Tokyo Medical & Dental University, Japan, ³University of Cologne, Germany, ⁴University of South Florida, USA

Ullrich congenital muscular dystrophy (UCMD) and Bethlem myopathy (BM) are diseases representing overlapping phenotypes of connective tissue and muscle. Both diseases are caused by genetic mutations in the genes encoding collagen VI. Recently COL12A1 gene mutations were identified in UCMD and BM-like patients harboring no COL6 mutations, indicating shared functions of these collagens for connective tissue homeostasis. We have previously demonstrated that the genetic deletion of Col6a1 or Col2a1 in mice cause altered osteoblast arrangement at bone forming sites that result in bone mass reduction and fragility. During bone formation, osteoblasts migrate toward appropriate bone forming sites where osteoblasts form well-organized cell communicating networks that is essential for healthy, strong bone formation. Therefore, we hypothesize that collagens VI and XII function together on the formation of osteoblast cell communicating networks at the site of bone formation. Because extracellular matrix proteins are accumulated in extracellular environment, it is hard to detect the initial localization *in vivo*. Thus, to elucidate the hypothesis, we examined collagens VI and XII localization in the process of cell-cell contact formation *in vitro*. Primary osteoblasts were obtained from neonatal mouse calvariae and were cultured in a medium supplemented with 10% FBS or osteogenic medium. The cells were harvested on day 2, 4, and 11 and then analyzed based on immunofluorescence microscopy using antibodies against collagen I, VI, and XII. The double staining analysis revealed that co-localization of collagen VI and XII was detected in the matrix bridges between adjacent cells on day 2 and 4 when initial cell-cell connections were detected. On the other hand, collagen I was localized in a region close to the cell surface where it was colocalized with collagen XII. However no clear localization of collagen I was detected in between adjacent cells on day 2 and 4. All the collagens were detected as a filamentous network surrounding osteoblasts on day 11. The percentage of the cells harboring collagens bridges was analyzed based on the immunostaining on day 2 and 4, demonstrating that matrix bridges were made via collagen VI and XII but not via collagen I. Our data indicate that collagen VI and XII have a novel coordinate function in the formation of cell communicating networks during bone formation.

Disclosures: Yayoi Izu, None.

MO0184

A Novel Role of MACF1: Positively Regulates Osteoblast Differentiation. Lifang Hu*¹, Peihong Su², Runzhi Li², Chong Yin², Kun Yan², Ge Zhang³, Peng Shang², Airong Qian². ¹Northwestern Polytechnical University, Peoples republic of china, ²Key Laboratory for Space Bioscience & Biotechnology, Institute of Special Environmental Biophysics, School of Life Sciences, Northwestern Polytechnical University, China, ³Institute for Advancing Translational Medicine in Bone & Joint Diseases, School of Chinese Medicine, Hong Kong Baptist University, China

Microtubule-actin crosslinking factor 1 (MACF1), also referred to as actin crosslinking factor 7 (ACF7), plays a key role in cell migration by regulating dynamics of microtubules and F-actins. Besides, MACF1 plays critical role in Wnt/β-catenin signaling activation through translocating Axin complex. We previously found that mechanical unloading inhibited osteoblast differentiation and bone formation, and

down-regulated MACF1 expression. Therefore, we propose a hypothesis that MACF1 may play an important role in regulating osteoblast differentiation. MACF1 knockdown pre-osteoblasts were constructed using MC3T3-E1 cells transfected with shRNA-MACF1 lentivirus vector and the MACF1 expression level was detected by real time PCR and western blot. After induction of osteoblast differentiation with osteogenic medium, alizarin red staining was applied to detect mineralized nodules formation and real time PCR was used to detect the mRNA expression of osteogenic genes including alkaline phosphatase (ALP) and runt-related transcription factor 2 (Runx2). Immunocytochemistry and western blot were used to examine β -catenin localization and nuclear translocation. In order to determine if MACF1 functions upstream of GSK-3 β and β -catenin signaling, lithium chloride (LiCl, 30 mM) was used to treat cells to inhibit GSK-3 β activation. The results showed that the expression of MACF1 was dramatically down-regulated after transfection with LV3-shRNA-MACF1 (Figure 1). MACF1 deficiency significantly inhibited the mineralized nodules formation and osteogenic gene expression (Figure 2). Besides, the translocation of β -catenin into nuclear was decreased by MACF1 knockdown (Figure 3A). However, 6 h treatment of 30 mM LiCl induced β -catenin nuclear translocation (Figure 3B) and inhibits GSK-3 β activation in MACF1 knockdown cells (Figure 4). The western blot detection of β -catenin expression in cytosol and nuclear confirmed the above findings (Figure 5). These findings showed that MACF1 deficiency inhibited osteoblast differentiation and the nuclear translocation of β -catenin, suggesting that MACF1 positively regulates osteoblast differentiation and may act through activating β -catenin signaling.

Effects of Bone Morphogenetic Protein-4 (BMP-4) on Adipocyte Differentiation from mouse Adipose-derived Stem Cells. Xueqin Wei*¹, Xiaoxiao Cai². ¹Sichuan University, Peoples republic of china, ²Sichuan University, China

Objectives: Mesenchymal stem cells (MSCs) could be easily isolated from adipose tissues and keep self-renewal and multipotent differentiation capacities, they hold promising possibilities to be extensively applied in tissue engineering. Bone morphogenetic protein (BMP) family members have been reported to provide instructive signals to MSCs to differentiate into several cell lineages. This study aims to investigate whether BMP-4 could promote Adipose-derived stem cells (ASCs) differentiation into adipocytes under various concentrations.

Materials and methods: ASCs were isolated from mouse inguinal adipose pads and cultured in vitro. 10 ng/ml and 50 ng/ml BMP-4 were added into adipogenic media for 8 days. Oil red-O staining, reverse transcription/polymerase chain reaction and immunofluorescent staining were performed to examine the differentiation of ASCs.

Results: As indicated by increased expressions of adipogenic and lipogenic genes (PPAR- γ , APN and LPL) and proteins, 50 ng/ml BMP-4 seems to induce mASCs to differentiate into adipocyte lineage compared to 10 ng/ml BMP-4 and control groups. In addition, lipid droplets accumulated within the adipocytes under 50 ng/ml BMP-4 stimulation, shown by oil red-O staining.

Conclusions: Our present study suggested that BMP-4, as an adipogenic inducing factor, could promote adipogenesis of ASCs at higher concentrations (50 ng/ml) and may be considered as a candidate for adipose tissue engineering.

Functionalized self-assembling nano-peptides promote osteogenic differentiation of human Mesenchymal Stem Cells (hMSCs) in vitro. Shaun Peggrem¹, Baichuan Wang², James Triffitt³, Zhidao Xia*¹. ¹Swansea University, United Kingdom, ²Union Hospital Affiliated to Huazhong University of Science & Technology, China, ³University of Oxford, United Kingdom

Self-assembling nanopeptides are of great interest in the field of regenerative medicine for their unique characteristics that help support tissue repair and regeneration. The aim of this study was to assess a functionalized self-assembling nano-peptide hydrogel for its osteogenic potential when used with either Coralline Hydroxyapatite/Calcium Carbonate (CHACC) or cuttlefish bone powder. We designed a new functionalized self-assembling nanopeptide (AcN-RADARADAR-ADARADAGGRGDARGDA-COHN2) with the functional group RGDA (The amino acid sequence for multiple calcium-binding sites were selected from the glycoprotein Thrombospondin). An additional group was created using RADA16

only (Puramatrix), the nano-fibres of which were coated in Bone Morphogenic Protein-2 (BMP-2) and the control group was composed of RADA-16 only. These self-assembling nano-peptide hydrogels were then integrated with either CHACC or cuttlefish bone particles in addition to human Mesenchymal Stem Cells (hMSCs) and cultured in alpha-MEM containing 10% FCS before testing for cytotoxicity and osteogenic potential. The functionalized nano-fibre scaffolds exhibited no cytotoxicity in comparison to the control group. hMSCs adhesion and differentiation in three-dimensional cell culture was prominent. AlamarBlue assay confirmed cell proliferation was statistically significant within each group comparing day 7 to day 1. Confocal microscopy was used to observe cell viability and cytochemical staining of alkaline phosphatase was used to assess osteogenic potential. Alizarin Red staining confirmed calcification had occurred significantly more in the functionalized peptide groups than in the RADA16 alone group. The functionalised nano-fibre scaffolds had excellent biocompatibility in vitro and showed improved osteogenic potential with hMSCs. These scaffolds could be very valuable for future use in the field of bone regeneration.

How Do Heavy Metal Ions Uncouple Bone Formation from Bone Resorption.

J. Edward Puzas*¹, Tzong-jen Sheu², Catherine A. Muzytchuk², Eric E. Beier². ¹University of Rochester School of Medicine, USA, ²University of Rochester School of Medicine & Dentistry, USA

Purpose

We have investigated the effects of heavy metal ions (lead and cobalt) on skeletal metabolism. With exposure to either of these agents we find a low bone mass phenotype resembling osteoporosis in mice. The studies with lead are clinically relevant in that mounting evidence shows that exposure to this metal ion decreases bone density and increases fracture risk. The studies with cobalt are also clinically relevant because of the observed high incidence of permanent bone loss and "metalosis" in patients receiving a metal-on-metal orthopaedic cobalt-chromium implant.

Our hypothesis is that lead and cobalt uncouple bone formation from bone resorption and lead to a permanent loss of bone. The mechanism for the uncoupling is through up-regulation of the expression of the formation inhibitor, sclerostin.

Methods

Mice were exposed to lead in their drinking water or gavaged with cobalt salts to achieve concentrations seen in the humans. In vitro experiments were also performed with lead and cobalt ions in the culture medium.

DXA and microCT imaging were used to measure bone density and bone quality. Sclerostin levels were measured in vivo and in vitro using ELISA assays and western blotting. Sclerostin null mice (SOST^{-/-}) were used as control animals for both in vivo experiments and from which to isolate cells for in vitro experiments. TGF β reporter activity was measured using P3TPLuc. Immunohistochemistry analyses were performed using standard methods.

Results

We have found an osteoporosis-like phenotype with DXA and microCT analyses in mice exposed to lead over a 3-6 week period. At the same time we found that sclerostin levels increased dramatically (over 7-fold) in both serum and bone tissue. We observed the same effect when osteoblasts were exposed to lead and cobalt ions in cell culture. We have also found that lead and cobalt block TGF β signaling through the p-Smad3 pathway. Blockade of this pathway up-regulates sclerostin production, implying repressor function for this transcription factor.

Conclusion

Our findings show that exposure of osteoblasts to lead and cobalt ions markedly depresses bone formation. This occurs, in part, through heavy metal ion up-regulation of sclerostin. Our data also support that the mechanism by which this occurs is through lead and cobalt inhibition of TGF β signaling, thereby de-repressing SOST gene expression. These findings point to new ways to combat this bone loss clinically.

MO0188

Inhibition of histone deacetylases enhances the osteogenic differentiation of human periodontal ligament cells. Nam Cong-Nhat Huvnh*¹, Vincent

Everts², Prasit Pavasant³, Ruchanee Salingcarnboriboon Ampornaramveth⁴. ¹Mineralized Tissue Research Unit, Faculty of Dentistry, Chulalongkorn University, Thailand, ²Department of Oral Cell Biology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam & VU University Amsterdam, Research Institute MOVE, Netherlands, ³Department of anatomy, Faculty of Dentistry, Chulalongkorn University, Thailand, ⁴DRU in Oral Microbiology, Microbiology department, Faculty of Dentistry, Chulalongkorn University, Thailand

When appropriately triggered, periodontal ligament (PDL) cells can differentiate into mineralized tissue, thus make it be a good candidate for autologous bone graft. However, the underlying mechanisms responsible for the plasticity of PDL cells are unknown. One possible mechanism might be related to epigenetics, since histone

deacetylases (HDACs) have been shown to play a role in osteoblast differentiation. This study was aimed to investigate the role of histone deacetylases (HDACs) in osteogenic differentiation of human periodontal ligament (hPDL) cells. Methods: hPDL cells were isolated from teeth subjected to be extracted from healthy volunteers. Activity of HDACs was blocked using the inhibitor trichostatin A (TSA). Effect of TSA on proliferation and cytotoxicity of primary hPDL cells was tested by MTT assay. Osteogenic and adipogenic differentiations were induced in the presence of TSA. Gene expression was assessed by semi-quantitative and real time RT-PCR. ALP activity and mineral deposition assays were used to assess osteoblast phenotype. Histone acetylation and the expression of different HDACs were also observed by WB. Co-polymer scaffold (PCL/PEG) was used to perform 3D culture and mineralization level was verified by Von Kossa and Alizarin red staining. Results: During the course of osteogenic differentiation in the presence of the HDAC inhibitor, osteoblast-related genes expression were accelerated in hPDL cells. ALP activity as well as bone nodule formation were also enhanced under these conditions. Inhibition of HDACs was quite specific to osteoblast lineage since it did not induce the differentiation into adipocyte lineage. hPDL highly expressed HDACs of both class I (HDAC 1, 2, 3) and class II (HDAC 4, 6). During osteogenic differentiation, HDAC 3 expression gradually decreased. This was apparent in the absence and presence of the inhibitor. The level of acetylated histone H3 was increased during osteogenic differentiation. Inhibition of HDAC activity also induced hyperacetylation of Histone H3. These data, therefore, post an important role of HDAC3 and histone H3 as a candidate target molecules for HDAC inhibition. The effect of TSA was also consistent when bone formation in 3D culture model was performed. In conclusion, hPDL cells express a distinguished series of HDACs and these enzymes appear to involve in the osteogenic differentiation. Inhibition of HDACs activity in hPDL cells might make it more applicable for bone regeneration therapy.

MO0189

Osteoblastogenesis increases through up-regulation of RUNX2, CX43 and beta-catenin after treatment with human serum collected 1 hour and 2 hour post dried plum ingestion. Paulina Cuenca*, Shirin Hooshmand. San Diego State University, USA

Recent studies showed that treatment with dried plum (*Prunus domestica* L.) polyphenols increased osteoblast alkaline phosphatase (ALP) activity, mineralization and increased the expression of bone marker genes RUNX2 and osterix. The purpose of this study was to determine if human serum collected 1 hour (1h) and 2 hour (2h) after dried plum ingestion influenced osteoblast cell activity and gene expression. Five healthy women were asked to consume 100g dried plum and serum samples were collected at baseline (before dried plum ingestion), and 1h, and 2h post-dried plum ingestion. MC3T3-E1 osteoblast cells were treated with 2% of the baseline, 1h and 2h post-dried plum ingestion serum for three and nine days. Treatment with human serum 1h and 2h post-dried plum ingestion for three and nine days significantly increased intracellular and extracellular ALP activity. Also, treatment with human serum 1h and 2h post-dried plum ingestion for three and nine days significantly increased the mRNA level of bone markers RUNX2 and CX43. Finally, treatment with human serum 1h and 2h post-dried plum ingestion for nine days increased the expression of beta-catenin. We concluded that treatment with human serum 1h and 2h post-dried plum ingestion for three and nine days increased osteoblast activity and function by up-regulating RUNX2, CX43 and beta-catenin.

Transgenic Expression of Dentin Phosphoprotein (DPP) Inhibits Long Bone Growth. Hua Zhang*¹, Peihong Liu², Chao Liu¹, Privam Jani¹, Xiaohua Xie¹, Yongbo Lu¹, Chunlin Qin¹. ¹Texas A&M University Baylor College of Dentistry, USA, ²Harbin Medical University School of Stomatology, China

Objectives: Dentin sialophosphoprotein (DSPP), the most prominent non-collagenous protein expressed by odontoblasts, plays an essential role in dentin formation. DSPP is expressed in the long bone at a much lower level. Previous studies have indicated a role of DSPP in bone turnover, however, the exact mechanism by which DSPP functions in the bone mineralization and remodeling remains largely unknown. DSPP is proteolytically processed into an N-terminal fragment called dentin sialoprotein (DSP) and a C-terminal fragment known as dentin phosphoprotein (DPP). These two fragments are believed to perform distinct roles in the formation and mineralization of mineralized tissues. The goal of this study was to investigate the functions of DPP in skeletal development. Methods: Transgenic mice were generated to overexpress the hemagglutinin (HA)-tagged DPP under control of a 3.6 kb type I collagen (Col1a1) promoter (referred to as "Col1a1-HA-DPP"). Combined approaches of Real-time PCR, Western immunoblotting and immunohistochemistry were used to validate overexpression of HA-DPP in the mineralized tissue of Col1a1-HA-DPP transgenic mice. Plain x-ray radiography, skeleton staining, histology and immunohistochemistry analyses were performed to characterize the skeletal phenotype in these transgenic mice. Results: Fifteen Col1a1-HA-DPP founder mice were obtained and were bred with C57BL/J mice to establish the transgenic lines. Transgenic expression of HA-DPP was confirmed at both mRNA and protein levels.

The Col1a1-HA-DPP transgenic mice were significantly smaller by weight, and they had smaller skeletons and shorter femurs than their wild-type littermates, as demonstrated by plain x-ray radiography. Histology analysis showed that the Col1a1-HA-DPP transgenic mice had narrower zones of the proliferative and hypertrophic chondrocytes in the growth plates of the long bones. Consistently, BrdU labeling revealed a reduction in the number of proliferating chondrocytes. In addition, the transgenic mice with high level of transgene expression displayed malformed joints and spontaneous long bone fracture. Conclusions: Overexpression of DPP inhibits long bone growth, suggesting that the balanced actions of both DSP and DPP may be required for normal skeletal development.

A gram positive bacterial toxin lipoteichoic acid induces inflammatory bone resorption through PGE2 production. Tsukasa Tominari, Michiko Hirata, Chisato Mivaura, Masaki Inada*. Tokyo University of Agriculture & Technology, Japan

Toll-like receptors (TLRs) are the mold receptors play a critical role in innate immunity, and various ligands for TLRs regulate the host defense against the pathogens. Lipopolysaccharide (LPS) is a potent toxin for inflammatory bone resorption such as periodontitis, that is an outer membrane component of gram-negative bacteria binds to TLR4. The other TLRs, TLR1/2 heterodimer recognizes triacylated lipopeptides from gram-negative bacteria, whereas TLR2/6 heterodimer recognizes diacylated lipopeptides from gram-positive bacteria. We have reported that synthetic ligands for TLR1/2 and TLR2/6 induced prostaglandin (PG) E₂-mediated and receptor activator of NFκB ligand (RANKL)-mediated osteoclast differentiation, and that TLR2 heterodimer signaling induced mouse experimental periodontitis in vivo. In this study, we examined the effects of a gram-positive bacteria originated lipoteichoic acid (LTA), a natural ligand for TLR2/6 heterodimer on inflammatory bone resorption. In cocultures of mouse primary osteoblast (POB) and bone marrow cell, LTA significantly induced osteoclast differentiation. In cultures of POB, LTA increased PGE₂ production in conditioned medium and up-regulated the mRNA expression of membrane bound PGE synthase (mPGES)-1, cyclooxygenase (COX)-2 and RANKL. Both osteoblasts and osteoclasts expressed TLR2 and TLR6 mRNAs. To compare the LTA induced NFκB inducing activity, the degradation of IκBα was measured. LTA promoted degradation of IκBα, suggesting RANKL production was increased by NFκB nuclear translocation in osteoblasts. Furthermore, to examine the direct actions of LTA on the survival in mature osteoclasts, RANKL treated RAW264.7 cells were treated with LTA. LTA enhanced the life span and cell survival in mature osteoclasts. In the organ culture of mouse calvaria, LTA induced bone resorbing activity in dose-dependent manner, and the effect was less than that of LPS. In conclusion, LTA induced TLR2/6 signaling to promote RANKL expression via mPGES-1 and COX2 mediated PGE₂ production and stimulate inflammatory bone resorption. TLR4 recognizes LPS from gram-negative bacteria and TLR2/6 recognizes LTA from gram-positive bacteria, and both signals simultaneously enhance the inflammatory activity at the sites of bacterial infection in periodontitis.

Expression of Collagen-Modifier Genes in the Gonads: Another Link between Bone and Reproduction. Sarah Zimmerman*¹, Roberta Besio², Milena Dimori¹, Melissa Heard¹, Frances Swain¹, Dana Gaddy¹, Larry Suva¹, Alberto Ferlin³, Patrizio Castagnola⁴, Roy Morello¹. ¹University of Arkansas for Medical Sciences, USA, ²University of Pavia, Italy, ³University of Padova, Italy, ⁴IRCCS, Italy

Sc65 (Synaptonemal complex 65, aka LEPREL4) is a poorly characterized member of the Leprecan gene family. Three members of this family are prolyl 3-hydroxylase enzymes (P3H1, P3H2, and P3H3) which hydroxylate certain proline residues on fibrillar collagens. The family also includes cartilage-associated protein (Crtap), and mutations in CRTAP and LEPREL1 (encoding P3H1) cause recessive osteogenesis imperfecta (OI). While Sc65 was first identified as a synaptonemal complex protein, we demonstrated that Sc65-null mice have a low bone mass phenotype, albeit milder than Crtap or P3H1 knockout mice. Since both Crtap and Sc65 are non-enzymatic proteins we hypothesized that similar to Crtap, Sc65 potentially interacts with fibrillar procollagen chains and collagen modifiers. To identify candidate Sc65 interacting proteins, a yeast 2-hybrid approach was utilized. Surprisingly, the most robust interactions occurred with spermatogenesis-associated proteins and included spermatogenesis-associated 4 (Spata4), Spata3 and spermatogenesis-associated serine-rich protein 1 (Spats1). Spata4 was further investigated since it had been shown by others to promote osteoblast differentiation. Indeed, Spata4 is expressed in mouse primary osteoblasts and a murine fibroblast cell line although preliminary co-immunoprecipitation results did not confirm that Sc65 and Spata4 interact. Immunofluorescence (IF) for Sc65 and Spata4 appeared to show no colocalization. Nonetheless, Sc65 gene expression was confirmed in mouse testis by RT-PCR and western blot analysis revealed higher levels of Sc65 expression in prepubertal versus adult testis, with even higher protein expression in ovarian tissue. Immunohistochemistry detected Sc65 protein in spermatogonia, spermatocytes, and developing spermatids and in the granulosa and theca cells of the ovary. Interestingly,

Crtap was also expressed in mouse testis and ovary in a pattern similar to Sc65. Despite this, neither Sc65 nor Crtap knockout mice have infertility issues. Conversely, IF detection of Sc65 and Crtap in adult human testis biopsies revealed a very different expression pattern with staining only in the interstitial cells and not the seminiferous tubules. Sirius-red collagen staining of adult murine testis sections showed no overt differences. Thus, Sc65 and Crtap do not appear to play a role in collagen modification in the gonads, or in spermatogenesis. A potential role in the synaptonemal complex is currently being investigated.

Disclosures: Sarah Zimmerman, None.

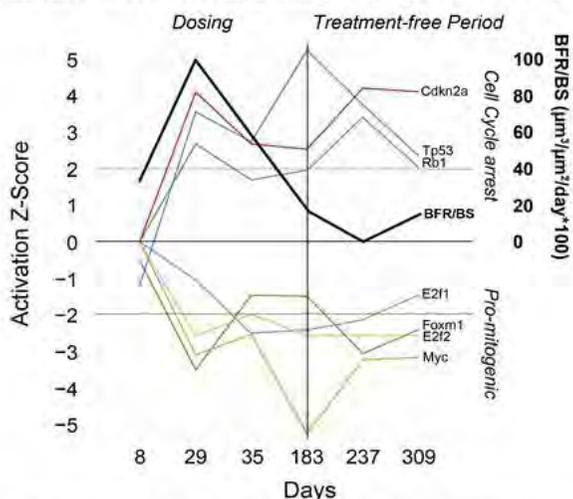

MO0193

Analysis of the Osteoblast Lineage Reveals Inhibition of Mitogenesis and Cell Cycle Progression Associated With Attenuation of Bone Formation in Response to Sclerostin Antibody in Ovariectomized Rats. Scott Taylor*, Paul Nioi, Rong Hu, Efrain Pacheco, Yudong He, Cynthia A Afshari, Ian Pyrah, Michael S Ominsky, Rogely W Boyce. Amgen Inc., USA

In aged ovariectomized (OVX) rats, sclerostin antibody (Scl-AbVI) rapidly increased vertebral bone formation rate (BFR/BS), which attenuated toward control values by 26 weeks. To gain insight into the signaling pathways that may be involved in self-regulation of BFR/BS, the transcriptional response of subpopulations of the osteoblast (OB) lineage was assessed. Microarray analysis of mRNA isolated from laser capture microdissection-enriched samples of lining cells (LC), OB, and osteocytes (OCy) from the vertebrae of OVX rats was evaluated following exposure to Scl-AbVI for 26 weeks and during a treatment-free period (TFP).

Six-month-old rats were OVX and after 8 weeks received vehicle or Scl-AbVI (3 or 50 mg/kg/wk) up to Day (D) 183. Animals were euthanized on D8, 29, 85, and 183 and during the TFP at intervals up to D309. In L4 vertebrae, progressive increases in bone volume (BV/TV) were observed through D183 (end of treatment) and gradually declined thereafter, while BFR/BS peaked at D29 before normalizing to control during the TFP. Co-expression analysis of differentially expressed genes (DEGs) from the 3 cell types collected from L3 vertebrae demonstrated that OCy displayed unique patterns of temporally regulated genes, with distinct gene modules split on D29 correlating to BFR/BS and BV/TV. Wnt target genes (*Wisp1/Twist* cluster) were similar in LC, OB, and OCy at D8. The OCy pattern changed at D29–183, with a sustained increase of *Wisp1* but not *Twist1*, coupled with upregulation of different Wnt targets including *Irx3*, *Id2*, and *Tcf4*. Furthermore, DEGs consistent with cell cycle arrest, such as increased *Cdkn1a* and decreased *Foxm1*, *Cdk1*, and *Ccnb1* were observed beginning on D29. DEGs were analyzed to predict activation or inhibition of upstream molecules based on downstream expression changes. The most significant effects were observed in OCy from D29–183 for the 50 mg/kg/wk Scl-AbVI group, with predicted activation of transcription factors (TFs), which are known tumor suppressors and inhibitors of cell cycle progression, and coincident inhibition of pro-mitogenic TFs (Figure). The onset of these TF changes mirrored the changes in BFR/BS. In the TFP, the status of these TFs trended toward control values. The temporal relationship between these transcriptional changes and changes in BFR/BS suggests that suppression of mitogenesis and cell cycle progression may contribute to the attenuation of bone formation observed with chronic Scl-AbVI treatment.

Ascorbic acid drives Tet-mediated methylcytosine hydroxylation to induce osteoblastogenesis in vitro. Casey Droscha*, Bart Williams, Van Andel Institute, USA

Ascorbic acid (AA) is a common supplement added to cell culture medium due to its functions both as an anti-oxidant and its ability to promote cell proliferation. AA is also an essential component of osteogenic media required to induce *in vitro* osteoblast differentiation. AA has long been known to facilitate prolyl-hydroxylation of nascent procollagen polypeptides required for extracellular collagen fibrillation, a marker of osteoblast differentiation. This function of AA has been assumed to underlie its role in promoting osteoblast differentiation. However, recent evidence demonstrates that AA is also a co-factor for the Ten-eleven-translocation (Tet) methylcytosine dioxygenase family responsible for hydroxylating methylcytosine (5mC to 5hmC) within the CpG moiety. The hydroxylation of methylated CpGs initiates active DNA de-methylation, which allows for a cascade of chromatin remodeling occurring within distal regulatory elements. This leads to substantial reprogramming of cells resulting in significant, epigenetically heritable changes in gene expression. We hypothesize that the role of AA in initiating demethylation of cytosine residues may also contribute to its function in inducing osteoblast differentiation. To address the requirement of active demethylation during AA-induced osteoblast differentiation, MC3T3-E1 cells lacking either Tet1 or both Tet1 and Tet2 were generated via CRISPR/Cas9 technology and differentiated for 0, 4, and 7 days in the presence of 50ug/mL ascorbic acid. As predicted, AA exposure resulted in a time dependent increase in global 5hmC. Currently, *in vitro* osteoblast differentiation assays are being performed on Tet single- and double-KO MC3T3-E1 to assess the necessity of Tet1/2 expression for differentiation. Osteoblast-specific gene enhancer activation and remodeling is assessed by global changes of 5mC to 5hmC via DNA Immunoprecipitation-sequence (meDIP-seq) in combination with ChIP-sequence analysis of the enhancer signature. Furthermore, identification of differentially methylated regions corresponding to enhancer signatures will be assessed by Nucleosome Occupancy Methylation-sequence (NOME-Seq) analysis to determine, at base pair resolution, both DNA methylation changes and nucleosome remodeling. This work aims to elucidate the role of Tet methylcytosine hydroxylases to regulate epigenetic remodeling and control developmental gene transcription during osteoblast differentiation.

Carbamazepine and Phenytoin Inhibit Native Sodium Currents in Murine Osteoblasts. Sandra Petty*¹, Carol J Milligan², Marian Todaro³, Kay L Richards², Pamu Kularathna⁴, Charles Pagel⁴, Elisa L Hill-Yardin⁵, Chris French⁶, Terence J O'Brien⁶, John D Wark⁷, Eleanor J Mackie⁴, Steven Petrou². ¹The University of Melbourne, Australia, ²The Florey Institute of Neuroscience & Mental Health, Australia, ³Melbourne Brain Centre at The Royal Melbourne Hospital, Australia, ⁴Faculty of Veterinary & Agricultural Sciences, The University of Melbourne, Australia, ⁵Department of Physiology, University of Melbourne, Australia, ⁶Melbourne Brain Centre at The Royal Melbourne Hospital, The University of Melbourne, Australia, ⁷Department of Medicine, The Royal Melbourne Hospital, The University of Melbourne, Australia

Purpose: Fracture risk is increased in epilepsy, however, understanding of the mechanism is limited. Osteoblasts express ion channels, which we hypothesized would be inhibited by anti-epileptic medication (AED), potentially altering signaling during bone remodeling. We aimed to investigate whether: (1) mouse primary calvarial osteoblasts express voltage-activated sodium current (NaV), and (2) carbamazepine (CBZ) and phenytoin (PHT) inhibit this current.

Methods: Immunocytochemistry, RNA-Seq (Illumina USA) and Patchliner (Nanion, Germany) recordings were performed on primary calvarial osteoblasts extracted from neonatal C57BL/6J mice. Cell samples were stained for alkaline phosphatase to confirm osteoblastic characteristics. The impact of AED on whole-cell current recordings was examined using the Patchliner. Currents were elicited using a range of voltage protocols designed to examine sodium channel biophysical and pharmacological properties. CBZ (50 μM) or PHT (50 μM) was applied to the cells in continued presence of internal and external tetraethylammonium (10 mM) and internal Cs⁺. Following washout of AED, 10 μM tetrodotoxin (TTX), a known NaV blocker was applied.

Results: NaV expression was demonstrated with immunocytochemistry and RNASeq. Robust voltage-activated inward currents were elicited. External application of AED resulted in significant inhibition of current amplitude: for CBZ $31.6 \pm 5.9\%$ ($n = 9$; $p < 0.001$), and for PHT $35.5 \pm 6.9\%$ ($n = 7$; $p < 0.001$), which was partially reversed upon washout. Subsequent application of TTX (10 μM) produced almost complete inhibition of current amplitude.

Conclusion: Mouse osteoblasts express native NaV which are sensitive to CBZ and PHT. Further study is required to determine whether these effects translate to alterations in osteoblast effector function producing clinically-important changes in bone signaling and bone quality.

Integrative Analysis of RNA-seq and ChIP-seq Data Identifies Wnt3a Inducible Genes and Regulatory Elements in Osteoblasts. Aimy Sebastian*¹, Nicholas R. Hum², Deepa K. Muruges², Sarah Hatsell³, Aris N. Economides³, Gabriela G. Loots⁴. ¹University of California, Merced, USA, ²Lawrence Livermore National Laboratories, USA, ³Regeneron Pharmaceuticals, USA, ⁴Lawrence Livermore National Laboratories; University of California, Merced, USA

Wnt3a is a canonical Wnt ligand that has been shown to promote bone formation, yet very few of its target genes are known in osteoblasts. To identify new Wnt3a target genes and regulatory elements, neonatal osteoblasts isolated from *C57Bl/6 (WT)* calvaria were treated with Wnt3a for 24 hrs and the transcripts were quantified by RNA-Seq analysis. In total, 452 genes including many Wnt pathway members such as *Porcn*, *Fzd1*, *Lef1*, *Tcf7* and *Axin2* were significantly differentially expressed between Wnt3a and sham treated osteoblasts. A gene ontology analysis with DAVID showed that Wnt3a regulates the expression of many major regulators of differentiation, proliferation, growth, apoptosis, ossification and extracellular matrix organization. We conducted the same experiment in Wnt3a treated *Lrp5^{KO}* osteoblasts and found 405/452 genes significantly changed in Wnt3a treated *WT* osteoblasts to overlap with the Wnt3a treated *Lrp5^{KO}* osteoblasts, suggesting that Wnt3a gene activation in osteoblasts is *Lrp5* independent. Next, we downloaded 21 TCF/LEF ChIP-Seq datasets from ENCODE and GEO, aligned them to the reference genome and identified 804,156 TCF/LEF binding peaks. Subsequently, we identified 56,854 putative regulatory elements in osteoblasts by computationally identifying regions with overlapping H3K4me1/2 and H3K27ac ChIP-Seq peaks (H3K4me1/2+, H3K27ac+) that are also enriched for DNase hypersensitive sites. To identify Wnt3a inducible regulatory elements, we mapped all the TCF/LEF binding sites to the putative regulatory elements in osteoblasts and identified 1,621 Wnt3a inducible distal regulatory elements near up-regulated genes. Of 212 genes up-regulated by Wnt3a administration, 162 (76%) had TCF/LEF binding sites in their promoter and/or a distal noncoding region. Transcription factor binding site analysis of the putative Wnt3a-inducible regulatory elements with HOMER identified several transcription factors, including *Fos2*, *Runx2* and *Foxo1*, with enriched binding motifs in these regions. This study identified 452 genes regulated by Wnt3a in osteoblasts, 1,621 putative Wnt3a inducible distal regulatory elements and transcription factors that may cooperate with TCF/LEFs to regulate the expression of these genes. Ongoing validation of these regulatory elements *in vitro* and *in vivo* will allow the characterization and modeling of Wnt3a-regulatory pathways in osteoblasts, and predict the role of transcription factors, enhancers and proteins in bone metabolic functions.

Pigment Epithelium Derived Factor Activates Wnt/b-Catenin Signaling Pathway in Mesenchymal Stem Cells via cross-talk with ERK Signaling Pathway. Christopher Niyibizi¹, Feng Li*², Joyce Tombran-Tink³. ¹The Pennsylvania State University College of Medicine, USA, ²Penn State College of Medicine, USA, ³Penn State College of Medicine, USA

Pigment epithelium-derived factor (PEDF) encoded by *Serpinf1* is found in a wide variety of fetal and adult tissues. Mutations in *Serpinf1* have been shown to be the cause of osteogenesis imperfecta type VI whose hallmark is defective mineralization. In these patients, there is excessive osteoid buildup and failure to mineralize the matrix. Mechanisms by which PEDF regulates matrix mineralization remain undefined. We and others reported that PEDF enhances human and mouse mesenchymal stem cell (MSCs) differentiation and increased osteoblastic mineralization *in vitro*. To begin to understand mechanisms by which PEDF plays a role in osteoblast differentiation and matrix mineralization, we determined signaling pathways activated by PEDF to enhance MSCs-osteoblastic differentiation. Human MSCs exposed to PEDF activated ERK signaling within 5 min to 48h of analysis. Erk activation led to increased phosphorylation of GSK-3beta and increased accumulation of LRP6 and beta-catenin. Exposure of human MSCs to PEDF in presence of ERK inhibitor prevented ERK activation and phosphorylation of GSK-3beta. Inhibition of ERK activation also reduced LRP6 and beta-catenin accumulation suggesting that Wnt/beta-catenin activation in human MSCs by PEDF occurs via a cross-talk with ERK signaling pathway. Examination of osteoblastic gene expression by MSCs exposed to PEDF for 48h showed increase in ALP, *Col1A1*, *Runx2* and *osterix* genes. Human MSCs exposed to PEDF in presence of ERK inhibitor reduced expression of all these genes. These data taken together strongly indicate that PEDF activates Wnt/beta-catenin in human MSCs via cross-talk with ERK signaling to enhance expression of osteoblastic genes that play a role in MSCs-osteoblastic differentiation.

SIT (SHP2-Interacting Transmembrane Adaptor) - A Novel Regulator of Bone Mass. Joseph Tarr*¹, Sarah Carrante², Lev Blekher², Brooke Marks², Samantha Dyckman², Elizabeth Figueiredo², Kaitlin Reilly², Luca Simeoni³, Thomas Owen², Steven Popoff¹. ¹Temple University School of Medicine, USA, ²Ramapo College of New Jersey, USA, ³Otto von Guericke University, Germany

SIT (SHP2-interacting transmembrane adaptor) is a member of the family of transmembrane adapter proteins which have tyrosine signaling motifs in their intracellular tails through which they are phosphorylated by kinases of the src and syk families. This allows them to subsequently recruit SH2 domain containing signaling molecules to the membrane and influence signaling pathways. SIT has been well studied in the immune system where it has been shown to be an important regulator of T-cell receptor signaling and T-cell activation. SIT was identified as being potentially involved in regulating bone mass in a study comparing gene expression changes between the bones of normal and osteopetrotic (op/op) mutant rats. On the RNA level, the expression of SIT was found to be lower in the bones of the op/op mutant rats than those of their wild-type littermates. SIT is expressed in cultures of primary rat calvarial osteoblasts where its RNA increases concurrently with the expression of alkaline phosphatase and peaks during the maturation phase prior to mineralization. Similarly in ROS 17/2.8 osteosarcoma cells SIT RNA increases with the rise in alkaline phosphatase activity. Overexpression of SIT in ROS 17/2.8 cells results in a delayed increase in alkaline phosphatase activity. Analysis of the bones from SIT knockout (KO) mice shows that deletion of SIT significantly altered a number of trabecular bone parameters. Sit KO mice exhibited increased trabecular bone volume fraction (BV/TV), number (Tb.N), connectivity (Conn) and connectivity density (Conn.Dn), and decreased trabecular thickness (Tb.Th) and spacing (Tb.Sp) compared to age-matched wild-type littermates. We are exploring the localization of SIT in bone by immunohistochemistry and are developing additional reagents through which to further explore the role of SIT in bone metabolism. It is possible that SIT is an integral part of signaling through many of the receptors which influence the development and activity of both osteoblasts and osteoclasts, and could also be intimately linked with the actions of c-src kinase in both cell types.

Trps1 Affects Signaling and Expression of Mineralization Genes in Response to Phosphate. Maria Kuzynski*¹, Sandeep Chaudhary², Morgan Goss², Callie Mobley², Dobrawa Napierala². ¹University of Alabama at Birmingham, USA, ²UAB, USA

Phosphate availability is critical for the initiation and progression of mineralization. When genes regulating phosphate are mutated, defective mineralization results. Besides being a component of hydroxyapatite crystals, phosphate is also able to act as a signaling molecule by mediating biphasic Erk1/2 activation and regulating expression of mineralization-related genes. *Trps1* is a transcriptional repressor identified to play a role in the mineralization process. In our previous studies identifying the molecular role of *Trps1* during mineralization, we uncovered a link between *Trps1* and phosphate. Specifically, *Trps1*-deficient cells had decreased levels of phosphatases (Phospho1 and Tissue non-specific alkaline phosphatase) and *Trps1*-overexpressing cells were unable upregulate genes involved in phosphate regulation (Phex and Vitamin D receptor) during the later stages of mineralization. To clarify the role of *Trps1* in phosphate signaling, we analyzed whether deficiency or upregulation of *Trps1* affects cellular response to phosphate by comparing Erk1/2 activation and phosphate-regulated gene expression. In pre-odontoblastic mineralizing cells deficient for *Trps1*, we observed a delayed second activation of Erk1/2 upon phosphate treatment. In contrast, cells overexpressing *Trps1* displayed an accelerated second activation of Erk1/2 in response to phosphate. To further understand *Trps1* function during phosphate signaling, we analyzed changes in the expression of mineralization-related genes in response to phosphate and uncovered that *Trps1* affects the expression of several of these genes. *Trps1*-deficient cells displayed a delayed response in the upregulation of Osteopontin and Dentin matrix protein 1 twelve hours after phosphate treatment. *Trps1*-overexpressing cells had a significantly greater decrease in the expression of *Runx2*, Vitamin D receptor, and Tissue non-specific alkaline phosphatase 48 hours after phosphate treatment. Altogether, these data suggest that *Trps1* participates in the phosphate-mediated signaling cascade by specifically affecting the second activation of Erk1/2 and regulating the expression of mineralization-related genes.

BCL11B a Transcriptional Regulator of Sutural Patency. Kenneth Philbrick*, Kateryna Kyrylkova, Urszula Iwaniec, Mark Leid, Oregon State University, USA

One in every 2,500 babies develops craniosynostosis. Untreated, craniosynostosis increases risk of deafness, blindness, developmental delay, and learning disabilities. Calvaria forms through primary intramembranous ossification. BCL11B is a transcription factor that plays a key role in the development of numerous tissues including skin, teeth, and the immune system. Data we report here provide evidence that BCL11B regulates intramembranous ossification and suggests that it may play a role in the etiology of craniosynostosis.

BCL11B expression was studied throughout mouse craniofacial development and in the perinatal period. Within osteogenic, calvarial tissues BCL11B expression was primarily detected within sutures and in mesenchymal cell condensates surrounding, but not immediately adjacent to the calvaria. In contrast, cells expressing Runx2, the master osteogenic transcription factor, were found immediately adjacent to and within the calvaria. BCL11B⁺ cells were found to form a halo around Runx2⁺ cells with only a minimal number of cells co-expressing these two transcription factors.

Microcomputed tomography analyses of newborn mice lacking BCL11B in the germline revealed that these mice exhibited synostoses of the facial and calvarial skeleton that were accompanied by mid-facial hypoplasia and malocclusion (Figure 1). Mice lacking BCL11B in tissues derived from neural crest and mesoderm exhibited loss of sutural patency in facial and calvarial sutures, respectively, with accompanying distortions of craniofacial structures (Figure 1).

These findings provide evidence that BCL11B is a top-level regulator of sutural patency and osteogenesis in the craniofacial skeleton. Further studies are ongoing to determine the molecular mechanism(s) through which BCL11B contributes to osteogenesis and maintenance of sutural patency. Manipulation of BCL11B expression and/or activity may provide an avenue for therapeutic manipulation of sutural patency in the treatment of craniosynostosis.

Ectoderm neural cortex 1 isoforms have disparate effects on MC3T3 osteoblast differentiation and mineralization. Leah Worton*¹, Yanchuan Shi², Elisabeth Smith², David Little³, Jon Whitehead⁴, Edith Gardiner¹. ¹University of Washington, USA, ²Garvan Institute, Australia, ³The University of Sydney, Australia, ⁴The University of Queensland, Australia

In recent years the importance of Wnt signaling in the skeleton has been repeatedly demonstrated but Wnt pathway mechanisms in bone cells are far from understood.

We previously found expression of a Wnt target gene, ENC1 (ectoderm neural cortex 1), in osteoblasts of mouse distal femur and *in vitro* during osteoblast differentiation, so we investigated its role in these cells. We first observed two ENC1 protein isoforms of 57 and 67kDa throughout MC3T3 (MC) cell differentiation (21 days). MC cell lines stably transduced with doxycycline-inducible shRNA lentiviral expression constructs were established. Simultaneous shRNA knockdown of both 57 and 67kDa ENC1 proteins from d 1 of culture reduced alkaline phosphatase staining and virtually abolished MC culture mineralization whereas selective targeting of only the 67kDa isoform had the opposite effect, increasing mineralized nodule formation above the level in a control scrambled GFP shRNA cell line (Fig.1). The distinctive mineralization patterns of the general 57/67kDa and the 67kDa-selective ENC1 knockdown cell lines both declined as initiation of doxycycline treatments was progressively delayed, but the effects of ENC1 shRNA remained significant even with induction as late as d 9. At confluence (d 3) with general 57/67kDa knockdown begun at d 1, there was a 68% reduction in *Osx* mRNA compared to the scGFP control. In these cells *Tnap* expression was also markedly reduced (10% of scGFP level) and there was significant and coordinated alteration of other genes involved in cellular phosphate biochemistry including *Phospho1*, *Ank*, *Enpp1* and *Opn*. At mineralization onset (d 13), expression of osteoblast marker genes reflected the reduced and enhanced mineralization phenotypes for the general 57/67kDa and 67kDa-selective ENC1 knockdown lines respectively. At this time point expression of the Wnt antagonist *Sfrp2* was up-regulated 2-fold with general 57/67kDa knockdown but reduced by 50% with 67kDa-selective knockdown compared to scGFP control. These results are the first to demonstrate a role for ENC1 in control of osteoblast differentiation and mineralization. In addition, the contrasting mineralization phenotypes and transcriptional patterns seen with coordinate knockdown of both 57kDa and 67kDa ENC1 vs the isoform-selective knockdown of 67kDa ENC1, suggest opposing roles for the isoforms in regulation of osteoblastic mineralized nodule formation through effects on phosphate cellular biochemistry and the Wnt pathway.

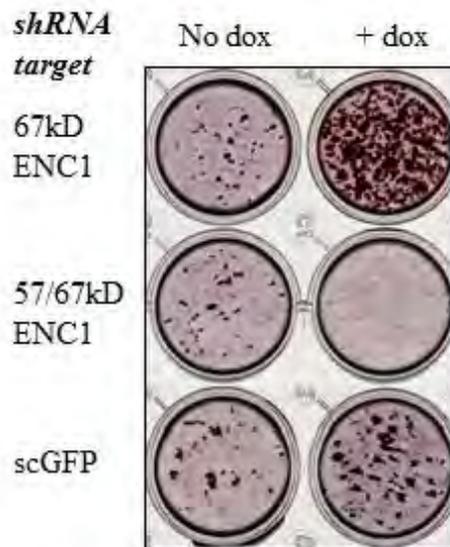

Figure 1. Knockdown of ENC1 isoforms alters MC cell differentiation. Cell lines expressing inducible shRNA sequences targeted to ENC1 isoforms or a scrambled GFP were differentiated in the absence or presence of doxycycline for 21 days and then stained with Alizarin Red.

Fig.1

Modulation of the extracellular matrix environment and epigenetic DNA methylation improves osteogenicity of human mesenchymal stromal cells. Roman Thaler*¹, Markus Schreiner¹, Eric A. Lewallen¹, Dakota L. Jones¹, David R. Deyle¹, Allan B. Dietz², David G. Lewallen¹, Andre J. van Wijnen². ¹Mayo Clinic, USA, ²Mayo Clinic, USA

Bone degeneration and nonunion of bone upon fracture in elderly patients may be reversed using bone regenerative therapies with human mesenchymal stromal cells (MSCs). We have shown that clinical-grade MSCs derived from adipose tissue

(AMSCs) and grown in human platelet lysate have the potential to differentiate into osteoblasts with a mineralizing extracellular matrix (ECM), which is known to mediate epigenetic feed-back control of gene expression in osteoblasts. Yet, expression of principal osteoblast-related transcription factors (TFs) like Sp7/Osterix or Dlx5, remains suppressed in these cells. In this study, we investigated whether the osteogenic effectiveness of AMSCs for skeletal therapies can be improved by manipulating epigenetic mechanisms (e.g., CpG methylation) linked to ECM dependent activation of osteogenic TFs. We first analyzed intact ECMs that were decellularized with deoxycholate and isolated from primary human AMSCs and human osteoblasts (hOBs) or mouse MC3T3-E1 osteoblasts cultured for 1 week in osteogenic media. Examination of ECM deposition by fluorescence spectroscopy and laser scanning microscopy reveals major structural differences between ECMs. While AMSCs produce a wide-meshed network of collagen fibrils, osteoblasts deposit a closed-mesh ECM structure with significantly higher amounts of collagen. When AMSCs cells are cultured on ECMs derived from MC3T3-E1 osteoblast (ost-ECM) or AMSCs (msc-ECM), the pre-deposited ost-ECM but not msc-ECM slows proliferation and marginally enhances osteoblastic differentiation. Neither ECM supported expression of the osteogenic TFs Sp7 or Dlx5. However, co-treatment of AMSCs with the DNA methylation inhibitor 5'Aza-cytidine (AzaC) strongly accelerates osteoblastic differentiation (e.g., alkaline phosphatase (ALP) activity) on ost-ECM compared to msc-ECM or plastic (control). Mechanistically, this osteogenic effect is attributable to both ost-ECM and AzaC-dependent activation of both Sp7/Osterix and Dlx5 (10-20 fold stimulation within 3d after induction of differentiation). We conclude that combinatorial modulation of both the ECM environment and the epigenetic landscape of multi-potent AMSCs promotes osteoblast lineage-commitment and maturation. This combination treatment of clinical grade adipose-tissue derived MSCs may represent a realistic approach for bone regenerative therapies.

Disclosures: Roman Thaler, None.

Rorb β , a Negative Regulator of Osteoblast Function, Regulates the Circadian Clock Through Upregulation of Bmal1 and Period Genes. [David Monroe](#)^{*1}, [Joshua Farr](#)², [Sundeep Khosla](#)². ¹Mayo Foundation, USA, ²Mayo Clinic, USA

Circadian rhythms control a wide variety of biological processes involved in virtually all aspects of metabolism. While the hypothalamic central clock regulates general metabolic events (entrained by the light/dark cycle), peripheral clocks located in all tissues, including bone, function to regulate tissue-specific events. These clocks rely on a transcriptional/translational feedback system where the transcriptional activators Bmal1/Clock activate expression of the Per1-3 and Cry1-2 genes, which feedback to inhibit Bmal1/Clock. Previous studies have demonstrated that genetic deletion of these genes in mice results in increased osteoblastic function and/or bone mineral density, suggesting that the clock inhibits bone formation. An additional modulatory loop consisting of the nuclear hormone receptor families Rev-erb and Ror form a fine-tuning loop which regulates Bmal1. We have demonstrated that Rorb β knockout (KO) mice exhibit increased trabecular vBMD, BV/TV and trabecular number, similar to what is observed in other clock KOs. Since Rorb β expression is elevated in osteoprogenitor cells from aged mice and humans, Rorb β may play a role in regulation of the clock. To investigate the role of Rorb β on the osteoblastic clock, we examined the effects of Rorb β on the clock genes in MC3T3-E1 pre-osteoblastic cells. Transient expression of an adenovirally-expressed Rorb β resulted in increased Bmal1 expression. In synchronized MC3T3 cells, Bmal1 and Rorb β expression exhibit identical patterns, with an amplitude maximum at Zeitgeber (ZT) circadian time ZT4. These data establish Rorb β as a regulator of Bmal1 in osteoblasts. In MC3T3 cells stably expressing Rorb β , which exhibit low mineralization potential, the steady-state levels of Per1-3 are significantly enhanced. Finally, Per3 expression is elevated in osteoprogenitors from aged mice (<12-mo), where Rorb β expression is high. Overall, these data are consistent with the notion that increasing clock activity in osteoblasts is associated with impaired osteoblast function. In summary, our data demonstrate that Rorb β affects the circadian clock in osteoblasts by upregulating Bmal1 and Per1-3 expression. This suggests that increased Rorb β expression in pre-osteoblastic cells, as seen in aged mice, would stimulate the clock possibly resulting in compromised bone metabolism. These data reveal a novel mechanism for Rorb β in aged bone and identifies a new pathway for future interventions in the treatment of age-related bone loss.

MO0204

Candidate Enhancer RNA Expression During α SMA+ Progenitor to Mineralizing Osteoblasts-Osteocytes: Exploration of the 'Dark Matter' of the Genome. [Stephen Harris](#)^{*1}, [Marie A Harris](#)², [Coralee Tye](#)³, [Ivo Kalajzic](#)⁴, [Jonathan Gordon](#)³, [Jane Lian](#)³, [Gary Stein](#)³. ¹University of Texas Health Science Center at San Antonio, USA, ²u. of Texas health science center at san antonio, USA, ³U. of Vermont Medical School, USA, ⁴U. of Connecticut Health Center, USA

Deletion of the Bmp2 gene in α SMA+ bone marrow progenitors (MSC) results in a profound decrease in bone formation rate and decrease in the number of expanding MSC to mineralizing osteoblasts-osteocytes, assessed by lineage tracing methods.

Using an α SMA+ MSC to osteoblast-osteocyte differentiation model, we determined the coding and non-coding transcriptome using RNA-seq. Of the coding transcripts, we identified 2968 genes (q value<0.01) that are regulated between the early α SMA+ progenitor/stem cell state to the mineralizing osteoblast-osteocyte state after 7days of in vitro treatment with rBMP2 (653 positive and 2316 negative), with 87 transcription factors (TF) with defined binding motifs. Using this transcriptome data from 2 hr. to 7 days, control and rBMP2 treatment, with ARACNe program, we developed a transcriptional gene network model with a subset of the TFs regulated during differentiation (e.g. Osterix and Egr2). Recently, in cancer biology, muscle cell differentiation, and other systems, enhancer RNAs, or eRNAs, have been shown to be critical for positive transcriptional regulation, acting as 3D scaffolds for complex TF interactions within a given enhancer. These eRNAs are found as a subset of the long-noncoding RNAs. Using the latest annotation file for long-coding RNAs (lncRNAs) thought to be a major component of the 'Dark Matter' of the Genome and transcribed asymmetrically from both Minus and Plus strands (Gencode vM4.long-noncoding_RNAs.gtf), we found 3764 lncRNAs regulated from progenitor state to mineralizing state (2049 Positive and 1750 Negative). We used only Minus strand data, to avoid confusion with Plus strand intronic and exonic regions. We then used H3K27ac Chip-seq data, which marks engaged active enhancers during α SMA cell differentiation to mineralizing osteoblast-osteocyte states, to intersect Minus strand lncRNAs genome dataset. Of the 2049 positively regulated Minus strand lncRNAs, 745 intersect with H3K27ac active enhancers and are activate during differentiation from progenitor state to mineralizing osteoblast-osteocyte state. These experiments define a set of candidate enhancer RNAs (eRNA) for osteoblast differentiation. Data on the Bmp2, Osterix, and Dmp1 genes will be presented as examples, including overlay Chip-seq data with Runx2, TCF/ β -catenin, and repressor-off markers (Ezh2 of the polycomb complex and H3K27me) that intersect with the lncRNA-H3K27ac domains that are modulated during osteoblast-osteocyte differentiation.

MO0205

Effect of Tryptophan on the stemness and osteogenesis of bone marrow-derived mesenchymal stromal cells *in vitro* and *in vivo*. [Hai Pham](#)^{*1}, [Mitsuaki Ono](#)², [Emilio Hara](#)², [Yasutaka Oida](#)², [Ha Nguyen](#)², [Kentaro Akiyama](#)², [Takuo Kuboki](#)². ¹Okayama University, Japan, ²Department of Oral Rehabilitation & Regenerative Medicine, Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sciences, Okayama, Japan, Japan

Amino acids are essential for life and cell metabolism. We hypothesized that amino acids can regulate the stem cell phenotype and differentiation ability of human bone marrow-derived mesenchymal stem/progenitor cells (hBMSCs). Thus, we performed a screening of 22 standard amino acids and found that D-Tryptophan (10 μ M) increased the number of cells positive for the early stem cell marker SSEA-4, and gene expression levels of *OCT-4*, *NANOG* and *SOX-2* in hBMSCs. Comparison between D- and L-tryptophan showed that the latter presents stronger effect in inducing the mRNA levels of *OCT-4* and *NANOG*, and increasing the osteogenic differentiation of hBMSCs. Additionally, L-tryptophan also enhanced chondrogenesis, but inhibited adipogenesis. Migration and colony forming ability of hBMSCs was also enhanced by L-tryptophan treatment. *In vivo* experiments delivering L-tryptophan (50 mg/kg/day) by intra-peritoneal injections for 3 weeks confirmed that L-tryptophan significantly increased the percentage of cells positive for SSEA-4, mRNA levels of *Nanog* and *Oct-4*, and migration and colony forming ability of BMSCs. Additionally, surgical defects of 1 mm in diameter were created in mouse femur to evaluate bone formation after 2 weeks of L-tryptophan injection. L-tryptophan accelerated bone healing, and increased bone volume and trabecular number compared to PBS-injected group. In summary, L-tryptophan enhances the stemness and osteoblastic differentiation of BMSCs, and may be used as an essential factor to accelerate bone healing and/or prevent bone loss, such as in the case of ageing and osteoporosis.

Fatty Acids and Energy Metabolism in Mesenchymal Stem Cells. [Laura Shum](#)^{*}, [Roman Eliseev](#). University of Rochester, USA

Purpose: During aging, bone quality declines and fat accumulates in the bone marrow. We hypothesize that the increased presence of fatty acids, such as palmitate, in bone marrow inhibit mesenchymal stem cell (MSC) differentiation towards osteoblasts by disrupting oxidative phosphorylation via induction of the mitochondrial permeability transition (MPT). The MPT is a large, non-selective mitochondrial pore, gated by cyclophilin D. Our goal is to fully characterize the effect of palmitate on the bioenergetic and osteogenic functions of MSCs.

Methods: C3H/10T1/2 cells are a mesenchymal stem-like mouse cell line. Cells were grown in osteogenic media for 14 days for differentiation. Clark electrode was used to measure oxygen consumption as an indicator of oxidative phosphorylation after treatment with 100 μ M palmitate for 24 hours. Mitochondrial Calcium Retention Assay was used to determine mitochondrial calcium buffering capacity, a measure of

sensitivity to the MPT. Mitochondrial uptake of calcium was measured with fluorescent calcium indicator, Calcium Green 5N. Real time RT-PCR was performed on differentiated cells in the presence or absence of palmitate using SYBR Green, and normalized to beta actin.

Results: Palmitate reduced ATP-linked respiration after 24 hour, as compared to control (0.3688 vs 0.7260 nmol/min/10⁶ cells, respectively). Treatment with palmitate for 24 hours reduced mitochondrial ability to buffer calcium by 80%. Osteogenically differentiated cells in the presence of palmitate significantly increased gene expression of alkaline phosphatase 2.7-fold, and increased PPAR-gamma 3.29-fold.

Conclusions: This study demonstrates the effects of palmitate on metabolism and differentiation of MSCs. The increase in alkaline phosphatase gene expression indicates that palmitate may not affect the early stages of osteogenic differentiation, which are less dependent on oxidative phosphorylation. However, the significant increase in the adipogenic marker (PPAR-gamma), indicates a shift away from osteogenic differentiation, and instead toward the adipogenic lineage, which is not dependent on oxidative phosphorylation. Furthermore, palmitate decreases oxygen consumption, and reduces mitochondrial capacity to buffer calcium due to the MPT induction. This indicates that even with short exposure, palmitate can affect metabolism and may uncouple oxidative phosphorylation in MSCs through induction of the MPT, potentially leading to reduced bone quality.

Foxd1 lineage tracing during skeletal development identifies a unique subset of osteogenic precursors. Jackie Fretz¹, Nancy Troiano², Rose Webb², Tracy Nelson². ¹Yale University School of Medicine, USA, ²Yale School of Medicine, USA

The Foxd1-cre is used in kidney research as a marker of the precursors to the glomerular mesangium and interstitial pericytes. While it is known that the Foxd1-cre driver is not specific to this subset of the kidney mesenchyme, its contribution to skeletal development has not been examined in detail. Through mating of the Foxd1-cre Tg with the mT/mG "flip" mouse we investigated the contribution of Foxd1-lineage cells to anabolic bone populations throughout the skeleton. These tracing experiments revealed that the presence or absence of Foxd1 expression during osteocyte and chondrocyte (Chd) development did not uniformly mark or exclude osteogenic populations in all bones. Instead, location-specific contributions of Foxd1+ cells were observed in reproducible patterns throughout the skeleton. Long bones of the hind leg lacked Foxd1-driven recombination, while vertebrae harbored significant GFP+ populations: 50-70% of the osteocytes and Chds in cervical and thoracic vertebrae, 70-90% of these osteogenic cells in the tail, and 20-40% of the osteogenic cells of the lumbar vertebrae. While Foxd1-driven recombination was apparent in approximately 10-15% of the osteoblast (Ob) and Chds within the humerus and ulna, it was rarely seen within the hip, and absent from the scapula. The clavicle, phalanges, carpals, and tarsals had recombination rates of 15-25%. Within the skull the relative contribution of Foxd1-lineage cells to the total Ob population ranged from the occipital bone (100% GFP+ cells) > interparietal bone (75-85%) > frontal bone (60%) > squamosal bone (50%) > parietal bone (40%) > maxillary bone (5%) > mandible (0%). Both fibrocartilage and hyaline cartilage were marked, and traced as complete columns of either RFP or GFP labeled cells suggesting that Foxd1 was expressed in a precursor cell or only in the first stages of cellular differentiation. Overall these results reveal that the promoter driving the Foxd1-cre identifies a unique subset of osteogenic progenitors that vary in their overall contribution to the skeleton in location-specific patterns. It presents the possibility that multiple types of mesenchymal progenitors contribute to the bone not only at different locations throughout the body but within a single bone as well. Furthermore, renal osteodystrophy generated using the Foxd1-cre mouse should be interpreted carefully and restricted to the femur and tibiae to minimize confounding contributions from recombination in the skeleton.

Human Platelet Lysate derived Exosomes affect Proliferation and Osteogenic Differentiation of Adipose Stem Cells. Behrouz Zandieh-Doulabi¹, Jenneke Klein-Nulend². ¹Department of Oral Cell Biology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam & VU University Amsterdam, MOVE Research Institute Amsterdam, Amsterdam, The Netherlands., Netherlands, ²Dept. Oral Cell Biology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam & VU University Amsterdam, Move Research Institute Amsterdam, Amsterdam, The Netherlands, Netherlands

Platelets contain bioactive substances such as growth factors for the expansion and differentiation of adipose stem cells (ASCs). Almost all cell types including platelets secrete exosomes, i.e. nanovesicles, ranging in size from 50 to 100 nm diameter. Exosomes contain proteins, mRNAs, and microRNAs, thereby providing a novel paracrine signaling mechanism in physiological and pathological processes. This study aimed to evaluate the potential use of platelet-derived exosomes for modulating proliferation and osteogenic differentiation of human ASCs after a short (6 hours)

treatment. To test the effect of exosomes on ASC proliferation and differentiation, ASCs were cultured in medium with exosome-free platelet lysate, and with or without exosomes at two concentrations (5 and 10 µg/ml) for 6 hours followed by an additional cell culture in absence of exosomes up to 7 days. Gene expression of the proliferation marker Ki67 as well as osteogenic differentiation markers RUNX-2, alkaline phosphatase (ALP) and osteonectin (ON), were determined after 6 hours, 3 days, and 7 days. Six hours of treatment with exosomes increased Ki67 gene expression in ASCs by 1.8-fold using 5 µg of exosomes at 6 hours and by 7-fold at day 3, but decreased Ki67 gene expression by 2-fold at day 7. Treatment with exosomes decreased RUNX-2 gene expression by 2-fold using 5 µg of exosomes at 6 hours, but no change was observed at 3 and 7 days in ASCs. Treatment with exosomes resulted in decreased ALP gene expression in ASCs by 0.3-fold using 5 µg exosomes at day 3, while treatment with 10 µg exosomes increased ALP expression by 2.5-fold at day 7. Treatment with 5 µg exosomes increased ON gene expression in ASCs by 2.8-fold after 6 hours, it decreased ON gene expression by 2-fold after 3 days, and increased ON expression by 2.5-fold and 3.9-fold after 7 days when ASCs were treated with 5 µg and 10 µg exosomes respectively. In conclusion our data indicate that platelet-derived exosomes increase ASC proliferation as indicated by enhanced Ki67 gene expression, and can be used as a cell culture additive for ASC expansion. Only 6 hours of treatment with exosomes affected osteogenic cell differentiation even after 7 days. Treatment with exosomes appears to downregulate osteogenic differentiation of ASCs in an early stage, followed by a significant upregulation of osteogenic differentiation at a later stage. This suggests a potential role of exosomes in bone tissue engineering.

Inhibition of Histone Methyltransferase SMYD2 Attenuates Lineage Commitment of Mesenchymal Stem Cells. Christopher Paradise¹, Amel Dudakovic, Scott Riester, Emily Camilleri, Allan Dietz, Andre van Wijnen. Mayo Clinic, USA

Lineage commitment of mesenchymal stem cells (MSCs) *in vivo* can drive pathogenic processes such as heterotrophic ossification and fatty degeneration of muscle and tendon. Therapies that can inhibit MSC differentiation in patients can be applied to treat these musculoskeletal disorders. Histone lysine methyltransferases (HKMTs) and their gene targets are key players in shaping the epigenetic landscape responsible for activating or silencing of lineage specific transcription factors. Specifically, tri-methylation of Histone 3 Lysine 4 (H3K4) in MSCs has been shown to promote osteogenic differentiation while suppressing the potential for alternative lineage commitment. Thus, small molecule inhibitors targeting HKMTs provide a unique approach to alter the epigenetic landscape and direct differentiation of MSCs. Here, we investigated whether the inhibition of SMYD2, an H3K4/K36 methyltransferase, via a small-molecule inhibitor AZ505 prevents commitment of MSCs to the osteogenic lineage. Human adipose-derived mesenchymal stem cells (AMSCs) as well as primary mouse bone marrow derived stem cells (BMSCs) were treated with AZ505 and cultured in either osteogenic or adipogenic differentiation medium. Expression of osteoblast-specific markers (SP7, RUNX2, BGLAP, ALPL, COL1A1, SPP1) and adipocyte-specific markers (ADIPOQ, FABP4, PPARγ, KLF3) was measured using real-time quantitative PCR (RT-qPCR). Our data demonstrate that expression of both osteoblast and adipocyte specific markers was decreased in AMSCs and BMSCs treated with SMYD2 inhibitor. A decrease in expression of these markers suggests prevention of commitment to both osteogenic and adipogenic lineages. Thus, inhibition of SMYD2 interferes with the differentiation of mesenchymal progenitors into at least osteogenic and adipogenic lineages. These findings suggest that pharmacologic inhibition of SMYD2 may have therapeutic applications for treating an array of orthopedic disorders including heterotrophic ossification and muscle/tendon degeneration.

Potential role of Secreted frizzled related protein (Sfrp2) in regulating activity of bone marrow stem/progenitor cells. Luis Fernandez De Castro¹, Brian Sworder², Agnes Berendsen³, Matthew Phillips³, Natasha Cherman³, Sergei Kuznetsov³, Kenn Holmbeck¹, Pamela Robey³. ¹NIDCR (NIH), USA, ²Boston University-NIDCR, USA, ³NIDCR, USA

Bone marrow stromal cells (BMSCs, also known as bone marrow-derived mesenchymal stem cells) are a population of fibroblastic reticular cells, a subset of which is composed of multipotent skeletal stem cells (SSCs). SSCs can recreate bone, marrow adipocytes and hematopoiesis-supportive stroma, upon *in vivo* transplantation with an appropriate scaffold, but more committed BMSCs make only bone or fibrous tissue. In an attempt to find specific genes that would distinguish SSCs from more committed BMSCs, we performed microarray analyses of human single-cell derived lines with known potency based on *in vivo* transplantation. The results identified SFRP2 as being highly represented in human multipotent clones. SFRP2 is thought to inhibit Wnt signaling, but its role in the bone marrow microenvironment is unclear. To assess the function of *Sfrp2* in bone, we analyzed *Sfrp2*-deficient (KO) mice by microCT analysis and found no significant differences between KO and wildtype (WT) mice in any parameter. However, colony forming efficiency, the closest approximation of the number of SSCs in the BMSC population, was reduced

in KO bone marrow by ~40% compared to WT. In addition, *Sfrp2* deficiency in BMSCs (using both KO BMSCs and siRNA knocked down mBMSCs) reduced expression of osteogenic transcription factors (*Runx2* and *Osx*) and reduced calcium accumulation *in vitro*. Moreover, the phosphorylation of the Wnt co-receptor Lrp6 and expression of the Wnt downstream target gene *Axin 2* were also reduced in these cells. These *in vitro* results suggested that *Sfrp2* is a positive regulator of Wnt signaling. However, there was no difference in growth rate between KO and WT BMSCs. Furthermore, no difference between WT and KO was found in ectopic ossicles formed by *in vivo* transplantation of mBMSCs in collagen sponges into immunocompromised mice, as well as those induced by BMP-soaked sponges transplanted into KO and WT recipient mice. Lastly, we assessed the role of *Sfrp2* in bone regeneration by creating a non-critical sized defect in femoral diaphyses of KO and WT mice and no significant differences in healing were noted. In conclusion, although *Sfrp2* appears to be a positive regulator of osteogenic cells *in vitro*, there is little effect caused by its deficiency *in vivo*. These phenomena may be related to redundancies (compensation by other *Sfrp* family members), and control of Wnt signaling by other factors that are present *in vivo*, but not in the *in vitro* setting.

SWI/SNF-mediated lineage determination in mesenchymal stem cells confers resistance to osteoporosis. Stephen Flowers*¹, Kevin Hong Nguyen¹, Fuhua Xu¹, Eric Himelman¹, Edek AJ Williams¹, J Christopher Fritton¹, Elizabeth Moran². ¹Department of Orthopaedics, New Jersey Medical School, Rutgers, The State University of New Jersey, Newark, NJ 07103., USA, ²Rutgers, The State University of New Jersey, NJMS Cancer Center, USA

The SWI/SNF chromatin-remodeling complex, which contains either brahma-related gene-1 (BRG1) or brahma (BRM) as the catalytic ATPase, functions as a master regulator of gene expression in development and differentiation. BRG1 is required for induction of essentially all tissue specific gene expression, such that BRG1-null mice die as pre-implantation embryos. Comparatively little is known about the role of the alternative ATPase, BRM, as BRM-null mice seem developmentally normal and live a full life span. The studies reported here now indicate that BRM-SWI/SNF represents a sensitive physiological point for control of osteoblast vs adipocyte lineage selection in mesenchymal stem cells. Key osteogenic genes are targeted directly by BRM-SWI/SNF for repression. Depletion of BRM causes dissociation of HDACs and other repressors from these promoters. Simultaneously, BRM-SWI/SNF cooperates with BRG1-SWI/SNF to promote expression of adipogenic genes. These effects are manifested at the earliest stages of stem cell differentiation, upstream of the important osteogenic or adipogenic transcription factors such as Runx2 or PPAR γ 2. BRM can be a precise target for increasing formation of osteoblast progenitors and sustaining osteoblast formation. The bone marrow stromal cell population of BRM-null mice shows an enhanced proportion of cells expressing markers of osteoblast precursors at the expense of cells able to differentiate along the adipocyte lineage. This altered precursor balance has no apparent negative developmental effects, but can have major physiological significance in conditions of osteoblast insufficiency. This is apparent in the BRM-null mouse model as protection against age-related osteoporosis. Scanning by micro-CT shows cortical porosity reaching an average of 7.2% in the femurs of wild type females by 18 months. BRM-null mice lose far less bone, averaging only 1.8% porosity at the same age. Wild type mice also lost more than 11% mineral density in their cortical tissue by 18 months, while BRM-null mice showed no significant loss.

Denosumab and Odanacatib as Reference Compounds in Human Osteoclast Cultures. Jussi Halleen*, Jenni Bernoulli, Jukka Rissanen, Katja Fagerlund. Pharmatest Services Ltd, Finland

Human osteoclasts can be generated from bone marrow-derived CD34+ mesenchymal stem cells in the presence of M-CSF and RANKL. In this study we report optimization of separate *in vitro* culture systems for determining osteoclast differentiation and activity, and validation of the RANKL inhibitor denosumab and the cathepsin K inhibitor odanacatib as reference inhibitors of osteoclast differentiation and activity, respectively. CD34+ human osteoclast precursor cells were cultured on bovine bone slices for 7 days. Different concentrations of denosumab (0.01 – 10 μ g/ml) were added in the cultures at day 0, and tartrate-resistant acid phosphatase isoform 5b activity (TRACP 5b) was measured in the culture medium collected at day 7 as an index of the number of formed osteoclasts. Osteoclast activity was studied by allowing the formed mature osteoclasts to resorb bone during an additional 3-day culture period. The culture medium was changed and different concentrations of odanacatib (0.001 – 1.0 μ M) were added into the cultures at day 7, and the amount of C-terminal cross-linked telopeptides of type I collagen (CTX-I) was measured in the culture medium collected at day 10 to quantitate bone resorption during days 7-10. Denosumab and odanacatib showed strong concentration dependent inhibition of osteoclast differentiation and activity, respectively, with EC50 values of 0.124 μ g/ml for denosumab and 0.0433 μ M for odanacatib. We conclude that we have validated denosumab as a reference compound of osteoclast differentiation and odanacatib as a

reference compound of and osteoclast activity in a human *in vitro* osteoclast culture system, and the culture system is a clinically reliable tool for identifying new osteoporosis drug candidates with anti-resorptive activity.

Elevated miR-214 level within osteoclasts associates with increased bone resorption in both postmenopausal osteoporosis and osteolytic bone metastasis. Defang Li*¹, Jin Liu¹, Baosheng Guo¹, Lei Dang¹, Chao Liang¹, Xiaojuan He¹, Aiping Lu¹, Ge Zhang². ¹Institute for Advancing Translational Medicine in Bone & Joint Diseases, School of Chinese Medicine, Hong Kong Baptist University, Hong Kong SAR, China, ²nstitute for Advancing Translational Medicine in Bone & Joint Diseases, School of Chinese Medicine, Hong Kong Baptist University, Hong Kong SAR, China

Objective and method: The diseases with elevated bone resorption, including postmenopausal osteoporosis and osteolytic bone metastasis, are still great clinical challenges to orthopedic surgeons. Emerging evidences indicate that microRNAs play an important role in regulating osteoclast-mediated bone resorption. Recent studies showed that the phosphatase and tensin homolog (PTEN) plays a unique role in regulating osteoclast differentiation and activities^[1,2]. In addition, miR-214 was shown to target PTEN in various cancer cells^[3,4]. These data prompt us to suppose that miR-214 could target PTEN to regulate osteoclastic bone resorption. So, we examined the expression profile of intraosseous miR-214 in human bone specimens from either postmenopausal osteoporosis or osteolytic bone metastasis and the expression profile of osteoclastic miR-214 in either ovariectomized mice or human breast cancer xenografted nude mice.

Results: We found that the miR-214 and the mRNA expression levels of *TRAP* and *CTSK* were elevated in bone specimens from either post-menopausal (PMO) fractured women or fractured women with breast cancer bone metastasis (Fig a). The correlation analysis showed that the miR-214 level was positively associated with the mRNA expression levels of *TRAP* and *CTSK* in either peripheral menopausal (Peri-MO) and PMO fractured women or the fractured women with and without bone metastasis (Fig b). Consistently, the data from mice model showed that the osteoclastic miR-214 level and the bone resorption-related histomorphometric parameters (Oc.S/BS and Oc.N/Pm) were progressively increased in either ovariectomized mice or human breast cancer xenografted nude mice when compared to their corresponding control group, respectively (Fig c). Further correlation analysis indicated that the level of osteoclastic miR-214 was positively associated with Oc.S/BS and Oc.N/Pm in both mice models, respectively (Fig d).

Conclusions: The elevated miR-214 level in osteoclasts associated with increased bone resorption in both postmenopausal osteoporosis and osteolytic bone metastasis of cancer. It implied a potential role of miR-214 within osteoclasts in regulating bone resorption in in these diseases with elevated bone resorption.

Leucine Rich Repeat Kinase 1 (Lrrk1) Regulates Osteoclast Function via Modulating RAC1 Serine/Threonine Phosphorylation and Activation.Weirong Xing¹, Subburaman Mohan². ¹Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran's Admin., USA, ²Jerry L. Pettis Memorial VA Medical Center, USA

Lrrk1 belongs to the ROCO protein family, and contains ankyrin repeats and leucine-rich repeats, a GTPase-like domain of Roc, a COR domain, and a serine/threonine kinase domain. We recently demonstrated that knockout (KO) of Lrrk1 in mice cause severe osteoporosis due to dysfunction of multinucleated osteoclasts (OCs). Lrrk1 KO mice are healthy and respond to anabolic PTH treatment, but are resistant to ovariectomy-induced bone loss. Mature OCs derived from Lrrk1 KO monocytes exhibited defects in cytoskeletal rearrangement, peripheral sealing zones and ruffled borders. In our previous studies on the mechanism by which Lrrk1 regulates OC functions, we determined that Src pY-416 phosphorylation was significantly reduced while Src pY-526 was increased in Lrrk1 KO cells, thus implicating a role for Src in the Lrrk1 signaling pathway. However, the observed osteoprotective phenotype of Src KO mice was much less severe than the Lrrk1 KO mice, suggesting involvement of additional regulators besides Src in mediating the Lrrk1 effect on OCs. To evaluate this possibility, we identified proteins that are differentially phosphorylated at serine/threonine residues in Lrrk1 KO osteoclasts by Western blot analysis. We found that one phosphorylated peptide of molecular weight 28 kD was dramatically reduced in Lrrk1 deficient OCs as compared to the WT cells. Because RAC/Cdc42 small G proteins run in SDS-PAGE with an estimated mass of 24-28 kD, and because mice with disruption of RAC1/2 exhibit a severe osteoporosis phenotype caused by impaired OC function, we examined the phosphorylation status of RAC/Cdc42 proteins by Western blot analyses, and RAC1 activation by pull down assays in Lrrk1 KO and WT OCs. We found a dramatic reduction in RAC1/Cdc42 serine 71 phosphorylation (28 kD), and more than a 50% reduction in RAC1 binding to the p21 binding domain of p21 activated protein kinase in Lrrk1-deficient OCs. Immunoprecipitation analyses found that RAC1 interacted with Lrrk1 in mature OCs. Our data suggest that Lrrk1 may regulate OC function via modulating RAC1 serine/threonine phosphorylation and activation, and that RAC1 is a key biological substrate of Lrrk1 in OCs.

Loss Of Gfi1 Disorganizes The Podosome Belt And Impairs Osteoclast Migration And Bone Resorption. Peng Zhang*, Quanhong Sun, Juraj Adamik, Deborah L. Galson. University of Pittsburgh, USA

Gfi1 was found to be a novel transcriptional repressor of the critical osteoblast differentiation factor Runx2. BMSC isolated from *Gfi1*^{-/-} mice were resistant to myeloma-induced osteoblast suppression. Gfi1-deficiency studies have revealed that Gfi1 has key regulatory roles in inner ear sensory hair cells, and a wide array of hematopoietic lineage cells (HSC, B cells, T cells, DC cells, and neutrophils). While *Gfi1*^{-/-} mice have roughly normal appearance within 1 week of birth, by 3 weeks postnatal, they have lower body weights and are smaller than WT and *Gfi1*^{+/-} mice, and this difference increases with increasing age. This suggests that Gfi1-deficiency may cause abnormalities in postnatal bone homeostasis. Histomorphometry revealed that the femurs of both male and female *Gfi1*^{-/-} mice at 10 weeks displayed higher trabecular and cortical bone mass (BV/TV) and cortical bone thickness than control mice. Therefore, we investigated the role of Gfi1 in osteoclast (OCL) function and bone resorption. We found that Gfi1 was upregulated by RANKL induction of OCL differentiation of WT mouse bone marrow monocytes (preOCL). Comparison of RANKL-induced OCL formation by preOCL from *Gfi1*^{-/-} and control mice on plastic revealed that *Gfi1*^{-/-} preOCL cells form similar numbers of TRAP+ multinuclear OCL, similar nuclei/OCL, but they are smaller with less cytoplasm and decreased spreading. The *Gfi1*^{-/-} cells on bovine cortical bone slices formed "ball-like" multi-nuclear cells unlike the shape of the WT OCL. Resorption assays revealed that while *Gfi1*^{-/-} OCL generated a similar number of pits as WT OCL, the resorption area was dramatically smaller indicating that *Gfi1*^{-/-} OCLs have reduced resorptive ability. The tiny individual lacunae with no trails generated by *Gfi1*^{-/-} OCL suggested that they might have a migration defect. Using time-lapse video, we confirmed that Gfi1-deficiency inhibits the migration of preOCL. Actin ring visualization demonstrated that Gfi1-deficiency strongly reduced podosome belt formation, which is required for osteoclast migration and resorption. We do not yet know the molecular mechanism by which Gfi1 supports OCL migration and resorption. However, the lack of Gfi1-deficient OCL function in concert with our findings that decreasing Gfi1 in BMSC reduces multiple myeloma suppression of bone formation suggests that Gfi1 is a promising target for treatment of multiple myeloma bone disease since that would decrease OCL function and increase bone formation.

Heme Oxygenase-1 Protects Bone Loss via Attenuating Oxidative Stress.KE KE¹, Hye-Seon Choi². ¹University of Ulsan, South Korea, ²Department of Biological Sciences, University of Ulsan, South Korea

Redox status has been shown a crucial role in the pathogenesis of osteoporosis by increasing bone resorption activity. Heme oxygenase-1 (HO-1), known as the enzyme to catalyze heme degradation, was found to play a pivotal role in protecting tissues from oxidative stress. In this study, we have explored the physiological role of HO-1 in bone metabolism using HO-1 knock-out (KO) mice. Compared with its littermate wild type, HO-1 KO mice showed a significant decrease of bone mineral density, bone volume, trabecular number, trabecular thickness, and with an increasing of trabecular space by μ CT. In vivo tartrate-resistant acid phosphatase (TRAP) staining of long bone from HO-1KO mice also exhibited increasing TRAP-positive OC number. Consistently, by investigating serum parameter of bone resorption markers, we found elevated levels of serum C-telopeptide of type 1 collagen and TRACP 5b in the absence of HO-1. While no change was found in bone formation markers, such as N-terminal propeptide of type 1 procollagen and osteocalcin. Additionally, we also observed absence of HO-1 resulted in elevated serum ROS level, indicating increased oxidative stress might contribute to higher bone loss phenomena observed in HO-1KO mice. Our results demonstrated the crucial role of HO-1 in maintaining bone density under physiological conditions, suggesting the therapeutic potential of HO-1 to protect from bone loss.

MO0217

Pit And Trench Forming Osteoclasts: a Distinction That Matters?. Ditte MH Merrild¹, Dinisha C Pirapaharan¹, Christina M Andreassen², Per Kjærsgaard-Andersen³, Ming Ding², Jean-Marie Delaisse¹, Kent Soe^{*1}.

¹Dept. of Clinical Cell Biology, Vejle Hospital, University of Southern Denmark, Denmark, ²Dept. of Orthopaedic Surgery & Traumatology, Odense University Hospital, University of Southern Denmark, Denmark, ³Department of Orthopedic Surgery, Vejle Hospital, University of Southern Denmark, Denmark

Osteoclasts (OCs) seeded on bone slices either drill round resorption pits or dig long resorption trenches. Trench-making OCs differ from the pit-forming ones by an asymmetrical organization of their cytoskeleton and sealing zone, a re-arrangement of the exocytosis and endocytosis routes and higher collagenolytic activity. Trenches reflect periods of continuous resorption and thus represent a faster resorption mode compared with the well-investigated pit resorption mode that reflects intermittent resorption. However, it has not yet been investigated whether the distinction between trench and pit resorption modes have any relevance with respect to the natural variation found in human OC populations of different origin, and therefore matter in a clinical context. OCs generated from CD14+ cells isolated from different human blood donors (n=28) show a widespread variation in the prevalence of resorption trenches (3% to 80% of the eroded surface). Male OCs (n=14 donors) made significantly more trenches (mean=41%) than female OCs (n=13)(mean=21%), and male OCs (n=30) also had a 1.6-fold higher gene expression level of CatK than female OCs (n=42). In addition, male OCs showed a positive correlation ($r^2=0.57$, $p=0.003$) between %ES and %trench-surface/ES, whereas female OCs showed a negative correlation ($r^2=0.40$, $p=0.012$). Thus, OCs from male and female donors seem different in vitro. Furthermore, OCs generated from human bone marrow CD14+ cells showed a higher likelihood of generating trenches (57% vs 26%) and a higher collagenolytic activity (2.5-fold higher CTX/ES), compared with OCs obtained from blood. A specific CatK inhibitor abrogated the generation of trenches, even when their prevalence was very high, while it still allowed the generation of pits. This indicates that CatK activity is more stringent for generating trenches than for generating pits. Finally, SEM of bone surfaces eroded in vivo show indeed resorption patterns corresponding to trenches and pits made by OCs in culture. We conclude that the distinction between trench and pit-forming OCs is not merely a laboratory peculiarity, but is relevant to the differences amongst OCs from different skeletal sites, different individuals and gender. We also confirm that the collagenolytic power of OCs determines their resorption mode. Thus, more attention should be given to the mechanism driving trench-making OCs. This is of special interest in the context of CatK inhibitors as anti-osteoporotic drugs.

Protein Kinase D2 (PRKD2) Regulation of the Actin Cytoskeleton during Osteoclast Differentiation. Amanda Leightner^{*}, Eric Jensen, Kim Mansky, Rajaram Gopalakrishnan. University of Minnesota, USA

The activity of osteoclasts and osteoblasts must be tightly balanced to maintain a healthy skeleton. Pathological bone loss in many adult skeletal diseases such as osteoporosis, metastatic bone disease and periodontal disease are caused by excessive osteoclast activity. Better understanding of gene regulatory mechanisms and signal transduction pathways controlling osteoclast differentiation and activity are necessary for development of new therapies. Previous work in our group identified the serine/threonine kinase Protein Kinase D2 (PRKD2) as a key regulator of osteoclast differentiation, necessary for fusion of mononuclear preosteoclasts into multinucleated mature osteoclasts. PRKD2 has many reported cellular functions including coordination of cell migration and invasion through modulation of the actin cytoskeleton and regulation of gene transcription. The goal of the current project is to better understand the mechanism of PRKD2 regulation of osteoclast differentiation and function. We hypothesize that PRKD2 may direct osteoclastogenesis through both control of preosteoclast fusion and regulation of the actin cytoskeleton. We first characterized PRKD2 subcellular localization during osteoclast differentiation from mouse bone marrow monocytes stimulated with RANKL and M-CSF. Active PRKD2 showed weak association with individual podosomes in the cluster or ring stage, but stronger localization to podosomes in the mature actin belt. Treatment of cultures with the PRKD2 inhibitor CID755673 showed that PRKD2 is dispensable for early steps of podosome cluster assembly where its inhibition prevented the transition from podosome clusters to belts and resulted in significant loss of mature podosome belts, confirming a role for PRKD2 in actin dynamics in osteoclasts. Phosphorylated PRKD2 also localized to filipodia where the protein may function in preosteoclast cell fusion. Current data suggest that PRKD2 regulates actin organization through phosphorylation of the actin regulatory protein cofilin. Inhibition of PRKD2 in post-fusion osteoclasts resulted in decreased resorptive activity and impeded cell migration, suggesting a requirement of PRKD2 in basic osteoclast functionality. These data suggest that PRKD2 may affect both progenitor fusion and actin cytoskeletal rearrangements during osteoclast differentiation.

Targeted inhibition of miR-214 in osteoclasts suppresses bone resorption in both ovariectomy-induced osteoporosis and osteolytic bone metastasis in vivo: A pilot study. Lei Dang^{*1}, Ge Zhang², Defang Li², Jin Liu², Baosheng Guo², Aiping Lu². ¹Hong Kong Baptist University, Hong kong, ²Hong Kong Baptist University, China

Introduction: Our previous study indicated that elevated osteoclastic miR-214 associated with increased bone resorption in postmenopausal osteoporosis and osteolytic bone metastasis (unpublished data). Recently, we developed an osteoclast-targeting delivery system (Liu et al., 2015), (D-Asp₈)-liposome, which facilitated examining the hypothesis that targeted inhibition of osteoclastic miR-214 could suppress bone resorption in mice with ovariectomy-induced osteoporosis and mice with osteolytic bone metastasis.

Objective: To examine the effect of antagomir-214 delivered by (D-Asp₈)-liposome in both ovariectomized mice and mice with osteolytic bone metastasis.

Methods: 16 6-month-old female mice were OVX or sham-operated. At day 3 after OVX, all mice were administrated intravenously with (D-Asp₈)-liposome-antagomir-214, (D-Asp₈)-liposome-antagomir-NC, Vehicle or PBS weekly for 4 weeks. Antagomir-214 was given at doses of 3, 5, 7 mg/kg body weight. All mice were sacrificed after treatment. The left mice were sacrificed as baseline before treatment. After sacrifice, femurs were dissected for microCT analysis. On the other hand, human breast cancer cells (MM231-LN) were xenografted into 14 female nude mice through intracardial injection. At day 3 after injection, all mice were divided into PBS, Vehicle, (D-Asp₈)-liposome-antagomir NC or (D-Asp₈)-liposome-antagomir-214 according to treatment. All above mice were sacrificed after treatment weekly for 5 weeks. Antagomir-214 was given at doses of 3, 5, 7 mg/kg body weight. The left mice were sacrificed as baseline. Before sacrifice, all mice were detected by biophotonic and X-ray imaging weekly.

Results: In the mouse model of OVX, microCT result showed that impaired trabecular microarchitecture was improved in the mice treated with (D-Asp₈)-liposome-antagomir-214 compared to other treatments. In the mouse xenograft model, biophotonic imaging showed that mice treated with (D-Asp₈)-liposome-antagomir-214 resulted in diminished bone metastasis. X-ray imaging showed that osteolytic lesions in limbs alleviated after treated with (D-Asp₈)-liposome-antagomir-214. In above models, bone resorption was in a dose-dependent inhibitory at doses of 3, 5, 7 mg/kg and the middle dose and high dose groups got similar results.

Conclusion: Targeted inhibition of osteoclastic miR-214 might suppress bone resorption in both ovariectomy-induced osteoporosis and osteolytic bone metastasis. We will increase sample size for further study.

The subcellular distribution of Siglec-15 in bone-resorbing osteoclasts implies complementary roles at the cell surface and ruffled border. Matthew Stuible^{*1}, Annie Fortin², Mario Filion², Gilles B. Tremblay². ¹Alethia Biotherapeutics, Canada, ²Alethia Biotherapeutics Inc., Canada

Siglec-15, a sialic acid-binding receptor, is required for differentiation of precursor cells into mature osteoclasts. In animal models, Siglec-15 can be targeted therapeutically to inhibit bone resorption while maintaining bone formation. Previous studies have reported that Siglec-15 is localized to the cell surface, where, in complex with DAPI2, it generates signals that promote osteoclast differentiation and function. We have found that in addition to its role in osteoclast differentiation, Siglec-15 continues to play a role in resorbing osteoclasts. Here, we report that culturing osteoclasts on bone has a dramatic effect on the subcellular distribution of Siglec-15. In addition to cell-surface staining, Siglec-15 becomes concentrated in punctate structures near the osteoclast ruffled border (RB). The acidic nature of the osteoclast resorption lacuna led us to examine the effect of these conditions on Siglec-15 ligand-binding. Indeed, in vitro binding assays showed that the affinity of Siglec-15 for sialylated substrates is dramatically increased at pH 4.5 vs pH 7. While co-localization of Siglec-15 with DAPI2 was readily observable at the cell surface, it was not observed in the Siglec-15-positive structures in the RB, suggesting a novel function at this location. Siglec-15 does not appear to be involved in the secretion of enzymes into the resorption lacuna; for example, Cathepsin K (CatK) is concentrated at the periphery of the RB while Siglec-15 is more central. The central subdomain of the RB is involved in uptake of hydrolytic enzymes (e.g., CatK) and degraded bone components for transport and secretion from the basolateral membrane (termed "transcytosis"). Specifically in the RB, Siglec-15 exhibits strong co-localization with the endosomal marker Rab9, which has a proposed role in vesicle trafficking between the RB and the transcytotic pathway. Furthermore, treatment of osteoclasts with Siglec-15 mAb AB-25E9 leads to nearly complete inhibition of CatK secretion. Transcytotic vesicles are an important site for continued degradation of bone structural proteins (i.e., collagen) as well as bone-derived growth factors (IGF-1, TGF- β , etc.) by CatK and TRAP. With regards to the maintenance of bone formation upon treatment with AB-25E9, our results suggest that in addition to osteoclast-intrinsic factors that may stimulate osteoblast activity, the reduced degradation of key bone-derived growth factors may also be of central importance.

Autophagy and Phospho-Inositide Dependent Kinase 1 (PDK1) -Related Kinome in Pagetic Osteoclasts. Stephen McManus*, Martine Bisson, Richard Chamberland, Michèle Roy, Shekeba Nazari, Sophie Roux. University of Sherbrooke, Canada

Background. In Paget's Disease of Bone (PDB), part of the pathology is due to osteoclasts (Ocs) that are increased in size and number, overactive and resistant to apoptosis. We have previously shown that PDK1 associates with p62 and PKC ζ , even prior to RANKL stimulation in pagetic Ocs. Given the established role of PDK1 in the Akt/PKB axis, and because we previously showed an increase in pAkt/Akt levels in pagetic Ocs, we hypothesized that PDK1 may play an important role in the Oc-related kinome regulation, from activation to autophagy (ATG) and survival.

Methods. We used an in vitro human Oc model from peripheral blood monocytes of patients with PDB and healthy donors (40 /group, no p62 mutations).

Results. In immunoblot studies of MAP kinase activation (n=4-6 /group), we observed that in Ocs, pERK/ERK levels were significantly increased in PDB vs. controls (p<0.001), but not pp38/p38 levels. The increased phosphorylation of Akt and of its substrate GSK3 β observed in pagetic Ocs was ablated upon treatment with a PDK1-specific inhibitor. Although inhibition of PDK1 did not affect ERK phosphorylation, it reduced that of RSK2. In addition to their roles in cell survival, both PDK1/Akt and ERK are implicated in ATG regulation. The phosphorylation of 4EBP1 and raptor (mTOR-interacting adaptor), which are both related to mTORC1 activation and ATG inhibition, were increased in pagetic Ocs (p<0.01), and both were reduced upon inhibition of PDK1 in normal and pagetic Ocs (p<0.05), suggesting a PDK1-dependent activation of mTORC1 in PDB Ocs. Using IF studies, LC3B puncta numbers per Oc in basal conditions were increased in pagetic Ocs (p<0.001), but did not further increase in the presence of protease inhibitors compared to controls (n=4/group, 15-20 Ocs each condition). Gene expression analyses (n=26/group) did not reveal any increase in several ATG-associated genes (except *ULK1*) in basal conditions. Finally, deprivation of MCSF and RANKL induced a significant increase in LC3B-II/I ratios in control Ocs, but only in the presence of PDK1 inhibitor in pagetic Ocs (p<0.01).

Conclusion. Our findings suggest that the induction of autophagy might be impeded in pagetic Ocs, which also exhibit defects in late autophagosome maturation. The results also indicate a strong potential regulatory role for PDK1 in Oc stimulatory pathways (Akt, ERK) and ATG induction (via mTORC1), which allow for further exploration of several survival and autophagic pathways in pagetic Ocs.

Cathepsin K deficiency suppresses disuse-induced bone loss. Shuichi Moriya*¹, Yoichi Ezura¹, Yayoi Izu¹, Masaki Noda². ¹TMDU, Japan, ²Tokyo Medical & Dental University, Japan

Unloading induces bone loss and causes disuse osteoporosis. This osteopenic condition is seen when patients are subjected to long term bed rest or they are suffering from neurological diseases. However, the mechanism underlying disuse osteoporosis is still incompletely understood. Here we examined the effects of CatK deficiency on disuse osteoporosis induced by using sciatic neurectomy (Nx) model. Male mice were used in the experiments. Cat-K KO and wild type (Wt) mice were anesthetized and a 5 mm segments of left sciatic nerve and femoral nerve were resected. The right sciatic nerve and femoral nerve were exposed surgically but were not resected. After four weeks of surgery, Cat-K KO and Wt mice were sacrificed and subjected to analysis. For cancellous bone rich region, Nx reduced the BMD compared to the sham operated side in Wt mice. In contrast, CatK deficiency suppressed such Nx-induced reduction of BMD in the proximal tibia. Nx also reduced the BMD in the mid shaft compared to sham side in Wt. In contrast, CatK deficiency suppressed such Nx-induced reduction of BMD in the mid shaft. Bone marrow cells were obtained from these mice were cultured for 3 weeks and the calcified nodules were measured. The area of calcified nodules tended to be slightly reduced by Nx. CatK deficiency reduced the levels of calcified nodule formation compared to wild type in the bone marrow cells obtained from loaded side femur. When the bone marrow cells obtained from Nx side femur were cultured, the levels of the calcified area in culture were increased. For osteoclast development, the levels of TRAP+ osteoclastic cell numbers tended to increase in the Nx side of the Wt mice. The levels of TRAP+ cells in culture was reduced in the CatK deficient bone marrow cells obtained from loaded limb. The levels of TRAP+ cell development in culture was also rescued in the cells obtained from femora of Nx side. Further examination of gene expression indicated that Nx suppressed the expression of genes encoding osteoblast-phenotype-related molecules such as Runx2 and alkaline phosphatase in Wt. In contrast, CatK deficiency suppressed such reduction. With respect to bone resorption markers, RANKL and OPG expression was reduced by Nx in Wt, but CatK deficiency suppressed such reduction. These data indicate that CatK is involved in the disuse-induced bone mass reduction.

C-reactive protein could promote osteoclastogenesis in rheumatoid arthritis. Sang-Hyon Kim¹, Sang-Heon Lee^{*2}, Young-Il Seo³, Sang-Il Lee⁴, Jinseok Kim⁵, Jung Soo Song⁶. ¹Div. of Rheumatology, South Korea, ²Division of Rheumatology, Konkuk University School of Medicine, Seoul, Republic of Korea, South Korea, ³Division of Rheumatology, Hallym University Medical Center, Ahnang, Republic of Korea, South Korea, ⁴Division of Rheumatology, Department of Internal Medicine, ²Department of Preventive Medicine, Gyeongsang National University School of Medicine, ³Clinical Research Institute, Gyeongsang National University Hospital, Jinju, Republic of Korea, South Korea, ⁵Department of Internal Medicine, Jeju National University Hospital, Jeju, Republic of Korea, South Korea, ⁶Division of Rheumatology, Department of Internal Medicine, Chung-Ang University Medical school, Seoul, Republic of Korea, South Korea

Background: C-reactive protein (CRP) is one of the biomarkers for the diagnosis and assessment of disease activity in rheumatoid arthritis (RA). CRP is not only the by-product of inflammatory response, but also plays pro-inflammatory and pro-thrombotic roles. Objectives: This study aims to determine the role of CRP on bone destruction in RA. Methods: CRP levels in RA synovial fluid (SF) and serum were measured using the immunoturbidimetric method. The expression of CRP in RA synovium was assessed using immunohistochemical staining. CD14+ monocytes from peripheral blood were cultured with CRP, and RANKL expression and osteoclast differentiation were evaluated by using real-time PCR, counting TRAP-positive multinucleated cells and assessing bone resorbing function. CRP-induced osteoclast differentiation was also examined after inhibition of Fc γ receptors. Results: There was a significant correlation between CRP levels serum and SF in RA patients. The SF CRP level was correlated with interleukin(IL)-6 levels, but not with RANKL levels. Immunohistochemical staining revealed that CRP was more abundantly expressed in the lining and sublining areas of the RA synovium, compared with the osteoarthritis synovium. CRP promoted RANKL production in monocytes, which in turn, induced osteoclast differentiation from monocytes and increased bone resorption in the absence of RANKL. Conclusions: CRP could play an important role in the bony destructive process in RA through the induction of RANKL expression and direct differentiation of osteoclast precursors into mature osteoclasts. In the treatment of RA, lowering CRP levels is a significant parameter not only for improving disease activity but also for preventing bony destruction.

Molecular Mechanism of Hyponatremia-Induced Osteoporosis. Julia (Julianna) Barsony*¹, Qin Xu², Joseph G Verbalis². ¹Georgetown University Hospital, USA, ²Georgetown University Medical Center, USA

Both animal and human studies have indicated that chronic hyponatremia (CH) increases fracture frequency in patients by inducing excess bone resorption and loss of bone mineral density and by impairing balance and increasing falls. The high prevalence of CH in the aging population due to comorbidities, medication use and the syndrome of inappropriate antidiuretic hormone secretion highlights the public health importance of CH-induced osteoporosis. Prior studies indicated that some of CH effects are mediated by direct signaling of low extracellular sodium concentration ([Na⁺]) to osteoclasts and neuronal cells. However, the [Na⁺] sensing and signaling mechanisms have not yet been elucidated. In these studies, we identified [Na⁺] responses in cultured murine primary osteoclastic cells, RAW264.7 derived osteoclasts, and murine neuroblastoma N2a cells. Rapid effects of [Na⁺] on mature osteoclasts included change of cell shape within one minute, lysosome acidification and shift to the ruffled border membrane within 5 minutes, increased actin ring formation within 2h, increased cell motility in a Boyden chamber, and increased mitochondrial ATP production within 24 hours. Consistent with CH-induced osteoclastogenesis, gene expression changes detected by whole genome microarray and qRT-PCR in osteoclastic cells consistently included upregulated expression of Slc8A1 sodium/calcium exchanger, Igf1, Vnt6, Mmp9, Mmp12, Mmp14, Tnf, Rex2 Apc2, and Myc1 and downregulated expression of the AVP receptor 1. Neuronal cells also responded with rapid gene expression changes to culture in low [Na⁺] media (upregulation of Tgfb1, Dram1, Tnf, Igf1, and downregulation of Sqstm1). Western blot analyses detected protein phosphorylation changes proportional to reduction in media [Na⁺], consistent with immediate activation of osteoclastogenesis. These results indicate that a membrane receptor mediated signaling pathway directly mediates hyponatremia induced target cell responses, leading to increased bone fragility and neurological deficits. Our rat studies indicated that CH also decreases bone formation, and we have observed that patients with CH generally have very low serum osteocalcin levels. However, the lack of effects of low [Na⁺] on cultured osteoblasts suggests that the effects of CH on bone formation may be indirect. These combined results provide a better understanding of the mechanisms that contribute to hyponatremia-induced osteoporosis and fall and fracture risks.

Role of Becn1 ubiquitination in RANKL-mediated osteoclastogenesis. Atsushi Arai¹, Sol Kim¹, Teresa Kim¹, Cindy Lee¹, Cun-Yu Wang¹, No-Hee Park¹, Reuben Kim^{2*}. ¹UCLA School of Dentistry, USA, ²UCLA, USA

Purpose: During osteoclastogenesis, RANKL activates osteoclast precursors to undergo differentiation to form multinucleated osteoclasts. Autophagic process, an important cellular mechanism that becomes activated under stress such as starvation, is recently shown to be involved in osteoclasts. However, the precise role of autophagy in normal physiological process of osteoclastogenesis is not clear. Here, we investigated role of autophagy and Becn1, a protein involved in autophagy initiation, during osteoclastogenesis upon RANKL stimulation. **Methods:** Bone marrow (BM) and RAW 264.7(RAW) cells were used to undergo osteoclastic differentiation upon RANKL treatment. Osteoclastic and autophagic genes were examined in a time-dependent manner using qRT-PCR and Western blotting. Protein expression of LC3B, a marker for autophagy, was monitored using Western blotting and confocal microscope. Bone resorptive functions were evaluated using dentin slices. Becn1 phosphorylation and ubiquitination at S14 and K117, respectively, were examined. Becn1 mutants, S14D, S14A, and K117R, were retrovirally overexpressed in RAW cells, and osteoclast differentiation was evaluated. TRAF6 was knocked down using siRNA, and ubiquitination of Becn1 was examined. **Results:** RANKL-treated BM and RAW cells exhibited significant increases in autophagic genes, LC3B protein expression and punctae in a time-dependent manner. Overexpression of Becn1 in RAW cells increased osteoclast differentiation and functions. Modulating S14 site of Becn1 did not have any effects on osteoclastic differentiation. However, RANKL treatment induced ubiquitination of Becn1. Knockdown of TRAF6 or overexpression of ubiquitination-incompetent Becn1-K117R resulted in suppression of Becn1 ubiquitination and osteoclastogenesis. **Conclusion:** Autophagy is physiologically important process during the RANKL-mediated osteoclastogenesis, and Becn1 may be a potential therapeutic target for managing osteoclast-specific bone-related diseases.

Smad4 In Osteoclasts Reduce Bone Mass by Inhibiting Osteoclast Differentiation. Mayu Morita^{1*}, Ryotaro Iwasaki², Hiromasa Kawana², Shigevuki Yoshida², Taneaki Nakagawa², Takeshi Miyamoto³. ¹Keio University, Japan, ²Division of Oral & Maxillofacial Surgery, Department of Dentistry & Oral Surgery, Keio University School of Medicine, Tokyo, Japan, ³Department of Orthopedic Surgery, Keio University School of Medicine, Tokyo, Japan, Japan

Background: Bone remodeling maintains constant bone mass by a delicate balance between bone-resorption followed by bone-formation. TGFβ1 is one of the TGFβ superfamily ligands including TGFβ1-5 and bone morphogenetic proteins (BMPs), and transduces their signals by binding to their specific receptors via receptor-regulated Smads (R-Smads), Smad2/3 and Smad1/5/8, respectively, and subsequently R-Smads form oligomers with common-mediator Smad, Smad4. Smad4 was reportedly played pivotal roles for mesenchymal stem cell migration and bone formation, role of Smad4 on osteoclasts remain largely unknown. Thus, objects of our study are to clarify the roles of Smad4 on osteoclasts.

Methods: Osteoclast specific Smad4 conditional knockout mice (*Ctskcrel+Smad4fl*) were generated, and *Ctskcrel+Smad4fl/fl* and control littermates were analyzed. 8 wk old mice were necropsied, and their hind limbs were removed, fixed with 70% ethanol, and subjected to DEXA analysis to measure bone mineral density and to bone histomorphometric analysis.

Results: We found that osteoclast-specific Smad4 conditional knockout mice exhibited significant reduction of bone mass with elevated osteoclast formation compared to controls.

Our data demonstrate that Smad4 in osteoclasts is required to inhibit osteoclastogenesis to maintain bone mass *in vivo*.

Pentosan Polysulfate Sodium Suppress RANK Ligand Induced Osteoclast Differentiation via IL-1R/TLR Signal Transduction Involving Fos-Jun/AP-1 Transcriptional Regulator Complex Repression. Suranji Wijekoon*, Sangho Kim, Jing Fang, Eugene C. Bwalya, Kenji Hosoya, Masahiro Okumura, Hokkaido University, Japan

One of the most important transcription factor complexes that is activated by RANKL/TRAF signals is Fos-Jun/AP-1 in osteoclastogenesis (OCLG). It is induced in rheumatoid arthritis (RA) by immunoregulatory molecules and provide valuable drug target for RA. It was newly recognized that beech wood derived pentosan polysulfate sodium (PPS) has an effect on osteoarthritis to reduce pain and inflammation. But mechanism of action of PPS over the OCLG and osteoclasts function is not fully understood. The purpose of the current study was to investigate the effect of PPS on inflammatory reaction of osteoclasts. Bone marrow derived

hematopoietic stem cells from five healthy dogs were treated for OCLG. After interleukin (IL)-1β stimulation for the fusion and survival of osteoclast, PPS, polysulfated glycosaminoglycan (PSGAG) and heparin (0.2, 1, 5 μg/ml) were supplemented. Specific genes expression such as carbonic anhydrase, cathepsin-k, MMP9 and c-fos, intracellular incursion of PPS, nuclei/cell and area/cell ratio were examined after completion of the differentiation by quantitative PCR, fluorescence assay and TRAP staining respectively. Even expression of carbonic anhydrase, cathepsin-k and c-fos were significantly (p<0.05) suppressed by PPS, effect of PSGAG and heparin were not significant. The master switch for regulating terminal differentiation of osteoclasts, NFATc1 was significantly down regulated by PPS and heparin at the concentration of 5 μg/ml. In this present study, IL-1 influenced MMP9 synthesis by osteoclasts was certainly reduced in significant (p<0.05) manner by three types of treatments at the concentration of 5 μg/ml. Even there was decline of AP1 gene expression with heparin in concentration dependent pattern, significant (p<0.001) effect were detected from PPS at 5 μg/ml. Comparative to PSGAG and heparin, significant genomic suppression of AP-1 thus altering of nuclei/cell and area/cell ratio in significantly (p<0.05) was perceived with PPS. The fluorescence images of interaction of PPS and c-Jun interface more endorsed that intra-nuclear invasion of PPS and effects on transcription factors. In conclusion, those outcomes have been revealed that the inhibitory effect of PPS on signaling components within the RANKL transduction pathway could moderate Fos-Jun/AP-1 transcriptional regulator complex expression and activation while stimulation of IL-1R/TLR. This manner of suppression of OCLG by PPS would be a novel therapeutic approach for RA.

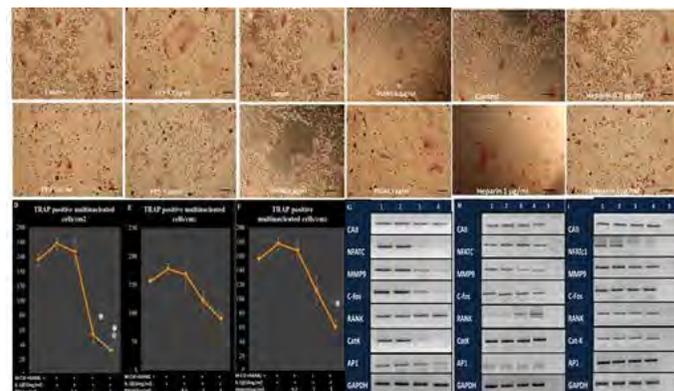

Figure 1: PPS suppresses API, c-Fos, MMP9 and NFATc1 activity but not alter RANK expression in bone marrow differentiated osteoclasts. M-CSF/RANKL induced osteoclasts formation and their morphology was altered in different degree by PPS, PSGAG and heparin treatments. A,B,C- PPS, PSGAG and heparin treatment respectively reduced osteoclasts formation. Bone marrow cells were differentiated in to osteoclasts by M-CSF/RANKL and treated with PPS, PSGAG, heparin for 7 days and then TRAP stained. Scale bar size 50 μm. D, E, F- TRAP stained multinucleated giant cells/cm² after treatment of PPS, PSGAG and heparin concentration of 0.2, 1 and 5 μg/ml. Number of osteoclasts significantly reduced at the concentration of 1 and 5 μg/ml of PPS and 5 μg/ml of heparin. Data expressed as mean ± standard deviation (n=5) for each value. * p<0.05, ** p<0.01 value expression relative to positive control that was stimulated by IL-1 without any treatment. G,H,I- Gel electrophoresis image shows the effect of PPS, PSGAG and heparin treatment on osteoclast specific genes: CAII: carbonic anhydrase, NFATc1, MMP9, c-Fos, RANK, CatK: cathepsin k, API: activator protein 1 and GAPDH housekeeping gene (1: Positive control, 2: 0.2, 3: 1, 4: 5 μg/ml, 5: Negative control)

Morphological and genomic expression of osteoclasts after treatment of PPS, PSGAG and heparin

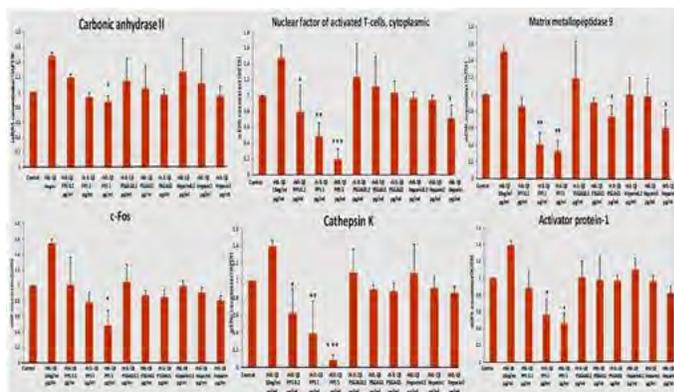

Figure 2: PPS regulates the mRNA level of API, c-Fos, NFATc1 and their target genes during osteoclastogenesis of bone marrow derived monocytes (BMDM). Isolated hematopoietic stem cells after 48 hours culture of BMDM were cultures in the presence of M-CSF (20 ng/ml), RANKL (50 ng/ml) and IL-1β (10 ng/ml) for 10 days with or without PPS, PSGAG and heparin (0.2, 1, 5 μg/ml) separately. mRNA expression of osteoclasts specific genes were quantitatively analyzed by quantitative real-time polymerase chain reaction. MMP9 was significantly down regulated by all treatment groups. When heparin suppresses the activity of NFATc1 at 5 μg/ml PPS is done it by all 3 concentrations. Carbonic anhydrase and cathepsin K genomic expressions are results of activation of transcription factors. Data expressed as mean ± standard deviation (n=5) for each concentration after normalizing for the expression of the housekeeping gene GAPDH. * p<0.05, ** p<0.01, *** p<0.001. Gene expression relative to osteoclasts stimulated with rhIL-1β alone.

Quantitative and comparative assessment of osteoclasts specific genes expression after treatment

DICAM attenuates macrophage differentiation via suppression of integrin $\alpha\text{V}\beta\text{3}$ -dependent Akt-Foxo3a-Irf7 pathway. Gunwoo Kim^{*1}, Youn-Kwan Jung², Seung-Woo Han³, Min-Su Han², Eun-Ju Lee², Hye-Ri Park², Ji-Ae Jang², Dong-Ju Shin⁴. ¹Fatima Research Institute & Daegu Fatima Hospital, Daegu, Republic of Korea, South Korea, ²Fatima Research Institute, Daegu Fatima Hospital, South Korea, ³Department of Internal Medicine, Daegu Fatima Hospital, South Korea, ⁴Department of Orthopedics, Daegu Fatima Hospital, South Korea

DICAM, a dual Ig domain containing adhesion molecule, is involved in cell-cell adhesion through a direct interaction with $\alpha\text{V}\beta\text{3}$ integrin. In our previous study showing the inhibitory role in osteoclastogenesis, we found a clue that DICAM also has a suppressive role in macrophage differentiation. To investigate the role of DICAM in macrophage differentiation, we induced the differentiation of macrophage from THP-1 cells by treatment of PMA for 3 days. Also we investigated the gain or loss of function of DICAM during THP-1 macrophage differentiation by infection of adenovirus or lentivirus system respectively. The expression of DICAM was decreased during PMA-induced THP-1 differentiation at day1, and increased time-dependently. The overexpression of DICAM in THP-1 cells suppressed PMA-mediated macrophage differentiation in the number of activated branched macrophage and macrophage marker expression, CD14 and CD68. However, DICAM does not affect the viability and proliferation of PMA-stimulated THP-1 macrophage. Functionally, DICAM attenuated the TNF- α secretion of differentiated THP-1 cells and their phagocytic activity as well. To investigate the molecular mechanisms for DICAM-mediated suppression of macrophage differentiation, we conducted microarray analyses, which revealed that overexpressed DICAM significantly suppressed type 1 interferon system. Among interferon regulatory factors (IRFs) family, IRF7 was most significantly reduced by DICAM. DICAM also attenuated Akt activation and increased a nuclear translocation of FoxO3a that is known to be a critical negative regulator of IRF7. Consistently, DICAM also decreased total integrin β3 level and integrin-linked kinase (ILK) phosphorylation, the major adaptor molecule of integrin β3 . Overexpression of integrin β3 in DICAM-mediated inhibition of THP1 differentiation rescued the expression of macrophage differentiation markers partially. These results show that DICAM potentially reduces differentiation and function of THP-1 macrophage via suppression of integrin $\alpha\text{V}\beta\text{3}$ -dependent Akt-FoxO3a-IRF7 pathway.

MO0230

Intravenous Immunoglobulin (IVIG) Attenuates TNF-induced Pathologic Bone Resorption and Suppresses Osteoclastogenesis by Inducing A20 Expression. Min Joon Lee*, Elisha Lim, Shwan Mun, Lionel Ivashkevich, Kyung-Hyun Park-Min. Hospital for Special Surgery, USA

Intravenous immunoglobulin (IVIG) treatment is an effective therapy in various autoimmune and chronic inflammatory diseases by suppressing autoantibody- and immune complex-mediated pathogenesis. Several possible mechanisms for the action of IVIG have been suggested, yet the component of IVIG that mediates the suppression of inflammation is not well understood. Many inflammatory diseases such as rheumatoid arthritis are often accompanied by excessive bone resorption but the effect of IVIG on osteoclasts, bone-resorbing cells, has not been studied. Thus, we investigated whether IVIG directly regulates osteoclast differentiation and has therapeutic potential for suppressing osteoclast-mediated pathologic bone resorption. For osteoclast differentiation, receptor activator of nuclear factor-kappa B ligand (RANKL) and macrophage colony-stimulating factor (M-CSF) are essential. IVIG suppressed RANKL-induced osteoclastogenesis and expression of osteoclast-related genes such as integrin $\beta 3$ and cathepsin K in a dose-dependent manner by downregulating RANKL-induced expression of NFATc1, the master regulator of osteoclastogenesis. IVIG functions by interacting with Fc γ Rs (Fc γ RIa, Fc γ RIIa, Fc γ RIb, and Fc γ RIIIa) and we have found that the engagement of Fc γ RIIIa with IVIG is important for the IVIG-mediated suppression of human osteoclastogenesis. Interestingly, unbiased transcriptomic analysis revealed novel negative regulators that are induced by IVIG. A20 is a well-known NF- κ B signaling inhibitor and the expression of A20 is increased by IVIG. Strikingly, the siRNA-mediated deletion of A20 has reversed the suppressive effect of IVIG. Consistent with our observation, IVIG suppressed NFATc1 expression by attenuating RANKL-induced NF- κ B signaling, explained in part by the induction of A20. Our in vitro observation was further corroborated in our in vivo model; IVIG administration attenuated in vivo osteoclastogenesis and suppressed bone resorption in the tumor necrosis factor (TNF)-induced calvarial osteolysis model. Take together, our findings show that, in addition to suppressing inflammation, IVIG directly inhibits osteoclastogenesis through a mechanism involving suppression of RANK signaling. Our results suggest that direct suppression of osteoclast differentiation may provide beneficial effects on preserving bone mass when IVIG is used to treat rheumatic disorders.

Proliferation-coupled osteoclast differentiation by RANKL. Sunao Takeshita*, M. Motiur Rahman, Kyoji Ikeda. National Center for Geriatrics & Gerontology, Japan

During a 4-day course of osteoclastogenesis ex vivo from bone marrow macrophages (BMMs) stimulated with M-CSF and RANKL, BMMs proliferate actively during the first half (0-48h), followed by cell-cycle arrest, cell fusion, and formation of multinucleated osteoclasts in the latter half. Although it is generally thought that osteoclast differentiation induced by RANKL is linked to the anti-proliferative activity of the cytokine, we have found that RANKL in the presence of M-CSF actually stimulates DNA synthesis and cell proliferation during the first-half proliferative phase (0-48h), while the same cytokine exerts an anti-proliferative activity in the latter half (48-96h). Inhibition of DNA synthesis with hydroxyurea (HU) during the first half almost completely inhibited osteoclastogenesis, as reported. However, the same HU-treated cells, when re-plated at 48h at increasing cell densities, restored osteoclast formation at 96h, suggesting that a sufficient number of cells, rather than prior DNA synthesis per se, is critical for osteoclast formation. In fact, when BMMs were plated at varying cell densities at 0h, 5×10^3 cells/96-well was optimal for osteoclast formation assessed on day 4, while $10-30 \times 10^3$ cells/96-well had given rise to mature functional osteoclasts already on day 3, most of which died by day 4. Interestingly, this accelerated differentiation with increased cell densities was not associated with up-regulation of osteoclastogenesis-related gene expression, suggesting that cells respond to RANKL with very similar gene expression patterns irrespectively of cell density, and that the accelerated osteoclastogenesis is not ascribed to an acceleration of the intrinsic genetic program. 5×10^3 BMMs are supposed to give rise to 20×10^3 pre-osteoclasts (preOCs) after two rounds of cell cycling for 48h. Evidently, when varying numbers of preOCs were plated on day 2, 20×10^3 cells/96-well, but neither lower or higher cell density, yielded the most osteoclasts on day 4. Taken together, it is suggested that proliferation of BMMs during the first half is important to secure a sufficient number of preOCs, that during the second half, a cell density of preOCs is critical for the formation of multinucleated osteoclasts, in which a stochastic factor, such as increased chances for preOCs to contact each other, is important for cell fusion and generation of multinucleated osteoclasts.

MO0232

Small leucine-rich proteoglycans may regulate osteoblast-osteoclast coupling through TNF-alpha sequestration. Vardit Kram*, Tina Kilts, Nisan Bhattacharyya, Marian Young. Craniofacial & Skeletal Diseases Branch, NIDCR, NIH, USA

Biglycan (Bgn) and Fibromodulin (Fmod) are two subtypes of the small leucine-rich family of proteoglycans, which are known to be highly expressed in the extracellular matrix (ECM) of bone and cartilage. They are known to regulate osteoblast proliferation and activity. Previously, we have shown that *Bgn/Fmod* double knockout (*Bgn*^{-/-}; *Fmod*^{-/-} DKO) have a low bone mass (LBM) phenotype, mis-articulation of joints, early onset osteoarthritis as well as ectopic bone formation and tendon ossification. In addition, by 5 weeks of age, the *Bgn*^{-/-}; *Fmod*^{-/-} DKO have increased osteoclast number and activity as can be seen by TRAP staining and pit formation assays. Tumor necrosis factor α (TNF- α), a multifunctional proinflammatory cytokine produced by a wide variety of immune and epithelial cells, has been shown to stimulate osteoclastogenesis in a RANKL independent manner by activating nuclear-factor of activated T-cell c1 (NFATc1), the master transcription factor in osteoclast differentiation. Moreover, TNF- α activation suppresses both RUNX2 transcription as well as MAPK-mediated osteoclast expression and its promoter activity in bone marrow stromal cells (BMSCs). Using solid phase binding assays as well as co-immunoprecipitation (co-IP), we show that both Bgn and Fmod directly bind TNF- α in a dose dependent manner. qPCR analysis of RNA extracted from primary osteoclast cultures derived from *Bgn*^{-/-}; *Fmod*^{-/-} DKO mice indicate increased expression of several osteoclast marker genes. Because neither Bgn nor Fmod are expressed by osteoclasts, we extracted RNA from CD45⁺ and CD11b⁻ (macrophage depleted) BMSCs and found elevated levels of TNF- α , DKK1 and RANKL in the RNA derived from *Bgn*^{-/-}; *Fmod*^{-/-} DKO mice. Additionally, increased levels of pDKK1, a NF κ B inhibitor, were found in protein isolated from *Bgn*^{-/-}; *Fmod*^{-/-} DKO BMSCs. Since soluble TNF- α can induce osteoclast differentiation and survival as well as suppress bone formation, we propose that Bgn and Fmod made by the BMSCs are novel coupling ECM components that serve to regulate osteoclast differentiation through TNF- α sequestration and therefore regulation of its bioavailability

Disclosures: Vardit Kram, None.

MO0233

TNF Promotes Osteoclastogenesis by Inducing M1 Macrophage Formation and Limits it through RelB Inhibition of NFATc1 Activity. Xiaodong Hou*¹, Zhijun Zhao², Chunyu Wang³, Xiaoxiang Yin², Yanyun Li¹, Rong Duan¹, Brendan F Boyce¹, Zhenqiang Yao¹. ¹University of Rochester, USA, ²Henan University First Affiliated Hospital, China, ³The First Hospital of Shangqiu City, China

TNF mediates osteoclast (OC) formation directly and indirectly, but it also limits OC formation by inducing expression of the inhibitory NF- κ B protein, p100. OC precursors (OCPs) are derived from cells classified as M1 (inflammatory) and M2 (resident) macrophages (Mac). However the mechanisms whereby TNF stimulates or limits OC formation, if these are through regulation of M1 and M2 differentiation, and if RelB (a partner of p100) is involved are poorly understood. We treated WT mouse bone marrow (BM) cells with M-CSF or M-CSF+TNF to enrich for OCPs, which we called M-OCPs and T-OCPs, resp. TNF inhibited RANKL-induced NFATc1 mRNA expression and OC formation from M-OCPs, but it stimulated OC formation from RANKL-treated T-OCPs. FACS showed that CD11b⁺F4/80⁺Gr1⁻Ly6C⁺ and CD11b⁺F4/80⁺Gr1⁻Ly6C⁻ cells comprised 38% & 68% of M-OCPs and 53% & 30% of T-OCPs, resp. After sorting, Gr1⁻Ly6C⁺, but not Gr1⁻Ly6C⁻, M-OCPs formed OCs in response to RANKL, while both cell types from T-OCPs formed more OCs than from M-OCPs (503 \pm 38 and 360 \pm 12 from T-OCPs vs. 125 \pm 16 and 0 from M-OCPs). Levels of M1 markers, iNOS and TNF, were 7-10-fold higher in Gr1⁻Ly6C⁺ T-OCPs than in Gr1⁻Ly6C⁻ T- and M-OCPs. TNF increased RelB mRNA and protein levels by 9- and 40-fold, while RANKL reduced RelB protein level (it also increased RelB mRNA). The proteasome inhibitor, MG-132, increased RelB protein by 7-fold in RANKL-treated M-OCPs. Importantly, in response to TNF, Gr1⁻Ly6C⁺ and Gr1⁻Ly6C⁻ cells from RelB^{-/-} BM cells comprised 24% and 54%, resp. of the CD11b⁺F4/80⁺ population vs 68% and 31% in WT cells. Overexpression of RelB in M-OCPs reduced RANKL-induced OC# (412 \pm 14 vs. 572 \pm 14 in GFP controls) and NFATc1 mRNA expression, while it increased TNF-induced OC# (412 \pm 24 vs. 17 \pm 5 GFP) without changing low NFATc1 mRNA levels. Transfection of RelB alone or with RelA or p52 reduced NFATc1 luciferase reporter activity. In summary: TNF inhibits RANKL-induced OC formation from M-CSF-primed OCPs, but promotes it from TNF-primed OCPs; TNF switches M-CSF induced Gr1⁻Ly6C⁻ to Gr1⁻Ly6C⁺ M1 Mac, which have enhanced OC forming potential; induction of RelB is required for TNF-induced Gr1⁻Ly6C⁺ M1 cell formation; RelB inhibits NFATc1 activity to inhibit OC formation and RANKL degrades RelB. We conclude that TNF induction of RelB enhances OC formation by promoting M1 Mac differentiation, which is independent of NFATc1, and blocking M1 Mac formation could be a novel strategy to limit OC formation.

MO0234

Twisted gastrulation-deficient osteoclast precursors are hypersensitive to RANKL and M-CSF due to changes in RANK and C-fms Expression. Melissa Stemig^{*1}, Raphael Huntley², Anna Petryk³, Kim Mansky², Rajaram Gopalakrishnan², Eric Jensen². ¹University of Minnesota School of Dentistry, USA, ²University of MN School of Dentistry, USA, ³University of MN School of Medicine, USA

Mice deficient for the BMP antagonist Twisted gastrulation (*Twsg1*) are osteopenic due to enhanced osteoclastogenesis mediated through increased BMP signaling. Culturing of bone marrow osteoclast precursors from *Twsg1*-deficient mice in RANKL and M-CSF is characterized by larger and increased number of osteoclasts compared to wild type mice. In the current study, we tested whether osteoclast precursors from *Twsg1*-deficient mice are hypersensitive to RANKL and M-CSF. Bone marrow derived osteoclast precursors from *Twsg1*-deficient and wild type mice were cultured with the concentration of M-CSF progressively increased while that of RANKL remained constant. In other cases, RANKL, but not M-CSF was varied. In both circumstances, the level of the invariant cytokine was below that used in our standard osteoclastogenic assays. Osteoclastogenesis was determined by TRAP staining. At all concentrations of RANKL and M-CSF osteoclasts derived from the *Twsg1*-deficient mice were both larger and had more nuclei per cell when compared to wild type cells. This increased sensitivity was more evident at lower concentrations of RANKL and M-CSF. Through immunostaining and flow cytometry, we determined that there was no difference in the proportional subpopulation of osteoclast precursors in *Twsg1*-deficient bone marrow compared to wild type mice. The hypersensitivity could be explained by the increased expression of *RANK* and *c-fms*, receptors for RANKL and M-CSF that we measured in *Twsg1*-deficient osteoclast precursors by real time RT-PCR. The transcription factors MTF and PU.1 have been shown to regulate the expression of *RANK* and *c-fms* in osteoclasts. Experiments are currently underway to determine if the increase in *RANK* and *c-fms* expression in *Twsg1*-deficient osteoclasts is due to changes in activity of MTF or PU.1. Additionally, we are performing starve/stimulate experiments with osteoclast precursors from wild type and *Twsg1*-deficient mice using either M-CSF or RANKL to determine which signaling pathway(s) are responsible for the hypersensitivity we observe in culture.

MO0235

Direct roles of osteocyte in bone mineralization and weightless-caused bone loss: beyond mechanosensors. Yuan Hui^{*1}, Rong Zhang², Yinshi Ren¹, Ying Liu¹, Jingya Wang¹, Lynda Bonewald³, Weiping Qin⁴, Jian.Q Feng². ¹Department of Biomedical Science, Texas A&M Baylor College of Dentistry, USA, ²Department of Biomedical Sciences, Texas A&M Baylor College of Dentistry, USA, ³University of Missouri-Kansas City School of Dentistry, USA, ⁴Medicine, Mount Sinai School of Medicine Researcher, James J. Peters VA Medical Center, USA

For many decades the osteocyte (Ocy) has been considered a "retired" bone builder with limited roles, such as a mechanosensor, despite its ideal anatomic location, huge cell numbers and large surfaces that are perfect for forming mineralized bone matrices. On the other hand, osteoclasts are considered to be responsible for weightless-caused bone loss, but they can't address a very basic fact: surface cells do not penetrate into the deep cortical bone. Using acid-etched and backscattered SEM, we found a close relationship between Ocy maturation and bone mineralization. The mature Ocy volume was reduced by 50% while its surface was >50% more due to increased dendrites, leading to the replacement of the decreased cell volume by minerals present in individual spheres and sheets (Fig 1). Confocal microscopy of DAPI nuclear-stained bone, labeled with calcein and alizarin red, clearly demonstrated the mineral deposition in the matrix surrounding the Ocy and at the mineralization front surrounding the Ocy canaliculi (Fig 1). To address the role of Ocy in weightless-related bone loss (induced by tail suspension for 4 weeks), we analyzed the tail-suspended long bone compared to the control using X-ray and FITC-confocal images. The tail-suspended long bone showed a minor reduction in bone thickness in radiographs but great changes of Ocy morphologies by FITC, in which Ocy lacunae appear much larger. The distribution of the Ocy is less organized, and the canaliculi are crooked and randomly oriented (Fig 2). Quantitative RT-PCR analyses in unloading bone showed: 1) an increase in osteoclast markers as observed in lactated long bone (osteolysis), with ~3 fold increase of *Trap*, ~5 fold increase of cathepsin K and ~3.5 fold increase of *Mmp13*; and 2) changes of Ocy marker, ~4 fold increase of sclerostin (Fig 2). Similar but more severe Ocy changes occurred in a rat model of spinal cord injury-induced bone loss (Fig 3). Finally, we showed demineralization by backscattered SEM images and remineralization by calcein-alizarin red stained confocal images in the same dog long bone slide (Fig 4). Collectively, these data indicate that Ocy is the key cells to maintain bone mineralization and remodeling in cortical bone, and that poorly-maintained bone remodeling due to the defective Ocy plays a key pathological role in weightless-caused bone loss. Thus, we propose that Ocy plays novel roles in bone remodeling beyond merely a simple role as mechanosensors.

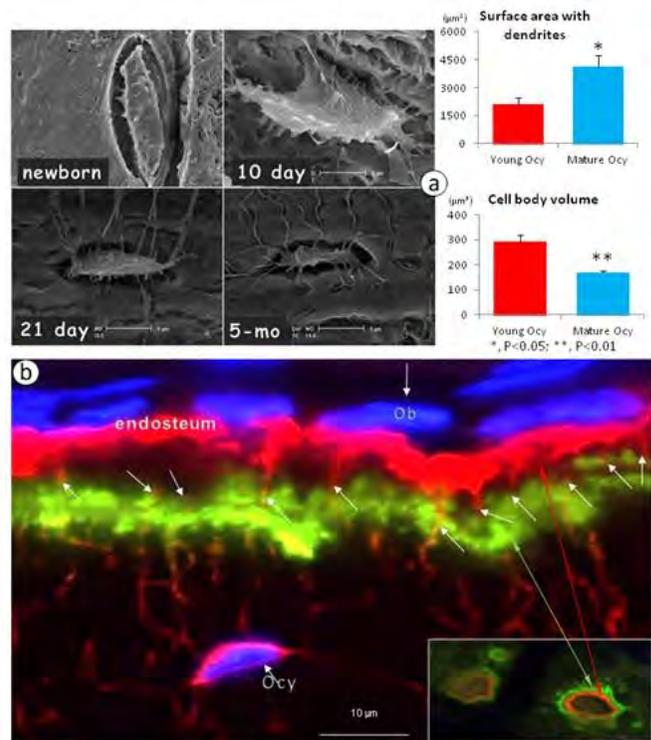

Figure 1. Bone mineralization is directly linked to osteocyte. (a). Acid-etching SEM shows mouse calvaria osteocyte maturation from newborn to 5 months of age. As it matures osteocyte volume was close to 50% reduced, but its surface was >50% increased, due to increased dendrites, leading to replacement of the decreased cell volume by well-defined mineral. (b). Double labeling + Dapi staining by confocal shows mineral deposition in the matrix surrounding the Ocy and at the mineralization front surrounding Ocy canaliculi.

Figure 1.

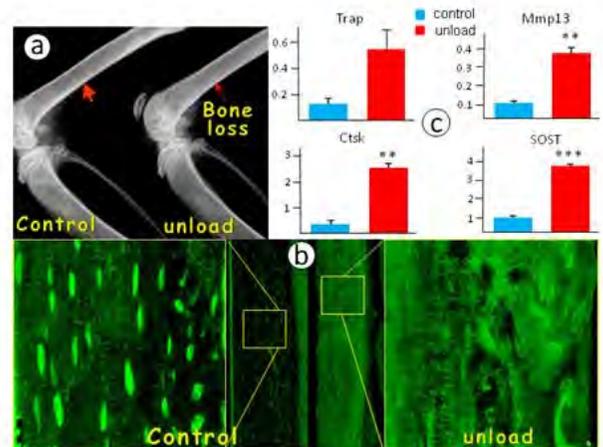

Figure 2. Unloading in mice lead to altered osteocytes morphology and increased bone resorption. (a). X-ray shows thinner cortical bone in unloaded mouse femurs. (b). FITC staining by confocal microscope reveals great changes of osteocyte morphologies, in which osteocyte lacunae appear much larger, the distribution of the osteocytes are less organized and the canaliculi are somewhat crooked and more randomly oriented. In contrast, the osteocyte lacunae in the control cortical bone appear highly organized and regularly spaced apart, generally in linear arrays. Furthermore, the canaliculi are mostly straight and run perpendicular to the long axis of the osteocyte. (c). RT-PCR quantitatively shows significantly higher expression of osteoclast markers by osteocytes like *Trap* and cathepsin K and osteocyte marker like *SOST*.

Figure 2

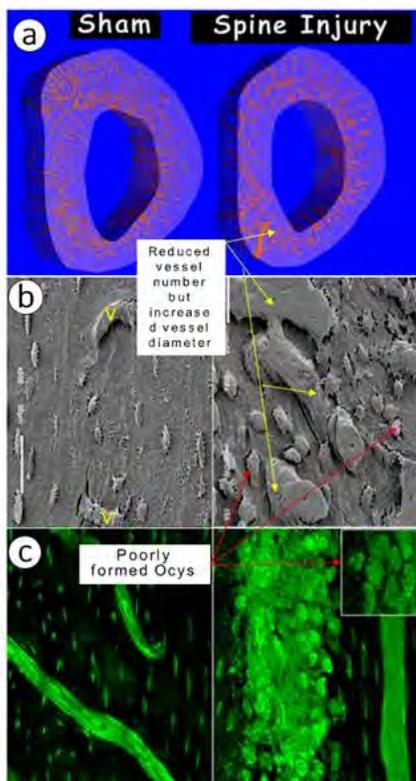

Figure 3. Unexpected changes in vessel number and size in the unloaded rat tibia caused by spinal cord injury (SCI), which is closely associated with sharp changes in osteocytes.

uCT data showed reductions in vessel (v) numbers but increases in vessel diameters, leading to a 11% reduction of vessel surface in SCI bone (Fig 3a). The acid-etched SEM (3b) and FITC (3c) images revealed severe pathological changes in osteocyte shape and organization in the SCI bone, suggesting osteocytes well-being are closely linked to bone quality.

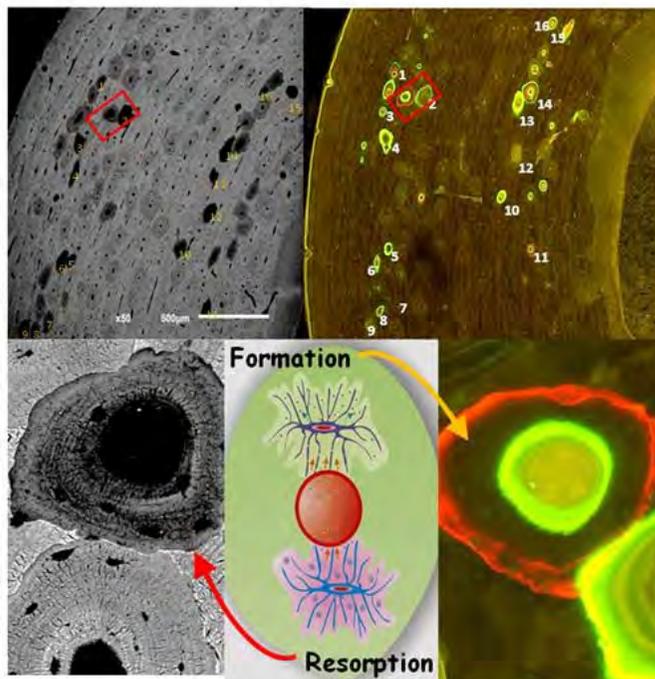

Figure 4. Demineralization by backscattered SEM images and remineralization by calcein-alizarin red stained confocal images in the same dog long bone slide. We used confocal double-labeled images to directly assess mineral deposition from Ocy's, and backscattered SEM images to define mineral resorption. Arrow showed the bone remodeling in the same osteon without cell replacement.

Figure 3.

Figure 4

Indirect Effects of Factors from Contracted Muscle on Osteoblasts via Osteocytes. Hisataka Kondo*, Ning Zhao, Matt Prideaux, Yukiko Kitase, Julian Vallejo, Sarah Dallas, Marco Brotto, Lynda Bonewald. University of Missouri Kansas City, USA

As exercise has a positive effect on both muscle and bone, we sought to determine if muscle-derived factors have an effect on osteoblasts. Extensor Digitorum Longus (EDL) and Soleus (SOL) muscles isolated from 5 month old C57Bl/6 mice were incubated in Ringer's solution alone (static) or stimulated at a frequency of 90Hz to maintain maximal force for 30 min (contracted) and the muscle conditioned medium (MCM) collected. Pre-osteoblastic MC3T3-E1 and osteoblastic IDG-SW3 (Day0) cells were treated with 10% MCM, however no effects were observed on proliferation, metabolic activity or mineralization. As we have shown previously that muscle factors have potent effects on osteocytes, we hypothesized that MCM may induce osteocytes to produce factors that affect osteoblast function. Day 28 IDG-SW3 cells that express the mature osteocyte phenotype were pretreated with 10% MCM for 24hrs and then the osteocyte conditioned media (OCM) was collected. Pretreatment of osteocytes with static EDL and SOL MCM had no significant effect on MC3T3 or IDG-SW3 (Day0) cell proliferation and metabolic activity compared to control, but contracted MCM significantly increased both proliferation and metabolic activity (ranging from 12 to a 35% increase). As both prostaglandin E2 and sclerostin are made by mature osteocytes, these were quantitated. OCM from day 28 IDG-SW3 cells pretreated with static MCM had approximately 500 pg/ml of PGE₂ which was increased 3-fold by pretreatment with contracted MCM. No PGE₂ was detected in MC3T3 and osteoblastic IDG-SW3 (Day0) cells directly treated with MCM. The effects of muscle-pretreated OCM on proliferation and metabolic activity of osteoblastic cells was inhibited by indomethacin. As PGE₂ has been reported to decrease osteocyte production of sclerostin, the effects of MCM on sclerostin levels in OCM were determined. Contracted MCM decreased Sost mRNA and sclerostin levels in day 28 osteocytic IDG-SW3 cells and this effect was also blocked by indomethacin. These results indicate that contracted muscle secretes factors that have indirect effects on osteoblasts through stimulating PGE₂ production and decreasing sclerostin in osteocytes. Osteocytes appear to be the target bone cells of muscle.

Inflammatory Bowel Disease Alters Osteocyte Protein Levels Controlling Bone Turnover. Corinne Metzger*¹, Anand Narayanan², Tatiana AzZani¹, Walter Cromer², David Zawieja², Susan Bloomfield¹. ¹Texas A&M University, USA, ²Texas A&M Health Science Center, USA

An inflammatory bowel disease (IBD) comorbidity is bone loss leading to elevated fracture risk. Chronic systemic inflammation causes increased bone resorption and decreased bone formation. Tumor necrosis factor- α (TNF- α), a pro-inflammatory cytokine, stimulates osteoclasts and inhibits osteoblasts. In addition, TNF- α is a transcriptional activator of sclerostin (Scl), the osteocyte protein inhibiting Wnt signaling. TNF- α , the receptor activator of nuclear factor κ B ligand (RANKL), and RANKL's decoy receptor osteoprotegerin (OPG) are key proteins controlling osteoclastogenesis. The RANKL:OPG ratio is altered in the serum of IBD patients. However, the *in vivo* response of these proteins in osteocytes, the primary regulators of bone, is unknown. Utilizing an IBD rat model, the goal of this study was to evaluate prevalence of TNF- α ⁺ RANKL⁺, OPG⁺, and Scl⁺ osteocytes in the cortical mid-shaft femur (cort-MSF), distal femur metaphysis (cort-DFM), and DFM cancellous bone (can-DFM) and correlate with markers of bone turnover. Male Sprague Dawley rats (2 months, n=16) were divided into two groups: IBD (induced via TNBS instillation over 4 weeks) and vehicle controls. Statistical difference was determined by p<0.05. Standard cancellous histomorphometry of the proximal tibia and 4th lumbar vertebrae revealed lower bone volume, lower bone formation rate (BFR), lower osteoid surface (OS), and higher osteoclast surface (Oc.S) in IBD. Tibia midshaft BFR was also lower in IBD. Immunohistochemical staining of the distal femur showed %TNF- α ⁺, %RANKL⁺, %OPG⁺, and %Scl⁺ osteocytes were elevated 1.4-2.2 fold in IBD can-DFM. %TNF- α ⁺, %OPG⁺ and %Scl⁺ osteocytes were elevated 1.4-1.7 fold in IBD cort-DFM. %RANKL⁺ and %Scl⁺ osteocytes were elevated 1.3-3.7 fold in IBD cort-MSF. With regression analysis, %RANKL⁺ osteocytes in can-DFM predicted the increase in cancellous Oc.S (R²=0.565). %TNF- α ⁺ osteocytes in can-DFM predicted increased %Scl⁺ (R²=0.588). %Scl⁺ predicted declines in cancellous OS (R²=0.581) as well as BFR in cancellous and cortical bone (R²=0.674, R²=0.908). In conclusion, systemic inflammation caused by IBD altered the prevalence of regulatory proteins in osteocytes that control bone resorption and bone formation contributing to IBD-induced bone loss. These data highlight the deleterious effect of systemic inflammation on bone, while providing a rationale for pharmacological and non-pharmacological treatment options to mitigate inflammatory bone loss.

MO0238

Osteocyte Conditional Deletion of Sirtuin 1 Results in Distinct Alterations in Bone Structure. Elizabeth Rendina-Ruedy*¹, Guillaume Vignaux², Nicole Fleming², Daniel Perrien³. ¹Vanderbilt University Medical Center, VA Tennessee Valley Healthcare System, USA, ²Vanderbilt University Medical Center, USA, ³VA Tennessee Valley Healthcare System, Vanderbilt University Medical Center, USA

Sirtuin1 (Sirt1) is a NAD⁺-dependent deacetylase that exists in the nucleus and cytosol to regulate many cellular functions including energy metabolism, inflammation, and aging. It has previously been reported that conditional deletion of Sirt1 in osteoblast (OB) progenitors (*Osx1-Cre*) or mature osteoblasts (*2.3kbColl1-Cre*) results in a low bone mass phenotype in female, but not male mice. Since these models also delete Sirt1 in osteocytes (OCY), it remained unclear which cell types were contributing to the overall bone phenotype. Therefore, we have characterized the targeted disruption of Sirt1 in OCY using *9.6kbDmp1-Cre:Sirt1^{fl/fl}* mice in which exon 4 of *Sirt1*, encoding the catalytic domain, is deleted rendering a functionally inactive protein (*Sirt1^{Ocy-/-}*). At 14 wks old, tibiae, femora, and vertebrae were harvested and trabecular bone microarchitecture were determined by *ex vivo* μ CT in male (n=9,6) and female (n=5) mice. Interestingly, male *Sirt1^{Ocy-/-}* mice had higher trabecular BV/TV in the proximal tibia compared to *Sirt1^{fl/fl}* mice. While the female phenotype was much more modest, several measures of trabecular structure including connectivity density, trabecular number, and trabecular separation were significantly improved in the femur and tibia of *Sirt1^{Ocy-/-}* vs. *Sirt1^{fl/fl}* mice. Trabecular number and connectivity density were also higher in the tibia, femur, and vertebra of male *Sirt1^{Ocy-/-}* mice. Despite these improvements, tissue mineral density was lower for the *Sirt1^{Ocy-/-}* mice compared to the *Sirt1^{fl/fl}* mice (femur and vertebra in males; tibia and femur in females). Together, these data define a novel role for Sirt1's catalytic activity in OCY, by demonstrating that OCY-conditional deletion of *Sirt1* results in a distinct structural bone phenotype in both genders. Furthermore, this study also suggests that the low bone mass phenotype in OB-conditional *Sirt1* deletion models is due to a distinct role in mature osteoblasts. As we continue to investigate this novel mouse model we will gain insight in to how Sirt1 functions in osteocytes to regulate bone metabolism, which could provide insight into new ways of preventing age-related bone loss.

Osteocyte-Driven Perilacunar Remodeling is Impaired in Glucocorticoid Induced Osteonecrosis. Tristan Fowler*¹, Faith Hall-Glenn¹, Aaron Fields¹, Hrishkesh Bale¹, Robert Ritchie², Thomas Vail¹, Jeffrey Lotz¹, Tamara Alliston¹. ¹University of California San Francisco, USA, ²Lawrence Berkeley National Laboratory, University of Berkeley, USA

Despite the multitude of therapeutic uses of glucocorticoids (GCs), the side effects on skeletal health can be serious, including bone fragility. The cellular mechanisms underlying GC-dependent regulation of bone mass through osteoblast, osteoclast, and osteocyte (OCY) activity have been widely recognized, however the mechanisms by which GCs compromise bone quality remain unclear. OCYs remodel matrix through a process of perilacunar remodeling (PLR), which is essential for the maintenance of bone quality. OCY-driven PLR involves acidification of the microenvironment and secretion of proteases including cathepsin K and matrix metalloproteases (MMPs). However, the extent to which PLR is involved during GC deregulation of bone quality remains unclear. Therefore, here we test the hypothesis that GCs repress the expression of PLR enzymes, which impairs the ability of OCY to maintain the lacunocanalicular network and bone matrix integrity by PLR. To test this hypothesis, we evaluated the effect of the GC dexamethasone (Dex) on PLR enzyme expression *in vivo* and *in vitro*. RNA was isolated from flushed femoral cortical bone from BALB/cJ mice following 14 days of treatment with Dex (0.1 mg/mL) or vehicle by the drinking water. GC-treatment caused a 2-fold reduction in MMP13 RNA expression, as well as a reduction of the percentage of MMP13-positive OCYs by immunohistochemistry (n>5, p<0.05). GCs also significantly repress the expression of PLR enzymes, MMP2, 13, and 14, in Dex-treated MLO-Y4 cells (1 μ M, 24h, n=4, p<0.05), even in the presence of the apoptosis inhibitor, DEVD. This suggests that GCs regulate PLR independently of apoptosis. To test the effect of GCs on PLR, functional outcomes were assessed in femora of Dex and vehicle-treated mice. Quantitative analyses of silver and picrosirius red stained histological sections showed significant GC-dependent decreases in lacunocanalicular area and collagen alignment, respectively (n=3, p<0.05). Parallel studies of normal and sclerotic bone from GC-treated patients also showed disrupted PLR with sclerosis, including deregulated MMP13 expression, disorganized collagen, hypermineralization, and reduced lacunar size as quantified by X-ray tomographic microscopy. These studies implicate MMP13 and GCs in the regulation of perilacunar bone matrix composition and organization, suggesting that deregulation of PLR may be one mechanism by which GC treatment impairs bone quality independent of apoptosis induction.

MO0240

Variation in systemic human cortical osteocyte lacunar density: relationships with intracortical porosity. Randee Hunter*¹, Amanda Agnew². ¹The Ohio State University, Us, ²The Ohio State University, USA

The objective of this study is to investigate variation in cortical osteocyte cell populations using their lacunae as a proxy. Osteocytes and their lacunocanalicular network have been identified as regulators of bone quality and function by exerting extensive influence over the remodeling process. Recent research has shown that osteocyte malfunction and apoptosis leads to a decrease in bone quality and increase in bone fragility. This study analyzes variation in osteocyte lacunar density and intracortical porosity from three skeletal sites to establish regional and systemic age and sex related trends. Bone samples were recovered from the midshaft femur, distal 1/3 diaphyseal radius, and midshaft 6th rib of 30 modern cadaveric individuals (15 males and 15 females) ranging from 49 to 100 years old. Thin ground histological (80 μ m) cross-sections were made, imaged and analyzed under bright field microscopy. Size measurements (total subperiosteal area Tt.Ar; cortical area Ct.Ar) were collected using ArcGIS for femora and ImageJ for radii and ribs. ImageJ was used to manipulate images to identify and count osteocytic lacunae (Ot.Lc.N) automatically over the entirety of the cross-section. Intracortical porosity area (Po.Ar) was measured using a semi-automatic method with extensive manual verification. Ot.Lc.N and Po.Ar were each normalized for size: osteocyte lacunar density (Ot.Lc.N/B.Ar) and Ot.Lc.N/Ct.Ar) and intracortical porosity (%Po.Ar). Independent samples t-tests indicated no significant sex differences between either variable in any element; thus analyses are performed on males, females and the pooled sample. Pearson correlations demonstrated an overall decrease in osteocyte lacunar density (Ot.Lc.N/B.Ar) and an increase in intracortical porosity (%Po.Ar) with age for each element. Intracortical porosity (%Po.Ar) was significantly negatively correlated with lacunar density (Ot.Lc.N/Ct.Ar) with varying strengths (see Figure 1). A systemic trend in the decrease in osteocyte lacunar density (Ot.Lc.N/B.Ar) with age was identified in males only between the femur and radius (p=0.029) but no relationship between the rib and radius, or rib and femur. These results indicate that although all elements are experiencing systemically influenced declines in osteocyte lacunar density with measurable effects on remodeling, there appears to be a differential effect at each anatomical site.

Activation of AMP-activated Protein Kinase Protects Against Homocysteine-Induced Apoptosis of Osteocytic MLO-Y4 Cells by Regulating the Expressions of NADPH oxidase 1 (Nox1) and Nox2. Ayumu Takeno*, Ippei Kanazawa, Ken-ichiro Tanaka, Masakazu Notsu, Maki Yokomoto, Toru Yamaguchi, Toshitsugu Sugimoto. Internal Medicine 1, Shimane University Faculty of Medicine, Japan

Background and aims: Elevated plasma homocysteine (Hcy) level is associated with the risk of osteoporotic fracture. Hcy is a potent pro-oxidant, and it has been reported that Hcy induces apoptosis of marrow stromal cells via increasing oxidative stress. On the other hand, AMP-activated protein kinase (AMPK), which plays a pivotal role as an intracellular energy sensor, ameliorates oxidative stress in various cells. However, to our best knowledge, no study has described the effects of Hcy and AMPK on osteocytes. Thus, the aim of our study was to examine the effects of Hcy and AMPK activators on the apoptosis of osteocytic MLO-Y4 cells and on the expressions of oxidant and antioxidant enzymes such as NADPH oxidase (Nox) and superoxide dismutase (SOD) in the cells. Materials and methods: We used MLO-Y4, a murine long bone-derived osteocytic cell line. DNA fragment ELISA assay and TUNEL staining were performed to evaluate apoptosis. To investigate the mRNA expression of AMPK subunits ($\alpha 1$, $\alpha 2$, $\alpha 1$, $\alpha 2$, $r 1$, $r 2$, and $r 3$) in MLO-Y4 cells, we performed reverse transcription (RT) PCR. To examine the expressions of Nox and SOD, quantitative real-time PCR and Western blot were performed. Results: DNA fragment ELISA and TUNEL staining assays showed that Hcy treatments (0.1–5.0 mM) induced apoptosis of MLO-Y4 cells in a dose-dependent manner. The detrimental effect of Hcy was partly but significantly reversed by an antioxidant (N-acetylcysteine) and Nox inhibitors (apocynin and diphenyleneiodonium). In addition, treatment with AICAR (0.05–0.1 mM) and metformin (10–100 μ M) ameliorated Hcy-induced apoptosis of the cells. The favorable effect of metformin on Hcy-induced apoptosis was completely cancelled by an AMPK inhibitor Ara-A. Hcy increased the expression levels of Nox1 and Nox2, while it had no effects on the expressions of Nox4, SOD1 or SOD2. Hcy-induced increases in the expressions of Nox1 and Nox2 were significantly decreased by treatments with AICAR. Conclusion: These findings suggest that Hcy induces apoptosis of osteocytes by increasing the expressions of Nox1 and Nox2, and that AMPK activation by AICAR and metformin effectively prevents the detrimental reactions. Thus, AMPK activation may be a potent therapeutic candidate for preventing Hcy-induced osteocyte apoptosis and the resulting bone fragility.

The transmembrane glycoprotein E11 is recognized to be critical for early osteocyte commitment. However, its precise role in osteoblast-osteocyte transition (osteocytogenesis) has yet to be established. Here we have explored the regulation and function of E11 expression during osteocytogenesis and bone formation. We have also examined whether these processes are compromised in osteoarthritis (OA) in which abnormal subchondral bone remodelling is observed. Increased expression of E11 protein/mRNA ($P < 0.001$) in MLO-A5 osteoblasts was concomitant with extensive osteocyte dendrite formation and matrix mineralization ($P < 0.001$). Over-expression of E11 exhibited significantly increased mRNA expression ($P < 0.001$) but no changes in protein levels, suggestive of post-translational regulation. Treatment of MLO-A5 cells and osteocytic IDG-SW3 cells with the proteasome inhibitor ALLN induced E11 protein expression and a profound increase in stellate cell morphology (50%, $P < 0.001$). MG132, lactacystin, Bortezomib, and Withaferin-A produced similar dose-dependent increases in E11 protein expression that was also observed in primary osteoblasts. These data implicate proteasome degradation in controlling post-translational E11 expression. We generated mice harbouring a conditional deletion of E11 in late osteoblasts (osteocalcin promoter driven) (*Oc-cre;E11^{fl/fl}*) and analysed its bone phenotype through histology, micro-CT scanning and 3-point bending. Immunohistochemistry and western blotting revealed selective deletion of E11 in *Oc-cre;E11^{fl/fl}* mice, whereas sclerostin expression and localization to osteocytes were normal. MicroCT analyses of 6-week old *Oc-cre;E11^{fl/fl}* mice revealed that cortical and trabecular parameters were normal. Similarly, 3-point bending revealed no significant differences in biomechanical properties at this age. To assess whether E11 dysregulation contributes to OA pathology, we performed immunohistochemistry on joint sections from a natural model of OA, the STR/Ort mouse, and human OA patients. Both revealed decreased E11 protein expression in subchondral bone osteocytes in regions of the joint where OA pathology was observed. Together these data suggest that proteasome-mediated E11 protein degradation limits acquisition of the osteocyte phenotype and that its deregulation may contribute to bone changes observed in OA. The function of E11 in normal bone formation remains, however, elusive.

Calcitonin modulates the osteocyte S1P signalling pathway and sclerostin expression. Jonathan Gooi*. The University of Melbourne, Australia

Calcitonin (CT) is widely known for its pharmacological role in inhibiting osteoclast bone resorption. Surprisingly however, recent studies utilizing genetically modified mice have suggested a role for CT as an inhibitor of bone formation. Recently, we demonstrated a potential mechanism by which CT could modulate bone formation, with CT treatment significantly increasing sclerostin expression in bone. More recently, it has been suggested that CT controls bone formation by inhibiting the release of sphingosine 1-phosphate (S1P) from osteoclasts. As we have previously reported freshly isolated osteocytes express calcitonin receptor (CTR) mRNA, raising the question of what is the action of CT treatment on osteocyte S1P and sclerostin signaling expression.

To resolve this question we used the Ocy454 cells, a novel murine osteocytic cell line. We have previously reported CTR and sclerostin expression are both lost in long-term cultures of osteocytes. Therefore it was necessary to ensure CTR expression in Ocy454 cells. Here, we report that CTR is expressed in Ocy454 cells and increases throughout differentiation. Furthermore, *Spk1* and *Spk2* mRNA, the two genes required for intracellular S1P production, *Spns2*, the transmembrane exporter protein necessary for the secretion of S1P, and the five receptors for S1P, *S1pr1-5* are expressed at high levels in osteocytes and increase in expression throughout osteocyte differentiation.

Treatment of differentiated (14 days) Ocy454 cells with salmon CT (10nM) for 3 hours significantly increased *Sphk1* (1.4 fold, $P < 0.01$) and *Spns2* (1.5 fold, $P < 0.05$) mRNA. In addition, *Sost* mRNA levels were increased (6.5 fold, $P < 0.01$) in Ocy454 cells.

Taken together, these results demonstrate that CT has significant and contrasting effects on S1P and sclerostin production. It is expected that the increased production of S1P promotes bone formation while conversely; increased sclerostin production promotes inhibition of bone formation. However it seems most likely that the dominant of CT treatment in osteocytes is promoting bone formation based on the increased level of expression of S1P related genes. This has profound implications for CT and osteocyte biology given the predominance of osteocytes throughout the human skeleton.

Further studies are ongoing to determine the mechanism of action by which CT modulates S1P and sclerostin signaling, and to determine the dominant effect of CT treatment on bone formation.

Validation of a novel *in vitro* 3D mineral-collagen model for the study of osteocyte biology. Maxime Gallant^{*1}, Brian Golz¹, Haisheng Yang¹, Jesus Delgado-Calle², Teresita Bellido², Sherry L. Voytik-Harbin¹, Russell P. Main¹. ¹Purdue University, USA, ²Indiana University School of Medicine, USA

In vitro studies of bone cell response to environmental stimuli have traditionally used 2D culture models. However, bone cells, particularly osteocytes, exist in a mineral-collagen matrix *in vivo* and form a 3D syncytium with neighboring cells. The objective of this study is to develop a 3D mineral-collagen tissue culture model to study the influence of physical or pharmacological stimuli on primary osteocytes.

Gt(ROSA)26Sor^{tm4}(ACTB-tdTomato,-EGFP)^{Luo}/J mice (RO/RO) were crossed with DMP1-8kb-Cre mice (Cre^{-/-}). In Cre^{-/-}; RO/RO offspring, all cells express membrane-tdTomato protein except in osteocytes where Cre expression prevents tdTomato expression and induces membrane-eGFP. Osteoblast-enriched cell samples were extracted from long bones of 4-6 wk/old male and female Cre^{-/-}; RO/RO mice using collagenase and EDTA digestion. Isolated cells were cultured for 14 days, and seeded in a 3D matrix prepared from type-I collagen oligomers (2.5 mg/ml) and hydroxyapatite (27 mg/ml) in osteogenic media for up to 28 days. 3D cultures were processed at 14d and 28d to assess gene expression by qPCR and at 3d and 28d to quantitate cell differentiation using confocal microscopy. By confocal microscopy, osteoblast differentiation to osteocytes was quantified by determining the proportion of red (tdTomato = osteoblast), green (eGFP = osteocyte), and yellow cells (co-expression = early osteocyte).

Expression of the osteoblast marker gene *alkaline phosphatase* was reduced 16-fold in 28d cultures compared to 14d cultures and native cortical bone. *El1gp38*, an early marker for osteocyte differentiation, was increased 3-fold in the 14d and 28d cultures compared to native bone samples. Consistent with these gene-level data, we measured a reduction in the proportion of red cells in the 3D cultures from 3d to 28d (-18%) and an increase in both green and yellow cells (+5% and +13%). Taken together, the gene-level and cell fluorescence data indicate differentiation of the primary cells seeded in the 3D cultures from osteoblasts (red) to mature osteoblast/early osteocyte (yellow) to osteocytes (green). Our approach combines a mineral-collagen 3D matrix and cells from a novel genetic reporter mouse model for longitudinal assessment of osteocyte differentiation in 3D culture. Future work with this model will use bone cells from novel transgenic mice to examine the independent and interactive effects of fluid flow-induced shear stress and pharmacological treatments on osteocyte biology.

High Bone Turnover is Associated with Hypocalcemia Induced by Denosumab in Women with Postmenopausal Osteoporosis. Koji Ishikawa^{*1}, Takashi Nagai¹, Kenji Ohara², Katsunori Inagaki¹. ¹Showa University School of Medicine, Japan, ²Department of Orthopaedic Surgery, Yamanashi Red Cross Hospital, Japan

Background: Hypocalcemia has been reported as the most common adverse events in patients with osteoporosis receiving denosumab. While close monitoring of calcium concentration is recommended in patients with kidney dysfunction, limited information is available on the risk factor for hypocalcemia. Accordingly, the aim of the present study was to identify the risk factors for hypocalcemia induced by denosumab for osteoporosis.

Methods: We retrospectively reviewed the records of patients who had received initial denosumab with supplementation of activated vitamin-D for osteoporosis at Yamanashi Red Cross Hospital between November 2014 and March 2015. Serum levels of the following bone metabolic markers were measured at baseline: BAP, total-PINP, TRACP-5b, urinary-NTX. Patients with hypocalcemia at baseline, kidney failure requiring hemodialysis, relatively severe hyperparathyroidism were excluded.

Results: Sixty-three patients were analyzed and sixteen patients (25.4 %) had hypocalcemia [corrected Ca levels <8.7 mg/dl, median (IQR): 8.4 (8.3-8.5) mg/dl] after administration of denosumab. All patients experienced hypocalcemia were asymptomatic, grade1 (CTCAG grade), and required daily oral calcium treatment (≥ 1000 mg). As shown in Figure1, levels of the bone metabolic markers at baseline were significantly different between patients without and those with hypocalcemia (BAP, total-PINP, TRACP-5b: all $P < 0.01$, u-NTX: $P < 0.05$). A positive correlation was observed between baseline bone metabolic marker levels and the reductions in calcium levels from baseline (BAP, total-PINP, TRACP-5b: $r=0.34-0.61$, all $P < 0.01$, u-NTX: $r=0.26$, $P < 0.05$). Multivariate logistic regression analysis revealed that the patients who had high level of TRACP-5b at baseline had a higher risk of hypocalcemia after denosumab treatment (OR = 9.64, CI = 1.75-53.11, $P < 0.01$, adjusted for baseline serum Ca levels, eGFR). Other bone metabolic markers showed the similar analysis as well.

Conclusion: Our reports suggest that higher baseline bone turnover sustaining serum calcium levels in patients with postmenopausal osteoporosis, inhibition by denosumab may have a greater impact on serum calcium levels. Routine measurement of bone metabolic markers before denosumab administration, is useful to identify the patients who have the risk of hypocalcemia. Furthermore, close monitoring of serum calcium levels is strongly recommended, especially those with high bone turnover.

MicroRNAs miR-29b-3p, miR-365a-3p, miR-550a-3p are correlated to histomorphometry and bone turnover markers in idiopathic osteoporosis.

Roland Kocijan^{*1}, Christian Muschitz², Astrid Fahrleitner-Pammer³, Rainer Dormann², Fabian Plachel², Susanna Skalicky⁴, Elisabeth Geiger⁴, Heinrich Resch², Heinz Redl⁵, Patrick Heimel², Johannes Grillari⁶, Matthias Hackl⁴. ¹St. Vincent Hospital Vienna, Austria, ²St. Vincent Hospital – Medical Department II, The VINFORCE Study Group, Academic Teaching Hospital of Medical University of Vienna, Austria, ³Department of Internal Medicine, Division of Endocrinology & Metabolism, Medical University of Graz, Austria, ⁴TAmiRNA GmbH, Muthgasse 18, 1190 Vienna, Austria, ⁵Ludwig Boltzmann Institute for Experimental & Clinical Traumatology Donaueschingenstraße 13, 1200 Vienna, Austria, ⁶Department of Biotechnology, University of Natural Resources & Life Sciences Vienna, Austria

Purpose: MicroRNAs (miRNAs) are small non-coding RNAs that are involved in several biological processes including osteogenesis, bone formation and resorption as well as bone homeostasis. Eighteen miRNAs discriminating pre- and postmenopausal women as well as male patients with idiopathic osteoporosis and low-traumatic fractures have been recently identified. Based on these findings, we tested the correlation between bone specific circulating miRNAs and bone histomorphometry as well as bone turnover markers (BTM).

Methods: Transiliacal bone biopsies were performed in 35 patients (46.6 ± 13.0 years) with idiopathic osteoporosis and low-traumatic fractures to assess bone histomorphometry (BV/TV, BS/BV, OS/BS, ES/BS, QS/BS, Tb.N, Tb.Th, MS/BS, MAR, BFR/BS). Time to last fracture was at least 6 months. Secondary causes for osteoporosis were excluded by careful clinical examination. BTM including iPTH, 25(OH)vitamin D, BALp, osteocalcin, PINP, OPG, RANKL, TRAP5b, CTX were analyzed. MiRNAs were measured by RT-qPCR.

Results: Bone specific miRNAs did not differ between pre-menopausal women, postmenopausal women and men, respectively. MiRNAs did not show any correlation to age. Three miRNAs which were up-regulated in patients with low-traumatic fractures were identified to be associated to histomorphometric parameters and bone turnover markers: miR-29b-3p was significantly correlated to PINP ($r=0.400$, $p=0.021$), RANKL ($r=0.421$, $p=0.021$), CTX ($r=0.415$, $p=0.013$) and by trend to TRAP5b ($r=0.311$, $p=0.078$). Significant correlations were found for miR-29-3p and MAR ($r=0.740$, $p < 0.001$) and BFR/BS ($r=0.536$, $p=0.022$). miR-365-3p was associated to PINP ($r=0.491$, $p=0.004$), osteocalcin ($r=0.368$, $p=0.030$), CTX ($r=0.337$, $p=0.048$), TRAP5b ($r=0.346$, $p=0.049$) and Tb.N ($r=-0.389$, $p=0.037$). No correlations were found between miR-550a-3p and BTMs. However, miR-550a-3p was negatively associated to BV/TV ($r=-0.435$, $p=0.018$) and Tb.Th ($r=-0.429$, $p=0.020$) and positively to BS/BV ($r=0.432$, $p=0.019$) and MAR ($r=0.535$, $p=0.018$). No significant correlations were found between histomorphometry data, BTM and the remaining 15 miRNAs.

Conclusion: This is the first study reporting correlations between miRNAs, BTMs and histomorphometry. Serum levels of miR-29b-3p and miR-365-3p, which

are well-known modulators of bone turnover in vitro, are associated to BTMs in patients with idiopathic osteoporosis.

Disclosures: Roland Kocijan, None.

Plasma periostin associates significantly with non-vertebral but not vertebral fracture in postmenopausal women: clinical evidence for the different effect of periostin depending on the skeletal site. Beom-Jun Kim^{*1}, Yumie Rhee², Chong Hwa Kim³, Ki Hyun Baek⁴, Yong-Ki Min⁵, Deog-Yoon Kim⁶, Seong Hee Ahn⁷, Hyeonmok Kim⁷, Seung Hun Lee⁷, Moo-Il Kang⁴, Jung-Min Koh⁷. ¹Asan Medical Center, South Korea, ²Department of Internal Medicine, Severance Hospital, Endocrine Research Institute, Yonsei University College of Medicine, South Korea, ³Department of Internal Medicine, Sejong General Hospital, South Korea, ⁴Division of Endocrinology & Metabolism, Department of Internal Medicine, Seoul St. Mary's Hospital, The Catholic University of Korea College of Medicine, South Korea, ⁵Division of Endocrinology & Metabolism, Department of Internal Medicine, Sungkyunkwan University School of Medicine, South Korea, ⁶Department of Nuclear Medicine, Kyunghee University School of Medicine, South Korea, ⁷Division of Endocrinology & Metabolism, Asan Medical Center, University of Ulsan College of Medicine, South Korea

Context: Periostin is preferentially expressed by the periosteum, which mainly covers the long bones. Therefore, the role of periostin in osteoporotic fracture (OF) may differ depending on bone type. **Objective:** To investigate whether periostin can serve as a predictor of OF risk, especially after dividing OFs into non-vertebral and vertebral fractures. **Design and Setting:** A case-control study conducted in a clinical unit in Korea. **Participants and Main Outcome Measures:** 133 cases having any kind of OF (i.e., non-vertebral and/or vertebral fractures) and age- and body mass index-matched 133 controls were enrolled among 532 consecutive postmenopausal women. Non-vertebral (i.e., wrist, forearm, humerus, hip, and pelvis) and morphological vertebral fractures were identified by an interviewer-assisted questionnaire and lateral thoracolumbar radiographs, respectively. Bone mineral density (BMD) and plasma periostin levels were also measured. **Results:** Plasma periostin was markedly higher in subjects with non-vertebral fracture than in those without this condition even after adjustment for BMD and potential confounders ($P = 0.023$). The odds for non-vertebral fracture were 2.33-fold higher in subjects in the highest periostin quartile compared with those in the lowest periostin quartile (95% CI = 1.06–5.10). However, associations between plasma periostin and vertebral fracture were not observed, regardless of adjustment. Consistently, plasma periostin levels associated inversely with proximal femur BMD ($P = 0.007$ to 0.030) but did not associate with lumbar spine BMD. **Conclusions:** Plasma periostin may be a potential biomarker of the risk of OF, especially in non-spinal skeletal sites, such as the limbs, rather than spine.

Disclosures: Beom-Jun Kim, None.

MO0248

Serial measurement of BMD and bone turnover to detect a treatment response to zoledronic acid: The HORIZON-PFT Trial. Katy J.L. Bell¹, Stephanie Harrison², Paul Glasziou³, Andrew Haven⁴, Les Irwig⁵, Richard Eastell⁶, Dennis M. Black², Douglas Bauer^{*2}. ¹University of Sydney & Bond University, Australia, ²University of California, San Francisco, USA, ³Bond University, Australia, ⁴University of New South Wales, Australia, ⁵University of Sydney, Australia, ⁶University of Sheffield, United Kingdom

Introduction: Bisphosphonate (BP) therapy is often monitored with serial BMD or bone turnover markers (BTMs) to estimate treatment response and adherence. Zoledronic acid (ZOL) is given intravenously once a year, and unlike oral BPs, adherence is known. Differences in the observed effects of ZOL between women are a result of both signal (true differences in response which contribute to variance of the ZOL group) and noise (background random variation due to within-person measurement variability which is reflected in the variance of the placebo group). We were interested in the 'detectability of response' which can be assessed by the ratio of signal (true treatment effects) to noise (random variation).

Methods: We analysed data from the Health Outcomes and Reduced Incidence with Zoledronic Acid Once Yearly Pivotal Fracture Trial (HORIZON-PFT), which compared the effects of 5mg once yearly infusions of ZOL with placebo in 7765 postmenopausal women with osteoporosis, to compare the detectability of response to treatment with the following monitoring tests: hip and spine BMD, serum N-terminal propeptide of type I collagen (PINP, Roche Elecsys) and C-telopeptide of type I collagen (sCTX, Roche Elecsys). The mean and between-person variation in treatment effects (signal) as well as background within-person variation (noise) were estimated by comparing the distributions of change in each monitoring test from baseline to 1 year (BMD and PINP) or 6 months (sCTX) in the ZOL and placebo groups.

Results: Data were available for 7056 women with hip BMD, 520 with spine BMD, 258 with serum PINP, and 484 women with sCTX. Although there was a (placebo adjusted) treatment effect on the mean change for all BMD sites and BTMs (Table), this was larger than random within-person variation only for sCTX

[(treatment - placebo mean)/placebo SD = 2.56]. A treatment effect on the variance was only seen with sCTX [(treatment - placebo variance)/placebo variance = 1.08]. This implies that (i) detection of the expected ZOL effect in an individual is most likely using sCTX, and (ii) between-women differences in treatment effects are negligible on all markers except sCTX where the between-women differences in treatment effect appear to be at least as big as the random within-person differences.

Conclusion: Among the BMD sites, BTMs and time periods we examined, change in sCTX at 6 months appears the most able to detect an individual's true response to ZOL treatment.

| Treatment group | Statistical measure | Hip BMD (g/cm ² , n=7056) [% change from baseline] | Spine BMD (g/cm ² , n=520) [% change from baseline] | PINP (log ng/mL, n=258) [% change from baseline] | sCTX (log ng/mL, n=484) [% change from baseline] |
|-----------------|---------------------|--|---|---|---|
| Placebo | Mean | 0.0014 [0.02%] | 0.0066 [0.8%] | 0.65 [5%] | -0.15 [1.4%] |
| | SD | 0.25 | 0.30 | 0.67 | 0.45 |
| Zoledronic acid | Mean | 0.018 | 0.035 | -0.57 [43%] | -1.30 [73%] |
| | Unadjusted | 0.018 [2.8%] | 0.029 [3.6%] | -0.62 [46%] | -1.15 [68%] |
| | Placebo-adjusted | 0.018 [2.8%] | 0.029 [3.6%] | -0.62 [46%] | -1.15 [68%] |

Microindentation Assessed Bone Material Strength is Associated with Areal BMD but not with Prevalent Fractures in Older Women. ROBERT RUDANG¹, MICHAEL ZOULAKIS^{*2}, ANNA DARELID², DANIEL SUNDH², DAN MELLSTROM², MATTIAS LORENTZON², LISA JOHANSSON². ¹INSTITUTE OF MEDICINE, SAHLGRENKA ACADEMY, Sweden, ²GERIATRIC MEDICINE, INSTITUTE OF MEDICINE, SAHLGRENKA ACADEMY, Sweden

Reference point indentation is a novel method for assessment of bone material strength (BMS) in vivo, where a probe is used to make microindentations in the bone surface of the midtibia. The aim of this study was to investigate the associations between BMS and areal bone mineral density (aBMD) and prevalent fractures in older women.

A total of 211 women with the mean age of 78.3 ± 1.1 yrs (range 75.1-80.7) were included in this cross-sectional, population-based study.

BMS was assessed by four operators using the Osteoprobe® (Active Life Scientific, USA), and calculated as the mean of at least 11 reference point indentations performed at the midtibia of the non-dominant leg on each subject. The coefficient of variation for the method was 3.2%, calculated by duplicate measurements performed on 30 study subjects. Areal BMD of the hip, spine and non-dominant radius was assessed by Dual-photon X-ray Absorptiometry (DXA, Discovery A, Hologic). Fracture history was retrieved by a standardized questionnaire, and vertebral fractures were identified using VFA (vertebral fracture assessment) by DXA, where fractures were graded mild, moderate or severe due to the semi-quantitative method of Genant.

A total of 198 previous fractures in 109 subjects were reported. By means of VFA, a total of 106 subjects with vertebral fractures were found, of which 58 subjects had moderate or severe fractures and 42 multiple fractures. Using Pearson correlation we found no correlations between BMS and any of the aBMD measurements, but there was an inverse correlation with weight ($r = -0.14$, $p = 0.04$) and BMS differed according to operator (Anova $p < 0.01$). Adjusting for weight and operator in a linear regression model we found that BMS was positively associated with aBMD of the total hip ($\beta = 0.14$, $p = 0.04$), non-dominant radius ($\beta = 0.17$, $p = 0.02$) and lumbar spine ($\beta = 0.14$, $p < 0.05$). Using independent samples T-test we found no differences in crude or weight- and operator-adjusted BMS between subjects with reported fractures and subjects with no reported fractures (Table 1). Neither could we detect any differences in BMS between subjects with VFA-verified vertebral fractures and non-fractured subjects (Table 1).

We conclude that microindentation assessed BMS is associated with aBMD in a population-based material of 211 older women. In contrast to previous studies we could not demonstrate any associations between reported prevalent fractures of any kind or VFA-verified vertebral fractures and BMS.

Table 1. BMS and prevalent fracture in older women

| Fracture category | BMS | | p ¹ | p ² |
|---|------------|-------------|----------------|----------------|
| | Fracture | No Fracture | | |
| All fractures (n=109) vs. Never fracture (n=102) | 74.9 ± 6.9 | 76.4 ± 8.2 | 0.18 | 0.39 |
| All fractures after age 50 (n=86) vs. Never fracture (n=102) | 75.4 ± 7.2 | 76.4 ± 8.2 | 0.39 | 0.65 |
| Peripheral fractures after age 50 (n=53) vs. Never fracture (n=102) | 75.5 ± 7.0 | 76.4 ± 8.2 | 0.49 | 0.73 |
| Wrist fractures after age 50 (n=40) vs. Never fracture (n=102) | 75.0 ± 7.3 | 76.4 ± 8.2 | 0.35 | 0.84 |
| Osteoporotic fractures after age 50 (n=53) vs. Never fracture (n=102) | 75.8 ± 7.1 | 76.4 ± 8.2 | 0.69 | 0.94 |
| VFA-verified vertebral fractures (n=106) vs. Never fracture (n=55) | 75.3 ± 7.6 | 75.8 ± 8.4 | 0.71 | 0.87 |
| VFA-verified moderate and severe vertebral fractures (n=58) vs. Never fracture (n=55) | 77.1 ± 7.5 | 75.8 ± 8.4 | 0.37 | 0.33 |
| Multiple VFA-verified vertebral fractures (n=42) vs. Never fracture (n=55) | 76.5 ± 7.5 | 75.8 ± 8.4 | 0.65 | 0.55 |
| VFA-verified vertebral fractures and all fractures (n=156) vs. Never fracture (n=55) | 75.6 ± 7.3 | 75.8 ± 8.4 | 0.88 | 0.96 |

Osteocalcin detection in human bone extracts by antibody microarray. Corinne Thomas^{*1}, Thao Nguyen², Timothy P. Cleland², Pankaj Karande², Deepak Vashishth². ¹Rensselaer Polytechnic Institute, USA, ²Rensselaer Polytechnic University, USA

Introduction: Osteoporosis is the most common human bone disease, characterized by the increased susceptibility of bone to fracture [1]. Osteoporosis is currently assessed using bone mineral density (BMD); however, recent studies have found normal or high BMD in bones with increased risk of fracture [2-4]. This may be explained by the bone matrix quality, including the concentrations of non-collagenous bone proteins. One of these proteins, osteocalcin, has been shown to contribute to bone structure and enhances the ability of bone to resist fracture through a more effective dissipation of energy [5]. The amount of osteocalcin found in bone has been shown to correlate to fracture properties of bone or clinical fracture [6,7].

The aim of this project is to develop and validate a new high throughput chip ELISA assay to characterize the osteocalcin content of bone as it changes with age and health.

Methods: We developed a high throughput ELISA Chip and optimized various parameters such as antibody concentration and slide type to measure the osteocalcin content of bone at physiological levels. We used the chip to test human cadaveric bone protein extracts from donors over a wide range of ages and from different locations along the same bone surface. We then evaluated these results against commercially available human osteocalcin ELISA.

Results: The chip yields measurable concentrations of osteocalcin from human bone samples as small as 0.4 mg. Measurements taken from multiple locations on the same donor bone establish the consistency of the measurements taken by the chip, and demonstrate the efficacy of chip as a diagnostic tool. The chip offers distinct advantages to current commercial methods as it uses a very small volume of sample for each measurement, is able to perform more measurements per run, and is easily expanded to test multiple antibodies against each sample.

TBS is lower in African American than in Caucasian American women referred for bone density testing. Tamara Vokes^{*1}, Disha Kumar², Rajesh Jain², Hans Didier³. ¹University of Chicago, USA, ²University of Chicago Medicine, USA, ³Lausanne University Hospital, Switzerland

Background: African Americans (AA) have lower fracture rates compared to Caucasians (CA) and this difference is only partly explained by the higher BMD in AA. We wanted to determine whether AA also have higher TBS (stronger bone) than CA.

Methods: In 893 women age 40 and over (48% AA) who were referred for bone densitometry as a part of their routine clinical care, we assessed the BMD, TBS and presence of vertebral fractures (VFX) on VFA using Prodigy. VFX (grade 2 or higher) were present in 18% of CA and 16% of AA women (p=0.4).

Results: AA women were older (69 vs. 64 years, p<0.0001), heavier (74 vs. 68 kg, p<0.0001), and had higher BMI (29 vs. 26, p=0.0001), and BMD T-scores at all skeletal sites (lowest of hip and spine T-score (low T) -1.9 vs. -2.4, p<0.0001). TBS

was lower in AA (1.24 vs. 1.28, p=0.0001), a difference of 0.25 standard deviations (SD). When controlling for age, BMI, and spine BMD, TBS was lower in AA than in CA women by 0.33 SD (p<0.001). Among CA women, TBS was lower in women with compared to those without VFX (1.20 vs. 1.29, p<0.0001). Among AA women the difference was smaller and less significant (1.21 vs. 1.25, p=0.05). In a multivariate model that included the known predictors of VFX, TBS was significantly associated with VFX in CA but not in AA women (table).

Conclusion: TBS is lower in AA than in CA women, at least among those referred for BMD testing as a part of their clinical care. The predictors of fragility may also differ between races: the association between prevalent VFX with BMD and with TBS is less significant while the use of glucocorticoids is more significant in AA.

Limitation: when studying densitometry population there may be a selection bias if clinicians refer AA women for BMD testing if they suspect high fragility and CA women as a matter of routine testing.

Implications: if confirmed, our results suggest that 1. TBS may need to be used differently in different races; and 2. Greater bone strength in AA may be due to cortical rather than trabecular compartment.

Table: Association of prevalent vertebral fractures with TBS and other predictors (multivariate logistic regression)

| Predictor | CA women | | AA women | |
|-----------------------------|------------|---------|------------|---------|
| | Odds ratio | p-value | Odds ratio | p-value |
| TBS/1 SD decrease | 1.50 | 0.011 | 1.11 | 0.49 |
| Age/decade increase | 2.05 | <0.001 | 1.70 | <0.001 |
| Low T/1 unit decrease | 1.61 | 0.004 | 1.30 | 0.057 |
| Glucocorticoid (yes vs. no) | 1.96 | 0.046 | 2.34 | 0.010 |

MO0252

Trabecular bone score improves identification of major osteoporotic and vertebral fractures in Polish postmenopausal women with non-osteoporotic BMD. Magdalena Ignaszak-Szczepaniak^{*1}, Michal Michalak². ¹Poznan University of Medical Science, Poland, ²Department of Computer Science & Statistics, University of Medical Sciences, Poznan, Poland, Poland

Many osteoporotic fractures (OP Fx) occur in patients with BMD outside the WHO-based definition of osteoporosis.

The aim of the study was to assess whether TBS can differentiate osteopenic and normal BMD women with prevalent major and vertebral osteoporotic fractures from those without fractures and to estimate how TBS can improve assessment of fracture risk in these patients.

Material and methods: Retrospective, case-control study on 439 female patients of Osteoporosis Specialty Outpatient Clinic over 50 years. Fracture status was reviewed in medical record and vertebral fractures (VFs) were identified by VFA for each subject. Spine DXA images were evaluated for all subjects (GE-Lunar Prodigy) and then reanalyzed using TBS iNsight version 2.1 (Med-Imaps). Further analysis considered only women with T-scores >-2.5SD, who were compared depending on TBS tertiles and fracture status (separately for major OP Fx and VFs). Statistical analysis was performed using Statistica 10 (StatSoft Inc).

Results: In 218 osteopenic and normal BMD women (mean age 71.7±7.4 y) we identified 72 prevalent major OP Fx and 43 VFs Genant grade 2/3, which are respectively 40% and 38% of all OP Fx observed in whole studied group. Mean TBS in major OP Fx was 1.13 vs 1.20 for non-fractured (p<0.001) and in VFs 1.08 vs 1.19 in women without VFs (p<0.001). 66% of major OP Fx was detected in the lowest (1st) TBS tertile and only 7% were over the highest (3rd) tertile. In group with VFs 81% had TBS <1.200 and only 1 woman had TBS >1.350. The difference was significant. In normal BMD patients 5 VFs were detected in 1st TBS tertile and no one with TBS>1.350 sustained vertebral fracture. Comparing only osteopenic women with and without major OP Fx depending on TBS thresholds, ORs were respectively: 3.3 for 1st vs 3rd tertile (p=0.02) and 2.34 for 1st vs 2nd tertile (p=0.02). Moreover osteopenic subjects whose TBS was in 1st tertile had 10.1 higher risk of VFs as compared to 3rd tertile (p=0.0008) and 4.8 higher when compared to 2nd (p=0.001). There were no differences when compared 2nd and 3rd tertiles for both major OP Fx and VFs.

Conclusions:

TBS better identifies osteoporotic fractures in postmenopausal women whose BMD is in non-osteoporotic range.

The difference between fractured and non-fractured women in TBS level is significant.

TBS improves fracture risk assessment in osteopenic female patients, particularly identification of women prone to vertebral fractures.

In osteopenia TBS<1.200 is related to 10 times higher risk of vertebral fracture as compared to TBS>1.350

TBS>1.350 and normal BMD exclude probability of VFs.

MO0253

Trabecular Bone Score (TBS) Predicts Incident Clinical and Radiographic Vertebral Fractures in Older Men: Findings from the Osteoporotic Fractures in Men (MrOS) study. John Schousboe¹, Tien Vo², Brent Taylor³, Peggy Cawthon⁴, Ann Schwartz⁴, Douglas Bauer⁴, Eric Orwoll⁵, Nancy Lane⁶, Elizabeth Barrett-Connor⁷, Kristine Ensrud⁸. ¹Park Nicollet Clinic/University of Minnesota, USA, ²University of Minnesota, USA, ³Center for Chronic Diseases Outcomes Research, Minneapolis VAMC; Department of Medicine, University of Minnesota, USA, ⁴University of California San Francisco, USA, ⁵Oregon Health Sciences University, USA, ⁶University of California Davis, USA, ⁷University of California San Diego, USA, ⁸Division of Epidemiology, University of Minnesota; Department of Medicine, University of Minnesota, USA

Background: TBS predicts fractures in those with body mass index (BMI) < 37 kg/m². It is unknown how well TBS predicts incident vertebral fractures in men independent of prevalent radiographic vertebral fracture (PVF)^{*} and other clinical risk factors. Our purpose was to estimate the associations of TBS with incident clinical vertebral fractures (iCVF) and radiographic vertebral fractures (iRVF) in men after adjustment for age, femoral neck bone mineral density (FNBMD), PVF, and other clinical risk factors. **Methods:** TBS was estimated on AP on baseline visit spine DXA scans for 5,862 men age = 65 years with a BMI < 37 kg/m². Incident clinical vertebral fractures were ascertained by self-report every 4 months and confirmed by centralized review of community acquired clinical images and baseline lateral spine radiographs. Visit 2 lateral spine radiographs were available and evaluable for 4,317 men with BMI < 37 kg/m². We defined an iRVF as an increase of = 1 Genant SQ grade on follow-up compared to baseline radiographs. The associations of TBS with iCVF and iRVF were estimated, respectively, with proportional hazards and logistic regression models. Model discrimination was tested in randomly selected split half samples; models were first run in 50 bootstrapped samples of the first half and model discrimination compared using Harrell's C and area under receiving operating characteristics (AUROC) curves statistics in the second half. **Results:** Mean (SD) TBS was 1.27 (0.12). 186 men had an iCVF over a mean follow-up time of 10.7 years, and 197 men had an iRVF on follow-up radiographs taken a mean 4.7 years after the baseline visit. A one SD decrease in TBS was associated with a 1.44 and 1.26 fold increased risk, respectively, of iCVF and iRVF adjusted for age and FNBMD (Table). These associations were only slightly attenuated with adjustment for PVF, and were even stronger when further adjusted for other clinical risk factors. By Harrell's C statistic, TBS improved discrimination of those with from those without incident clinical vertebral fracture. Results from models substituting lumbar spine BMD for FN BMD were similar, except that the association of TBS with iRVF when adjusted for PVF was attenuated and no longer significant. **Conclusion:** TBS is associated with incident clinical and radiographic vertebral fractures in older men independent of PVF and other clinical risk factors, and improves prediction of incident clinical vertebral fractures.

Table: Associations TBS with Incident Clinical & Radiographic Vertebral Fracture

| Predictors | Clinical Vertebral Fracture (n=5280) | | Radiographic Vertebral Fracture (n=4317) | |
|--|--------------------------------------|--------------------------|--|--------------------------|
| | HR (95% C.I.) | Harrell's C (95% C.I.) | OR (95% C.I.) | AUROC (95% C.I.) |
| Model 1: Age + FNBMD | | 0.72 (0.66 to 0.78) | | 0.60 (0.57 to 0.68) |
| Model 2: TBS (per SD decrease) + Age + FNBMD | 1.52 (1.32-1.75) | 0.75** (0.70 to 0.81) | 1.31 (1.13-1.52) | 0.62** (0.57 to 0.68) |
| Model 3: TBS + Age + FNBMD + PVF* | 1.43 (1.24-1.65) | 0.76** (0.71 to 0.82) | 1.21 (1.04-1.40) | 0.69* (0.64 to 0.75) |
| Model 4: All Predictors ^A | 1.78 (1.48-2.14) | 0.77** (0.72 to 0.83) | 1.29 (1.06-1.56) | 0.69* (0.64 to 0.74) |

MO0254

Why Are Additional Women with Fracture Identified by Measurement of Cortical Porosity than Identified by FRAX? Marit Osima¹, Rajesh Shigdel², Ragnar M Joakimsen³, Erik F Eriksen⁴, Ashild Bjornerem⁵. ¹Department of Community Medicine, UiT – The Arctic University of Norway, Norway, ²Department of Health & Care Sciences, UiT – The Arctic University of Norway, Norway, ³Department of Clinical Medicine, UiT – The Arctic University of Norway, Norway, ⁴Department of Clinical Endocrinology, Oslo University Hospital, Norway, ⁵UiT The Arctic University of Norway, Norway

The Fracture Risk Assessment Tool (FRAX) is useful to identify persons at risk for fracture but has limitations due to low sensitivity. Moreover FRAX does not take into account the cortical porosity, which is important for bone strength and is associated with fracture independent of FRAX. It is not clear why some women with fracture are identified by FRAX, while others are identified by cortical porosity. We wanted to 1) test the sensitivity and specificity for fracture when cortical porosity was combined with FRAX, and 2) compare the additional fracture cases captured by cortical porosity with those captured by FRAX.

We quantified FRAX score with femoral neck areal bone mineral density (FN aBMD) using dual-energy x-ray absorptiometry, and femoral subtrochanteric architecture using StrAx1.0 software in 211 postmenopausal women aged 54-94 years with non-vertebral fractures and 232 fracture-free controls in Tromsø, Norway.

Of 211 fracture cases, FRAX score >20% identified 45 women; the sensitivity was 21% (95% confidence interval (CI) 16-28) and specificity 93% (89-96), while porosity cut-off >80th percentile identified 61 women; the sensitivity was 29% (23-36) and specificity 88% (83-92). When porosity >80th percentile was combined with FRAX, the sensitivity was 43% (36-50) and specificity 83% (78-88). The additional fracture cases identified by porosity >80th percentile exhibited lower FRAX score (12.3 vs 27.4%) than those identified by FRAX alone, were younger, a smaller proportion had prior fracture (15.9 vs 69.7%), all p < 0.001, and marginally higher FN aBMD (796 vs 753 mg/cm², p = 0.07). They exhibited higher porosity of the total cortex (48.5 vs 41.7%), compact cortex (38.5 vs. 33.9%) and the transitional zone (61.8 vs 57.9%), thinner cortices (3.76 vs 4.17 mm), larger total and medullary cross-sectional areas (649 vs 566 and 231 vs 173 mm²), and lower cortical and total volumetric BMD (946 vs 1059 and 599 vs 722 mg HA/cm³), higher cross-sectional moment of inertia (2528 vs 2247 mm³), but lower buckling ratio (21 vs 28%), all p < 0.001.

Combining cortical porosity with FRAX increased the sensitivity and maintained high specificity for fracture, which is suggesting that cortical porosity capture additional elements of bone strength not captured by FRAX. We infer that the architecture in the additional fracture cases identified by cortical porosity, but not identified by FRAX, offset the positive impact of larger bone size on bone strength.

Efficacy of Dual Energy Xray Absorptiometry for Evaluation of Biomechanical Properties. Il-Hyung Park¹, Sung Hwa Seo², Joo-Mi Lee³, Wonju Jeong⁴. ¹Kyungpook National University Hospital, South Korea, ²Department of Health & Medical Tourism, Gyeongju University, South Korea, ³Department of Orthopaedic Surgery, Kyungpook National University School of Medicine, South Korea, ⁴Department of Orthopaedic Surgery, Kyungpook National University Hospital, South Korea

Purpose: Bone mineral density (BMD) is an important index in diagnosis of osteoporosis and other metabolic bone diseases, prediction of fractures, and monitoring treatment. This study was to find a more feasible technique for prediction of osteoporotic fracture between DXA and QCT and to reveal the actual change of bone strength when BMD was changed. **Materials and Methods:** Ten of these 20 specimens were used as the demineralized group and the other 10 as the control. Each specimen was immersed in HCl solution at for a period of at least 10 minutes, up to 100 minutes, at an interval of 10 minutes for different levels of demineralization. BMD was measured using DXA and QCT. Uniaxial compression tests were conducted to measure biomechanical parameters. Pearson correlation analysis was used respectively between BMD and biomechanical parameters and between DXA and QCT. **Results:** Elastic modulus ($\gamma=0.87$) and yield stress ($\gamma=0.84$) showed a statistically significant correlation with DXA BMD. Through correlation analysis with QCT BMD and elastic modulus, correlation coefficient showed hemivertebra ($\gamma=0.80$) and trabecular ($\gamma=0.68$). In yield stress, there was a statistically significant correlation in hemivertebra ($\gamma=0.87$) and trabecular bone ($\gamma=0.84$). **Conclusion:** DXA is a current standard technique not only for diagnosis of osteoporosis but also for prediction of fracture risk compared to QCT. Actual decrease of bone strength was much greater than that of BMD by both DXA and QCT.

Functional muscle-bone unit assessed by 3D-DXA: Study in a cohort of post-polio syndrome patients. Luis Del Rio*¹, Silvana Di Gregorio¹, Yves Martelli², Dolors Grados³, Ludovic Humbert². ¹CETIR Grup Medic; RETICEF Instituto Carlos III, Spain, ²Galgo Medical, Spain, ³Reumatologia, Hospital Sant Rafael, Spain

Muscular weakness is the main symptom of post-polio syndrome (PPS) and is related to bone mass status as part of functional muscle-bone unit. Subjects suffering PPS have a low bone mass in the affected extremity and propensity to fall which increases the fracture risk. The aim of this study is to assess the influence of muscle atrophy and weakness on volumetric bone density and cortical thickness using the new 3D-DXA technology. Method: We analyzed the total body composition and hip DXA scans of 29 women (57.12 ± 7.51 years old) suffering PPS. The iDXA bone densitometer (GE Healthcare) was utilized. The 3D-DXA software (Galgo Medical) was used to obtain 3D patients-specific models from hip DXA scans. The algorithm uses a statistical model of shape and BMD distribution obtained from an atlas of quantitative computed tomography scans. The 3D modeling is performed in an intensity based 3D-2D registration process that maximizes the similarity between a projection of the statistical volumetric model and the 2D DXA image. We assessed the lean mass in limbs and bone mass (BMC) of integral bone (trabecular + cortical), Cortical Bone Mineral Content (CBMC), Trabecular Bone Mineral Content (TBMC), Cortical Thickness (CT) and volumetric Bone Mineral Density (vBMD) at total femur area. Comparison between affected and non-affected limb were performed using t-test. A multiple regression approach was used to assess correlations between parameters (3D parameters and lean mass in legs). To categorize the patient's cohort the results were compared with proprietary reference data of Spanish healthy adult young women. Results: Left limb was the most affected side. All parameters were significantly lower in the affected side in comparison with non-affected. Parameters measured at the non-affected side were below reference values. Six patients had a normal areal BMD, but all 3D parameters were lower in the affected side. Cortical volumetric BMD -vBMD-was significantly lower at affected leg when compared with non-affected leg. Limb lean mass had a negative correlation with all 3D parameters, and the correlation was especially high with cortical thickness ($R^2: 0.752$). Conclusion: This study demonstrates that PPS induces a significant decrease in the density of the bones the affected area. The information from the new 3D-DXA software indicates that cortical thickness is the main parameter affected by PPS, and was highly correlated with the decrease of lean mass.

Vertebral Fracture Assessment vs X-ray in severe osteoporosis. Peter Schwarz¹, Linn Deleskog*², Barbara Nielsen³. ¹Glostrup Hospital, Denmark, ²Endokrinologisk Klinik PE, Rigshospitalet, Denmark, ³Research Centre of Ageing & Osteoporosis, Denmark

Background and Purpose: Vertebral fracture assessment (VFA) by dual X-ray absorptiometry (DXA) has been under evaluation for many years and its use is still debated. Radiographic imaging (X-Ray) of thoracolumbalis is considered to be gold standard in the assessment of vertebral fracture (VF). In a cross sectional setting we aimed to compare VFA and X-ray in patients with severe osteoporosis. As a second objective we wanted to study VFA as an effect marker in the evaluation of Teriparatide treatment.

Patients and Methods: A total of 23 patients suffering severe osteoporosis, 4 (17%) men and 19 (83%) women with a mean age of 69.2 years, had DXA and VFA performed at baseline and after 18 months of Teriparatide treatment. Of the 23 subjects, 18 patients (78%) were evaluated by X-ray image at baseline. VFs were defined in accordance with the grading system assessed by Genants, subdividing fractures after its deformity into mild (20-24%), moderate (25-39%) and severe ($\geq 40\%$).

Results: At baseline X-ray showed in total 41 VFs of whom 29 fractures were at the Th10 to L4 level: 5 ($\geq 20\%$); 21 (25-39%); and 3 ($\geq 40\%$). These numbers are in contrast to in total 53 vertebral fractures diagnosed by VFA ($p < 0.001$), at Th10 to L4 level: 22 ($\geq 20\%$); 13 (25-39%); and 18 ($\geq 40\%$).

After 18 months of Teriparatide treatment, the VFA showed 77 fractures in 23 participants, which was unchanged from the 77 fractures observed at baseline. Baseline fractures were: 31 ($\geq 20\%$); 19 (25-39%); and 27 ($\geq 40\%$) compared to: 26 ($\geq 20\%$); 22 (25-39%); and 29 ($\geq 40\%$) at 18 months of treatment. Five fractures had progressed one step to the next severity grade, 4 fractures were incident; 3 of them mild and 1 was of grade 3. Four mild fractures at baseline were evaluated normal at 18 month of treatment. However none of these assessments showed a change of vertebral height of more than 1-2 %.

Discussion: A very low specificity was seen using X-ray as reference and almost twice as many fractures appeared with VFA. In our cases evaluation of fractures above Th10 seemed impossible due to risk of misclassification. After 18 months of Teriparatide treatment VFA showed no increase in the total amount of fractures, even though 4 incident fractures were observed; 3 mild and 1 severe fracture.

Conclusion: Our pilot data demonstrates that VFA is inferior to X-ray in the diagnosis of VFs at all levels when using the same grading scale of fractures.

MO0258

Bone Structure and Osteocyte Lacunar Properties in Kidney Patients. Brad Hugenroth¹, Laura Armas¹, Mohammed Akhter*². ¹Creighton University, USA, ²Creighton University Osteoporosis Research Center, USA

Chronic kidney disease (CKD) is a major cause of skeletal fragility and subsequent fractures in patients. While fracture rate has increased, the mechanism and its treatment is still under investigation. This project provides both the qualitative and quantitative assessment of bone structure and unique osteocyte lacunar properties in iliac crest biopsies from stage 4 chronic kidney disease patients on dialysis (CKD4D) compared to data from healthy adults. Using MicroXCT200 system, bone biopsies were scanned at both macro (10 μ m resolution, Figure 1a, b) and submicron (0.6 μ m, Figure 1c) levels to study the trabecular bone structure and osteocyte lacunar characteristics. Five biopsies from CKD4D patients (age range 39 to 72 yrs) were analyzed. For macro scanning, we measured trabecular bone volume fraction (BV/TV). For high resolution scanning a 300 μ m thick section was cut and analyzed for two trabecular (nodes) and one cortical regions of interest. Images from high resolution (0.6 μ m) scans were analyzed for osteocyte lacunar void characteristic (volume and density). Osteocyte lacunar distribution is shown (Figure 1c) in a trabecular node as an example. All analyses were done using Avizo 9.0 software (FEI). Finally, the data were compared to healthy adults (n=8). Trabecular bone volume fraction (were lower in biopsies from the CKD4D patients 28 ± 10 , n=5) as compared to comparable healthy males (32 ± 6 , n=5). In addition, the osteocyte lacunar volume and density were lower (both cortical and trabecular) in CKD4D patients as compared to healthy adults (Figure 2). We note that the majority of biopsies from CKD4D patients show less cortical bone as result of trabecularization (Figure-1b) compared to healthy adults (Figure 1a), which may also be the major source of skeletal fragility. Declining osteocyte lacunar void volume and density (Figure-2) may suggest the filling in of spaces (voids) with mineral (osteopetrosis), thus increasing the brittleness of bone tissue. While these unique data may be helpful in understanding the skeletal fragility, additional work is needed to further investigate bone tissue properties in patients with chronic kidney disease to develop better therapies for fracture prevention.

Comparative Analysis of Human Lumbar and Thoracic Vertebrae Using Micro Computed Tomography (micro-CT) and the Fine Structure Analysis (fineSA®) MRI Technique. Kirk McGilvray, PhD*¹, Samantha Telfer, PhD², James Rafferty, PhD², Amanda Cox², Lance Farr², Mario Mendoza³, Snehal Shetye, PhD¹, Christian Puttlitz, PhD¹. ¹Colorado State University, USA, ²Acuitas Medical Ltd, United Kingdom, ³University of California, Santa Barbara, USA

Introduction There is a need for a clinical in vivo imaging method to examine bone architecture that avoids ionizing radiation exposure; but which delivers detailed information comparable to high resolution CT. MRI avoids radiation exposure but it has traditionally provided relatively poor resolution and low signal-to-noise ratio at central sites. To address these limitations, we have developed a novel Fine Structure Analysis algorithm (fineSAU) based on MRI data that, delivers at selected locations a high resolution (typically =100 μ m depending on acquisition parameters) spatial

frequency spectrum representative of repetitive structure within the region of interest (ROI). fineSA was applied to human cadaveric spine specimens and the resulting structural metrics compared to those obtained from micro-CT structural analyses. Methods Ten vertebral bodies (VB) (T7-L5) from two cadaveric human spines were individually imaged via micro-CT and MRI modalities. Micro-CT scanning was performed with an isotropic voxel size of 37 μm (Scanco USA Inc. Wayne, PA), followed by fineSA MRI data acquisition (Siemens TrioTim 3.0T). fineSA trades the reduction from 2D imaging to a 1D spatial frequency spectrum for higher resolution sampling along the corresponding line of k-space. Features from the fineSA spectrum were extracted and used in linear support vector regression (SVR) against target values of trabecular number (Tb.N) calculated from micro-CT data to produce a fineSA metric. One example of extracted features is the mean spectral intensity calculated for selected frequency ranges. Rigid-body image registration was used to match the position of ROI acquired by MRI to the corresponding location in the micro-CT images. Two ROIs within each VB (anterior section and central) were acquired. Results Strong and statistically significant correlations were found between the fineSA metric and the micro-CT Tb.N data. The best result gave a Pearson correlation coefficient $R=0.98$, $p<0.05$, and showed the linear relationship between the MRI fineSA metric and Tb.N data, Figure 1. Conclusion The data demonstrated close similarity between the information provided by micro-CT and the fineSA analyses on a set of cadaver vertebrae. These data indicate the utility of MRI-based fineSA for extracting a measure strongly correlated to Tb.N for in vivo applications such as the determination of osteoporosis and potential fracture risk. Figure 1: Metrics derived from the FSA application compared to the micro-CT Tb.N data. Strong and statistically significant correlations (Pearson correlation coefficient $R=0.98$, $p<0.05$ and $R^2=0.96$) were observed.

MO0260

Effect Of PTH (1-84) Treatment On Bone Quantity And Quality. Jorge Malouf^{*1}, Berta Magallares¹, Silvia Herrera¹, Ana Marin¹, Silvana DiGregorio², Luis Del Rio². ¹Hospital de la Santa Creu i Sant Pau, Spain, ²Cetir Medical Group, Spain

Objective: It has been demonstrated that PTH (1-84) treatment induced an improvement of both bone quality and quantity. The aim of the study is to assess effect of PTH (1-84) treatment on bone microarchitectural texture at lumbar spine using TBS. Method: A group of 20 osteoporotic women with a mean age and BMI of 70.1 \pm 6.8 yrs and 24.8 \pm 3.5 kg/m² were included in this study. All the patients had PTH (1-84) treatment during 24 months. DXA scans at lumbar spine L1-L4 were obtained using a Discovery densitometer (Hologic, USA) and acquired at baseline, and after roughly 12 and 24 month of treatment. The follow-up changes were analyzed by T-Test. Variation in % and in SD from baseline were assessed and normalized at 12 and 24 months. Responder and agreement analysis were performed. Statistical significance was set at $p<0.05$. Results: After normalization, both BMD and TBS at spine exhibited an increase at 12 and 24 months as presented figure 1. After 12 months and compared to baseline, significant increases ($p<0.05$) of +0.37 SD (+2.6%) and +0.42SD (+6.1%) were observed for TBS and BMD. After 24 months, BMD still increased significantly ($p<0.001$) to reach +0.52SD (+8.9%) while TBS remained stable +0.39SD (+2.7%, $p=0.08$). TBS and BMD changes at 12 and 24 months were not correlated ($r=0$; $p>0.8$). Interestingly, considering subjects who exhibited an increase, TBS exhibited an increase of 4.9% (70% of subjects) and 6.4% (60% of subjects) were observed at 12 and 24 months while increases of 8.4% (80% of subjects) and 10.9% (90% of subjects) were observed for BMD. Finally, agreements

between BMD and TBS in terms of changes were 80% and 70% at 12 and 24 months respectively. Conclusion: This study confirms that PTH (1-84) induces both BMD and TBS increases which is more pronounced in terms of BMD. Mean TBS and BMD increases are consistent with those previously published in the literature. After 12 months, TBS remained stable indicating a possible differentiating effect of the treatment on trabecular and cortical compartments supporting a finite modification of the trabecular structure recently hypothesized by Del Rio et al. (Bone 2015).

Establishing Bone Mineral Density Reference Curves for HR-pQCT. Lauren Burt^{*1}, Tolulope Sajobi², David Hanley³, Steven Boyd⁴. ¹University of Calgary, Canada, ²Department of Community Health Sciences & O'Brien Institute for Public Health, University of Calgary, Canada, ³CaMos Centre Director, Departments of Medicine, Community Health Sciences, & Oncology, University of Calgary, Canada, ⁴McCaig Institute for Bone & Joint Health, Department of Radiology, Faculty of Medicine, University of Calgary, Canada

High-resolution peripheral quantitative computed tomography (HR-pQCT) provides volumetric information on bone density and microarchitecture. For HR-pQCT to be used as a clinical assessment tool, used to identify individuals with osteoporosis or poor bone quality, normative reference data must be established. In our population-based cohort we aimed to define sex-specific reference intervals for bone mineral density and microarchitecture at the radius and tibia from 16 to 80+ years of age.

Participants from the Calgary cohort of the Canadian Multicentre Osteoporosis Study (CaMos) received a HR-pQCT scan of their non-dominant radius and left tibia (Scanco Medical, Switzerland). Total volumetric BMD (Tt.BMD), cortical BMD (Ct.BMD), trabecular BMD (Tb.BMD) and cortical porosity (Ct.Po) were assessed. Centile curves were generated for males and females at the tibia and radius using the Box-Cox power exponential (BCPE) method in the generalized additive models for location, scale and shape (GAMLSS) statistical package in R.

The study cohort consisted of 468 participants (308 females) with a median age of 53 (range 16 to 85) years. Sex-specific centile curves for age were created at the distal radius and tibia. Similar trends are observed for males and females. At the radius, Tt.BMD declines from 50 years onwards for both males and females. The percentage of cases below the 25th centile for Tt.BMD at the radius is 24% for females and 26% for males. The percentage of cases above the 75th centile for Tt.BMD at the radius is 26% for females and 25% for males. Ct.BMD increases up to 50 years, and then begins to decrease. As Ct.BMD decreases with age, Ct.Po increases substantially (50+ years). Similar curves were detected at the tibia.

We have developed sex-specific reference curves using HR-pQCT for the assessment of bone density and microarchitectural parameters at the distal radius and tibia. These data are valuable normative reference data for assessing bone health with HR-pQCT.

Factors causing curved femur in elderly women. Hiroyuki Tsuchie¹, Naohisa Miyakoshi¹, Yuji Kasukawa², Yoichi Shimada². ¹Akita university graduate school of medicine, Japan, ²Akita University Graduate School of Medicine, Japan

Purpose: Multiple factors are involved in the development of atypical femoral fracture (AFF), and excessive curvature of the femur is thought to be one of the factors. However, the pathogenesis of femoral curvature in elderly women is unknown. Therefore, we evaluated the influence of factors related to bone metabolism and posture on the development of femoral curvature in elderly women. Methods: One hundred and thirty-nine women who consented (mean age: 75 years) participated in the present study. Curvatures were measured using antero-posterior and lateral radiography of the femur, as within a previous report (mean angle: lateral curvature: 3.0°±3.3 degrees, anterior curvature: 9.8°±2.5 degrees). We divided the women into 2 groups, curved and non-curved groups, based on the average plus standard deviation at the cut-off between the groups (lateral curvature: 6.3 degrees, anterior curvature: 12.3 degrees). We compared the age, some laboratory examination items, such as alkaline phosphatase (ALP), calcium (Ca), inorganic phosphorus (IP), intact parathyroid hormone (PTH), 1,25-hydroxyvitamin D3 (1,25(OH)2D), 25-hydroxyvitamin D (25(OH)D), pentosidine, homocysteine, intact procollagen I N-terminal propeptide (PINP), and tartarate-resistant acid phosphatase 5b (TRACP5b), the bone mineral density (BMD) of the lumbar spine and proximal femur, lumbar lordosis angle, lumbo-sacral angle, and steroid usage. Results: On comparing the curved (n=25) and non-curved (n=114) groups with respect to the lateral curvature, age, intact PTH, pentosidine, and homocysteine level in the curved group were significantly higher than in the non-curved group (P<0.01, p<0.05, p<0.05, and P<0.05, respectively), and the Ca, 25(OH)D level, and proximal femur BMD in the curved group were significantly lower than in the non-curved group (P<0.05, P<0.01, and p<0.01, respectively). In a further comparison of the curved (n=19) and non-curved (n=120) groups with respect to the anterior curvature, age, intact-PTH level, and pentosidine in the curved group were significantly higher than in the non-curved group (P<0.01, p<0.05, and P<0.05, respectively), and the 25(OH)D level and proximal femur BMD in the curved group were significantly lower than in the non-curved group (P<0.01 and p<0.01, respectively). Conclusion: Femoral curvature in elderly women was strongly influenced by the age, presence of osteomalacia, a low BMD, and deterioration of bone quality.

MO0263

Intravertebral Heterogeneity of Lumbar Vertebral Trabecular Bone Density is Associated with Vertebral Fracture Independently of Average BMD. Elise Morgan^{*1}, Brett Allaire², Paul Fein³, Darlene Lu⁴, Alexander Adams³, Douglas Kiel⁵, Serkalem Demissie⁴, Elizabeth Samelson⁶, Mary Bouxsein⁷. ¹Boston University, USA, ²Beth Israel Deaconess Medical Center, Harvard Medical School, USA, ³Department of Mechanical Engineering, Boston University, USA, ⁴Department of Biostatistics, Boston University, USA, ⁵Department of Medicine, Harvard Medical School, USA, ⁶Institute for Aging Research, Hebrew SeniorLife, USA, ⁷Beth Israel Deaconess Medical Center, Harvard Medical Center, USA

Purpose: The spatial variation, or heterogeneity, in bone density within the vertebral centrum has been proposed as a major reason why measures of the average BMD in the vertebra explain only 60-80% of the variation in bone strength and exhibit low sensitivity in identifying fracture risk. *In vitro* studies using CT scans of

cadaveric spine segments have identified measures of the intravertebral heterogeneity in trabecular density that are associated with vertebral strength, independent of average BMD [1,2]. The present study evaluated whether these heterogeneity measures are associated with prevalent vertebral fracture.

Methods: We conducted a case-control study from 148 subjects enrolled in the Framingham Heart Study Multidetector CT study. Cases included individuals (16 women, 21 men, ages 50-81) with moderate or severe prevalent vertebral fracture (VFX) in a level other than L3. Three age- and sex-matched controls (48 women, 63 men) with no VFX were selected for each case. Volumetric QCT scans of L3 were analyzed to determine integral BMD (iBMD) and to quantify the intravertebral heterogeneity in trabecular density. For heterogeneity measures, we first subdivided the trabecular centrum into 5mm contiguous cubic regions and then calculated the BMD for each cube. Two measures of heterogeneity were calculated from the cube BMD values for a given vertebra: 1) the interquartile range (IQR); and 2) the quartile coefficient of variation (QCV) in cube BMD values [2]. iBMD, IQR, and QCV were compared between cases and controls using Wilcoxon Rank Sum tests. Conditional logistic regression was used to test for associations with prevalent fracture.

Results: Individuals with prevalent VFX had higher QCV (0.19 vs. 0.15, p=0.003), similar IQR (28.6 vs. 32.7 mg/cm³, p=0.145), and lower iBMD (0.13 vs. 0.17 g/cm³, p<0.001) than controls. Increased QCV was associated with increased odds of VFX both with (p=0.014) and without (p=0.004) adjustment for iBMD and weight. After adjusting for iBMD and weight, individuals in the highest tertile of QCV had more than six-fold increased odds of VFX as compared to those in the lowest tertile (OR=6.47; 95% CI: 1.63-25.78) (Table 1).

Conclusions: Increased intravertebral heterogeneity in trabecular density, as measured by QCV in QCT scans of the lumbar spine, was associated with prevalent VFX, independent of average BMD.

QCT-based hip structural analysis: comparison between osteoporotic and non- osteoporotic patients. Wojciech Glinkowski¹, Jerzy Narloch^{*2}. ¹Medical University of Warsaw, Poland, ²Chair & Department of Orthopaedics & Traumatology of Locomotor System, Center of Excellence "TeleOrto", Medical University of Warsaw, Poland, Poland

Introduction: Fracture risk of the femoral neck can be determined by the geometry of the proximal femur. Quantitative computed tomography (QCT) offers thorough 3D analysis with high spatial resolution. It provides information regarding bone geometry separately for cortical and trabecular bone. The aim of the present study was to investigate hip structural analysis differences between patients with diagnosed osteoporosis and those not.

Methods: In a preliminary study 24 patients aged 53-88 years (mean, 71.95 ± 9.12 years), diagnosed and treated in our department, underwent CT scan due to the history of low back pain after minor trauma. The patient's height ranged from 151 to 170 cm (Avg 161,6cm). The weight ranged from 41 to 88 kg (Avg. 63,35). T scores were utilized for analysis of proximal femoral geometry using QCTPro Software (Mindways Software Inc., Austin, TX). Patients were divided into two groups, based on T-score - osteoporotic (below -2,5 SD) and non-osteoporotic (above -2,5 SD). We compared 20 structural indices between the groups. Furthermore, correlations between selected bone density and morphometric variables were evaluated. Statistical analysis was performed using SAS 9.3 (SAS Inc., Cary, NC).

Results: Wilcoxon two-sample test revealed there were significant differences (p<0.05) between the groups concerning cortical indices: femoral neck BMD, intertrochanteric BMD, total BMD. Similarly for trabecular parameters, though there was the additional significant difference regarding trochanteric BMD. No significant differences were found for neck-trochanter angle (p=0.4), femoral neck width (p=0.23), height or weight. Patients meeting the densitometric criteria of osteoporosis were significantly older than the other group (p=0.02). Pearson correlation coefficients revealed strongest correlations of femoral neck cortical perimeter and area with femoral neck cortical BMD. Femoral neck cortical analysis showed that 42% of patients with no osteoporosis have a consistent distribution of cortical bone, compared to 8% in another group. The average results for the group are provided in the table:

| | Min. | Max. | Avg |
|-----------|-------|--------|---------|
| fnCBMD | 672,2 | 2147,9 | 1142,02 |
| itrCBMD | 809 | 975,3 | 884,37 |
| itrTBMD | 74,6 | 173,1 | 105,69 |
| totTBMD | 79,1 | 158 | 107,69 |
| FNTrangle | 34,7 | 51,6 | 43,35 |
| FNwidth | 25,7 | 41,8 | 30,19 |
| TOTscore | -4,2 | 0,54 | -2,3825 |

Conclusions

The fracture risk assessment determination in osteoporosis of the femoral neck can be determined by the geometry of the proximal femur. The study showed that structural, morphological and densitometric differences can be observed between patients with or without diagnosed osteoporosis when Quantitative computed tomography (QCT) was employed for thorough 3D analysis with high spatial resolution.

Racial and Sexual Dimorphism in Cortical Porosity Requires Appropriately Positioned Regions of Interest (ROI). Ali Ghasem-Zadeh¹, Xiao-Fang Wang², Afrodite Zendeli², Ashild Bjørnerem³, Andrew Burghardt⁴, Roger Zebaze², Ego Seeman². ¹Austin Health, University of Melbourne, Australia, ²Depts Medicine & Endocrinology Austin Health, University of Melbourne, Australia, ³Dept of Health & Care Sciences, UiT The Arctic University of Norway, Norway, ⁴Department of Radiology & Biomedical Imaging, University of California, USA

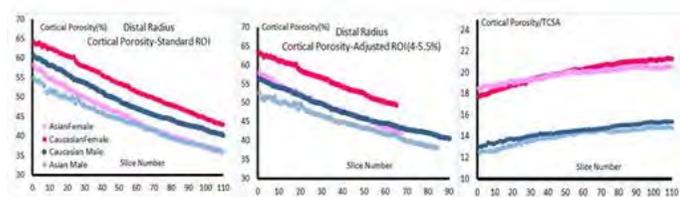

Rational Several studies report higher cortical porosity in men than women, and higher cortical thickness and lower cortical porosity in Asians than Caucasians [1,2]. Similarly, taller persons are reported to have relatively thinner and more porous cortices [3].

Men and Caucasians have a longer and wider radius and tibia compared with women and Asians respectively. When comparing, the automatically selected ROI is more distal in taller than shorter individuals; features that may partly account for some of these observations. The ROI selected scanning using by HR-pQCT is 9.5 mm and 22.5 mm proximal to the mid-joint line for distal radius and tibia, respectively in all individuals regardless of bone length which may over or underestimate traits being quantified.

Methods We imaged the non-dominant distal radius of 80Caucasian and Asian females and males, age range (25-46 yrs) using HR-pQCT the standard ROI and analysed slice by slice using StrAx 1.0 [4]. The ROI and number of slices were positioned at 4-5.5% forearm length and porosity was quantified comparing the Standard ROI vs ROI Adjusted for length alone and then length and total cross sectional area.

Results Biologically and statistically significant sex and racial differences in cortical porosity resulted after adjusting the ROI for length and total CSA such that only sex differences remain with high porosity in females than males in each race. However, after adjustments, neither males of different race, nor females of difference race differed in porosity [Fig 1-3].Conclusion Failure to correctly position the ROI produces misleading information concerning cortical porosity; erroneously suggesting men have higher porosity than women and that racial differences are present when they are not. Differences in appendicular length and total CSA need to be considered in the study of morphology in growth, aging, disease and drug therapy.

MO0266

The Reliability of Peripheral Quantitative Computed Tomography-Derived Marrow Fat Density and Area Measures Using Three Analysis Techniques. Zachary Brown¹, Jenna Gibbs¹, Andy Kin On Wong², Beverley Catharine Craven³, Jonathan D Adachi⁴, Lora Giangregorio⁵. ¹University of Waterloo, Canada, ²University Health Network, Canada, ³University Health Network - Toronto Rehabilitation Institute, Canada, ⁴McMaster University - St. Joseph's Health Care, Canada, ⁵University of Waterloo -Toronto Rehabilitation Institute, Canada

Purpose: To compare the precision for peripheral quantitative computed tomography (pQCT)-derived bone marrow density (MaD) and cross-sectional area (MaA) segmentation using three analysis techniques. Methods: Secondary data analysis of pQCT scans collected in 85 participants: young adults, n=18; mean age (SD): 25.4±3.2yr; older adults, n=48; mean age (SD): 71.9±8.2yr; and individuals

with spinal cord injury (SCI) (American Spinal Injury Association Impairment Scale categories A-C) (n=19; mean age (SD): 43.5±8.6yr) were completed. Repeat scans of the tibial shaft (66%) were performed using pQCT (Stratec XCT2000). Comparisons of test-retest precision error for MaD (mg/cc) and MaA (mm²) using a watershed algorithm (WS) method (Sliceomatic version 4.3) and two threshold-based edge detection methods (Stratec version 6.0 (S-TB) and BoneJ version 1.3.14 (BJ-TB)) were conducted. Intra-rater reliability calculations of the WS method were performed. Root mean square standard deviation (RMSSD) and root mean square coefficient of variation (RMSCV; root mean square coefficient of variation percent [RMSCV%]) were calculated to determine interrater and intrarater reliability. Results: RMSCV% for segmentation of MaD was ≥10% for all techniques (S-TB: 11.81-12.83%; BJ-TB: 14.46-24.58%; WS: 13.69-20.16%), RMSCV% for MaA were <5% for all techniques, except in the older adults group using the BJ-TB and WS methods (S-TB: 1.96-4.35%; BJ-TB: 2.37-5.09%, and WS: 2.25-6.65%). RMSCV% and RMSSD for MaD were similar between the young adult (12.83-14.83% and 2.61-2.82 mg/cc) and SCI groups (12.08-15.63% and 2.32-2.78 mg/cc), respectively. In the older adult group, RMSCV% and RMSSD were lower using S-TB (11.81% and 2.72 mg/cc) compared to BJ-TB (24.58% and 3.18 mg/cc) and WS (20.16% and 2.98 mg/cc). The lowest RMSCV% and RMSSD of MaA were achieved using S-TB (1.96-4.35 and 3.26-6.91 mg/cc) compared to BJ-TB and WS techniques (2.60-5.09% and 3.49-7.30 mg/cc; 2.25-6.65% and 3.81-12.63 mg/cc). Intra-rater RMSCV% for MaD using the WS method was lowest in younger adults (7.35%) followed by SCI (7.43%) and by older adults (11.23%) subgroups. Conclusion: The precision error for segmentation of pQCT-derived MaD using all three techniques exceeded 10%; whereas the precision for MaA using all three techniques ranged from 2.0% to 6.7%. Further investigation is necessary to determine alternative analysis methods with improved precision error for pQCT-derived MaD and MaA segmentation.

Table 1. Comparison of the reliability of peripheral quantitative computed tomography marrow fat measures, obtained using S-TB and BJ-TB and WS in study participants organized by subgroup.

| Reliability Data Variable and Method | Precision Error for Test-Retest Imaging Compared Between Methods | | | | | |
|---|--|--------------|------|-----------------|--------------|-------|
| | RMSSD (units) | | | RMSCV (% error) | | |
| | Young Adults | Older Adults | SCI | Young Adults | Older Adults | SCI |
| Marrow Density (mg/cc) | | | | | | |
| S-TB | 2.61 | 2.72 | 2.32 | 12.83 | 11.81 | 12.08 |
| BJ-TB | 2.69 | 3.18 | 2.78 | 14.46 | 24.58 | 15.63 |
| WS | 2.82 | 2.98 | 2.44 | 14.83 | 20.16 | 13.69 |
| Marrow Area (mm²) | | | | | | |
| S-TB | 3.26 | 6.91 | 3.80 | 1.96 | 4.35 | 2.05 |
| BJ-TB | 3.98 | 7.30 | 3.49 | 2.60 | 5.09 | 2.37 |
| WS | 3.81 | 12.63 | 5.75 | 2.25 | 6.65 | 2.44 |

BJ-TB – BoneJ Threshold Based Segmentation Method; MaA – Bone Marrow Cross-sectional Area; MaD – Bone Marrow Density; RMSSD – Root Mean Squared Standard Deviation; RMSCV – Root Mean Squared Coefficient of Variation; SCI – Spinal Cord Injury; S-TB – Stratec Threshold Based Segmentation Method; WS – Watershed-guided Manual Segmentation Method

MO0267

Genetic Risk Score Based on the Lifetime Prevalence of Femoral Fracture in 924 Consecutive Autopsies of Japanese Males. Heying Zhou¹, Seiji Mori¹, Tatsuro Ishizaki², Masashi Tanaka², Kumpei Tanisawa³, Makiko Mieno⁴, Motoji Sawabe⁵, Tomio Arai¹, Masaaki Muramatsu⁵, Yoshiji Yamada⁶, Hideki Ito¹. ¹Tokyo Metropolitan Geriatric Hospital, Japan, ²Tokyo Metropolitan Institute of Gerontology, Japan, ³Waseda University, Japan, ⁴Jichi Medical University, Japan, ⁵Tokyo Medical & Dental University, Japan, ⁶Mie University, Japan

Purpose: Recent large-scale meta-analyses of genome-wide association studies have identified a number of single nucleotide polymorphisms (SNPs) associated with low bone mineral density (BMD) or increased risk of fracture. However, the clinical utility of these SNPs for identifying individuals who are at increased risk of osteoporosis has been limited owing to relatively low odds ratios (ORs) for single SNPs to predict disease occurrence. The aim of this study was to develop a genetic risk score (GRS) by including multiple SNP profiles for predicting fracture risk based on lifetime prevalence of femoral fractures in 924 consecutive autopsies of Japanese males. Methods: A total of 922 non-synonymous SNPs located in 62 osteoporosis susceptibility genes were genotyped and evaluated for their association with the prevalence of femoral fracture in autopsy cases. GRS values were calculated as the sum of risk allele counts (unweighted GRS) or the sum of weighted scores estimated from logistic regression coefficients (weighted GRS). Results: Five SNPs (a-L-iduronidase rs3755955, C7orf58 rs190543052, homeobox C4 rs75256744, G patch domain-containing gene 1 rs2287679, and Werner syndrome rs2230009) showed a significant association (P < 0.05) with the prevalence of femoral fracture in 924 male subjects. The receiver-operating characteristic curves show that both the unweighted and weighted GRS adequately predicted femoral fracture; for the model predicted by the unweighted GRS with and without the effect of age at autopsy, areas under curves

(AUCs) were 0.750 (95% CI: 0.660–0.840) and 0.808 (95% CI: 0.728–0.887), respectively; for the model predicted by the weighted GRS with and without the effect of age at autopsy, AUCs were 0.770 (95% CI: 0.681–0.859) and 0.816 (95% CI: 0.736–0.895), respectively. The unweighted and weighted AUCs did not differ significantly. Multiple logistic regression analysis revealed that the OR for the association between fracture prevalence and unweighted GRS = 3 (n = 124) was 8.39 (95% CI: 4.22–16.69, P < 0.001) relative to a score < 3 (n = 797). Likewise, the OR for a weighted GRS of 6–15 (n = 135) was 7.73 (95% CI: 3.89–15.36, P < 0.001) relative to scores of 0–5 (n = 786). Conclusions: The GRS based on risk allele profiles of the five SNPs could help identify at-risk individuals and enable implementation of preventive measures for femoral fracture.

A Reduction in Kidney Function is Associated with Bone Mineral Density and Bone Loss in Elderly Swedish Women aged 75-85 years. Linnea Malmgren*, Fiona McGuigan, Anders Christensson, Kristina Åkesson, Lund University, Sweden

Introduction: Chronic Kidney Disease (CKD) is associated with bone mineral density and bone loss, but longitudinal studies in elderly women are scarce. Most studies estimate kidney function (estimated GFR, eGFR) from serum creatinine which is affected by muscle mass and diet while most eGFR equations were not developed in the elderly. Cystatin C (CysC), a GFR-marker which is relatively independent of body size, may be more appropriate in the elderly who typically have low muscle mass.

We estimated kidney function using CysC in the population based OPRA cohort of Swedish women (n=1044), all aged 75 years at baseline and followed for 10 years. We investigated the association between kidney function and BMD and specifically, how BMD, bone loss and bone markers differ between stages of CKD.

Methods: Plasma CysC was measured at age 75 (n=981), 80 (n=685) and 85 (n=365). Estimated GFR was calculated using the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI). At each visit, BMD was measured by DXA and biochemical bone markers were assayed. Multi-linear regression adjusted for weight, smoking and serum vitamin D was performed with kidney function as a continuous variable at ages 75-85. Women were stratified by CKD stage (1-2, 3A or 3B-5) to determine association between kidney function, BMD, bone loss and bone markers.

Results: Kidney function was associated with femoral neck (FN) BMD at age 75 and 80 (p=0.028; p=0.001). FN BMD did not differ with CKD stage, but women with stage 3A or 3B-5 had higher total body (TB) BMD (p<0.05 for age 75, 80 and 85). Stage 3A or 3B-5 lost more bone between age 75-80 at FN compared to stage 1-2 (p=0.016 and p=0.007) and stage 3B-5 lost more bone at TB (p=0.030). Apart from increased bone loss, women in CKD stage 3B-5 had higher PTH, phosphate, osteocalcin and ALP levels at baseline (all p<0.001). There was no association between kidney function and TB BMD or FN BMD at age 85 and the association between kidney function and bone loss was not significant from 80-85y.

Conclusion: Kidney function estimated by cystatin C is associated with BMD at the femoral neck in elderly women. Women with the worst kidney function have a higher rate of bone loss and increased levels of bone markers. The association between kidney function, BMD and bone loss is not seen in women >80 years, suggesting that in the very elderly the general decline in health outweighs the kidney specific decline with increasing age.

Differences in the Trajectory of Change in BMD Measured at the Total Hip and Femoral Neck between Men and Women Following Hip Fracture. Alan Rathbun*, Michelle Shardell², Denise Orwig¹, Richard Hebel¹, Gregory Hicks³, Thomas Beck⁴, Marc Hochberg¹, Jay Magaziner¹. ¹University of Maryland School of Medicine, USA, ²National Institutes on Aging, USA, ³University of Delaware, USA, ⁴Beck Radiological Innovations, USA

Approximately 260,000 older adults per year experience a hip fracture in the US, an event associated with increased morbidity and mortality. However, few studies have assessed sex differences in the sequelae of hip fracture. Women experiencing hip fracture have excess decline in bone mineral density (BMD) in the year following fracture compared to normal decrements due to aging. This study examined differences in BMD change between older men and women in the year after hip fracture. The sample (n=286) included persons enrolled in the Baltimore Hip Studies 7th cohort, a study that frequency matched (1:1) men and women on calendar time of fracture and hospital, who underwent dual-energy x-ray absorptiometry (DXA) measurement. DXA assessments occurred at study enrollment and two, six, and twelve months after hip fracture. Inverse-probability weighted independence estimating equations with robust standard error estimators, which accounted for missing data, selective survival, and within-patient clustering, were used to estimate sex differences in femoral neck and total hip BMD changes (g/cm²). Estimates were adjusted for baseline covariates selected a priori: age, race, weight, height, smoking, alcohol use, comorbidity, functional disability, depressive symptoms, bisphosphonates, hormone replacement therapy, and calcium supplements. Crude femoral neck

and total hip baseline BMD was significantly higher in men. Men also had larger average annual adjusted percent decline in BMD at both sites. There was a statistically significant adjusted twelve months percent decrease at the femoral neck of -4.8% (95% CI: -7.9%, -1.7%) in men and a statistically insignificant decline of -1.8% (95% CI: -4.7%, 1.0%) in women (Table 1). However, the difference (3%) in femoral neck change by sex did not reach statistical significance (P=0.16). Men had increasing prospective BMD decrements, while women had a decreasing rate of BMD decline. The differences in total hip BMD decline by sex were lower in magnitude and more similar between men and women (Table 2). The results suggest that men experience greater decrements in BMD compared to women after hip fracture, even after adjustment for age, body size, and use of bone-active treatments. Previous research has indicated that men and women have different patterns of bone loss associated with aging. Thus, these findings are likely due to sex differences in bone turnover or structural geometry following hip fracture.

Table 1. Unadjusted and adjusted percent change in femoral neck BMD between men and women following hip fracture at 2, 6, and 12 months.

Femoral Neck Cortical and Trabecular bone and Mortality: The AGES-Reykjavik Study. Elisa Marques¹, Vilundur Gudnason², Gunnar Sigurdsson³, Thomas Lang⁴, Osório Meirelles⁵, Fjola Johannesdottir⁶, Kristin Siggeirsdottir⁷, Lenore Launer⁵, Gudny Eiriksdottir⁸, Tamara Harris⁵. ¹National Institute on Aging, USA, ²Icelandic Heart Association Research Institute, Kópavogur, Iceland; University of Iceland, Reykjavik, Iceland, ³Icelandic Heart Association Research Institute, Kópavogur, Iceland; University of Iceland, Reykjavik, Iceland; Landspítalinn University Hospital, Reykjavik, Iceland, ⁴Department of Radiology & Biomedical Imaging, University of California, San Francisco, CA, USA, ⁵Laboratory of Epidemiology & Population Science, Intramural Research Program, National Institute on Aging, National Institutes of Health, Bethesda, MD, USA, ⁶Faculty of Industrial Engineering, Mechanical Engineering & Computer Science, University of Iceland, Reykjavik, Iceland, ⁷Icelandic Heart Association Research Institute, Kópavogur, Iceland, ⁸Icelandic Heart Association Research Institute, Kópavogur, Iceland, USA

Objective: This study examined associations of femoral neck trabecular and cortical volumetric bone mineral density (vBMD) with all-cause mortality over 12 years of follow-up.

Methods: We conducted a prospective study in the Age Gene/Environment Susceptibility (AGES) –Reykjavik cohort. A total of 4,777 participants (2,091 men

and 2,686 women), aged 66-96 years were included in the present analyses. Femoral neck trabecular and cortical vBMD (g/cm^3) and minimal cross-sectional area (cm^2) of the femoral neck were calculated from quantitative computed tomography data. A Cox proportional hazard model was used to examine independent associations between trabecular and cortical BMD and total mortality.

Results: At baseline, men had significantly more cortical and trabecular bone in the femoral neck than women. Men also had larger femoral necks than women. During 12 years of follow-up with an average follow-up time of 10 years, 990 (47.3%) men and 917 (34.1%) women died. In men, every standard deviation (SD) increment in femoral neck trabecular vBMD was related to a significantly lower mortality risk (HR=0.92, $p=0.011$) and femoral neck cortical vBMD (per SD increment) was also associated to a significantly lower mortality risk (HR=0.91, $p=0.006$) after adjustment for age, body mass index, education, history of osteoporosis or medication known to affect bone health and femoral neck minimal cross-sectional area. In women, no significant associations were observed.

Conclusions: Trabecular and cortical bone density of the femoral neck is associated with mortality over 12 years of follow-up independent of bone size. Preventive strategies should be considered to increase and maintain high bone mass at both cortical and trabecular compartments at the femoral neck in older adults, particularly in men, to reduce mortality risk. The divergent results between men and women suggest complex relationships between the possible factors (such as vascular calcification and diabetes) associated with the mechanisms explaining the causal relationship between BMD and mortality risk.

MO0272

Physical exercise and vitamin D level improve BMD independently of each other and sex in Young Adults. Rune Tønnesen^{*1}, Lars Thorbjørn Jensen², Peter Hambak Hovind³, Peter Schwarz⁴, ¹Center of ageing & osteoporosis, Denmark, ²Department of Clinical Physiology & Nuclear Medicine, Herlev University Hospital, Denmark, ³Clinical Physiology & Nuclear Medicine, Righospitalet Glostrup University Hospital, Denmark, ⁴Research Centre of Ageing & Osteoporosis, Departments of Medicine & Diagnostics, Glostrup University Hospital, Denmark

Background & Purpose: Vitamin D in various forms has a very important role in bone health. Bone mineral density and exercise have an acknowledged positive association, both in short and long-term. Young men and women accrue the majority of their bone mass in the teens and twenties. Rarely investigated is the effect of exercise on BMD in late skeletal maturation.

We comparatively examine the effect of physical exercise and S-25[OH]D level on aBMD (areal BMD) measured at the femoral neck, total hip, (both sides) and the lumbar spine (L2-L4) in both sex.

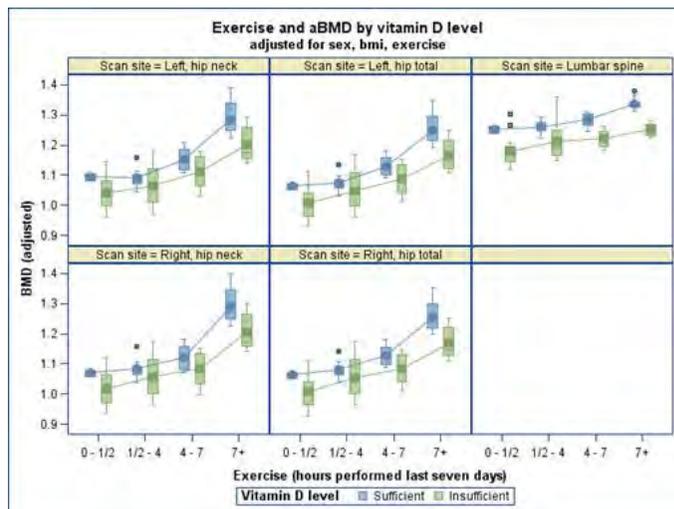

Material & Methods: We present data from a cross-sectional study examining exercise, aBMD measured with DXA and vitamin D level in a population of healthy young adults age 18 to 25 years. We grouped participants based on their Vitamin D levels into two groups; insufficient S-25[OH]D < 50 nmol/L and sufficient S-25[OH]D > 80 nmol/L. We grouped exercise (hours the last seven days) into four levels; 0-1/2, 1/2-2, 2-4, 4-7, or 7 hours or more

Results: The group with insufficient S-25[OH]D level had a systematic lower aBMD -0.080 (-0.138, -0.021) g/cm^2 ($p=0.008$) at all DXA-scan sites compared to the group with sufficient S-25[OH]D level.

We found a positive association between exercise and aBMD at all DXA-scan sites ($p_{trend}=0.0001$). All DXA-scan sites benefitted equally on aBMD from exercise, as there was no interaction between exercise and DXA-scan site ($p=0.09$).

Gender and DXA-scan site interacts ($p=0.002$) as men do not systematically have higher aBMD than women for all scan sites. The effect of gender on aBMD was only present at the hips, both total and femoral neck while it was absent at lumbar spine.

Conclusion: We conclude that aBMD in young healthy adults is influenced by physical activity independently of gender and S-25[OH]D status. Sufficient S-25[OH]D does not improve the effect of exercise; the group with sufficient S-25[OH]D had a systematically higher aBMD for all levels of exercise. Both genders had the equal effect of exercise.

BMD and Exercise for Vitamin D levels

MO0273

Loneliness and Osteoporotic Fractures in Older Adults. Meltem Zeytinoglu^{*1}, Elbert Huang², Megan Huisinigh-Scheetz³, Diane Lauderdale⁴, Tamara Vokes⁵. ¹University of Chicago, USA, ²University of Chicago, Department of Medicine, Section of General Internal Medicine, USA, ³University of Chicago, Department of Medicine, Section of Geriatric & Palliative Medicine, USA, ⁴Department of Public Health Sciences, USA, ⁵University of Chicago, Department of Medicine, Section of Endocrinology, Diabetes, & Metabolism, USA

Objective: To determine whether osteoporotic fractures are associated with loneliness and other dimensions of psychological wellbeing, all of which have been shown to influence health domains in the elderly.

Methods: We used data from Wave 2 of the National Social Health and Aging Project (NSHAP), a study of social life and health in a nationally-representative cohort of older adults. Our main outcome of interest was osteoporotic fracture (Fx). Predictors of interest were subjective loneliness, depression, and anxiety. In multivariable analyses, we adjusted for age and gender.

Results: Among 2724 adults aged 57-89, 124 (4.5%) reported Fx in the past 5 years: 31 hip, 37 leg, 43 wrist, and 13 vertebrae. Compared to subjects without osteoporotic fractures, those with fracture were older (73.8 years vs 72.0, $p=0.017$), were higher percentage female (68% vs 54%, $p=0.002$), and had higher 12-month history of falls (18.9% vs 11.9%, $p=0.001$). There were no differences by Fx status in race ($p=0.98$), weight ($p=0.40$), or BMI ($p=0.50$). While self-reported physical activity was lower in Fx patients, the contrast was not statistically significant ($p=0.07$). We used the Center for Epidemiologic Studies Depression Scale to examine the association of depressive symptoms with Fx. When controlling for age and gender, subjects' report of "was lonely" was the only component associated with Fx [Odds Ratio (OR) 1.29, $p=0.023$]; overall depression score was not. In a separate analysis using the Hospital Anxiety and Depression Scale, anxiety and depression were associated with Fx ($p=0.043$), but this significance was lost when adjusting for loneliness ($p=0.167$). In a third independent analysis using questions from the UCLA loneliness scale, and controlling for age and gender, there was an association between Fx and "feel isolated" (OR 1.62, $p=0.002$), and "feel left-out" (OR 1.42, $p=0.024$), but not "lack companionship" (OR 1.11, $p=0.438$). The UCLA loneliness scale composite trended towards, but did not reach a statistical significance (OR 1.45, $p=0.062$).

Limitations: The small number of incident Fx within survey population. The cross-sectional nature of the survey data does not allow for determination of whether feelings of loneliness occurred prior to or following the Fx.

Conclusions: Feelings of loneliness, but not other indicators of emotional wellbeing, are associated with Fx. Further research is needed to understand whether loneliness is a cause or consequence of Fx.

Disclosures: Meltem Zeytinoglu, None.

MO0274

Total Protein and Dietary Protein Food Pattern are Not Associated with Bone Mineral Density (BMD) Among Protein Replete Middle-Aged Adults. Kelsey Mangano¹, Shivani Sahni², Robert McLean², Alyssa Dufour², Douglas Kiel², Katherine Tucker³, Marian Hannan⁴. ¹Institute for Aging Research/Hebrew SeniorLife/Harvard Medical School, USA, ²Institute for Aging Research, Hebrew Senior Life, Harvard Medical School, BIDMC, USA, ³Department of Clinical Laboratory & Nutritional Sciences, University of Massachusetts, USA, ⁴Institute for Aging Research, Hebrew SeniorLife, Harvard Medical School, BIDMC, USA

Total protein intake has been shown to be positively associated with BMD in adults, yet little is known about the influence of protein food source on bone health. It is advantageous to examine protein from a dietary pattern perspective due to nutrient-nutrient and food-food interactions within the diet, which may affect bone differentially. We examined the cross-sectional association of total protein and dietary protein patterns with BMD in a wide age range of men and women. BMD of the hip (n=2,921) and spine (n=2,840) were measured in Framingham 3rd Generation Study participants (2008-2011; GE Lunar Prodigy). Dietary intakes were estimated using the Willett food frequency questionnaire (2002-2005). Cluster analysis (SAS FASTCLUS) by the k-means method classified participants into clusters (protein patterns), determined by major source of dietary protein. First, multivariable linear regression was used to assess the relation between total protein and BMD. Next, analysis of covariance was used to compare crude and adjusted mean BMD among protein patterns. Models adjusted for age, sex, estrogen status, BMI, physical activity (PASE), supplemental use of calcium and/or vitamin D, current smoking, total energy and total protein (cluster models only). Average age 41 ± 9y (range: 19-72y; 85% <50y); 46% men; mean total protein intake 96 ± 18g/d (approximately 1.2g/kg/d on average; well above the recommended daily allowance [RDA] for protein 0.8g/kg/d). Total protein was not significantly associated with BMD at any site (p-range: 0.19-0.51). Five dietary protein patterns were identified based on the top food contributors to overall protein intakes (Table). Crude models showed significantly greater femoral neck BMD in the chicken pattern (1.008 ± 0.006g/cm²) compared to the red meat pattern (0.986 ± 0.006g/cm², p=0.03); no other statistically significant associations were observed at any other bone site. Following multivariable adjustment, no significant differences were observed across the protein patterns at any BMD site (p-range: 0.25-1.0). Results were similar when men and women were analyzed separately. Overall, in this cohort of men and women across a wide age range, dietary protein patterns were not associated with BMD of the hip or spine following adjustment for other factors associated with bone. These results suggest that among young to middle aged adults with protein intakes above the RDA, variation in protein intake is not associated with bone health.

MO0275

A Useful Clinical Model to Predict Hip Fracture in U.S. Nursing Home (NH) Residents: the first step in developing a screening tool in the nursing home. Sarah Berry¹, Zullo Andrew R², Yoojin Lee², Vincent Mor², Ralph D'Agostino³, David Dosa², Jeffrey Hiris², Geetanjali Banerjee², Douglas P Kiel⁴. ¹Hebrew SeniorLife/Beth Israel Deaconess Medical Center, USA, ²Brown University, USA, ³Boston University, USA, ⁴Hebrew SeniorLife & Beth Israel Deaconess Medical Center, USA

Purpose: Strategies used to screen community dwellers for fracture (fx) risk are unlikely to be useful in the NH setting because they fail to account for the variable functional status and life expectancy of NH residents. The purpose of our study was to use readily available clinical characteristics of NH residents to develop a model to predict 2-year risk of hip fx.

Methods: Medicare claims data was linked with the Minimum Data Set (MDS), a federally mandated needs assessment performed on all U.S. NH residents at least quarterly. We identified 1,461,909 long-stay residents with ≥ 100 days in the same

facility in 2007. We restricted the sample to residents aged ≥ 65 years with Medicare Parts A and D, not enrolled in Medicare Advantage or Hospice, and not prescribed an osteoporosis drug (n=784,779). A 2/3 random sample was selected to develop our model. Hip fx was defined using Medicare Part A diagnostic codes. Information on 40 characteristics from 8 domains (demographics, cognitive/function, neuropsychiatric, pain, falls, nutrition, sensory, and co-morbidities) was obtained using the baseline MDS assessment closest to the date the resident qualified as long-stay. Residents were followed until the first event of hip fx, death, or 2-yr follow-up. Competing risk regression was used to model univariate associations. An interaction with cognition and transfer ability was considered given observed differences in univariate and multivariate results. Characteristics associated with hip fx (p≤0.05) in the univariate models were entered into 8, domain-specific stepwise models. Characteristics from each domain that remained significant were entered into a final model.

Results: Among 523,169 residents, mean age was 84 yrs and 72% were female. During a mean follow-up of 1.5 yrs, 3.3% of residents experienced a hip fx, whereas 46.1% died without a hip fx. The association between characteristics and hip fx that remained in the final model are shown in the Table.

Conclusions: Using readily available clinical characteristics, we developed a useful model to predict hip fx in NH residents. In contrast to community based tools where age and prior fracture are strong predictors of fx, an interaction between cognition and transfer ability was the strongest predictor of hip fx. We will refine our model and validate it in the remaining 1/3 sample. If validated, this tool could identify a clinically meaningful risk threshold to guide osteoporosis treatment in the NH.

atypical femoral fractures: Radiographic features in 40 patients and Histomorphometric features in 11 patients. Waleed Hashem¹, aliya khan², zohair rahman², angela cheung³, ken pritzker³, brain lentle⁴. ¹McMaster University, Saudi arabia, ²McMaster University, Canada, ³university of toronto, Canada, ⁴british columbia university, Canada

This study describes characteristics, histomorphometric in 11 patients and radiographic features in 40 patients with AFF referred for evaluation. Methods: All patients referred for evaluation of AFF were reviewed. Patients meeting the ASBMR criteria were further evaluated and tetracycline labeled bone biopsies were completed. Radiographs were reviewed by musculoskeletal radiologists. Results: All fracture lines were transverse or short oblique and cortices were thickened. 12 patients had bilateral fractures. 72% of the fractures occurred spontaneously with 28% occurring after a fall. All patients were female except 2 men; average age was 67.5 years. 4 were Chinese, 9 were East Indian and the rest being Caucasian. We report 40 cases of AFF in patients on long term bisphosphonate (BP) therapy. Average BP duration of use was 10.5 years. 20 patients were on ALN alone, 3 patients were on RIS alone, 8 patients were on ALN and RIS sequentially, one of them intravenous ZOL was given for three years later and another one received two doses of Dmab. 2 patients were on PAM, 1 for 15 years then received ALN for 3 years for OI and the other one for 16 years as a part of MM protocol. 4 patients were treated by ALN then by Dmab. After they received ALN, 2 years of Teriparatide, and Dmab. 2 patients had AFF. 1 patient was on ALN for 3 years followed by Strontium Ranelate for 4 years. Thigh pain was seen in 26 patients for 1 to 15 months. PPI use was present in 14 patients and 12 women used HRT. 3 patients were on prednisone for RA and 1 patient for MS and 3 patients on inhaled steroid for asthma. All patients had 25OH Vit D > 50 nmol/L. 7 patients had CKD, however renal osteodystrophy was not evident. 1 patient had PHPT developed AFF while she was on Dmab. BMD T-score at any site, FN, TH, LS or 1/3R, was as following: 18 patients T-score ≤ -2.5, 19 patients T-score > -2.5 but < -1.0 and 3 patients had normal BMD. Conclusion: There was an evidence of tetracycline label in all of the biopsy specimens with the exception of 1 patient with necrotic biopsy. This indicates that bone mineralization is not impaired. Bone remodeling was variable

based on the static parameter, OS/BS. The majority of subjects had low OS/BS consistent with the MoA of BPs. Receiving Dmab after prolonged use of BP may increase the risk of AFF. Improved understanding of the pathophysiology leading to these fractures may be gained with further histomorphometric data, particularly from the site of AFFs, in large numbers of patients.

Disclosures: *Waleed Hashem, None.*

MO0277

Characteristics of Prevalent Vertebral Fractures Enhance Prediction of Prevalent Osteoporosis and Incident Fractures. Magnus Karlsson*¹, Mehrsa Kherad², Ralph Hasseri², Jan-Åke Nilsson², Inga Redlund-Johnell³, Caroline Karlsson⁴, Claes Ohlsson⁵, Dan Mellström⁶, Mattias Lorentzon⁶, Björn Rosengren⁷. ¹Skåne University Hospital Malmö, Lund University, Sweden, ²Departments of Orthopedics & Clinical Sciences, Lund University, Skåne University Hospital, Malmö, Sweden, ³Departments of Radiology & Clinical Sciences, Lund University, Skåne University Hospital, Malmö, Sweden, ⁴Departments of Orthopedics & Clinical Sciences, Lund University, Skåne University Hospital, Malmö, Sweden, ⁵Center for Bone & Arthritis Research, Institute of Medicine, Gothenburg University, Sahlgrenska University Hospital, Sweden, ⁶Department of Geriatric Medicine, Gothenburg University, Sahlgrenska University Hospital, Sweden, ⁷Departments of Orthopedics & Clinical Sciences, Lund University, Skåne University Hospital, Sweden

Purpose: Prevalent vertebral fractures are associated with low BMD and high fracture risk. We evaluated if characteristics of prevalent vertebral fractures enhance prediction of osteoporosis and new fractures. **Methods:** MrOS Sweden is a population based prospective observational study of 3014 community living men aged 69-81 years. 1453 underwent at baseline a lateral thoracic and lumbar spine radiograph (1427 readable) in which prevalent vertebral fractures were characterized according to the Genant semi-quantitative method. Total hip (TH) BMD was measured by DXA. During the 5-year follow-up, all incident fractures were objectively registered through radiographs. **Results:** 15% of the men had at baseline at least one prevalent vertebral fracture. Men with a prevalent vertebral fracture had lower TH BMD than men without (0.85±0.14 vs 0.94±0.14 g/cm²; p<0.001) (mean±SD). The lowest BMD was found in men with 3 or more vertebral fractures, biconcave vertebral fractures and fractures with vertebral body compression in the worst quartile (all p<0.05 compared to men with other vertebral fractures). The OR [mean (95% CI)] for prevalent osteoporosis with any type of prevalent vertebral fracture was 6.1 (3.9, 9.5) 3 or more vertebral fractures 21.2 (7.1, 63.6), a biconcave vertebral fracture 8.5 (2.5, 28.8) and a vertebral body compression in the worst quartile 22.2 (8.3, 58.8) compared to men with no baseline fracture. Men with a prevalent vertebral fracture had during the 5 year follow-up a relative risk (RR) [mean (95% CI)] of 3.3 (2.6, 4.3) to sustain incident fractures, 4.7 (3.5, 6.3) osteoporotic fracture and 2.9 (1.5, 5.5) hip fractures. The RR to sustain new fractures with one prevalent vertebral fracture at baseline was 2.0 (1.4, 3.0) with 2 or more fractures 5.5 (3.7, 7.8), with different types 5.7 (3.6, 8.5), with fractures in both thoracic and lumbar region 6.4 (4.5, 8.8) and with fracture in the worst compression quartile 4.0 (2.6, 5.9). Results remained after adjustment for number of prevalent fractures at baseline. **Conclusions:** Old men with a prevalent vertebral fracture have 6 times higher risk of having prevalent osteoporosis and during the next 5 year 3 times higher risk of sustaining fractures than men without prevalent vertebral fractures. Old men with 2 or more prevalent vertebral fractures, different types, fractures in both the thoracic and lumbar region and/or a vertebral body compression in the worst quartile are at especially high risk to sustain new fractures.

MO0278

Development of models for predicting fracture-associated outcomes. Tuan Nguyen*¹, Steve Frost², Jacqueline Center³, John Eisman⁴. ¹Garvan Institute of Medical Research; University of Technology, Sydney, Australia, ²University of Western Sydney, Australia, ³Garvan Institute of Medical Research, Australia, ⁴Garvan Institute of Medical Research; University of Notre Dame School of Medicine, Australia

Background and Aim — A fragility fracture signals a series of adverse events, including recurrent fracture and mortality. Existing predictive models in osteoporosis have been developed to predict the risk of an initial fracture only, and do not predict the risk of subsequent fractures. In this study, we sought to examine the inter-relationships between an initial fracture, subsequent fracture, and mortality.

Methods — This study was based on a population-based cohort consisting of 757 men and 1224 women, aged 60 years and older, whose fracture status and health outcomes had been continuously monitored for up to 24 years. Fragility fractures were ascertained using X-ray report and circumstance of fracture. The incidence of mortality was obtained from individual participant during the follow-up period. Femoral neck bone mineral density and risk factors (eg lifestyle factors, physical activity, and concomitant illnesses and medications) were also ascertained at the initial visit as well as during the study period. A multistate Markov style of the Cox's

proportional hazards model was used to estimate the transition probabilities between three statuses (ie initial fracture, refracture, and mortality).

Results — The average age of participants was 70 years (range: 60 to 101). Approximately 25% of women and 12% of men had osteoporosis (BMD T-scores <-2.5). Among women without a fracture, approximately 37% would remain fracture-free during the subsequent 10-year follow-up; 24% would suffer a fracture, and 8% went on to refracture, and another 32% would die during this 10-year period. Among women with an initial fracture, 56% died after within 10 years, and 60% died after a recurrent fracture. Among men without a fracture, 38% would remain fracture-free, 14% would sustain a fracture, and 45% would die during the next 10 years. Among men with an initial fracture, the risk of a recurrent fracture was 16%, and the risk of death was 76%. However, in both genders, the risks of subsequent fracture and mortality were increased with advancing age and reduced BMD.

Conclusions — Individuals with an initial fracture have an increased risks of subsequent fracture and mortality, and the risk of fracture-associated mortality in men is greater than in women. The strong effects of advancing age and reduced BMD on the three related events of fracture, refracture, and mortality allow an individualized approach to the risk assessment for a man and woman. Such an assessment can aid patients and doctors to reach an informed decision concerning treatment in individuals with an initial fracture to reduce fracture and mortality in the general population.

MO0279

Falls predict death differentially by type of fall in postmenopausal women. Risto Honkanen*¹, Nadia Afrin¹, Heli Koivumaa-honkanen¹, Toni Rikkonen¹, Joonas Sirola², Marjo Tuppurainen², Heikki Kröger¹. ¹University of Eastern Finland, Finland, ²Kuopio University Hospital, Finland

Fragility fractures are usually sustained in falls. We found that falls are related to morbidity differentially by type of fall and that falls also predict fractures differentially by type of fall. The purpose of this study was to estimate if and how a fall history predicts death in postmenopausal women before old age.

Methods: The study population was selected from the population-based Kuopio Osteoporosis Risk Factor and Prevention (OSTPRE) Study cohort, Eastern Finland by including all women aged 57-66 (N=10210) who responded to the fall question of the 10-year follow-up enquiry in 1999. Falls were classified into slip falls and nonslip falls. Information on deaths in 1999-2009 was obtained from the national population register. Kaplan-Meier and Cox regression were used as statistical methods.

Results: A total of 1962 women reported a fall during the preceding 12 months in 1999: 1069 women reported a single fall and 893 women reported two or more falls (frequent faller). A fall due to a slip was reported by 921 women and a fall due to other mechanism (nonslip) by 781 women.

A total of 722 women died during the 10-year follow-up: 152 out of 1962 fallers (7.7 %) and 570 out of 8248 non-fallers (6.9 %) (log rank p=0.179). Mortality in women who fell due to a slip was similar (6.6%) to that of non-fallers (p=0.741), while it was 9.3 % for women with a non-slip fall (p=0.009). In Cox regression, the hazard ratio (HR) for risk of death related to non-slip fall was 1.38 (p=0.009). Adjusting for strong predictors of death – smoking, self-rated health, No. of prescribed drugs, waist circumference and life (dis)satisfaction – weakened the HR of history of nonslip fall to 1.28 (p=0.077).

In conclusion, nonslip falls are a moderate predictor of death in women before old age, while slip falls are not. Apparently, nonslip falls are more related to health status but slip falls more to environmental factors.

MO0280

Incidence and mortality after distal radius fractures over 50 years of age in South Korea. Tak Kim¹, Hyung Moo Park*², Yongchan Ha². ¹Korea University Anam Hospital, South Korea, ²Chung-ang University, South Korea

Abstract

Purpose: The purpose of this study was to assess the incidence and mortality of distal radius fracture in Koreans over 50-years-of-age using a nationwide claims database from 2008 to 2012.

Methods: This study was performed on patients ≥50-years-of-age treated for distal radius fractures with diagnosis code (ICD10; S52.5, S52.6). All patients were followed using patient identification code to identify deaths. The standardized mortality ratios (SMR; observed/expected deaths) of distal radius fracture were calculated based on age and gender-specific rates in the entire Korean population.

Results: The number of distal radius fractures increased by 48.1% over the 5-year study period (55,243 in 2008 and 82,230 in 2012). The incidence of distal radius fractures was 161.6/100,000 for men and 643.7/100,000 for women in 2008, and 187.7/100,000 for men and 818.2/100,000 for women in 2012. The cumulative mortality rate over the first 12 months after distal radius fracture was steady at 1.9% (1,052/55,243) in 2008 and 1.5% (1,206/82,230) in 2012. The mean year mortality over 5 years in men (3%, 1,497/59,835) over the first 12 months was 1.5-times higher than in woman (2%,

4,457/291,369). The mean of SMR of distal radius fracture at 1 year post-fracture was 1.24 in man and 0.99 in woman.

Conclusions: The nationwide data demonstrate that distal radius fractures are increasing, as is fracture-related mortality in South Korea. A public health strategy to prevent the distal radius fracture is necessary to minimize secondary osteoporotic fractures, reduce the economic burden, and improve public health.

MO0281

Mortality Risk, Cause of Death and Hip Fracture: A Prospective Study Over Two Decades of Hip Fracture Patients and Their Background Controls. My von von Friesendorff¹, Alicja Wizert², Jonas Ranstam², Fiona McGuigan³, Cecilia Rogmark⁴, Anna Holmberg¹, Anthony Woolf⁵, Kristina Åkesson¹. ¹Clinical Sciences Malmö, Lund University & Dept Orthopedics Malmö, Skåne University Hospital, Sweden, ²Lund University, RCSI, Skane University Hospital, Lund, Sweden, ³Lund University, Sweden, ⁴Dept of Clinical Sciences Malmö, Lund University & Dept Orthopedics Malmö, Skåne University Hospital, Sweden, ⁵Dept of Rheumatology, Royal Cornwall Hospital, Truro, United Kingdom

Background: The association between hip fractures in the elderly and mortality, particularly in the first year post fracture is well documented. But we still lack a clear picture if hip fracture is associated with higher mortality over the remaining lifetime and to which extent post-fracture mortality risk is influenced by age and sex over many years. We address these questions and identify the leading causes of death in hip fracture patients against the perspective of the background population.

Methods: The cohort consists of prospectively followed low-trauma hip fracture cases (757 women; 256 men) and 2026 individually matched community controls, from Malmö, Sweden who were followed for 22 years. Cause of death was obtained from the National Board of Health and Welfare, Sweden. Mortality risk within specific time windows (0-3 months, 3 months-1 year, 1-5 years, 5-10 years and 10-22 years) was analysed using Cox survival models. Fine and Gray models were used to determine short- and long term cause of death in a competing risks setting.

Results: Men were younger than women when they fractured (76 vs. 81). For both sexes and at all ages, excess mortality in hip fracture patients was evident across the study period. Men lost more life years than women ($p < 0.001$) and life expectancy was shorter, particularly after age 85. Among women, mortality risk was 2-times higher for up to 15 years post-fracture (RR 2.0 [95% CI 1.8-2.3]) and continued to be 50% higher for the 7 years until the end of the study (RR 1.6 [1.4-1.7]). For the same time periods, among men mortality risk was ~3-times (RR 2.7 [2.2-3.4]) and 2-times higher (RR 1.9 [1.6-2.2]). CVD, pneumonia, neurological diseases and musculoskeletal trauma were the most common causes of death among hip fracture patients and incidence was higher than in the background population. In the first 12 months post fracture, the highest risk of mortality was from CVD (RR 3.8 [2.0-7.2]); women RR 3.6 [2.5-5.1] and pneumonia (men RR 4.7 [1.9-11.3]; women RR 3.4 [1.6-7.1]). Men continued to be at risk of pneumonia in the long term (RR 2.1 [1.2-3.7]).

Conclusions: Patients who sustain a hip fracture and survive the first year continue to have a higher mortality rate than the background population for up to 20 years. These findings may be valuable in developing multi-disciplinary strategies that are specific to age and risk to improve outcome not just in the immediate post-fracture period, but thereafter.

Peri-Aortic Fat Is Associated with a Higher Risk of Vertebral Fracture and Negatively Associated with Volumetric Bone Mineral Density, Cross-Sectional Area and Compressive Strength of Lumbar Vertebrae: The Framingham Osteoporosis Study. Yi-Hsiang Hsu¹, Mary Bouxsein², Udo Hoffmann³, David Karasik⁴, L. Adrienne Cupples⁵, Caroline Fox⁶, Douglas Kiel⁷. ¹HSL Institute for Aging Research, Harvard Medical School, USA, ²Center for Advanced Orthopedic Studies, Beth Israel Deaconess Medical Center, USA, ³Massachusetts General Hospital, Department MR PET CT & Harvard Medical School, USA, ⁴Hebrew SeniorLife Institute for Aging Research, USA, ⁵Dept of Biostatistics, Boston Univ. Sch. of Public Health, Boston, USA, ⁶Brigham & Women's Hospital, Division of Endocrinology & Harvard Medical School, USA, ⁷Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA

Both obesity and osteoporotic fracture are increasingly recognized as major health problems worldwide. The long prevailing view that BMI defined obesity is associated with beneficial effects on the skeleton has recently been challenged by contrasting studies demonstrating that visceral fat is associated with lower bone density. Peri-aortic adipose tissue volume (PAAT) is the adipose tissue surrounding the aorta, which is anatomically adjacent to the spine. Excess fat deposits at peri-aorta has been

found to be associated with a higher risk of CVD and CHD. We hypothesized that PAAT is associated with vertebral fracture risk and bone measures; and it may be due to its local paracrine effect on the adjacent lumbar vertebrae. Methods: To determine the association between PAAT and vertebral fracture risk as well as, volumetric integral BMD (In.vBMD); volumetric trabecular BMD (Tb.vBMD); and cross-sectional area (CSA), L3 lumbar vertebrae were measured by qCT on 3,138 men and women from the Framingham Study. The Compress Strength (CS) of vertebrae body was calculated. Subcutaneous abdominal tissue volume (SAT) and visceral abdominal tissue volume (VAT) were also estimated from the same qCT scans. Multivariable regression models were used to calculate least-squares means and to assess regression coefficients for the vertebral fracture risk and bone measures across PAAT quartiles. Results: Significantly negative correlations between PAAT and the bone measures were found in both men and women after adjusting for age, height, BMI and menopause status (women only). The magnitude of the correlations was stronger than that between BMI and the bone measures, and was in the opposite direction. PAAT was associated with a higher risk of vertebral fractures. Participants in the highest PAAT quartile had 2.2 times higher risk (OR=2.2; 95%CI=1.4~3.3) comparing to the participants in the lowest PAAT quartile. This association is not mediated by Tb.vBMD and independent from the effect of VAT, BMI and diabetes status, suggesting that excess fat deposits adjacent to vertebrae may have a detrimental paracrine effect on bone mass and strength of the adjacent lumbar vertebrae. To identify potential factors that may mediate the relation between high PAAT and a higher risk of vertebral fracture, we screen ~300 metabolites and lipids as well as ~180 protein biomarkers via proteomics on the same Framingham participants. These results will be presented at the ASBMR annual meeting.

MO0283

Post-Fracture Care: Do we need to educate the patients rather than the doctors? The PREVOST Randomized Control Trial. Blandine Merle¹, Roland Chapurlat², Emmanuelle Vignot³, Thierry Thomas⁴, Julie Haesebaert⁵, Anne-Marie Schott³. ¹INSERM, France, ²Hospices Civils Lyon, France, ³Hospices Civils de Lyon, France, ⁴Hospital Bellevue, France, ⁵PIMER Hospices Civils de Lyon, France

Osteoporotic fractures predispose to future fractures and related morbi-mortality, but so far only a minority of patients with recent osteoporotic fracture receives adequate therapy. Therefore, we implemented a patient-centered post-fracture care program, Prevost (PREvention of OSTeoporosis) and evaluated its impact on BMD prescription and/or anti-osteoporotic treatment prescription. We enrolled 436 women aged 50 to 85 years in a multicenter, randomized controlled trial, while visiting emergency and orthopaedic departments of 21 hospitals from Region Rhône-Alpes, France, for a low-energy fracture of the radius/ulna or humerus, between march 2012 and december 2013. The randomization was stratified on age, hospital department type and site of fracture. The intervention was performed by a centralized coordinator who provided information solely to the patient about fragility fractures and osteoporosis, and encouraged her to contact her primary care physician for a follow-up concerning prevention of fragility fractures and osteoporosis. Patients from control group received usual care. All patients completed a standard questionnaire at baseline and 6 months later. Data were analyzed in intention to treat. At 6 months of follow-up, we found a significant increase in the primary endpoint, ie the proportion of women who initiated a post-fracture care, with 53% in the intervention group versus 33% for usual care (OR:2.3, 95%CI [1.54-3.36], $p < 0.001$). Post-fracture management was more frequent after wrist than humerus fracture (46% versus 31%, $p = 0.009$), and for women aged 50 to 69 than for those aged 70 and older, in both arms (48% versus 36%, $p = 0.01$). The intervention resulted in 50% of Bone Mineral Density (BMD) prescription versus 33% in usual care (OR:2.0, 95% CI [1.35-2.94], $p < 0.001$), and 41% of BMD test performed versus 25 % for usual care (OR:2.1, 95%CI [1.37-3.10], $p < 0.0005$). BMD results showed that 87% of women had a low BMD: 28% had a t-score $< -2.5SD$, 59% had a $-2.5 < t\text{-score} < -1SD$. Having performed a BMD test significantly increased the set-up of a pharmacological treatment: +22% (OR:3.3, 95%CI [4.08-16.8], $p < 0.001$) and Calcium/vitamin D supplementation: +38% (OR:5.1, 95%CI [3.26-8.12], $p < 0.001$). However, only 24% of women with humerus fracture were treated at 6-months post-fracture. In conclusion, our trial showed that a patient-centered care program with a dedicated coordinator can significantly improve post-fracture BMD testing and treatment initiation

MO0284

Potential Years of Life Lost Following Low-Trauma Fractures in Canada. Robert B. Hopkins¹, Jonathan D. (Rick) Adachi¹, Louis Bessette², Natasha Burke¹, Jacques Brown², William D Leslie^{3,4}, Suzanne Morin⁴, Alexandra Papaioannou¹, Louisa Pericleous⁵, Jean-Eric Tarride¹. ¹McMaster University, Canada, ²Laval University, Canada, ³University of Manitoba, Canada, ⁴McGill University, Canada, ⁵Amgen Canada Inc., Canada

Purpose: To estimate the potential years of life lost (PYLL) due to low-trauma fractures in Canada.

Methods: Two national administrative databases from the Canadian Institute for Health Information were used to identify a cohort of Canadians age 50 years and

older with low-trauma fractures for years 2007 to 2011. Low-trauma fractures were categorized using ICD-10-CA codes as hip, humerus, vertebral, distal forearm, other sites (ribs/sternum, pelvis, trunk, clavicle, scapula, femur, patella, tibia/fibula), and multiple sites fractures (more than 1 of the preceding). PYLLs were calculated for each age group, sex and fracture type by adjusting the provincial and sex-based standard life tables estimate of life expectancy for the increased risk of death associated with a fracture. Results were compared with PYLL estimates due to other diseases reported by Statistics Canada in 2007.

Results: Based on an estimated 133,500 low-trauma fractures in Canada in 2011, the PYLL due to low-trauma fractures was 89,247 years (52,131 years for women, 37,116 years for men). While being only 23% of fractures hip fractures accounted for 43% of all PYLL. Specifically, a hip fracture at ages 50 to 59 years decreases life expectancy by 4.0 years for women and 3.9 years for men, which corresponds to a loss of 15% of life expectancy relative to the national average life expectancy. While the percent loss of years for hip fracture versus typical life expectancy was constant across age groups for women, it increased with age for men (up to 24% by age 90 to 99). After hip fracture, fractures at 'other sites' and vertebral fractures were the two other types of fractures contributing the most to PYLL (28% and 12% of the total PYLL, respectively). Although women have more fractures, the PYLL was on average 1.57 times higher per fracture for men than for women. When compared to other diseases, the PYLL for low-trauma fractures (89,247 years) is less than the PYLL for all respiratory diseases (159,117), breast cancer (138,808), colorectal cancer (127,560), and cerebrovascular diseases (104,971) but higher than the PYLL associated with other conditions such as pneumonia and influenza (44,462), HIV (36,312), and prostate cancer (21,812).

Conclusion: Low-trauma fractures are associated with a significant loss of life expectancy and burden of illness. Strategies to reduce the risk of fracture and improve post-fracture care should be implemented and optimized.

MO0285

Presence of low bone mass and osteoporosis and cognitive impairment contribute to an increased risk for falls and fractures in older cancer patients. Beatrice Edwards*, Holly Holmes, Juhee Song, Ming Sun, MD Anderson Cancer Center, USA

Background: Chemotherapy associated cognitive impairment has been recently described. This study aimed to typify the baseline bone health status and cognitive function in older adults prior to allogeneic stem cell transplant (HSCT), and during the care of solid tumors such as breast and prostate cancer.

Methods: This is a retrospective study at the Program for Healthy Aging at MD Anderson Cancer Center between January 1, 2013 and June 30, 2014. Patients with hematologic malignancies and solid tumors were assessed. Functional and cognitive status were determined with the Lawton instrumental activities of daily living, the Katz activities of daily living, and the Montreal cognitive status exam. Bone health status was determined by bone densitometry and risk factor analysis. Montreal cognitive testing was considered normal if score was >26/30, mild (19-25), moderate (12-18), and severe (<12/30). Patients with bone loss or osteoporosis and patients with normal bone density were compared utilizing Wilcoxon rank-sum test for continuous variables and Chi-square test or Fisher's exact test for categorical variables. Univariate logistic regression analysis was performed to identify factors associated with increased risk of bone disease. A p-value of less than 0.05 indicated statistical significance. SAS 9.4 (SAS Institute INC, Cary, NC) was used for data analysis.

Results: Fifty two patients, 24 with hematologic malignancies (myeloma, lymphoma, leukemia, and myelodysplastic syndrome), and 28 with solid tumors (breast and prostate cancer) were assessed. The mean age was 76 ± 5.6 years, 55% were female, 66% White, 27% African American, and 4% Latinos, 38 patients had low bone mass or osteoporosis (73%). Cognitive impairment was evident in 57% of patients of which 22 were mild (58%), 7 were moderate (19%) and one case was severe. Age predicted low bone mass with an OR of 1.139 per additional year of life, (95% CI, 1.019-1.274, $p=0.0223$). When the age at the time of bone test was dichotomized as ≥ 72 vs. < 72 , OR of age ≥ 72 comparing to age < 72 is 5.905 (95% CI, 1.548-22.530) and showed a significant association ($p=0.0093$). Coexistence of low bone mass/osteoporosis and cognitive impairment was evident in 55% of cases.

Conclusions: Cognitive impairment and bone loss/osteoporosis are common in cancer patients. Their co-existence likely contribute to falls and fractures in this population. Greater research in this area is needed.

Disclosures: Beatrice Edwards, None.

MO0286

Prospective study of C-reactive protein and risk of hip fracture. Junjuan Li*¹, Shouling Wu¹, Shivani Sahni², Chunpeng Ji¹, Xiang Gao³, Katherine Tucker⁴. ¹Kailuan Hospital, China, ²Institute for Aging Research, Hebrew SeniorLife, Harvard Medical School, USA, ³The Pennsylvania State University, USA, ⁴University of Massachusetts, Lowell, USA

Inflammation has been hypothesized to have a role in pathogenesis of bone fracture. However, few prospective studies have examined this hypothesis to date. We,

thus, investigated whether higher high-sensitivity C-reactive protein (CRP), a marker of chronic systemic inflammation, was associated with risk of developing hip fracture in ~ 100,000 Chinese adults from the Kailun cohort.

We included 96,689 Chinese participants (76,890 men and 19,799 women), aged 18 years or older, who were free of hip fracture, cardiovascular diseases, and cancer, and had available information on CRP at baseline (2008). Plasma CRP concentrations were determined using a high-sensitivity particle-enhanced immunonephelometry assay with the detection limit of 0.1 mg/L. Incident hip fracture cases over the follow-up (from 2008 to 2013) were identified by reviewing medical records. We used Cox proportional hazard models to assess the hazard ratio (HR) of hip fracture during follow-up, by baseline CRP status (< 0.5 mg/L, 0.5-0.99 mg/L, 1-2.99 mg/L, or 3+ mg/L), adjusting for age, sex, body mass index, physical activity, smoking status, alcohol intake, diabetes, and menopausal status (for women only).

The mean age was 52 y (range: 18-98). During 5.4 years of follow-up, we documented 187 new hip fracture cases. Participants with higher baseline CRP concentration had higher risk of hip fracture (P-trend < 0.0001). The adjusted HRs were 1(ref), 1.55, 1.98, and 1.89 (95%CI: 1.11, 3.22), for CRP concentration < 0.5 mg/L, 0.5-0.99 mg/L, 1-2.99 mg/L, and 3+ mg/L, respectively (Figure). We did not observe significant interaction between CRP and sex (P-interaction=0.54).

In conclusion, we observed a significant dose-response relation between higher CRP and increased hip fracture risk. This finding suggests that inflammation may be an important risk factor for hip fracture.

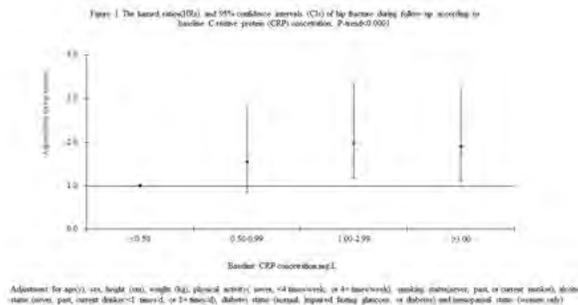

Fig. Adjusted HRs for hip fracture, according to baseline CRP status

MO0287

Risk for Hip Fracture Ten Years Before and After Total Knee Replacement Surgery in the Entire Swedish Population. CECILIE HONGSLO VALA*¹, Johan Kärrholm², Sabine Sten³, Magnus Karlsson⁴, Valter Sundh², Mattias Lorentzon², Dan Mellström². ¹University of Gothenburg, Sweden, ²Goteborgs Universitet, Sweden, ³Uppsala Universitet, Sweden, ⁴Skåne University Hospital Malmö, Lund University, Sweden, ⁵Sahlgrenska University Hospital, Sweden

13,328 primary arthroplasties were 2013 reported in Sweden and from the literature it is known that osteoarthritis (OA) in the knee is associated with high bone mass. We therefore studied the risk of having a hip or vertebral fracture during the ten years before and after total knee replacement (TKR), in addition with mortality rates after surgery.

We followed the total Swedish population born 1902-1952 (n=4 546 820) during the period 1987-2002. We identified from the patient register coordinated by the Swedish National Board of Health patients with diagnosis and surgical code for TKR due to primary OA (n= 51 631), for hip fracture (n= 200 522) and vertebral fracture (n= 33 351). These data were linked with information from national census registers (Statistics Sweden) on mortality, marital status, migration, living place, professional occupation, income and education level. The risk time analyses were based on a Poisson regression models. Patients with total hip replacement were excluded. Data is reported as mean with 95% confidence interval within brackets.

A total of 3719 patients had both a TKR and a hip fracture. The relative risk (RR) for patients with knee OA to have sustained a hip fracture during the ten years preceding TKR was 0.59 (0.55-0.64) and during the ten year after the surgery 1.06 (1.01-1.11). The RR for patients with knee OA to have sustained a vertebral fracture during the ten years preceding TKR was 0.49 (0.42-0.58) and during the ten year after the surgery 1.21 (1.07-1.32). The lower risk of hip or vertebral fracture before and the higher risk of hip or vertebral fracture after TKR remained after adjustment for income, education, occupation and latitude. The RR for mortality the first five years after TKR was 0.26 (0.25-0.27) and after 10 years after TKR 0.99 (0.95-1.04).

Individuals with TKR due to primary OA had a low risk for hip or vertebral fracture the decade before surgery. This might be explained by the association between OA and high bone mass, but also by decreased physical activity level due to pain. After TKR the risk for hip and vertebral fracture increased. This might be explained by pain, increase of physical activity due to rehabilitation, and other biomechanical factors. The mortality rate was low after TKR, probably due to a selection bias for surgery.

The Predictive Value of Falls History for Incident Fracture Decreases With Time: MrOs Sweden. Helena Johansson*¹, Nicholas Harvey², Anders Odén³, Magnus Karlsson⁴, Björn Rosengren⁴, Östen Ljunggren⁵, Cyrus Cooper⁶, Eugene McCloskey⁷, John Kanis⁷, Claes Ohlsson⁸, Dan Mellström⁸. ¹Centre for Metabolic Bone Diseases, University of Sheffield Medical School, Sweden, ²MRC Lifecourse Epidemiology Unit, University of Southampton, Southampton, UK; NIHR Southampton Biomedical Research Centre, University of Southampton & University Hospital Southampton NHS Foundation Trust, Tremona Road, Southampton, UK, United Kingdom, ³Centre for Bone & Arthritis Research (CBAR), Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden; Centre for Metabolic Bone Diseases, University of Sheffield, Sheffield, UK, Sweden, ⁴Clinical & Molecular Osteoporosis Research Unit, Department of Clinical Sciences, Lund University & Department of Orthopedics, Skane University Hospital, Malmö, Sweden, Sweden, ⁵Department of Medical Sciences, University of Uppsala, Uppsala, Sweden, Sweden, ⁶NIHR Musculoskeletal Biomedical Research Unit, University of Oxford, Oxford, UK, United Kingdom, ⁷Centre for Metabolic Bone Diseases, University of Sheffield, Sheffield, UK, United Kingdom, ⁸Centre for Bone & Arthritis Research (CBAR), Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden, Sweden

A history of falls is a strong risk factor for future falls but its predictive value wanes with time. The aim of the present study was to determine whether the predictive value of past falls for fracture remained stable with increasing follow-up time.

1836 elderly men recruited from the Swedish population to the MrOs study was studied. Baseline data included falls history, clinical risk factors, BMD at the femoral neck and calculated FRAX probabilities. 187 men experienced one or more incident major osteoporotic fracture during an average of 5.5 years follow-up. An extension of Poisson regression was used to investigate the relationship between falls history and FRAX to the risk of incident fracture. All associations were adjusted for age and time since baseline. To enable comparison with past falls, FRAX probability (without BMD) was dichotomised to above (high FRAX) and below (low FRAX) 15% for major osteoporotic fracture, which equalised the prevalences of high risk categories.

At enrolment 15.5% of the men had fallen during the preceding 12 months (past falls). Overall the HR of past falls vs no past falls was 1.61 (95% CI: 1.14-2.28) for incident osteoporotic fracture. The overall HR of high FRAX vs low FRAX was for incident osteoporotic fracture was 1.53 (95% CI: 1.07-2.17). After one year follow-up the HR of past falls for incident osteoporotic fracture was 2.21 (95% CI: 1.37-3.56) and after 5 years was 1.11 (95% CI: 0.63-1.96), with $p=0.081$ for the interaction between past falls and follow-up time. In contrast, after one year the HR for osteoporotic fracture for high FRAX above vs low FRAX was 1.58 (95% CI: 0.95-2.64) and after 5 years was 1.47 (95% CI: 0.88, 1.46). Thus the predictive ability of high versus low FRAX probability at baseline appeared to be stable with time (p for interaction between fracture probability and time > 0.30).

Although a history of falls is predictive of future osteoporotic fracture, the magnitude of this risk wanes with time, suggesting that inclusion of falls history in algorithms for calculation of long-term fracture risk may have limited utility.

Wrist Fracture and Risk of Subsequent Fracture: Post-hoc Findings from the Women's Health Initiative Study. Carolyn Crandall*¹, Kathleen Hovey², Jane Cauley³, Christopher Andrews⁴, Jeffrey Curtis⁵, Jean Wactawski-Wende⁴, Nicole Wright⁵, Wenjun Li⁶, Meryl LeBoff⁷. ¹University of California, Los Angeles, USA, ²State University of NY at Buffalo, USA, ³University of Pittsburgh, Graduate School of Public Health, USA, ⁴State University of NY at Buffalo, Buffalo, NY, USA, ⁵University of Alabama at Birmingham, USA, ⁶University of Massachusetts Medical School, USA, ⁷Brigham & Women's Hospital, Harvard Medical School, USA

Purpose. Wrist fractures are common in postmenopausal women and are associated with functional decline. Fracture patterns after wrist fracture are unclear. The goal of this study was to determine the frequency and types of fractures that occur after a wrist fracture among postmenopausal women.

Methods. We carried out a post-hoc analysis of data from the Women's Health Initiative Observational Study and Clinical Trials (1993-2010) carried out at 40 U.S. clinical centers with a mean follow-up duration 11.8 years. Participants were postmenopausal women aged 50-79 at baseline. Main measures included incident wrist, clinical spine, humerus, upper extremity, lower extremity, hip, and total non-wrist fractures and bone mineral density (BMD) in a subset.

Results. Among women who experienced wrist fracture, 15.5% subsequently experienced non-wrist fracture. The hazard for non-wrist fractures was higher among women who had experienced previous wrist fracture than among women who had not experienced wrist fracture: non-wrist fracture overall (hazard ratio [HR] 1.40, 95% confidence interval [CI] 1.33-1.48), spine (HR 1.48, 95% CI 1.32-1.66), humerus (HR 1.78, 95% CI 1.57-2.02), upper extremity (non-wrist) (HR 1.88, 95% CI 1.70-2.07), lower extremity (non-hip) (HR 1.36, 95% CI 1.26-1.48), and hip (HR 1.50, 95% CI 1.32-1.71) fracture (Table 1). Associations persisted after adjustment for BMD, physical activity, and other risk factors. Risk of non-wrist fracture was higher in women who were younger when they experienced wrist fracture (interaction p -value 0.02). Associations between incident wrist fracture and subsequent non-wrist fracture did not vary by baseline BMD category (normal, low bone density, osteoporosis).

Conclusions. A wrist fracture is associated with increased risk of subsequent hip, vertebral, upper extremity, and lower extremity fractures. There may be substantial missed opportunity for intervention in the large number of women who present with wrist fractures. The WHI program is funded by the National Heart, Lung, and Blood Institute, National Institutes of Health, U.S. Department of Health and Human Services through contracts HHSN268201100046C, HHSN268201100001C, HHSN268201100002C, HHSN268201100003C, HHSN268201100004C, and HHSN271201100004C.

Table 1. Associations between Incident Wrist Fracture and Subsequent Fracture

| | Total N | Event | Wrist Fracture | |

Determining interdependency structure of contributors to bone microarchitecture: The Framingham Osteoporosis Study. Roby Joehanes*¹, Kerry Broe², David Karasik¹, Shivani Sahni¹, Robert McLean¹, Kelsey Mangan¹, Ching-An Meng², Yi-Hsiang Hsu¹, L. Adrienne Cupples³, Elizabeth Samelson¹, Marian Hannan¹, Mary Bouxsein⁴, Douglas Kiel¹. ¹Harvard Medical School, USA, ²Hebrew SeniorLife, USA, ³Boston University School of Public Health, USA, ⁴BIDMC & Harvard Medical School, USA

Previous studies of risk factors for BMD have largely focused on areal BMD measured using DXA. There have been very few studies looking across multiple risk factors for bone microarchitecture. Since some of these risk factors may exhibit interdependency structure, deciphering such structure may reveal the underlying pathways associated with bone microarchitecture. Here we present a study to investigate such structure.

Distal radius cortical porosity percent (CtPo) from high-resolution peripheral quantitative computed tomography (HR-pQCT) was measured in men and women in the Framingham Offspring cohort (2012-2014; n = 1,109; 43.2% male;

age=70.2 ± 7.7y, range: 46-92y). Based on previous studies of DXA-derived BMD, the contributing factors in our study included sex, age, height, weight, body mass index (BMI), smoking status, physical activity (assessed using the Physical Activity Scale for the Elderly), fasting blood glucose, type 2 diabetes, alcohol, and total intake of vitamin D and calcium. Structural Equation Modeling (SEM) using Onyx was used to confirm and explore the interdependency structure. Three latent variables, metabolic (from BMI, weight, physical activity, diabetes, and fasting blood glucose), nutritional (from vitamin D and calcium intakes), and behavioral (from smoking and alcohol intake) factors, were created as surrogate measurements inferred from observed variables.

Figure 1 shows the interdependency structure. Age, weight, and alcohol intake were directly positively associated with CtPo. Physical activity, height and the latent metabolic factor were significantly negatively associated with CtPo. Type 2 diabetes, after adjusting for fasting blood glucose, was not significantly associated with metabolic factor or CtPo. Smoking status is not significantly associated with CtPo (either directly or indirectly), and hence, behavior factor was dropped. Nutritional factors (vitamin D and calcium intakes) were indirectly associated with CtPo acting through the metabolic factor.

Significant associations between the latent metabolic factor and CtPo suggests that radius cortical porosity reflects a long-term metabolic status. Significant associations between CtPo and other factors, such as physical activity, age, height, weight, and alcohol intake, suggest additional pathways may influence cortical porosity.

Figure 1 note: Each edge is statistically significant (p<0.05). B refers to the beta coefficients.

Fracture Risk is Increased in Middle-aged Persons with Lower but Normal Range Serum Sodium Concentration: Results from the NEO study. Chantal Wiepjes¹, Renée de Mutsert², Anne de Boer², Natasia Appelman², Frits Rosendaal², Martin Den Heijer³. ¹VUMC / LUMC, Netherlands, ²LUMC, Netherlands, ³VU Medical Center Pb 70571007 MB Amsterdam, The Netherlands

Background Hyponatremia is the most common electrolyte disorder and sodium plays a role in the mineralisation of bone. Recent studies indicate that mild hyponatremia is associated with fractures in the elderly, but most studies were retrospective. The aim of this study was to prospectively investigate the association between serum sodium concentration with the occurrence of fractures in middle-aged men and women. Methods The Netherlands Epidemiology of Obesity (NEO) study is a population-based cohort of 6,671 men and women aged 45 to 65 years. At the baseline visit several measurements were performed including fasting blood sampling and anthropometry. Fractures during follow-up were obtained through the medical records of the general practitioners of the participants using the International Classification of Primary Care (ICPC) codes and search terms. We performed logistic regression analysis to calculate the odds ratio and 95% confidence intervals for a first fracture after the baseline visit associated with serum sodium, adjusted for age, sex, total body fat, waist circumference, physical activity, alcohol use, diuretic use, prevalent diabetes mellitus, and for menopausal status in women. Results After exclusion of participants with a fasting glucose concentration higher than 15 mmol/L (because of pseudohyponatremia, n=28) and missing values of serum sodium concentration (n=38), 6256 participants (43.8% men) were analyzed, with a mean and standard deviation (SD) of age: 56 (6) years, BMI: 26.3 (4.4) kg/m², serum sodium concentration: 142.3 (2.0) mmol/L. At baseline, 0.2% of the participants had hyponatremia (<135 mmol/L). During a mean follow-up of 2.5 years, 2.3% of the participants had at least one fracture. In the crude model, per mmol/L higher serum sodium concentration the odds ratio for fractures was 0.86 (95% CI: 0.78, 0.95). The odds ratio remained similar after adjustment for age, sex, total body fat, waist circumference, physical activity, alcohol use, diuretic use, prevalent diabetes mellitus, and menopausal status in women (OR 0.89, 95% CI: 0.81, 0.99). Conclusion Even within a normal range of serum sodium concentration, lower serum sodium concentration was associated with an increased risk of fractures in middle-aged persons.

Imminent Fracture Risk in Elderly Osteoporotic Women: Underlying Relationships Between Risk Factors and Outcome. Rich Barron¹, Derek Weycker², John Edelsberg³, Alex Kartashov³, Barry Crittenden¹, Andreas Grauer¹, James Lani⁴. ¹Amgen Inc., USA, ²Policy Analysis Inc. (PAI), USA, ³Policy Analysis Inc., USA, ⁴Statistics Solutions Inc., USA

Background: Evidence on factors contributing to imminent risk for fracture within the next year among elderly women with osteoporosis is sparse. Moreover, data are limited about the underlying relationships between risk factors and the nature of their relationship with fracture.

Methods: A retrospective cohort design and data from the Study of Osteoporotic Fractures (SOF)—which includes 20 years of prospectively collected data on osteoporosis care and outcomes—were employed. The study population comprised all women aged ≥ 65 years with osteoporosis (T-score ≤ -2.5 at total hip) in the Caucasian cohort. Hip and other non-vertebral fractures were ascertained over a 1-year follow-up period. Potential predictors of fracture included anthropometric measures, BMD, cognitive function, comorbidities, drug use, fracture/fall history, lifestyle variables, medical symptoms, physical function/performance, quality of life, and vision status. Latent constructs (i.e., combinations of predictors that measure the same domain [e.g., physical function]), and inter-relationships between candidate risk factors and outcomes, were evaluated using factor analysis and structural equation modeling (SEM).

Results: The study population included 2,499 women who contributed 6,811 observations. During the 1-year follow-up, 2.2% had a hip fracture and 6.6% had a non-vertebral fracture. Latent constructs that were measured by factors with good model fit included: poor physical function (e.g., impairment in activities of daily living [ADL], physical activity), physical diseases (e.g., stroke, Parkinson's), cognitive diseases (e.g., Alzheimer's), metabolic diseases (e.g., BMD, prior fracture), and poor health (e.g., self-reported health). Direct and indirect predictors of hip and non-vertebral fractures—including individual variables and latent constructs—are reported in the Figure.

Conclusions: Indirect predictors of imminent fracture risk among elderly women with osteoporosis include age, physical function, physical diseases, and cognitive medications, which were related to each other and contributed to fall risk, cognitive function, overall health status, and metabolic diseases. Assessment of fracture risk for patients should be individualized considering the full picture of their health status, risk factors, and relationships between risk factors and fracture.

Insulin Resistance Independently Had the Negative Association with the Bone Mineral Density in Korean young women. Sangmo Hong^{*1}, Woong Hwan Choi². ¹Hanyang University, South Korea, ²Department of Internal Medicine, Hanyang University College of Medicine, South Korea

Abstract Body The relationships between insulin resistance and BMD are not clear. Therefore, we conducted a cross-sectional study to examine the relationship between insulin resistance and BMD among Korean young adult population. This study is based on the Korea National Health and Nutrition Examination Survey (KNHANES) from 2008-2010. BMD and body composition were measured by DXA method. Insulin resistances were obtained by HOMA-IR equation. The relationship between BMD and HOMA-IR were analyzed with multiple regression models, which were adjusted with age, body weight, alcohol drink, exercise level and 25(OH) vitamin D level. We analyzed 1936 persons who were aged between 20-39 years old. HOMA-IR showed positive correlations with lumbar BMD and femur BMD in men and all BMD in women. However we adjusted with age body weight, alcohol drink, exercise level and 25(OH) vitamin D level, insulin resistance had negative relationship with Lumbar BMD (B=-0.123, p<0.001), femur neck BMD (B=-0.057, p=0.01). In this study, BMD were decreased with the increase of insulin resistance in Korean young adult.

MO0294

Serum phosphate levels are related to all-cause, cardiovascular and COPD mortality in men: the Rotterdam Study. Natalia Campos^{*1}, Lies Lahousse², Guy G Brusselle³, Bruno H Stricker⁴, Albert Hofman⁴, Henning Tiemeier⁵, Oscar H Franco⁴, André G Uitterlinden⁶, M Carola Zillikens⁶. ¹Erasmus MC, The Netherlands, ²Department of Respiratory Medicine, Ghent University, Belgium, ³Department of Respiratory Medicine, Ghent University Hospital, Belgium, ⁴Department of Epidemiology, Erasmus Medical Center, Netherlands, ⁵Department of Psychiatric Epidemiology, Erasmus Medical Center, Netherlands, ⁶Department of Internal Medicine, Erasmus Medical Center, Netherlands

High serum phosphate levels have been associated with increased mortality risk in chronic kidney disease (CKD) but the nature of such a relation in the general population is unclear. In two cohorts from the Rotterdam Study (RS-I and RS-II) we assessed the relation between phosphate levels and all-cause and cause-specific mortality divided into 7 groups, using ICD-10: cardiovascular diseases (CVD), cancer, external causes, infectious diseases, dementia, chronic lung diseases and other causes. In 3732 elderly participants from RS-I and 2494 from RS-II serum phosphate levels were measured in the fasting state and assessed with same technique. Cox and competing risk regression models were applied, adjusted for age, BMI and smoking; results from both cohorts were meta-analyzed applying fixed-effect model. Pooled HRs (95% CI) are expressed for each 1 mg/dL increase in serum phosphate levels. Due to interaction by gender, we performed sex-stratified analyses. Average follow-up was 14.5 y (RS-I) and 10.9 y (RS-II). A significant positive association was found between phosphate and all-cause mortality in men 1.46 (1.27-1.69) but not in women (0.90 (0.77-1.04)). In men, higher phosphate increased the risk for CVD mortality (1.66 (1.29-2.14)), other causes (1.67 (1.16-2.41)) and chronic lung disease mortality (1.96 (1.02-3.76)), the latter driven by mortality due to Chronic Obstructive Pulmonary Disease (COPD) (4.39 (2.12-9.07)). No significant relations were found for mortality due to infections, cancer, dementia or external causes in men. Analyses restricted to male subjects with phosphate levels within normal range yielded essentially same results. Our findings were not essentially modified after adjustments for calcium and 25-hydroxyvitamin D levels; further adjustment for eGFR produced only slight attenuation: CVD 1.62 (1.27-2.08), other causes (1.82 (1.26-2.62)), lung diseases 1.94 (1.03-3.64), COPD 3.70 (1.89-7.27). We observed no associations between phosphate levels and cause-specific mortality in women. In conclusion, even within normal range serum phosphate levels are associated with increased all-cause, cardiovascular and COPD mortality in men but not women not explained by calcium, 25-hydroxyvitamin D levels or kidney function. Our results suggest that the concept of phosphotoxicity beyond CKD population deserves further attention. The novel finding of an association of phosphate levels with COPD mortality needs further research on underlying mechanisms.

MO0295

The Association Between Inflammatory Markers and Measures of Hip Bone Density, Geometry, and Strength in Older Men: the Osteoporotic Fractures in Men Study. Kamil Barbour^{*1}, Stephanie Harrison², Eric Orwoll³, Jane Cauley⁴. ¹University of Pittsburgh, USA, ² California Pacific Medical Center Research Institute, San Francisco, CA, USA, USA, ³Portland VA Medical Center, & Oregon Health Sciences University, Portland, Oregon, U.S.A, USA, ⁴Department of Epidemiology, University of Pittsburgh, Pittsburgh, PA, USA, USA

Introduction: Despite compelling evidence linking inflammation and fractures, the mechanism by which inflammatory markers influence bone biology is not well understood. The relatively weak association between inflammatory markers (IM) and bone mineral density (BMD), has led investigators to hypothesize that inflammation may increase fracture risk through other mechanisms (e.g., geometry, and strength).

Methods: To test this hypothesis, we examined the association between IM and measures of bone density, geometry, and strength in 239 men (mean age= 73.7 ± 5.8 years) from the Osteoporotic Fractures in Men Study (MrOS). Interleukin-6 (IL-6), tumor necrosis factor alpha (TNF-α), and soluble receptors (SR) for IL-6 (IL-6 SR) and TNF-α (TNF SR1 and TNF SR2) were measured using enzyme-linked (ELISA). C-reactive protein (CRP) was measured with an immunoturbidimetric assay. All bone measures were assessed using quantitative computed tomography (QCT) of the proximal femur. Linear regression models were used to determine the association between inflammatory marker levels and the bone measures. Multivariate models were adjusted for age, race, BMI, clinic site, fracture history, diabetes, heart disease, rheumatoid arthritis, areal BMD (aBMD), smoking, physical activity, health status, total calcium and vitamin D intake , and use of non-steroidal anti-inflammatory drugs, statins, corticosteroids, and selective serotonin reuptake inhibitors.

Results: Levels of IL-6, TNF-α, TNF SR1 and TNF SR2 were not associated with hip vBMD or structure. Higher levels of CRP were associated with greater trabecular volumetric BMD (vBMD) of the total hip and trochanter, but lower cross-sectional area (for both trochanter and femoral neck) and proximal femoral strength. Moreover, men with 2 or 3-6 inflammatory markers in the highest quartile compared with men who had 0 or 1 inflammatory marker(s) in the highest quartile had significantly lower trochanteric cross-sectional area (32.3 and 32.8 vs. 34.0 cm², respectively), p-trend=0.03. Conversely, higher IL-6 SR was associated with increased cortical volume of the total hip, femoral neck and trochanter, and higher proximal femoral strength.

Conclusions: Higher levels of inflammatory markers were not associated with lower vBMD, but a high inflammatory burden was associated with lower trochanteric cross-sectional area, and higher CRP was associated with lower cross-sectional area and proximal femoral strength. On the other hand, men with higher IL-6-SR levels had greater cortical volume and bone strength. Our findings suggest that inflammation may play a larger role for bone geometry as opposed to bone density.

Table: The association between inflammatory markers and measures of hip bone density, geometry, and strength in older men: the Osteoporotic Fractures in Men Study (MrOS)

MO0296**The Saudi Central Osteoporosis Registry (T-Score): A Kingdom-Wide Observational and Longitudinal Registry for Saudis with Osteoporosis.** Nasser Al-Daghri*. King Saud University, Saudi Arabia

Background: Epidemiologic evidence points to increased incidence of osteoporosis in KSA. The aim of this research registry is to obtain the incidence, prevalence and patterns of osteoporosis and risk factors in KSA. Methods: The registry was launched last July 2014 after the completion of the registry website and ethical approval from the College of Science, King Saud University in Riyadh, KSA. Data collection started in several hospitals in Riyadh (central region) but encompasses several regions in KSA as well to enrol Saudi patients with osteoporosis and related diseases based on bone mineral density (BMD) assessment. The follow-up part of the registry are to be completed at specified times in-line with the patient's treatment. A general and validated questionnaire is to be administered to all enrolled patients which contains demographic and anthropometric measurements, family history, medications taken and results from imaging and several bone-related markers. As of January 2015, a total of 325 cases have been registered (excluding males) and is expected to increase since it is on-going. Pilot results will be presented based on the aims of the registry, including FRAX assessment specific to KSA patients. Results: Preliminary data revealed that women with osteoporosis had a significantly higher percentage of illiteracy than controls, with a significantly higher prevalence of divorcees and widows (p-values<0.01). In the clinical category however, the control group had a significantly higher waist circumference and circulating levels of total cholesterol than the osteoporosis group (p-values<0.01). The control group also had a higher prevalence of mild activity and a lower prevalence of allergy to medicines (p-values<0.01). Conclusion: Pilot data reveals marked differences in demographic and metabolic indices between patients with and without osteoporosis. Prospective evaluation is necessary to include medications that will account for a more accurate picture of osteoporosis burden in KSA.

MO0297**Catch-a-Break: A novel approach to detect osteoporosis after an incident fracture.** Angela Juby¹, Liz Evens², David Hanley³, Lara Osterreicher⁴, Members Bone Joint Health Strategic Clinical Network⁵. ¹University of Alberta, Canada, ²Alberta Bone & Joint Health Institute, Canada, ³University of Calgary, Canada, ⁴Health Link Alberta, Alberta Health Services, Canada, ⁵Alberta Health Services, Canada**Purpose**

In Alberta, 80% of fragility fractures over age 50, are not assessed or treated for osteoporosis (OP). This project addresses that care gap with a phone-out approach, utilizing a pre-existing phone-in health information service (Healthlink).

Methods

Patients are identified from Emergency Department, Urgent Care Centre, Cast Clinic, or Ortho/Fracture Clinic with the following criteria: age >49; Alberta resident; ICD code for fracture (includes vertebrae, ribs, pelvis, shoulder, arm, wrist, lower leg, ankle, and any pathological fracture associated with osteoporosis); ICD code for mechanism of fracture conducive to a fragility fracture (e.g., unspecified fall). Identified patients are called at home by the Health Link Alberta team. Screening questions identify those at high risk of having had a fragility fracture. If high-risk patients have not seen their Family Physician (FP), they are followed-up every 3 months to ensure they visit their physician. All high-risk patients will be followed up at 12 months to complete an evaluation survey. In high risk patients, their FP is sent a letter reinforcing a low impact fracture is a risk for osteoporosis; and both the FP and patient receive educational materials about osteoporosis and links to Osteoporosis Canada guidelines

Results

Catch-a-Break launched in June 2014. Currently, Alberta-wide, of 8,135 patients called: 19% were not reached, 1% had died and 5% are in progress. Of those contacted (6,166), 65% were high risk, 17% low risk, and 18% chose not to participate. Results from the initial call, indicated 24% of high risk patients already had a diagnosis of OP, and 71% had seen their FP about their recent fracture. In September 2014, 3 month follow up calls were made to those patients indicating they had not seen their FP at the time of the initial call (1012 patients): 12% were not reached, 2% refused, and 33% are in progress. Of those contacted to date (525), 73% of patients had seen their FP since the initial call, and indicated it was a due to the Health Link Alberta contact. Upcoming 12 month (June 2015) data, will allow further evaluation, including OP investigations and therapy for those at high risk, and a full economic evaluation (qualitative and quantitative).

Conclusion

Using a pre-existing phone in service, for call-out screening, resulted in an increased identification of suspected OP fractures and led to increased FP follow up.

Disclosures: Angela Juby, None.

MO0298**Decline in BMD testing: a nation-wide study in France.** Eric Lespessailles^{*1}, Pierre Gabach², Daniel Buchon³, Maryline Douge², Jean Marc Feron⁴, Laurent Grange⁵, Claire Leboucher², Erick Legrand⁶, Gabrielle PEYRE-LANQUAR², Eleonore Ronfle², Pascal Guggenbuhl⁶, Thomas Thierry⁶. ¹Centre Hospitalier Regional Orleans, France, ²CNAMTS, France, ³Universitary Limoges, France, ⁴Saint Antoine Hospital, France, ⁵CHU Grenoble, France, ⁶CHU, France**Background**

The assessment of bone mineral density (BMD) remains crucial for the general management of osteoporosis (OP). Since 2006, French national health insurance provides conditional reimbursement for bone density testing by dual-energy x-ray absorptiometry (DXA).

Methods

We aimed to evaluate the evolution of the number of BMD testing between 2011 and 2013 using the sources of national health insurance information system (SNIRAM). In addition, we sought to describe in the population of patients hospitalized for fragility fracture in 2012 the dispensation of BMD testing in the following year.

Results The total number of BMD testing went down by 13%, essentially in private activity which represents 90% of the BMD measurements in France (table).

Among patients hospitalized for a fragility fracture, only 0.8 % of patients had a BMD testing in the month following their fracture hospitalization. This percentage slightly increased to 6% and 8.5% at 6 and 12 months respectively.

Only 25% of the patients having a BMD testing, received an anti-osteoporotic treatment within 6 months following the exam.

Discussion

These data showed that there is a declining number of BMD testing from 2011 to 2013 with a 6.4% annual decrease. While the number of BMD testing plateaued in men, the downward trend of BMD testing was the most prominent in women. There is a substantial post-fracture BMD testing and treatment gap. These worrying findings underlined important undertreatment of patients with osteoporosis, especially after the fracture. Procedures that will improve post-fracture coordination between health care professionals are needed for a better management of these patients with the objective of reducing future fracture risk.

Number of BMD testing realized in the private sector

| Year | 2011 | 2012 | 2013 |
|-----------------|---------|---------|---------|
| Male | 32 942 | 32 883 | 32 043 |
| Female | 552 710 | 511 665 | 474 964 |
| Badly filled in | 189 | 173 | 111 |
| Total | 585 841 | 544 721 | 507 118 |

Source: DCIR, 2011-2013

Number of BMD testing realized in the public sector

| Year | 2011 | 2012 | 2013 |
|-----------------|--------|--------|--------|
| Male | 8 380 | 8 648 | 9 632 |
| Female | 54 224 | 53 677 | 54 157 |
| Badly filled in | 4 811 | 4 269 | 518 |
| Total | 67 415 | 66 594 | 64 307 |

MO0299

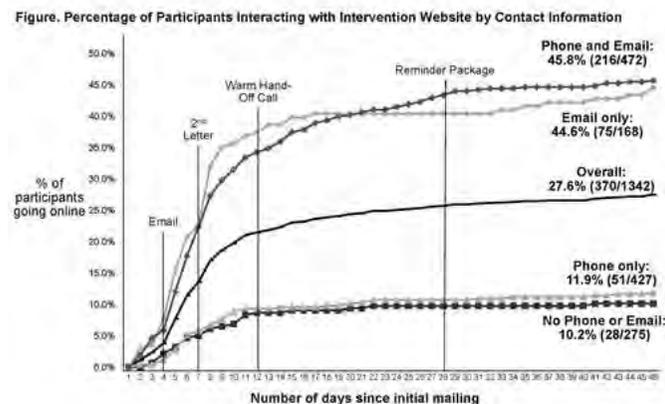

Design and Uptake of a Multi-modal Intervention for the Activating Patients at Risk for Osteoporosis (APROPOS) Study: a Cluster-randomized Trial within the GLOW Cohort. Maria Danila¹, Ryan Outman¹, Tammi Thomas¹, Jeroan Allison², Fred Anderson², Jeffrey Curtis¹, Susan Greenspan³, Andrea LaCroix⁴, Michael Miller⁵, Jeri Nieves⁶, Monika Safford¹, Stuart Silverman⁷, Ethel Siris⁶, Amy Warriner⁸, Nelson Watts⁹, Kenneth Saag¹. ¹University of Alabama at Birmingham, USA, ²University of Massachusetts Medical School, USA, ³University of Pittsburgh, USA, ⁴University of California at San Diego, USA, ⁵University of Oklahoma, USA, ⁶Columbia University, USA, ⁷Cedars-Sinai Center of Excellence, USA, ⁸University of Alabama at Birmingham, USA, ⁹Mercy Health Osteoporosis & Bone Health Services, USA

Purpose: Initiation of osteoporosis treatment is suboptimal, even among older women with history of a prior fracture. We designed a tailored intervention to increase use of osteoporosis medications in the GLOW cohort, a prospective cohort study of women aged 55 years and older at risk for fractures.

Methods: US GLOW women with a prior fracture and not currently using anti-osteoporosis therapy were eligible. Four nominal groups including 41 racially/ethnically diverse women identified osteoporosis treatment barriers. We used the Information, Motivation, Behavior Skills model to develop a direct-to-patient intervention to mitigate potentially modifiable barriers. The intervention included videos tailored by race/ethnicity, barriers, and stage of change and grounded in "story telling" narratives, based on stories from osteoporosis patients and portrayed by actresses of different race/ethnicity. Other videos addressed fracture risk awareness and patient-provider communication. Participants were randomized to either intervention or usual care. The intervention group was sequentially sent a letter and email (if an email address was provided) with a web link and a "code" to access the personalized videos online and a DVD. Those who provided phone numbers were called by staff members a week after the DVD was mailed followed a week later by an interactive voice response technology call.

Results: 2684 GLOW women met eligibility criteria with 1342 randomly assigned to the intervention. 860 women did not rank a barrier to treatment, 364 ranked 3 or more, and 118 noted 4 or more barriers. For those that ranked a barrier, preference for natural treatments was ranked highest (n=130, 27%) and concerns about osteonecrosis of the jaw was the most commonly ranked barrier (n=322, 67%). Overall, 28% (n=370) viewed the educational videos online. Of those who provided an email address, 45% (291/640) viewed the videos online versus 11% (79/702) of those who did not provide an address. Uptake of the DVD component is not yet available.

Conclusion: We describe implementation science methods used to develop a multi-modal patient activation intervention within the GLOW cohort. A large proportion of women assigned to the intervention arm viewed the videos online, particularly those with email addresses, reflecting the growing proportion of older women who access the Internet. Low cost, generalizable web-based interventions have potential to address osteoporosis treatment barriers.

Electronic Decision Support for the Investigation and Management of Osteoporosis. Yvonne Selecki¹, Tuan Nguyen¹, Jackie Center¹, John Eisman². ¹Garvan Institute of Medical Research, Australia, ²Garvan Institute of Medical Research, Australia

The increasing use of computerised patient records has opened new opportunities to use this virtual database to improve health outcomes.

Clinical decision support systems have been designed and tested with the aim of closing the gap between evidence based guidelines and daily practise.

We have developed clinical decision support software to assist doctors and patients in the investigation and treatment of Osteoporosis.

The software expands from the Garvan Fracture Risk Calculator to provide individualised risk calculations and recommendations for treatment.

Graphic displays of fracture risk and how this risk changes with treatment are provided.

Uniquely this software connects with patient records so the software self populates enabling seamless use during a consultation.

The development of clinical software requires unique collaborations between doctors and IT professionals. Early utility testing in rural Australia is described.

Disclosures: Yvonne Selecki, None.

MO0301

Integrated Osteoporosis, Sarcopenia, Fall Related Screening, Education, and Health Promotion Program for High Risk Population in Taiwan. Rong-Sen Yang¹, Ding-Cheng Chan¹, Chih-Hwa Chen², Hung-Yi Chiou³, Jaw-Shan Hwang⁴, Shih-Te Tu⁵, Kuang-Hung Hsu⁶, Fang-Ping Chen⁷, Jung-Fu Chen⁸, Chung-Yhu Yang⁹, Lay-Chin Lim¹. ¹National Taiwan University Hospital, Taiwan, ²Taipei Medical University Hospital, Taiwan, ³Taipei Medical University, Taiwan, ⁴Chang Gung Memorial Hospital, Taiwan, ⁵Changhua Christian Hospital, Taiwan, ⁶Chang Gung University, Taiwan, ⁷Keelung Chang Gung Memorial Hospital, Taiwan, ⁸Kaohsiung Chang Gung Memorial Hospital, Taiwan, ⁹Kaohsiung Medical University, Taiwan

Purpose

To determine the effects of 4 independent but integrated programs for intervention of osteoporosis, sarcopenia, fall related screening, education, and health promotion in Taiwan.

Methods

Sponsored by the Wang Jhan-Yang Charitable Trust Fund (WJYCTF), and the Taiwanese Osteoporosis Association (TOA), the study included 4 programs with 8 sub-programs targeting community adults with high risks for fall/osteoporosis/fracture/sarcopenia. Core assessments include demographics, osteoporosis/fracture/fall risks, sarcopenia indices, and nutrition. Interventions include combinations of educations to improve awareness, screening and referral, exercise programs, nutrition evaluation and consultation, and post-fracture care management.

Results

In total 3,911 subjects were enrolled. Program #1 found that 70% of subjects had low bone mineral density (BMD) and 15% with osteoporosis. Less exercise, higher fat mass, and lower muscle mass were associated with lower BMD ($p < 0.05$). The exercise intervention improved muscle strength but not muscle mass. Program #2 found that 3 exercise interventions for 3 months resulted in significant and similar improvements in sarcopenic indices including walking speed (+8.3%), hand grip strength (+8.7%) and knee extensor strength (+24.9%). Program #3 found that group health promotion improved medication adherence rate to >80%. The basic muscle exercise improved grip muscle strength (+18.2%). Advanced core body muscle exercise significantly increased muscle mass (+1%), decreased fat mass (-3.2%), and increased grip strength (+20.4%) (all, $p < 0.05$). One sub-program using commercial X-box exercise program for 3 months improved physical performance ($p < 0.05$). Program #4 found that individualized exercise specialist program showed improvements in muscle endurance (standing-up repetitions from sitting position (+55.3%), lifting weight in 1-minute (+38.4%)), walking speed (+17.2%), heart beats after step on-the-spot (-9.3%) (all, $p < 0.05$). One sub-program #4 showed an average of 1.2 falling episodes/year, 80% occurred at home (bathrooms, 60%). Fracture liaison service program significantly improved on osteoporosis and medication knowledge.

Conclusions

This national integrated education and screening campaign were highly appreciated and showed significant results in improving osteoporosis awareness, most sarcopenic indices through short-term muscle exercises programs. Further efforts will be made to show their effects on the decreasing the falling episodes and fragility fractures.

MO0302

Mortality and re-fracture benefits of Orthogeriatric and Fracture Liaison Service Models of Care: A UK Population Based Study. Muhammad Javaid¹, Samuel Hawley², Jose Leal¹, Daniel Prieto-Alhambra², Alastair Gray¹, Nigel Arden², Janet Lippett³, Sally Sheard¹, Cyrus Cooper⁴, Andrew Judge². ¹University of Oxford, United Kingdom, ²NIHR Musculoskeletal Biomedical Research Unit, University of Oxford, United Kingdom, ³Royal Berkshire Hospital, United Kingdom, ⁴MSc Lifecourse Epidemiology Unit, University of Southampton, United Kingdom

Purpose: a) To evaluate the clinical and cost-effectiveness of specialist orthogeriatric (OG) and nurse-led fracture liaison service (FLS) care for patients presenting with a hip fracture; b) To estimate UK hospital costs of hip fracture up to two years post fracture.

Methods: Using routine administrative data, a cohort of patients with hip fracture between 2003 and 2011 were identified from 11 secondary care centres in a region of England, UK. For each centre, the time when an OG or FLS was introduced/expanded was identified. The effect of these interventions on subsequent mortality (using multivariable Cox regression) and second hip fracture rates (using competing risks survival models accounting for death) was determined within a before and after study design. For estimation of hospital costs, non-parametric censoring methods were used for estimating average annual costs and generalised linear models for the determinants of cost.

Results: 33,152 patients (mean age 83yrs, 75% women) were identified as having a hip fracture. 3033 (9.5%) and 9662 (29.8%) died within 30-days and 1-year respectively. 1288 (4.2%) sustained a second hip fracture within 2-years. The pooled estimated impact of OG and FLS models demonstrated clinically significant reductions in mortality but not re-fracture (table). Mean censor-adjusted 1-year hospital costs after index hip fracture were £14,163 (95%CI: £14,008 to £14,317) giving a UK estimate hospital cost of £1.1 billion / year for hip fractures. Only 60% of the first year costs were due to the index admission and were significantly higher for men and those with complications including re-fracture.

Conclusions: The data demonstrate that OG and FLS models of post-hip fracture care have large beneficial effect on subsequent mortality rates with no evidence for a reduction of second hip fracture rate. Secondary care costs following hip fracture are high and provide a strong economic incentive for effective FLSs that reduce the risk of the index and subsequent hip fractures.

| | Orthogeriatrician | | Osteoporosis Nurse Specialist | |
|--------------------------|-------------------|-------------------------|-------------------------------|-------------------------|
| | Hazard Ratio | 95% Confidence Interval | Hazard Ratio | 95% Confidence Interval |
| Mortality (30-days) | 0.73 | 0.65-0.82 | 0.80 | 0.71-0.91 |
| Mortality (1-year) | 0.81 | 0.75-0.87 | 0.84 | 0.77-0.93 |
| Hip re-fracture (2-year) | 0.95 | 0.79-1.15 | 1.03 | 0.82-1.31 |

MO0303

Real-world Persistence to Injectable Osteoporosis Therapy. Ankita Modi¹, Shiva Sajjan^{*2}, Ralph Insinga², Jessica Weaver². ¹Merck & Co., Inc., USA, ²Merck & Company, USA

Background: Relatively poor persistence to oral bisphosphonate therapy for osteoporosis (OP) is well known in the US. Little research has been conducted regarding real-world persistence to injectable (IV) OP therapies. It is important to understand real-world and long term persistence to IV OP therapies in order to understand their long term value.

Objectives: This study was designed to describe treatment persistence among patients who initiate IV OP therapies and to examine predictors of persistence among OP patients who started on IV OP therapies.

Materials and Methods: This retrospective, observational study utilized an administrative claims database from a large US managed care plan to measure persistence to IV OP therapy at 6 month intervals over 2 years. Patients included were ≥55 years of age, and had newly initiated IV OP therapy between January 2008 and June 2012. Eligible patients were continuously enrolled in the health plan for 1 year prior to the index date (date of start of first OP medication) and for 1.5 years after the index date, although patients that had data for up to 2 years were also followed. IV OP treatments included in the analysis were ibandronate (IBN), zoledronic acid (ZOL), teriparatide (TER) and denosumab (DEN). Patients receiving IV OP therapy prior to the index period, patients with Paget's disease or neoplasms, and patients on chemotherapy were excluded. Persistence to treatment was assessed for each drug using Kaplan-Meier survival analysis. A 90 day grace period after the date of the next indicated time point for administration was allowed for flexibility in scheduling of re-administrations.

Results: 4,756 patients met the inclusion criteria for the study, with 233 on IBN, 3,128 on ZOL, 778 on TER and 617 on DEN. Depending on treatment type, the mean age of patients at index date ranged from 71.5 years (IBN) to 73.5 years (DEN). 9.4% (IBN) to 31.2% (TER) had a history of recent osteoporotic fracture, and mean Charlson comorbidity scores ranged from 0.51 (ZOL) to 0.61 (TER). At 12 months, persistence was 51.2% among patients using DEN, followed by ZOL (40.6%),

TER (32.9%) and IBN (31.8%). By 24 months, persistence was lower for each treatment, at 36.4% for DEN, followed by ZOL (24.2%) IBN (14.3%) and TER (14.1%). Conclusion: For the majority of patients, real world persistence with IV OP treatment beyond 1 year is lacking, as has previously been observed for patients initiating oral bisphosphonates.

MO0304

Specialty Care Increases Odds of Osteoporosis Screening and Diagnosis in Postmenopausal Women Medically Homed in an Academic Multispecialty Practice. Clare O'Connor^{*}, Christie Bartels, Karen Hansen. University of Wisconsin School of Medicine & Public Health, USA

Half of postmenopausal white women sustain an osteoporotic fracture, causing significant morbidity and mortality. The US Preventive Services Task Force recommends bone mineral density (BMD) screening for women = 65 years old yet screening remains suboptimal. We assessed predictors of screening and diagnosis of low BMD in postmenopausal women receiving care in an academic multispecialty practice. We hypothesized that specialty care would increase odds of screening, as reported by others. We studied 8,217 women age =65 years old who were medically homed (=2 primary care visits in 2010-2011) at an academic health center. We calculated multivariate odds ratio and 95% confidence intervals for BMD screening and/or diagnosis of osteopenia or osteoporosis since age 60. Covariates included sociodemographic factors (age, marital status, race, language), health habits (body mass index, tobacco use), comorbid conditions (29 conditions, Elixhauser score), and healthcare utilization (number of primary and specialty visits). Subjects were 72.6 years old, predominantly white (97%) and English-speaking (99%). In the cohort, 86% were screened for and/or diagnosed with low BMD. Women seeing specialists had higher screening/diagnosis rates than women without specialty care (86% versus 78%, p<0.001). A dose-response relationship between specialty visits and screening/diagnosis was observed (Table). Other factors associated with greater odds of screening/diagnosis were English language (2.87, 95% CI 1.72-4.67), marriage (1.29, 95% CI 1.13-1.47), hypothyroidism (1.23, 95% CI 1.03-1.48) and Elixhauser score =4 (1.41, 95% CI 1.10-1.82). Women 70-80 years old were more likely to be screened or diagnosed than those younger or older (Table). Factors associated with reduced screening and diagnosis included primary care visits (0.90, 95% CI 0.86-0.95), tobacco use (0.58, 95% CI 0.46-0.74), obesity (0.55, 95% CI 0.48-0.63), heart failure (0.53, 95% CI 0.37-0.75) and diabetes (0.75, 95% CI 0.63-0.91). In our study, specialty visits increased, while primary visits reduced, the odds of osteoporosis screening and diagnosis. Such findings might reflect specialist adherence to guidelines, indication bias and/or competing demands in primary care. Although tobacco use increases fracture risk, tobacco users had reduced odds of screening and diagnosis. Remaining gaps support the need for systems-based interventions such as primary care nurse orders to further improve osteoporosis screening.

| Characteristic | Odds Ratio | 95% CI |
|------------------------|---------------------------|------------------|
| Specialty Care | referent | |
| No Visits | 1.36 | 1.14, 1.63 |
| 1 Visit | 1.52 | 1.24, 1.87 |
| ≥2 Visits | | |
| Age | referent | |
| 65-69 | 1.62 | 1.37, 1.92 |
| 70-74 | 1.43 | 1.19, 1.72 |
| 75-79 | 1.09 | 0.91, 1.32 |
| ≥80 | | |
| Language | English | 2.87, 1.72, 4.67 |
| Married | Yes | 1.29, 1.13, 1.47 |
| Tobacco | Current | 0.58, 0.46, 0.74 |
| Obesity | BMI ≥30 kg/m ² | 0.55, 0.48, 0.63 |
| Comorbid Conditions | Congestive Heart Failure | 0.53, 0.37, 0.75 |
| | Diabetes Mellitus | 0.75, 0.63, 0.91 |
| | Hypothyroid | 1.23, 1.03, 1.48 |
| | Elixhauser Score ≥4 | 1.41, 1.10, 1.82 |
| Healthcare Utilization | Any ambulatory visit | 1.09, 1.05, 1.13 |
| | PCP Visit | 0.90, 0.86, 0.95 |

An odds ratio >1 indicates higher odds of screening or diagnosis of low bone mineral density. 95% CI denotes the 95% confidence interval for the odds ratio. "PCP" indicates primary care provider. The multivariate model was highly significant (p<0.0001) and provided an area under the curve of 0.67 to predict testing.

MO0305

The Ethics of Treating Osteopenia: What are we Preventing?. Loren Greene^{*}. New York University School of Medicine, USA

First you have a drug. Then you have a test for a disease, then you need to treat people who become patients with a drug. Furthermore, you market the test and then create a perception of need for treatment. In 1995, a drug was approved, and simultaneously, the disease could be diagnosed by bone density testing. This led to

treatment for a new class of disease, that could be prevented and treated. BMD itself became an indication for treatment and the improvement in BMD became a standard measure of drug efficacy, rather than the harder to achieve true clinical outcome, the reduction in fracture. The marketing problem was solved by expanding testing, and expanding awareness by medical professionals and the public.

The use of bone density criteria greatly expanded the number of people who might be diagnosed to have osteoporosis or low bone density and therefore requiring or requesting medication to treat or prevent osteoporosis. Marketing to and by the medical community, as well as to the general public created a huge demand for medication to treat osteoporosis and low bone density. Susceptible to influences from pharmaceutical companies and device manufacturers, physicians helped to expand the market for these drugs through consultant meetings for "thought leaders", "education (including dinner meetings and CME, and provisions for inexpensive (though not precise) bone density testing at "alternative sites" or loans for bone density machines. Direct-to-consumer marketing served to increase patient awareness and understanding, but also the acceptance by new "patients" who "needed" pharmacologic prevention as well as treatment of osteoporosis, with questionable medical and economic and even psychological results..

MO0306

Why patients still untreated 1 year after a Fragility Fracture refuse an intervention to treat osteoporosis?. Noémie Gionet Landry*¹, François Cabana², Isabelle Gaboury¹, Gilles Boire², Sophie Roux², Nathalie Carrier², Marie-Claude Beaulieu¹. ¹Université de Sherbrooke, Canada, ²CHUS, Canada

OBJECTIVE: To determine the reasons underlying refusal or acceptance of an intensive intervention to improve bone health 1 year after a fragility fracture (FF). **METHODS:** The OPTIMUS program is a strategy implemented in fracture clinics to educate patients and empower primary care physicians (PCPs) to treat osteoporosis (OP) after a FF. Women and men over 50 with an incident FF were randomly assigned to Standard Care (SC) or to either minimal (MIN) or intensive (INT) interventions and followed up (FU) by phone calls (up to 4 yrs). Interventions consisted in information letters to PCPs at baseline and when patients remained untreated during the first year FU. Relative to MIN, INT patients had a prescription for baseline laboratory tests and more frequent FU phone calls. At year 1, untreated patients in SC and MIN groups were offered an INT intervention. **RESULTS:** We included 563 patients in SC (n=192) and in MIN (n=371) groups, of which 531 had a 12-month FU. At year 1, 267 patients (50.3%) remained untreated (SC 113/184 (61.4%) vs MIN 154/347 (44.4%), p<0.001). Only 69 (25.8%) of these patients accepted the INT intervention. Untreated patients who agreed to switch from SC or MIN to INT were more likely to have a family history of OP (43.2% vs 24.1%, p=0.035); lower FRAX for major FF [med (EIQ) 9.7 (7.6-14.5) vs 12.0 (8.7-20.3), p=0.003] or for hip FF [1.3 (0.8-2.9) vs 2.2 (1-7.2), p=0.002]; were younger (61.3 ± 8.9 vs 66.1 ± 11.9, p=0.006); and more physically active (= 1 day/week) (31.3% vs 16.0%, p=0.012). In patients accepting an INT intervention, the main reason given to explain absence of treatment at 1 year was that they had not seen their PCP yet (65%). Most patients declining the INT intervention while untreated (58.8%) stated no need for treatment. Qualitative interviews were conducted to further explore the reasons for declining the intervention to treat OP. **CONCLUSION:** One year after a FF, patients have little interest to investigate and potentially treat underlying OP. Those patients who did accept the intervention were younger, more physically fit and at lower risk than those who refused. The major hurdles explaining the absence of treatment in those willing to be investigated appeared to be the lack of an evaluation by their PCP, knowledge problems and wrong beliefs from both patients and PCPs. Our data further support the concept of a window of opportunity closing within the first year after a FF.

Change in Physical Function Following Hip Fracture among Elderly Osteoporotic Women. Derek Weycker*¹, Rich Barron², John Edelsberg³, Alex Kartashov³, Barry Crittenden², Andreas Grauer². ¹Policy Analysis Inc. (PAI), USA, ²Amgen Inc., USA, ³Policy Analysis Inc., USA

Background: While hip fractures among elderly women with osteoporosis are known to lead to a decline in functional status, the extent of short-term and long-term functional loss that is attributable to hip fracture is not well established.

Methods: A retrospective matched-cohort design and data from the Study of Osteoporotic Fractures (SOF)—which includes 20 years of prospectively collected data on osteoporosis care and outcomes at periodic exams—were employed. The source population included all women in the SOF Caucasian cohort. From the source population, each woman who had an adjudicated fracture of the hip ("Fx subject") between exams was matched to a woman who did not have a hip fracture between

those exams ("comparison subject"); matching was implemented based on age, baseline physical function, and propensity score (fixed 1:1 ratio). Change in physical function from the pre-fracture exam to each post-fracture exam was measured using the Total Functional Difficulty (TFD) score, and was defined dichotomously by a clinically meaningful functional deficit (increase ≥5 vs. <5 units). The TFD score is the sum of responses (range, 0 [no difficulty] to 3 [unable to perform]) to five activities of daily living including meal preparation, heavy housekeeping, ability to climb ten stairs, shopping, and getting in/out of a car.

Results: A total of 334 Fx subjects were matched to comparison subjects; mean (SD) age was 80 (5) years and mean (SD) pre-fracture TFD score was 1.8 (2.7) and 1.7 (2.6), respectively. Between the pre-fracture exam and first post-fracture exam (~3 years), 37% (95%CI 32-43) of Fx subjects had ≥ 5-unit increase in TFD score, versus 13% (95%CI 10-18) of comparison subjects; differences between cohorts decreased but generally persisted over time (up to ~7 years) (Figure).

Conclusions: While apparent age-related decline in functional status was observed in the fracture and non-fracture subjects, hip fractures among elderly women with osteoporosis worsened this decline during the period from 2-3 years post-fracture up to 7 years post-fracture. Further research is needed to confirm the specific ways in which hip fracture impacts physical function, as well as the relative contribution of fractures versus other age-related comorbidities to declining functional status in this population.

Health Utility Following Osteoporotic Fracture Using SF6D: Results from ICUROS US. Stuart Silverman*¹, Deborah T Gold², John T Schousboe³, Loretta H Pearson⁴, Mackenzie R Bronson⁴, Fergus E McKiernan⁵, Robert A Yood⁶, John I Reed⁶, Daniel H Solomon⁷, Chad Deal⁸, William Griffith⁹, Michael B Nichol¹⁰, Susan Gallagher⁴, Kristin Anton⁴, Anna NA Tosteson⁴. ¹Cedars-Sinai/UCLA, USA, ²Duke University, USA, ³Park Nicollet Clinic, HealthPartners, USA, ⁴Geisel School of Medicine at Dartmouth, USA, ⁵Marshfield Clinic, USA, ⁶Reliant Medical Group, USA, ⁷Brigham & Women's Hospital, USA, ⁸Cleveland Clinic, USA, ⁹University of Wisconsin, USA, ¹⁰USC Pharmacy, USA

Introduction: Osteoporotic fractures result in loss of quality of life, which can be measured as health utility (HU) using EQ5D and SF6D. ICUROS (International Costs and Utilities Related to Osteoporotic Fractures Study) is a global study of medical costs and HU following osteoporotic fractures. Although all ICUROS participants completed EQ5D, only U.S. participants completed SF6D and these data are presented here.

Methods: We report HU using SF6D for hip, wrist, humerus, and vertebral fracture. Vertebral fracture is described by type of management: vertebral augmentation or non-operative care. At the time of enrollment, post-fracture HU was collected along with pre-fracture HU (retrospectively by recall). Subsequently, HU was prospectively measured at 4, 12, and 18 months post-fracture. Mean HU changes from pre-fracture (Δ post-fx - pre-fx) and standard deviations (SD) are reported for each post-fracture time point. Regression analyses were undertaken to assess changes in HU by fracture type over time after adjusting for age and gender.

Results: Mean pre-fracture SF6D HU was lowest for vertebral fracture patients. All patients had significant HU losses post-fracture, which lessened over time (Table). Mean HU changes for vertebral fracture patients were comparable for those treated with augmentation vs. non-operative care; while non-operatively treated patients had a smaller loss of HU at 18 months compared to baseline (-0.040 vs. -0.083, p-value=0.13). For all fracture types, improvements in HU (changes that became smaller with time since fracture) were seen. By 18 months post-fracture, only wrist fracture patients had attained pre-fracture HU levels. Hip, humerus and vertebral fracture patients had persistent loss of HU relative to pre-fracture through 18 months.

Conclusions: We conclude that health utility measured using SF6D decreases significantly following fracture but improves with time. The loss in HU and gains over time vary between fracture types.

| Mean pre-fracture SF-6D HU and mean changes (Δ) from pre-fracture. | Hip n=58 mean (SD) | Wrist n=47 mean (SD) | Humerus n=31 mean (SD) | Vertebral: non-operative n=109 mean(SD) | Vertebral: augmentation n=35 mean (SD) |

MO0309

The Osteoporosis Care Gap: Evaluation of Solutions for Remote and Rural Communities. Rosemary Hollick*¹, Alison Black², Lorna McKee³, David Reid³. ¹Aberdeen Royal Infirmary, United Kingdom, ²NHS Grampian, United Kingdom, ³University of Aberdeen, United Kingdom

A significant care gap exists between evidence based management of osteoporosis and clinical practice. In Scotland a significant proportion of the population live in remote and rural communities, posing challenges to the delivery of healthcare. The ageing population is increasing faster in rural communities, who are also disadvantaged by geographical access to services with an associated cost premium. Local experience suggests significant unmet need in access to DXA in rural areas where populations are older. Mobile DXA services were proposed to address inequalities in access to care for those living rurally. Similar UK interventions have failed, having only outcome evaluation and excluding evaluation of process implementation, or factors influencing sustainability.

We undertook an implementation and outcome evaluation of the new service at multiple levels; macro, meso and micro to explain 'how and why' innovations are translated into practice. Specifically we performed an implementation process evaluation with comparison of local service implementation to similar successful/unsuccessful mobile services in England, using a participatory action research (PAR) framework. The implementation process and outcome evaluation involves three local case studies; two island communities and one rural mainland community, using a real-time, before and after approach. We use mixed methods with both quantitative

(surveys, fracture risk assessment tool) and qualitative (in-depth interviews, ethnography) and secondary data. Quantitative data is analysed using descriptive statistics. Qualitative data is analysed thematically using a conceptual framework derived from organisational and implementation theory, with triangulation of data from different sources.

Pre-implementation, referrals from islands are younger than those from the mainland, Table 1, with significantly more subjects <65 yrs referred for DXA in the islands. Survey data showed that age, frailty and travel distance were significant barriers to referral. Journey length/complexity and accessibility to public transport also influenced access to DXA. Data 6 months post implementation reveals a 53% increase in referrals, with a 4 fold increase in referrals > 75 yrs. Early data indicates that multiple interactions of political, sociocultural, educational and contextual factors influence service implementation.

In summary we report the first service implementation evaluation in osteoporosis using a PAR framework.

| Age at time of DXA scan | City | Rural mainland | Island 1 | Island 2 |
|-------------------------|-----------------|-----------------|-----------------|-----------------|
| Mean (yrs) | 63.75 (14.8) | 63.51 (14.3) | 60.22 (12.1) | 58.82 (12.9) |
| Range (yrs) | 6 - 93 | 9 - 93 | 28 - 79 | 19 - 86 |

Table 1. Mean age of referrals, pre-implementation of mobile DXA service

Table 1. Mean age of referrals, pre-implementation of mobile DXA service

MO0310

A low dietary calcium intake is a major health problem in Hong Kong postmenopausal Chinese women. Rick Chung*¹, Connie Au², Gabrielle Lee², Ivy Wong², Selegne Wong², Novem Lam², Edith Lau². ¹Center for Clinical & Basic Research (CCBR) (Hong Kong), Hong kong, ²CCBR Hong Kong, Hong kong

Background and objectives

Osteoporosis is a major and increasingly important public health problem in Hong Kong. Previous studies showed 1/3 of Hong Kong postmenopausal women have osteoporosis. Adequate calcium intake has been found to prevent bone loss and osteoporotic fractures. The objective of current study is to investigate the updated dietary calcium intake of Hong Kong postmenopausal Chinese women in order to provide a basis for future public health recommendations.

Method

The dietary calcium intake was carried out using a food frequency questionnaire (FFQ). The FFQ contained 133 food which are calcium rich and commonly eaten in the Hong Kong Chinese diet. A total of 620 Hong Kong Chinese postmenopausal women aged 50-86 were recruited from the community and interviewed with the FFQ from Jul 2014 to Mar 2015.

Subjects were required to answer the number of times they consumed each food item daily or weekly with the serving sizes based on their usual diet for the last three month period. The total daily dietary calcium intake was calculated by multiplying the consumption frequency, portion sizes and calcium contents of the foods. The subjects also provide the data that if they are on calcium supplement.

Results

The results showed that the mean calcium intake from the dietary record was 649.2 \pm 354.8 mg/day. 91.5% of the subjects failed to meet the RDA for calcium (1,200 mg/day), while only 45.6% had intakes above 600 mg/day (Figure 1). Figure 2 demonstrated that most of the calcium for Hong Kong Chinese women was from dairy product (28.7%) and vegetable/fruit (24.5%). There were 40.2% of subjects did not consume dairy product regularly and 22.1% of subjects took dairy product daily. 77.3% of subjects were not on calcium supplement, while only 6.6% and 16.1% took calcium supplement daily and occasionally, respectively.

Conclusions

The dietary calcium intake of Hong Kong Chinese postmenopausal women is low, the mean value is only around half of the RDA. It is a major health issue in Hong Kong.

In the common Hong Kong diet, most of the calcium is from dairy product and vegetable/fruit.

Dairy product is one of the main source of dietary calcium intake, however, 77.9% of subjects did not consume dairy product regularly.

There were 77.3% of subject not on calcium supplement.

Encouragements for high calcium diet and calcium supplementation are important for Hong Kong women, in order to prevent osteoporotic fracture.

MO0311

A Short, Quick, and Easy Questionnaire to Estimate Daily Dietary Calcium Intake of Osteoporosis Patients. Linda Rasch¹, Marian de van der Schueren², Irene Bultink³, Lilian van Tuyl³, Willem Lems^{*3}. ¹Amsterdam Rheumatology & immunology Center, VU University Medical Center, The Netherlands, ²Department of Nutrition & Dietetics, VU University Medical Center, Netherlands, ³Amsterdam Rheumatology & immunology Center, VU University Medical Center, Netherlands

Background: Calcium supplements are widely used for the prevention and treatment of osteoporosis. However, recent literature suggests that too much calcium supplementation may be associated with cardiovascular events (1). For this reason, calcium supplementation should be based on actual and adequate dietary calcium intake. A previously designed calcium intake list appeared to be invalid (2) and other alternatives are too time consuming for clinical practice. Therefore, we developed a new calcium intake list, to accurately estimate dietary calcium intake, which was validated in this study.

Objectives: The aim of this study is to validate a short, quick, and easy calcium intake list, to be able to estimate dietary calcium intake, with an extensive dietary history (DH) as a reference method.

Methods: This cross-sectional study included consecutive patients attending the outpatient rheumatology department at the VUmc in Amsterdam, the Netherlands, for the treatment of primary or secondary osteoporosis. Based on the food groups which contribute most to daily dietary calcium intake and portion sizes determined from our earlier validation study (2), a short three-item calcium intake list was designed. As a reference method, an extensive DH with specific focus on calcium products and extra attention for portion sizes was performed. Before starting the study, a difference of 250 mg calcium or more between both methods was determined as clinically relevant. Performing the short calcium intake list took about 3 minutes, performing the DH took 60 minutes.

Results: In this study, 66 patients with primary (n=40) and secondary (n=26) osteoporosis were included. The three-item calcium intake list showed a small, clinically

non-relevant, difference with the DH of 25 ± 350 mg calcium per day (p=0.568), see table 1. Sensitivity and specificity of the short calcium intake list, compared to the DH, were respectively 73% and 80%. In 50% of the individuals, a clinically relevant difference of 250 mg calcium or more was observed between the calcium intake list and the DH, while in 17% a difference of 500 mg or more was observed.

Conclusions: The short calcium intake list is a three-item, quick and easy questionnaire to accurately estimate dietary calcium intake of osteoporosis patients at a group level, and thus very helpful for clinical studies. The mean calcium intake is within the currently advocated recommendation of 1000-1200 mg calcium per day. Since calcium supplements are prescribed in patients with an adequate intake in approximately 30% of patients, this indicates that a large proportion of the osteoporosis patients are "over-supplemented". In contrast, clinicians should be aware of not identifying a deficient calcium intake in approximately 20% of the patients.

MO0312

High serum uric acid concentration show different association between vitamin C intake and spine Quantitative Computed Tomography (QCT) bone measures in women. Shivani Sahni^{*1}, Katherine Tucker², Caroline Fox³, Douglas Kiel¹, Marian Hannan¹. ¹Hebrew SeniorLife, Institute for Aging Research & Harvard Medical School, USA, ²University of Massachusetts, USA, ³Framingham Heart Study, NHLBI, Harvard Medical School, USA

Higher Vitamin C intake has been associated with lower serum uric acid (sUA) concentration and less bone mineral density (BMD) loss over time. sUA (an antioxidant within normal range: 3-7mg/dL) has been associated with higher BMD. However, at elevated concentration, sUA can act as a pro-oxidant, contributing to inflammation. Given the inter-relation between vitamin C and sUA, it is unclear if the association of vitamin C and bone varies by uric acid concentration. The trabecular bone compartment may be a sensitive indicator of change due to inflammation-mediated bone loss. Thus, we examined the association of vitamin C intake with QCT volumetric measures of bone [vBMD (g/cm³), integral and trabecular vBMD], cross-sectional area (CSA, cm²) and vertebral compressive strength (VCS, N) at the L3 level of the spine in men and women from the Framingham 3rd Generation Cohort. Associations were further examined within categories of sUA [normal physiological levels =7 men; =6mg/dL women) and high sUA].

In this cross-sectional analysis, 802 women and 965 men (ages 32-72y) had measures of vitamin C intake (mg/d) from the food frequency questionnaire, and sUA (mg/dL) and QCT spine measures (2002-05). VCS was estimated from the QCT data. Sex-specific multivariable linear regression was used to calculate the association of vitamin C with each QCT measure, adjusting for covariates. Interactions of vitamin C intake and sUA were tested. If significant (P<0.10), associations were examined by sUA sub-group.

Mean ages were 44 (± 6) y in men and 46 (± 6) y in women. Mean vitamin C intakes (mg/d) were 240 (men) and 271 (women). Mean UA concentrations (mg/dL) were 6.28 (± 1.24) (men) and 4.44 (± 1.09) (women). Significant interactions of sUA and vitamin C intake were seen for CSA (men, P=0.06; women, P=0.005) but not for other QCT measures (P range: 0.56-0.90). Among women with sUA>6 mg/dL, higher vitamin C was associated with higher integral vBMD (P=0.005), trabecular vBMD (P=0.02) and VCS (P=0.01) but these were not significant in women with lower sUA concentration (Table). No significant associations were seen in men.

Although the sample size was limited in women with high sUA (n=53), these findings suggest that higher vitamin C intake may be protective of bone in women with high sUA (pro-oxidative state). The sex differences observed could be due to higher vitamin C intake in women compared to men. Future work should examine vitamin C and sUA (as an antioxidant and pro-oxidant) in relation to QCT bone changes over time.

Table. Association of vitamin C intake with spine QCT bone measures by serum uric acid levels.

Hypophosphatemia Associated with Elemental Formula Use in Children with Feeding Problems. Luisa Gonzalez Ballesteros^{*1}, Nina Ma², Leanne Ward³, Philippe Backeljauw⁴, David Weber⁵, Linda DiMeglio⁶, Julie Gagne⁷, Robert Stein⁸, Declan Cody⁹, Kimber Simmons¹⁰, Paul Zimakas¹¹, Linda Casey¹², Erik Imel⁶, Thomas Carpenter¹³. ¹Yale University, USA, ²Boston Children's Hospital, USA, ³Children's Hospital of Eastern Ontario, Canada, ⁴Cincinnati Children's Hospital, USA, ⁵University of Rochester, USA, ⁶Indiana University, USA, ⁷Centre hospitalier de l'Université Laval, Canada, ⁸Children's Hospital of Western Ontario, Canada, ⁹Our Lady's Children's Hospital, Crumlin, Ireland, ¹⁰Children's Hospital Colorado, USA, ¹¹University of Vermont Medical Center, USA, ¹²British Columbia Children's Hospital, Canada, ¹³Yale University School of Medicine, USA

We encountered 18 cases of hypophosphatemia occurring in children receiving elemental formula feeds at 7 US and 3 Canadian sites, as well as one case in Ireland. Due to a variety of underlying diagnoses, all patients had feeding difficulties and were fed Neocate or the related products (Neocate Infant, Junior). Hypophosphatemia was severe and, usually occurred in association with overt rickets disease. Elevation in serum alkaline phosphatase activity and appropriate renal conservation of phosphate (P) were evident in all cases where examined. Tubular reabsorption of P was >99% in 3 cases, and 90% in 1 case, and not calculable due to undetectable urine P in 10 cases. No urine P data is available in the remaining 4 cases. P levels corrected with either P supplementation or a change in formula. Age, sex, biochemistry, and treatment responses are summarized in the table.

Neocate may be associated with hypophosphatemic rickets due to impaired intestinal absorption of P in certain children with feeding difficulties. The mechanism for this phenomenon is unclear, however considerations include altered P absorption due to GI pH alteration particular to the product, an inhibitor or binder of P, or inclusion of a phosphate species in the formula composition that is not readily absorbed. Genetic predisposition to impaired P absorption may also be possible.

These cases emphasize the need to consider nutritional etiologies in the evaluation of children with metabolic bone disease, even in a controlled hospital setting. Specifically, we raise the consideration that the bioavailability of phosphate in Neocate may be compromised in certain children and recommend monitoring of serum phosphate and for the development of bone disease during the use of elemental formulas.

Low ingestion of calcium and magnesium and high odds of hip fracture: a cross-sectional study. Juliana Brondani, Raisa Bringhenti, Felipe Langer, Giovanni Sartori, Adnan de Vieira, Antonio Codevilla, Fabio Comim, Melissa Premaor*. Federal University of Santa Maria, Brazil

Background: A health nutrition represents an important role in bone formation. A balanced alimentation, both in quality and quantity, probably will supply the necessary nutrients to maintain, at least in part, bone health during the aging. Furthermore, it could be a possible protection factor for the main consequences of the osteoporosis in elderly. Objectives: the aim of our study was to compare the alimentary consumption of calcium, phosphorus, magnesium, and proteins in hospitalized women with hip fracture with outpatient women without fractures. Methods: We carried out a cross-sectional study at the Santa Maria University Hospital, Santa Maria - Brazil. All women, 55 or older with hip fractures were invited to participate. The outpatient women were recruited from an ongoing cohort study (1). Sixty-two women were recruited (42 women with fractures and 20 women without fractures). Information about clinical data and social history were recorded. An anthropometric evaluation was performed. A Questionnaire Quantitative of the Frequency of Foods (QQFA) to evaluate the ingestion of calcium, phosphorus, magnesium and proteins was applied. Results: the ingestion of calcium and magnesium was significant lower in women with fractures [446.9 mg/day vs. 689.90 mg/day and 135.49 mg/day vs. 188.92 mg/day, respectively]. In the logistic regression analysis of fractures, high ingestion of calcium and magnesium were associated with a low odds of fracture. This result was adjusted for age and BMI. There were no differences in the protein intake between the groups. Conclusion: a high dietetic ingestion of calcium and magnesium evaluated by QQFA was protective against hip fractures in our study. 1) Copós RM, et al. MO0315

Calgary Vitamin D Trial: Safety of Supplementation up to 10,000 IU Vitamin D Daily, 12 Month Pilot Data. Erin Hildebrandt*, David Hanley, Steven Boyd. University of Calgary, Canada

The beneficial effects of vitamin D have been widely investigated, including its role bone health. The 2011 Institute of Medicine report identified a Recommended Dietary Intake for skeletal health of 600 IU vitamin D/day (from all sources) and a Tolerable Upper Limit (TUL) of 4,000 IU/day for adults under 70 years. Benefits of higher doses of vitamin D have not been systematically explored or identified, perhaps because of safety concerns. Very high doses of vitamin D have been associated with hypercalciuria and hypercalcemia, although Vitamin D toxicity is usually associated with doses above 40,000 IU/day. The present study was designed to evaluate the safety of taking daily doses of up to 10,000 IU of vitamin D daily as part of an ongoing controlled trial in Calgary by assessing markers of calcium and bone metabolism after 12 months of supplementation in a small pilot cohort.

Healthy men and women with normal parameters of calcium metabolism between 55-70 years (N=362) were recruited for a three year, randomized, double blind trial of 400, 4,000 or 10,000 IU vitamin D daily. The primary outcome of this study is to assess the relationship between vitamin D dose and bone health. Participants had baseline 25(OH)D levels between 30-120 nmol/L and were excluded if they had osteoporosis or medications or other conditions affecting calcium metabolism. A subset of participants (N=62; 18 M, 44 F; age 63.2 ± 4.1 yrs) formed a pilot cohort, for which we report first year parameters of calcium metabolism.

Safety parameters measured are depicted in Table 1. Four participants withdrew from the study for reasons unrelated to vitamin D supplementation (2 diagnosed with malignancy, 2 withdrew for non-medical reasons). We remain blinded to supplementation levels, but tested serum 25(OH)D. At 12M average 25(OH)D was 144.4 ± 69.3 nmol/L (min: 61.1 nmol/L, max: 325 nmol/L). There was no relationship between 25(OH)D and serum calcium or urinary calcium excretion. One high serum calcium was detected at 6 months, but normalized on re-testing. All urine calcium/creatinine ratios were below the upper normal limit (<1.0 mmol/L).

In this small study, there were no safety concerns with taking doses of Vitamin D at or above Health Canada's TUL Level of 4,000 IU/day for one year. We are also currently completing analysis of bone remodeling biomarkers CTX and PINP for this cohort.

Table 1: Biomarker safety data from pilot cohort at baseline (0M) and one year (12M). Healthy ranges are presented below each biomarker, with males and females split for liver enzymes.

| | 0M | 12M |
|---|--------------|---------------|
| 25(OH)D (nmol/L) | 76.2 (±17.4) | 144.4 (±69.3) |

Relationship of Directly Measured Free 25(OH) Vitamin D and Total 25(OH) Vitamin D: Effect of Daily Vitamin D Supplementation in Postmenopausal Women. Gretta Borchardt*, Ellen Fidler, Diane Krueger, Neil Binkley, University of Wisconsin, USA

Background: The free hormone hypothesis holds that biological activity of a hormone is due to its unbound (free) rather than protein-bound concentration. As such, it is plausible that free 25(OH)D concentration is a better measure of an individual's vitamin D status than is total 25(OH)D. Free 25(OH)D measurement has previously faced technical challenges; direct measurement by immunoassay has recently become available, but data are limited regarding the relationship of free to total 25(OH)D. This study evaluated the effect of daily vitamin D supplementation on total and free 25(OH)D in postmenopausal women.

Methods: Sixty-two postmenopausal women were randomly assigned to receive daily vitamin D₃ 2,000 IU or matching placebo for 4 months. Their mean (SD) age and BMI was 67.8 (9.1) years and 28.5 (6.1) kg/m² respectively. Blood was drawn at baseline and following 1 and 4 months of supplementation. Total and free 25(OH)D were measured by ELISA using kits from Diasource (Louvain-La-Neuve, BE). Repeated measures ANOVA and regression analyses were performed.

Results: Overall, baseline 25(OH)D and free 25(OH)D mean (SD) were 35.2 (11.0) ng/mL and 5.1 (1.8) pg/mL respectively; both total and free 25(OH)D were higher at baseline in the vitamin D₃ supplemented group (Table). Supplement compliance was 98%. With daily supplementation, both free and total 25(OH)D increased ($p < 0.0001$) while neither changed in the placebo group (Table). Free and total 25(OH)D were highly correlated (R^2 0.35-0.55) at all timepoints. After 4 months of supplementation the increase in free 25(OH)D was highly correlated with the increase in total 25(OH)D; $R^2 = 0.58$; $p < 0.001$

Conclusion: In this study the circulating concentration of free 25(OH)D was less than 0.02% of the total 25(OH)D concentration. Free and total 25(OH)D levels were highly correlated and both increased with supplementation. Further research is needed to define the utility of free 25(OH)D measurement.

Table: Effect of daily vitamin D₃ supplementation on total and free 25(OH)D

| Group | Total 25(OH)D (ng/mL) | | | Free 25(OH)D (pg/mL) | | |
|-------------------------------|-----------------------|-------------|-------------|----------------------|-----------|-----------|
| | Baseline | 1 mo | 4 mo | Baseline | 1 mo | 4 mo |
| Daily D ₃ 2,000 IU | 38.5 (11.0) | 45.6 (10.5) | 52.1 (13.7) | 5.8 (1.9) | 7.1 (1.7) | 8.0 (2.1) |
| Placebo | 32.0 (10.2) | 33.3 (11.1) | 33.4 (13.2) | 4.4 (1.4) | 4.3 (1.3) | 4.5 (1.8) |

MO0317

Relationship of Serum 25-Hydroxyvitamin D Measured by Liquid Chromatography-Mass Spectrometry to Bone Turnover Markers and Parathyroid Hormone and Bone Mineral Density in Korean Adult Males with Low Bone Mass. Da Young LEE*¹, Ju Young Jang², Tae Yang Yu², Won Jung Hong², Yong Joo Hong², Yong-Ki Min², Jae Hoon Chung², Jae Hyeon Kim², Kyu Yeon Hur³, Moon Kyu Lee², Sun Wook Kim². ¹Samsung Medical Center, South Korea, ²Division of Endocrinology & Metabolism, Department of Medicine, Samsung Medical Center, Sungkyunkwan University School of Medicine, South Korea, ³Division of Endocrinology & Metabolism, Department of Medicine, Samsung Medical Center, South Korea

1. Objective

Vitamin D is involved in bone and mineral metabolism, and its deficiency is associated with metabolic bone disease such as osteoporosis. Measurement of serum 25-hydroxyvitamin D [25(OH)D] is the best approach to assess an individual's vitamin D status. However, there is no consensus on the optimal level of serum 25(OH)D. Liquid chromatography-mass spectrometry (LC-MS/MS) is the method of choice for the analysis of 25(OH)D. Nevertheless, previous studies were based on 25(OH)D measured by immunoassay, and focused on postmenopausal women rather than men. The aim of this study is to assess vitamin D status measured by LC-MS/MS in adult men with low bone mass and its relationship to bone turnover markers, parathyroid function, and bone mineral density.

2. Method

We investigated medical record of 258 adult men newly diagnosed with osteopenia or osteoporosis whose serum 25(OH)D were measured by LC-MS/MS (Agilent Technologies, Inc.) in Samsung Medical Center from July 2009 to February 2014. Subjects were divided into 3 groups by serum 25(OH)D concentration: <10 (group A), 10-20 (group B), and >20 ng/mL (group C). Serum concentrations of bone-specific alkaline phosphatase (BS-ALP), C-telopeptide (CTX), intact parathyroid hormone (iPTH) and bone mineral density (BMD) were compared. All patients underwent BMD using dual-energy X-ray absorptiometry.

3. Result

The age of the subjects was 56.8 ± 12.2 years, 93.4% of them were diagnosed with osteoporosis. The mean of 25(OH)D was 20.4 ± 8.9 ng/mL. The concentrations of BS-ALP in group A, B and C were 23.6 ± 12.7, 20.2 ± 12.2 and 18.8 ± 13.8 μg/L, respectively. The concentrations of CTX were 0.528 ± 0.249, 0.464 ± 0.310, 0.409 ± 0.312 ng/mL and those of iPTH were 70.5 ± 95.3, 36.7 ± 20.8, 34.9 ± 25.5 pg/mL, respectively. The concentration of 25(OH)D was negatively correlated with those of BS-ALP, CTX and iPTH significantly. The concentrations of BS-ALP and CTX in group A were higher than group C, not group B. In case of iPTH, that in group A was higher than other groups.

The femur neck BMD in group A, B and C were 0.659 ± 0.114, 0.733 ± 0.122 and 0.722 ± 0.084 g/cm², respectively. And total femur BMD were 0.710 ± 0.122, 0.795 ± 0.116, 0.794 ± 0.094 g/cm², respectively. In femur neck and total femur BMD, group A was significantly lower than group B and C.

4. Conclusion

In Korean adult males with low bone mass, the serum concentration of 25(OH)D above 20 ng/mL would not be able to give further benefits in bone health markers such as BS-ALP, CTX, iPTH and BMD.

MO0318

The effects of vitamin D on bone mineral density in rheumatoid arthritis and systemic lupus erythematosus. Chang-Hee Suh¹, Ju-Yang Jung^{*2}, Hyoun-Ah Kim². ¹Ajou University School of Medicine, South Korea, ²Ajou University Hospital, South Korea

Introduction: Vitamin D has been revealed to involve immunologic pathogenesis in rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). Moreover, vitamin D plays a pivotal role in bone formation, which tends to be vulnerable in RA and SLE. We studied the effects of vitamin D on bone mineral densities (BMD) in RA and SLE.

Materials and Methods: Age matched 94 female patients with SLE and 92 female patients with RA were recruited. The medical data including levels of 25-OH-vitD

from March to May, and T-scores on BMD which were measured by Dual energy X-ray absorptiometry were collected.

Results: The L-spine and hip T-scores were not different between RA and SLE patients, and the T-scores were not different between the patients with vitamin D deficiency and patients without it. In SLE, the patients with osteoporosis had higher ESR than those without osteoporosis did (31.4 ± 23.9 vs 16.4 ± 11.9 , $p=0.008$). Among the patients taking vitamin D replacement, RA patients had lower levels of 25-OH-vitD than SLE patients (19.83 ± 8.07 vs 24.33 ± 10.45 , $p=0.011$), and L-spine and hip T-scores in RA patients were lower than those in SLE patients. On multiple regression analysis, age, duration, vitamin D replacement, and steroid dose were shown to contribute to BMD in RA patients, while nothing contributed to BMD in SLE patients. Conclusions: There was no difference of BMD between RA and SLE, and there was no difference in BMD in the presence or absence of vitamin D deficiency. Only in RA, age, disease duration, vitamin replacement, and steroid dose were shown to contribute on BMD.

MO0319

The effects of vitamin D3 versus 25-hydroxyvitamin D3 on serum vitamin D metabolites and markers of calcium balance in a multi-ethnic cohort of healthy adults. Albert Shieh^{*1}, Christina Ma², Emily Sondergaard², Yang Shen², Kathryn Zavala², Philip Liu², John Adams². ¹University of California, Los Angeles, USA, ²UCLA, USA

Purpose: Vitamin D deficiency is associated with multiple adverse health outcomes, and disproportionately affects minority U.S. populations. Pharmacologic 25-hydroxyvitamin D3 (25D3) has a smaller volume of distribution than parent vitamin D3 (D3); 25D3 may therefore more quickly and robustly restore serum levels of 25-hydroxyvitamin D (25D). The aim of this study is to examine the effects of D3 versus 25D3 on serum vitamin D metabolites and markers of calcium balance in a multi-ethnic cohort of healthy adults.

Methods: Study participants will include a multi-ethnic cohort of 48 healthy adults >18 years of age (12 White, 12 Asian, 12 Black, 12 Latino) who have baseline 25D levels <20 ng/ml. Subjects are being randomized to receive 60 mcg/day of D3 or 20 mcg/day of 25D3. Serum and urine are collected at baseline and 4, 8, and 16 weeks follow-up to assess changes in serum vitamin D metabolites and markers of calcium balance.

Results: To date, 20 subjects have been randomized (2 White, 8 Asian, 5 Black, 5 Hispanic) with 11 receiving D3 and 9 receiving 25D3. As only 5 subjects have completed all study visits at present time, no statistical tests of significance for within-group changes and between-group differences were performed beyond 4 weeks. At baseline, 25D (16.1 ± 1.2 v. 17.8 ± 0.5 ng/ml), 1,25-dihydroxyvitamin D (1,25D) ($53. \pm 5.6$ v. 65.3 ± 7.4 pg/ml), serum calcium (Ca) (9.5 ± 0.1 v. 9.5 ± 0.2 mg/dl), urinary calcium:creatinine (U/Ca/Cr) (0.06 ± 0.01 v. 0.06 ± 0.01), and immunoreactive parathyroid hormone (iPTH) (39.4 ± 4.7 v. 30.9 ± 3.8 pg/ml) levels were similar between D3 v. 25D3 groups. By four weeks, 25D levels had increased significantly in D3 (mean within-group change 10.0 ng/mg; $p=0.02$) and 25D3 (mean within-group change 20.2 ng/ml; $p=0.001$) groups, but mean 25D level at this time point was significantly higher in those taking 25D3 (38.0 v. 27.3 ng/ml; $p=0.02$). Within-group changes in 1,25D, Ca, U/Ca/Cr, and PTH from baseline to 4 weeks were not statistically significant. Between-group differences in each parameter at 4 weeks were also not statistically significant.

Conclusions: Preliminary data from our pilot study demonstrates that subjects with baseline vitamin D deficiency experienced faster and more robust increases in 25D level taking 20 mcg/day of 25D3 v. 60 mcg/day of D3. There was no hypercalcemia or hypercalciuria in either group. We continue to collect data on the effects of completing both regimens on free 25D and markers of calcium balance.

MO0320

Vitamin D Replacement in Bariatric Surgery: A Critical Appraisal of Current Guidelines. Marlene Chakhtoura^{*1}, Ghada El Hajj Fuleihan², Nancy Nakhoul², Elie Akl¹, Christos Mantzoros³. ¹American University of Beirut, Lebanon, ²American University of Beirut - Lebanon, Lebanon, ³Harvard Medical School, USA

Introduction:

Bariatric surgery is the most effective therapeutic option to reduce weight in morbidly obese individuals, but it results in a number of mineral and vitamin deficiencies. Clinical Practice Guidelines (CPGs) attempt to balance those benefits and harms to provide guidance to patients and to their physicians.

Objectives:

The objectives of this paper are to compare and evaluate the quality of the development process, and of the evidence of current CPGs providing recommendations on vitamin D replacement in patients undergoing bariatric surgery.

Methods:

We searched 3 databases, with no time restriction, to identify relevant and current CPGs. Two reviewers assessed eligibility and abstracted data, in duplicate. They evaluated the quality of CPGs development process using the Appraisal of Guidelines, Research, and Evaluation II (AGREE II) tool that consists of 6 domains. A content expert verified those assessments.

Results:

We identified 3 eligible CPGs: (1) the Endocrine Society (ES) Guidelines (2010); (2) the American Association of Clinical Endocrinologists (AAACE), The Obesity Society (TOS), and the American Society for Metabolic & Bariatric Surgery (ASBMS) Guidelines (update 2013); and (3) the Interdisciplinary European (IE) Guidelines (IEG) on Metabolic and Bariatric Surgery (latest update 2014).

The ES and the AAACE/TOS/ASBMS guidelines recommend high doses of vitamin D, varying from 3,000 IU daily to 50,000 IU 1-3 times weekly. Vitamin D doses were not mentioned in the IE guidelines.

In terms of quality, only the IE guidelines described their search methodology but none of the CPGs provided details on evidence selection and appraisal. None of the three CPGs rigorously assessed the preferences of the target population, resource implications, and the applicability of these guidelines. According to the AGREE tool, we rated the ES guidelines as average in quality, while the other two as low in quality.

The recommendations were based on a low quality of evidence, if any, or limited to a single high quality trial, for some outcomes.

Conclusion:

Current CPGs recommendations on vitamin D supplementation in bariatric surgery differ between societies. They do not fulfill criteria for optimal guideline development, possibly due to limited resources, and are based on expert opinion. Thus, the pressing need for high quality randomized trials to inform CPGs, ideally developed using commonly accepted standards.

MO0321

Higher Body Fat Mass is Associated with Reduced Serum 1,25-dihydroxyvitamin D Levels in Healthy Postmenopausal Women. Magaly Hars, Andrea Trombetti, Mélyny Hars, Claire Durosier, Emmanuel Biver, Thierry Chevalley, Serge Ferrari, René Rizzoli^{*}. Division of Bone Diseases, Geneva University Hospitals & Faculty of Medicine, Switzerland

It is well established that higher body fat mass and obesity are associated with lower 25-hydroxyvitamin D (25(OH)D) and higher parathormone (PTH) levels. However, the relation between 1,25-dihydroxyvitamin D (1,25(OH)2D) and adiposity is much less recognized, though it has been suggested that 1,25(OH)2D may favor the development of fat tissue. The present study aimed at assessing the association between serum 1,25(OH)2D levels and body fat mass in a homogeneous cohort of 65-year old healthy women.

Cross-sectional data of 728 healthy postmenopausal women (age 65.0 ± 1.4 years), enrolled in the Geneva Retirees Cohort (GERICO) study, were analyzed. Fat mass was assessed using dual X-ray absorptiometry (Hologic Discovery W). Serum concentrations of 1,25(OH)2D were ascertained by a chemiluminescence immunoassay (IDS) and IGF-I was measured with an automated chemiluminescence-based immunoassay using two monoclonal antibodies. 25(OH)D and PTH were determined using Roche Diagnostics reagents. Univariate and multivariate regression analyses were performed.

The mean concentration of 25(OH)D was 67.5 ± 27.7 nmol/L. Three percent of participants had serum 25(OH)D below 25 nmol/L and 30% serum levels below 50 nmol/L. Univariate regression analyses showed that serum 1,25(OH)2D and 25(OH)D levels were negatively associated with total body fat mass ($P < 0.004$ and $P < 0.001$, respectively) while a positive association was found between 1,25(OH)2D and PTH ($P < 0.004$), but not with IGF-I. The negative association between 1,25(OH)2D and total body fat mass remained significant in a multivariate stepwise regression model with 25(OH)D, PTH, calcium intakes, dietary protein intakes retained in the final model ($P < 0.004$). It was not related to renal function.

Our results showed a strong inverse association between serum 1,25(OH)2D levels and body fat mass in 65-year old healthy postmenopausal women, despite higher PTH levels. These findings do not support the hypothesis of 1,25(OH)2D favoring body fat mass accumulation.

MO0322

Changes in Gene Expression in Osteoblastic cell line SCP1 after Stimulation with Adult Crohn's Disease Patient Serum. Martina Blaschke¹, Regine Koepf², Marina Komrakova², Matthias Schieker³, Heide Siggelkow^{*2}. ¹Georg-August Universität, Germany, ²University Medical Center, Germany, ³Ludwig-Maximilians-Universität, Germany

Introduction: Crohn's disease (CD) is associated with a higher prevalence of osteoporosis, a complication that is recognized as a significant cause of morbidity. Its pathogenesis is still controversial, but the activity of CD is thought to be one contributing factor.

Methods: Serum levels of inflammatory cytokines IL-6, IL-1 beta, and TNF alpha were measured in CD patients during acute phase. A combination of these cytokines and CD-patient sera were evaluated using the human cell line SCP-1 (osteoblastic cell model). SCP1 cells were stimulated for 14 days with CD patient sera or control sera supplemented with cytokines. The gene expression of osteogenic marker genes and the RANKL/OPG ratio were determined using RT-PCR 48 hours or 14 days after stimulation.

Results: The combination of cytokines, but not the individual cytokines IL-6, IL-1 beta nor TNF alpha at relevant concentrations, increased the receptor activator of NF-kappaB ligand/osteoprotegerin (RANKL/OPG) ratio. None of other bone gene expressions were affected (COL1A1, OC, PPARg, RUNX2, SPP1, bAP, SP7) Application of serum obtained from male CD patients to SCP-1 cells resulted in increased RANKL expression. This effect was not present when applying serum obtained from female CD patients.

Discussion: Our results show that factors in serum from adult patients with acute CD are involved in bone remodeling and that gender specific factors might contribute to development to osteoporosis.

Disclosures: Heide Siggelkow, None.

MO0323

Circulating levels and liver protein and gene expression of sclerostin in patients with primary biliary cirrhosis. Correlation with hepatic histological features. Silvia Ruiz-Gaspa¹, Laia Gifre¹, Rosa Miquel², Marta Dubreuil¹, Pilar Peris¹, Ana Monegal¹, Ana Arias¹, Albert Pares³, Nuria Guanabens⁴. ¹Metabolic Bone Diseases Unit, CIBERehd, Hospital Clinic, University of Barcelona, Spain, ²Department of Pathology, Hospital Clinic, University of Barcelona, Spain, ³Liver Unit, CIBERehd, IDIBAPS, Hospital Clinic, University of Barcelona, Spain, ⁴Metabolic Bone Diseases Unit, Hospital Clinic, IDIBAPS, CIBERehd, University of Barcelona, Spain

Sclerostin is involved in the regulation of osteoblastogenesis and little is known about its role in the development of bone disease in primary biliary cirrhosis (PBC), characterized by low bone formation. Therefore, we have assessed the circulating levels and the liver expression of sclerostin in this cholestatic disease. Serum sclerostin levels were measured in 83 women with PBC (mean age: 60 ± 12 years) and 101 control women. Lumbar and femoral BMD as well as parameters of mineral metabolism and bone remodeling were measured. Moreover, sclerostin gene expression in the liver was assessed by real time PCR in samples of liver tissue taken by biopsy in 11 PBC patients and in 5 normal liver specimens. Presence and distribution of sclerostin was evaluated in liver slices from 11 patients by immunohistochemistry. The severity of histologic lesions was assessed semiquantitatively in the same liver samples. 77% of patients had low BMD (22% osteoporosis and 55% osteopenia). PBC patients had higher sclerostin levels than controls (76.7±38.6 vs. 32.5±14.7 pmol/L, $p < 0.001$). Serum sclerostin correlated inversely with markers of bone formation and resorption. Sclerostin mRNA in the liver was overexpressed as compared with control samples (2.7±0.3 fold vs healthy liver). Sclerostin was detected by immunohistochemistry in 7 of the 11 liver samples and mainly located in the bile ducts. Liver sclerostin was associated with the severity of cholangitis ($p=0.02$) and indirectly with the degree of lobular inflammation ($p=0.03$). Sclerostin mRNA expression was higher in samples positive by immunohistochemistry (2.9±0.4 vs 2.5±0.3, $p.n.s.$), and particularly in those with lobular granuloma (3.6±0.6 vs 2.4±0.2, $p=0.02$). The increased expression of sclerostin in the liver and the association with histologic cholangitis may explain the high serum levels of this protein in patients with PBC, thus suggesting that sclerostin influences the decreased bone formation in this cholestatic disease.

Deficiency of C/EBP Homologous Protein Enhances Bone Mineral Density Loss in Female Mice. Shing-Hwa Liu^{*}, Cheng-Tien Wu, Rong-Sen Yang. National Taiwan University, Taiwan

Introduction: Endoplasmic reticulum (ER) stress has been shown to be involved in the imbalanced bone remodeling that leads to osteopenia or osteoporosis. Expression of CCAAT/enhancer binding protein (C/EBP) homologous protein (CHOP) is induced during ER stress, which is related to apoptosis in several cell types. CHOP null mice have been exhibited to decrease bone formation. However, a study of transgenic mice overexpressing CHOP in the bone microenvironment showed that CHOP overexpression impairs the osteoblastic function leading to osteopenia. The regulatory role of CHOP in bone formation is controversial and still remains to be clarified. Here, we investigate the alterations in bone structure of CHOP knockout mice using a micro-computed tomography (μ CT).

Methods: Mice lacking the *Chop* gene (C57BL/6 background) were purchased from Jackson Laboratories. Adult female and male mice of wild type (C57BL/6) and CHOP knockout (*Chop*^{-/-}), weighing 18-25 g, were used in this study. Bone mass and microarchitecture analysis in wild-type and CHOP knockout mice were determined by μ CT. The bone marrow stromal cells (BMSCs) were also isolated and cultured. The animal study was approved by institutional animal research committee.

Results: CHOP genome typing experiment demonstrated the gene knockout in the CHOP knockout mice. The results of μ CT analysis showed that bone mineral density (BMD), bone volume ratio (BV/TV), trabecular number, and trabecular thickness were significantly decreased and trabecular space was significantly increased in *chop*^{-/-} mice as compared with wild type control ($p < 0.05$, $n=6$, Figure 1). The BMD, bone volume ratio, trabecular number, and trabecular thickness of trabecular bones were significantly decreased more for female than for male *chop*^{-/-} mice ($p < 0.05$, $n=6$, Figure 1). Similarly, the cortical mineral density of cortical bone was also decreased

more for female than for male *chop*^{-/-} mice ($p < 0.05$, $n=6$). Moreover, the activities of alkaline phosphatase and mineralized nodule formation were significantly decreased in BMSCs isolated from female *chop*^{-/-} mice ($p < 0.05$, $n=6$, Figure 2).

Conclusion: These results indicate that ER stress-related CHOP signaling may play an important role in bone formation especially in females. Proper regulation of CHOP signaling may be a clue to further target for treatment of osteoporosis.

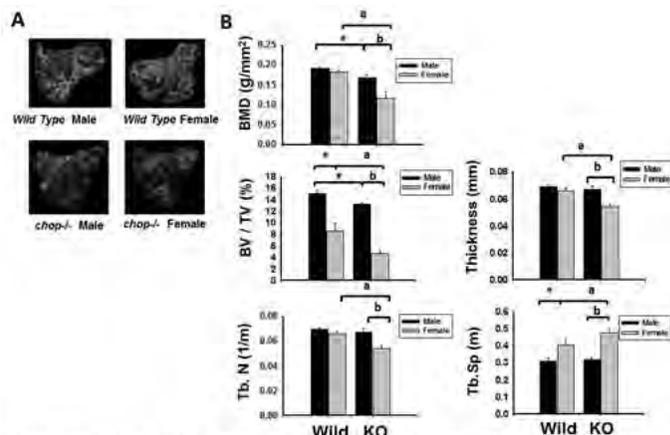

Figure 1. Changes of trabecular microarchitecture in wild type and *chop*^{-/-} (KO) mice. (A) Representative photomicrographs of trabecular bone of the proximal tibia by μ CT. (B) Morphometric results for trabecular bone (BMD, BV/TV, number (Tb.N), thickness and space (Tb.Sp)). Discovery of Small Molecules to Promote BMP Signaling and Bone Formation. Chao Liang^{*1}, Mengyang Xu², Xin Zhou³, Kavan Wang⁴, Jun Xu², Baoting Zhang⁴, Aiping Lu³, Ge Zhang³. ¹Hong Kong Baptist University, Hong kong, ²Research Center for Drug Discovery & Institute of Human Virology, School of Pharmaceutical Sciences, Sun Yat-Sen University, China, ³Institute for Advancing Translational Medicine in Bone & Joint Diseases, School of Chinese Medicine, Hong Kong Baptist University, Hong kong, ⁴School of Chinese Medicine, The Chinese University of Hong Kong, Hong kong

Objective: Metabolic skeletal diseases with impaired bone formation are public health issues. The only FDA-approved bone anabolic agent is parathyroid hormone. However, the dominant bone resorption after 2-year use is of serious concern¹. BMP signaling plays a significant role in bone formation and Smurf1 negatively regulates BMP signaling by ubiquitinating critical factors (Smad1/5) for degradation². Thus, Smurf1 could be a promising pharmacological target for developing bone anabolic agents. Here, we aim to discover small molecules to block the interaction between Smurf1 and Smad1/5 by high-throughput in silico screening and test the effect of the most likely hits on BMP signaling and bone formation.

Methods: We defined a potential ligandable pocket on WW domains of Smurf1 as a docking site for more than 100,000 compounds in virtual screening. We incubated mouse osteoblast MC3T3-E1 with the most likely hits in differentiation medium and

evaluated the protein level of phosphorylated Smad1/5 (p-Smad1/5), cell viability, mRNA expression of differentiation markers (ALP, Osterix and Osteocalcin) and ALP activity by western blot, MTT assay, real-time PCR and ALP staining, respectively. We established drill-hole defect mouse model³ and examined the effects of the most likely hits on bone formation and bone healing by bone histomorphometry and microCT, respectively.

Results: Based on Smurf1-Smad1 interaction, an area on the WW domains, surrounded by R214, Y247, L245 and W251, was defined as a hydrophobic pocket to satisfy the requirement of accommodating small molecules in the concave groove and a chalcone derivative exhibited the most preferable binding model (Fig. 1). Furthermore, *in vitro* data from western blot showed that the chalcone derivative elevated the protein level of p-Smad1/5 in dose dependent manner (Fig. 2). MTT assay, real-time-PCR and ALP staining demonstrated that chalcone derivative had no cytotoxicity (Fig. 3) and promoted the mRNA expression of ALP, Osterix and Osteocalcin and ALP activity, respectively (Fig. 4, 5). After local administration, bone histomorphometry and microCT analysis indicated that chalcone derivative improved MAR, BFR/BS (Fig. 6) and bone healing of the defect region on mid-diaphyseal femur at 21 d (Fig. 7).

Conclusion: Chalcone derivative could be a promising agent to promote BMP signaling and bone formation.

GPR120 As a Molecular Target For Inflammatory Bone Diseases. Md Rahman*¹, Stephen Harris², Wasim Chowdhury². ¹University of Texas Health Science Center, USA, ²UTHSCSA, USA

Bone homeostasis is maintained by a balance between bone resorption by osteoclasts and bone formation by osteoblasts. Chronic inflammation in bone microenvironment can increase bone resorption, decrease bone formation resulting in an uncoupling of bone formation from resorption. As such chronic inflammation can favor excessive resorption leading to osteoporosis. Activation of NF-κB and MAPK, two key pro-inflammatory signaling pathways are directly linked to reduced bone formation and accelerated bone resorption in inflammatory bone diseases. Activation of G protein coupled receptor (GPR)120 signaling pathway has been shown to be associated with down-regulation NF-κB and MAPK signaling activation. GPR120, also known as free fatty acid receptor (FFR)4 is a ligand for long chain polyunsaturated fatty acids (PUFAs). We have previously demonstrated the anti-bone resorbing and anti-osteoporotic effect of omega-3 PUFAs. Therefore, GPR120

could be a potential target for the drug development for the prevention and treatment of inflammatory bone diseases. Interestingly, osteoclast precursors, osteoclasts, osteoblast precursors, osteoblasts and chondrocytes are reported to express GPR120. Our gene array data from *ex vivo* mouse long bone osteocyte enriched bone tubes and calvarial osteoblast cells reveals that both osteoblasts and osteocytes express GPR120, however, the expression level of GPR120 in long bone osteocytes is 190 times higher than calvarial osteoblasts. On the other hand, GPR40, another omega-3 FFR4 was not expressed in our system. Osteocytes are now believed to be the master regulator of both osteoblastogenesis and osteoclastogenesis. Our cell culture data further reveals that knock-down of GPR120 by shRNA augments RANKL-induced osteoclast differentiation of RAW264.7 cells. Moreover, GPR120 knocked-down cells generate giant osteoclasts. Knock-down of GPR120 by siRNA also partially abrogated the anti-osteoclastogenic effect of GPR120 agonists. Our preliminary studies suggest that activation of GPR120 signaling pathway by GPR120 specific agonist may have a potential preventive/therapeutic effect in inflammatory bone diseases. Further studies with cell specific culture models and tissue specific knockout animal models with specific pharmacological agonists and antagonists of GPR120 are warranted to determine the utility of GPR120 as a molecular target to treat inflammatory bone diseases.

Relation of serum serotonin levels and rates of bone loss in men. Kihyun Baek*, Mooil Kang, Jeho Han. The Catholic University of Korea, South Korea

Background: Recent genetic studies in rodents have demonstrated a key role for circulating serotonin (5-hydroxytryptamine, 5-HT) in regulating bone formation and skeletal mass.

Further support for an important role for serotonin in bone metabolism comes from studies in patients treated with selective serotonin reuptake inhibitors (SSRIs), which increase extracellular serotonin levels. This study assessed the impact of serum serotonin on bone loss rates in an elderly population-based cohort of 180 healthy (or ambulatory) men, aged 56-70 years and followed up for a median of 3.7 years.

Method: Serum serotonin, serum creatinine, and mobility test were assessed at baseline. Bone mass at the lumbar spine, femoral neck and total hip was measured at baseline and at follow up by dual energy X-ray absorptiometry.

Results: Serotonin levels were inversely associated with lumbar spine BMD ($r = -0.174, P=0.028$). No associations were found between femur neck & total hip BMD and serotonin levels. The annual rates of bone loss in the lumbar spine, femoral neck and total hip was $-0.07, -0.5$ and -0.49% , respectively. Serum serotonin at baseline did not predict bone loss rates at all skeletal sites. Lower limb disability (Get Up and Go test) at baseline predicted bone loss at the lumbar spine and total hip.

Conclusions: Serum serotonin (circulating serotonin) is not associated with loss rate of bone density in elderly men.

Relationship between acetylcholine levels and bone loss in the early stages of Alzheimer disease: a mouse study. Yun Ma*¹, Randy Blakely², Florent Elefteriou³. ¹Vanderbilt University, USA, ²Department of Pharmacology, Vanderbilt University, USA, ³Department of Medicine, Department of Pharmacology, Department of cancer biology, Vanderbilt Center for Bone Biology, Vanderbilt University, USA

Alzheimer disease (AD) is characterized by central nervous system atrophy and memory decline. It is also associated with low parasympathetic nervous system (PSNS) and high sympathetic nervous system (SNS) outflow, low bone mineral density and increased fracture risk at early stages of the disease, prior to plaque development, reduced locomotor activity and skeletal unloading typical of later-stage AD. In mice, high peripheral SNS and low central acetylcholine signaling, due to deletion of the muscarinic acetylcholine receptor 3, both cause low bone mass. Because early stages of AD are characterized by reduced central acetylcholine levels (generated by parasympathetic neurons), acetylcholine esterase inhibitors (AChEIs) are used to treat these patients. Interestingly, the use of AChEIs is associated with reduced fracture risk in AD patients. These observations led us to ask if and how changes in PSNS activity contribute to the early bone loss observed in patients with AD.

To address this question, we used both gain and loss of function approaches to alter acetylcholine levels in mice and measure consequences on the skeleton. Acetylcholine levels were increased globally or peripherally by using AChEIs that pass or do not pass the blood brain barrier (BBB) in adult wildtype (WT) mice. *ChT*^{+/-} mice with reduced level of the choline transporter, which is necessary for neurons to generate acetylcholine, were used as a model of low PSNS outflow. Microcomputed tomographic and histomorphometric analyses were used to quantify treatment or gene deficiency impact on the skeleton.

ChT was not detected in MSC, osteoblast, osteocyte, chondrocyte or osteoclast cultures, regardless of their differentiation stage, whereas *AchE* was detected in osteoblast cultures, suggesting that osteoblasts can catabolize acetylcholine released by PSNS nerves but cannot synthesize it. Treatment of 3 month-old C57BL6 mice for

6 weeks with galantamine or donepezil, two AChEIs that pass the BBB, significantly increased bone turnover (increased osteoblast and osteoclast number/bone surface) and bone volume/tissue volume, whereas pyridostigmine, an AChEI that does not cross the BBB, increased osteoclast number and reduced bone volume. On the other hand, 3 month-old *ChT+/-* mice displayed a low bone mass phenotype compared to WT littermates.

These results support a model by which reduced central PSNS signaling contributes to the bone loss observed in early-stage AD patients.

Highly expressed CKIP-1 inhibits BMP signaling pathway to suppress osteogenic differentiation and mineral deposition in osteoblast during glucocorticoid treatment *in vitro*. Jin Liu^{*1}, Changwei Lv², Baosheng Guo³, Defang Li⁴, Chao Liang⁴, Xiaohua Pan⁵, Lingqiang Zhang⁶, Baoting Zhang⁷, Aiping Lu⁴, Ge Zhang¹.¹ Hong kong, ²Institute for Advancing Translational Medicine in Bone & Joint Diseases, Hong Kong Baptist University, Hong Kong, Department of Orthopedics, Xijing Hospital, The Fourth Military Medical University, Hong kong, ³Institute for Advancing Translational Medicine in Bone & Joint Diseases, Hong Kong Baptist University, Hong Kong, Hong kong, ⁴Institute for Advancing Translational Medicine in Bone & Joint Diseases, Hong Kong Baptist University, Hong kong, ⁵Department of Orthopedics in Second Hospital of Medical College (Shenzhen), Jinan University, China, ⁶State Key Laboratory of Proteomics, Beijing Proteome Research Center, Beijing Institute of Radiation Medicine, Beijing, China, ⁷School of Chinese Medicine, The Chinese University of Hong Kong, Hong kong

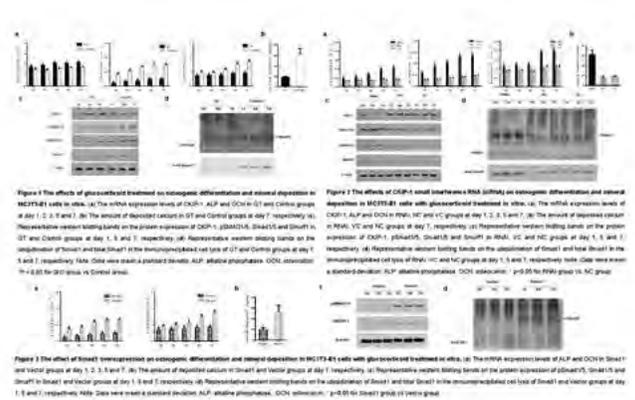

Introduction: The molecular mechanism for bone formation reduction during glucocorticoid-induced osteoporosis (GIO) remains unclear. It has been documented that the BMP pathway, a critical intercellular pathway responsible for osteoblastic bone formation, was repressed in osteoblast after glucocorticoid (GC) treatment. We have identified CKIP-1 as a novel negative regulator of BMP pathway, which specifically targets the linker region of Smurf1 to promote ubiquitin-mediated degradation of Smad1/5 (Lu et al. 2008). In our preliminary study, we found increased CKIP-1 expression and decreased Smad1/5 phosphorylation within osteoblast during bone formation reduction in rodent model with GIO. In this study, we tested the hypothesis that highly expressed CKIP-1 could inhibit BMP pathway to suppress osteogenic differentiation and mineral deposition in osteoblast during GC treatment *in vitro*.

Aim: To investigate the role of CKIP-1 in osteoblastic MC3T3-E1 cells during GC treatment *in vitro*.

Methods: We performed qPCR, Alizarin Red-S staining and immunoblotting to examine: (1) the effect of GC treatment on CKIP-1 expression, osteogenic differentiation, mineral deposition and BMP pathway activity in MC3T3-E1 cells *in vitro*; (2) the effect of CKIP-1 siRNA on osteogenic differentiation, mineral deposition and BMP pathway activity in MC3T3-E1 cells treated with GC *in vitro*; (3) the effect of Smad1 overexpression on osteogenic differentiation, mineral deposition and BMP pathway activity in MC3T3-E1 cells treated with GC *in vitro*.

Results: The CKIP-1 mRNA expression was higher, whereas the mRNA expression of osteoblastic genes was lower in GT group than Control group during GC treatment (Fig 1a). The amount of deposited calcium was lower in GT group than Control group at day 7 during GC treatment (Fig 1b). The CKIP-1 protein level was higher, while the protein level of phosphorylated Smad1/5 and total Smad1/5 were both lower in GT group than Control group during GC treatment (Fig 1c). The ubiquitination level of Smad1 was higher in GT group than Control group during GC treatment (Fig 1d). Impressively, the above inhibitory effect of GC on MC3T3-E1 cells could be either reversed after CKIP-1 siRNA treatment (Fig 2) or attenuated after transfection with Smad1 lentivirus vector (Fig 3).

Conclusion: Highly expressed CKIP-1 could inhibit BMP signaling pathway to suppress osteogenic differentiation and mineral deposition in osteoblast during GC treatment *in vitro*.

Modulation of Apolipoprotein E on Estrogen Mediated Bone Metabolism. Ling Wang^{*1}, Yu-Yan Gui², Xue-Min Qiu². ¹Fudan University, Institute of Obstetrics & Gynecology, Obstetrics & Gynecology, Peoples republic of china, ²Laboratory for Reproductive Immunology, Hospital & Institute of Obstetrics & Gynecology, IBS, Fudan University Shanghai Medical College, Shanghai 200011, China, China

Osteoporosis and atherosclerosis are among the most frequent morbidities in postmenopausal women because of the disorder occurred in lipid metabolism and bone metabolism due to estrogen deprivation. Apolipoprotein E (ApoE), which plays a major role in the transport and metabolism of lipids by acting as a ligand for low density lipoprotein receptors, was induced strongly during osteoblastogenesis *in vivo*. Estrogen could up-regulate the ApoE level in peripheral blood. Mice lacking ApoE raised by chow displayed a high bone mass phenotype, while by high-fat diet presented decreased bone mass accounted for increased osteoblast apoptosis. To investigate the underlying mechanism, we isolated the osteoblast from the skull of ApoE^{-/-} and WT newborn mice respectively. Afterwards, ALP staining and ALP activity assay were conducted to detect the osteoblast activity. Bone formation *in vitro* was performed then confirmed by alizarin red staining and von kossa staining. Cell proliferation and apoptosis were detected by flow cytometry. Co-culture of ApoE^{-/-} or WT osteoblast with ApoE^{-/-} or WT osteoclast was done respectively to observe the direct and indirect effects of osteoblast on osteoclastogenesis. Expression of type I collagen, Runx2, osterix, RANKL and OPG were measured by real-time PCR, and these proteins were identified with ELISA or western blot. Our results showed that ApoE gene deficiency attenuated the osteoblast activity and osteoblastogenesis via down-regulating the osterix. Moreover, ApoE gene deficiency enhanced the osteoclastogenesis indirectly through decreasing the OPG secretion without affecting RANKL. Further study need to be done to investigate the related molecular mechanism and signaling pathway. We will treat WT osteoblast with serial concentrations of estrogen during osteogenesis *in vitro*, then the expression and translation of ApoE would be detected by real-time PCR as well as western blot. Selective estrogen receptor antagonist would be used to explore the molecular mechanism of estrogen regulating ApoE. Moreover, we will build animal model of postmenopausal osteoporosis with ovariectomized mice to observe ApoE's effects on bone phenotype after estrogen deprivation. In conclusion, ApoE gene plays an important role in osteoblastic differentiation and function through regulating the expression of osterix and OPG, might modulate bone mass on estrogen mediated bone metabolism.

Longitudinal changes of trabecular bone score during aromatase inhibitor treatment in Korean breast cancer patients. A Ram Hong^{*1}, Jung Hee Kim², Sang Wan Kim², Chan Soo Shin². ¹Seoul National University Hospital, South Korea, ²Department of Internal Medicine, Seoul National University College of Medicine, South Korea

Objective: We were to examine the effects of treatment with aromatase inhibitor (AI) on bone mineral density (BMD) measured by dual-energy X-ray absorptiometry (DXA) and trabecular bone score (TBS), a novel grey-level index of bone microarchitecture based on DXA images in postmenopausal women with hormone receptor-positive early breast cancer.

Methods: We retrospectively included 190 patients who were treated with AI at least 3 years and baseline T-score > -2.5 from January 2006 to March 2015 at Seoul National University Hospital. Patients who were taking anti-osteoporosis medications including bisphosphonate, selective estrogen receptor modulator, or estrogen therapy at baseline or during treatment with AI were excluded. Patients with prior treatments with tamoxifen or other hormone replacement, and disease progression during follow-up were further excluded. Lumbar spine TBS and lumbar spine, femur neck, and total hip BMD were measured annually.

Results: Mean age of patients was 58.8 years and mean duration of follow-up was 4.27 years. Ninety-nine patients (47.9%) had osteopenia at baseline. Lumbar spine BMD was significantly decreased during follow-up (From baseline, 1, 2, 3, 4, 5 year; 1.068 ± 0.010 , 1.038 ± 0.011 , 1.030 ± 0.011 , 0.999 ± 0.009 , 1.013 ± 0.011 , 0.991 ± 0.013 ; $P < 0.001$) after adjusting for age, and body mass index (BMI). Femur neck and total hip BMD were also significantly decreased (0.860 ± 0.007 , 0.840 ± 0.008 , 0.833 ± 0.008 , 0.813 ± 0.008 , 0.804 ± 0.007 , 0.796 ± 0.011 in femur neck; 0.921 ± 0.007 , 0.895 ± 0.008 , 0.887 ± 0.008 , 0.871 ± 0.008 , 0.866 ± 0.007 , 0.862 ± 0.010 in total hip; both $P < 0.001$). Lumbar spine TBS was significantly decreased from baseline after adjusting for age, BMI, and baseline lumbar spine BMD (1.330 ± 0.006 , 1.321 ± 0.008 , 1.304 ± 0.007 , 1.292 ± 0.007 , 1.291 ± 0.007 , 1.296 ± 0.009 ; $P < 0.001$).

Conclusion: Lumbar spine TBS was significantly decreased during treatment with AI independent of BMD in Korean early breast cancer patients.

Use of ibuprofen before, but not after, exercise blunts the serum IL-6 response in older women and men. Sarah Wherry*, Catherine Jankowski, Pamela Wolfe, Robert Schwartz, Wendy Kohrt. University of Colorado, USA

Prostaglandin E2 (PGE2) is involved in the signaling pathway by which mechanical loading stimulates bone formation. Inhibition of PGE2 synthesis with non-steroidal anti-inflammatory drugs (NSAIDs) impairs the bone formation response to mechanical loading in animals when the NSAID is present before loading but not when it is introduced after. However, NSAIDs also have the potential to have anti-resorptive effects in bone by suppressing inflammatory cytokines, such as interleukin-6 [IL-6], that have pro-resorptive effects. The aim of this study was to determine if the timing of ibuprofen use two hours before versus immediately after an exercise bout has acute effects on serum IL-6 and markers of bone resorption (C-terminal telopeptide; CTX) and formation (bone-specific alkaline phosphatase; BAP). **Methods:** This was a sub-study of a larger trial involving exercise training and ibuprofen use in which participants were randomized to 3 drug treatment groups: placebo before and placebo after exercise (PP), ibuprofen before and placebo after exercise (IP), or placebo before and ibuprofen after exercise (PI). A subgroup of 42 participants (12 PP, 17 IP, 13 PI) participated in the current study. At week 8 of the 36-week exercise intervention, blood was sampled before and immediately, 30 minutes, and 60 minutes after an exercise bout for the measurement of IL-6, BAP, and CTX. Participant characteristics at baseline were compared across groups by one-way ANOVA for continuous measures and by a chi square test for categorical variables. The effects of ibuprofen and the timing of ibuprofen relative to exercise were evaluated by maximum likelihood estimates in a repeated measures model regressing each outcome measure on the baseline value of the outcome measure, sex, and an indicator for treatment group by time. **Results:** Increases in IL-6 were blunted in response to IP when compared to PI 60 minutes after exercise ($p < 0.001$). There were no significant differences in the change in IL-6 between the PI and PP or the IP and PP groups (all $p > 0.05$). There were no significant differences among the groups in the BAP or CTX responses. **Conclusion:** Taking ibuprofen prior to exercise dampened the IL-6 response to exercise in older adults, whereas taking ibuprofen after exercise did not. Although there was no apparent effect of ibuprofen use on markers of bone turnover, it may be necessary to track changes for a longer duration of time after exercise.

MO0333

Trabecular Bone Score (TBS) is associated with pulmonary function and severe vertebral fractures in chronic obstructive pulmonary disease(COPD). Reiko Watanabe*¹, Takeshi Tanaka¹, Keisuke Aita¹, Masaaki Hagiva¹, Hiroaki Masaki¹, Nobuyuki Tai¹, Jvunko Hirano¹, Kyoko Yokosuka², Hisami Yamakawa², Toshiaki Homma¹, Tsutomu Yaritha², Daisuke Inoue¹, Ryo Okazaki¹. ¹Teikyo University Chiba Medical Center, Japan, ²Yarita Hospital, Japan

Background&Aim: Chronic obstructive pulmonary disease (COPD) has recently been recognized as a major secondary cause of osteoporosis. We also reported a high prevalence of vertebral fractures and osteoporosis in Japanese male patients with COPD. The mechanism of COPD-associated osteoporosis however remains elusive. A population-based study in Manitoba has suggested that COPD is associated with reduced Trabecular Bone Score (TBS), a novel measure of bone microarchitecture. Thus, the aim of the present study is to investigate bone status including TBS and relationship between pulmonary function in COPD.

Subjects&Methods: In this cross-sectional study, 61 Japanese male COPD subjects (age, 70.0 ± 8.2 ; BMI, 21.7 ± 3.9 kg/m²) were enrolled. They were 19,23,13, and 6 subjects in each of GOLD 1-4 stage. The number and severity of existing vertebral fractures(VFx) were assessed by lateral spine x-rays, and bone mineral density (BMD) was measured by DXA scan. Bone metabolic markers and parameters of calcium metabolism were measured by standard assays.

Results: We found prevalent VFx in 46 (75.4%), SQ Grade 2 or 3 VFx in 12 (19.7%), and multiple VFx in 34 (55.7%), mean number of VFx per person was 2.1 ± 1.8 . Lumbar spine and femoral neck BMD T scores were -1.005 ± 1.46 and -1.87 ± 1.27 , respectively. In severe VFx group (Grade 2 or 3 fracture), FEV_{1.0}, BMI, BMD, TBS and serum Ca levels were significantly lower, whereas intact PTH and hsCRP were higher compared to non- or Grade1 VFx group by student t-test. Osteoporosis defined as BMD T score < -2.5 was found 23 subjects (37.7%). BMD was significantly decreased with advanced GOLD stage while the number of VFx was not. Interestingly, TBS was correlated positively with BMD and pulmonary function parameters including FEV_{1.0} and %VC, and negatively with height loss, SQ grade, levels of intact PTH, Tracp-5b, and hsCRP. Among these correlates, intact PTH, Tracp-5b and hsCRP were not correlated with BMD. In multilogistic regression analysis, BMD, FEV_{1.0}, and hsCRP were independent determinants of TBS after adjustment for age, height, BMI. In addition, when osteoporotic subjects were divided into 3 groups according to the levels of TBS, the lowest TBS tertile had more severe VFx.

Conclusions: We demonstrated the first time pulmonary function is associated with pulmonary function in COPD subjects. Decreased TBS may be a critical component of bone fragility associated with pulmonary dysfunction and can be a predictor of severe VFx in COPD.

MO0334

Acceleration of Fracture Healing and Improvement of Quality of Life with Teriparatide: about 16 Cases. Delphine Stoll¹, Bérengère Aubry-Rozier*², Elena Gonzalez Rodriguez², Didier Hans², Olivier Lamy². ¹Centre a bone diseases, Switzerland, ²Center of Bone Diseases, Bone & Joint Department, Lausanne University Hospital, Lausanne, Switzerland, Switzerland

Introduction: A non-healing fracture (Fx) may affect severely the quality of life. It is defined by a non-union after > 3-6 months or a pseudoarthrosis > 9 months after the Fx occurrence. This raises the question of increasing the bone formation and of accelerating the Fx healing by medical intervention with an anabolic treatment. Some cases reports suggest that Teriparatide (TP) improve bone healing and functional state.

Method: We used TP in complex cases of non-healing Fx based on the surgeons' judgment. The delay between Fx and non-union was > 6 months. The surgeons estimated that the clinical and radiological (RX) evolution was not successful and a new surgery was too risky. Some patients had already had 2 or 3 previous orthopaedic interventions. Every patient received calcium and vitamin D. Between 01.2013 and 12.2014, 16 patients fulfilled these criteria.

Results: 12 women and 4 men, mean age 64.5 y. (min. 26, max. 89), mean vitamin D 53.5 ± 24.3 nmol/l, received TP for > 2 months. The Fxs were: humerus (5), pelvis (5), tibia (4), femur (2). The median time between the Fx and the beginning of TP was 9.5 months (min 6, max.108). The mean duration of TP treatment at the time of RX evaluation was 4.7 months (min. 2, max. 12). Rx evolution was excellent (mean follow-up 8 months) or good (mean follow-up 8 months) in 73% of cases. In the 4 cases without Rx consolidation, the follow-up was 3 months. The clinical evolution was excellent or good in 69% and partially good in 13% of cases (patients' judgments). For three patients with instable and complex Fx, the consolidation obtained allowed a new conclusive surgical intervention while still on TP. Two patients who had lived in wheel chairs for several months because of instability due to the Fx (femur or tibia) could walk again (with or without stick) after TP treatment. Two patients with humeral Fx and severe functional deficits could use their arms nearly normally again after TP treatment.

Conclusions: This series has several limitations. It is not a randomized controlled study. We don't know what would have been the natural evolution without TP treatment. There were no selection criteria in terms of age, fracture localization, underlying osteoporosis or duration of evolution from the fracture. The clinical severity and the lack of alternative guided the decision of treatment with TP. Nevertheless as far as fracture healing was concerned the results were generally spectacular.

Disclosures: Bérengère Aubry-Rozier, None.

MO0335

Biochemical Markers of Bone Turnover and the Prediction of the BMD Response to Teriparatide, Denosumab or Both in Postmenopausal Women in the DATA Study. Joy Tsai¹, Paul Wallace¹, Sherri-Ann Burnett-Bowie¹, Alexander Uihlein², Robert Neer², Hang Lee³, Benjamin Leder⁴.
¹Endocrine Unit, Massachusetts General Hospital, USA, ²MGH Endocrine Unit, USA, ³Biostatistics Center, Massachusetts General Hospital, USA, ⁴Massachusetts General Hospital Harvard Medical School, USA

Background: Baseline and early changes in the levels of serum markers of bone turnover (BTMs) predict the long-term bone mineral density (BMD) response in patients treated with anabolic and antiresorptive medications. In the DATA study, we reported that the combination of denosumab (DMAB) and teriparatide (TPTD) increased BMD more than the individual agents. We now report the relationship between BTMs and BMD in each of the treatment groups. Methods: 94 postmenopausal osteoporotic women (age 51-91) with no recent bisphosphonate use were randomized to receive TPTD (20 mcg SC daily), DMAB (60 mg SC every 6 months), or both for 2 years. BMD (DXA) of the hip, spine and 1/3 distal radius and serum osteocalcin (OC) and C-telopeptide (CTX) were measured at 3, 6, 12, 18, and 24 months. Pearson's correlation coefficients (r) were calculated to determine the relationship between BTMs (baseline levels and changes) and 2-year BMD changes. Significance was determined by Fisher's z-transformed normal approximation. Results: In women receiving TPTD, baseline BTMs did not correlate with 2-year BMD changes at any site while the 12-month increase in OC was positively associated with the 2-year increase in spine BMD (r=0.43, P=0.029). In women receiving denosumab, baseline levels of OC were positively associated with 2-year spine BMD increases (r=0.51, P=0.02), while the changes in OC and CTX at 3, 6, and 12 months negatively correlated with the 2-year change in spine BMD (all r values between -0.44 and -0.51, P<0.05). Similar negative associations were found between BTMs and 2-year BMD changes at the total hip. In women receiving both drugs, there were no significant associations between BMD and baseline BTMs. The 2-year increase in distal radius BMD, however, was positively associated with the 12-month change in CTX (r=0.53, P=0.03) with a trend towards similar relationship with 3-month changes in OC (r=0.44, P=0.075) and CTX (r=0.48, P=0.052). Summary and Conclusions: In women treated with either teriparatide or denosumab, early changes in BTMs (increases and decreases, respectively) predict 2-year BMD gains, especially at the spine. In women treated with combination therapy, greater increases in radius BMD are associated with less suppression of bone turnover. These results suggest that the superior efficacy of combination therapy at cortical sites such as the radius may depend on persistent bone turnover despite RANKL inhibition.

Genome-Wide Analysis Identifies Significant Predictors of Therapeutic Response to Teriparatide in Severe Osteoporosis. Nerea Alonso¹, Philip Riches², Bente Langdahl³, Stuart Ralston².
¹University of Edinburgh, United Kingdom, ²Rheumatic Diseases Unit, CGEM-IGMM, University of Edinburgh, United Kingdom, ³Department of Endocrinology & Internal Medicine THG, Aarhus University Hospital, Denmark

Osteoporosis is a common disease associated with low bone mass and an increased risk of fragility fractures. Teriparatide, an anabolic agent, is the preferred treatment for severe osteoporosis, since substantial bone loss has already occurred by the time osteoporosis first presents. Studies have demonstrated superiority to oral bisphosphonates in preventing vertebral fractures, but treatment costs for TPTD are high and the response is variable. Identifying markers to response to TPTD is crucial to target treatment more effectively, but there are no established means of doing this at present. We performed a genome wide association study (GWAS) of 162 patients from UK and Denmark, using an Illumina Omni Express array. Standard quality control tests were applied. Statistical analysis tested the percentage of change in lumbar spine BMD following treatment with TPTD, adjusted by duration of treatment (18-24 months). The data from the two cohorts were analysed separately and results were combined using an inverse-variance meta-analysis. No evidence of inflation was found ($\lambda=1.001-1.003$). Adjusting for gender, age, smoking, alcohol intake, dietary calcium intake, age at menopause and previous bisphosphonate therapy was also performed with similar results to the unadjusted test. We identified a genome wide significant association between changes in spine BMD following TPTD therapy and a SNP on chromosome 3, within the neuroigin 1 gene (p=8x10⁻⁹), with a substantial effect size (beta=0.654 [95%CI=0.43-0.87]); heterozygote carriers of the rare A allele (good responders) had a 28% gain in BMD over 24 months compared with a 11.7% gain in GG homozygotes - a clinically significant difference over 11 standard deviations. Besides, five separate signals in chromosomes 2, 15, 13, 1 and 9 were found suggestively associated to the trait (p=1x10⁻⁷-1x10⁻⁶). We combined information from these six hits finding a highly significant association with the number of response alleles carried and change in BMD (24 month change in BMD in those who carried < 2 responder alleles was 8.8% compared with 33.8% for those who carried five or more responder alleles (p=4.95x10⁻¹¹)). Our results will help to gain greater understanding of the genes and pathways responsible for the bone formation. Furthermore, we have established an allelic score in response to TPTD that could be

used to improve treatment decisions in clinical practice. An extended study and replication are currently in progress.

Disclosures: Nerea Alonso, None.

A Retrospective Cohort Study Assessing the Incidence of Non-Vertebral and Hip Fractures in Women Receiving Treatment for Postmenopausal Osteoporosis in Routine Clinical Practice. Maurille Feudjo Tepie¹, Lung-I Cheng², Paula Dakin², Leslie Spanger², Brad Stolshek², Rachel Wagman², J. Michael Sprafka².
¹Amgen Ltd, United Kingdom, ²Amgen Inc., USA

Purpose

There are few fracture outcomes studies of therapies for postmenopausal osteoporosis (PMO) in the community setting. This study used MarketScan data to assess the effectiveness of antiresorptive agents in women with PMO in routine practice by assessing non-vertebral fracture (NVFX) and hip fracture (HPFX) rates.

Methods

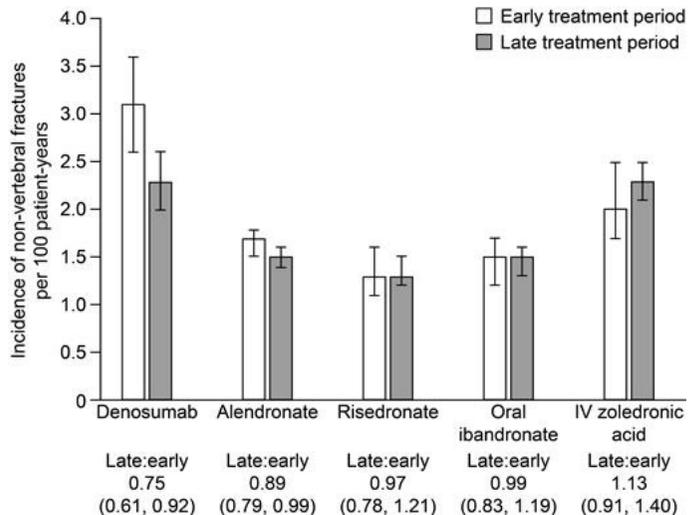

Eligible women were ≥50 years, had initiated treatment for PMO (index event) between 1 Jan 2010 and 31 Dec 2012, and had data available for ≥12 months prior to, and ≥4 months after, the index date. Women were considered independent of their persistence or compliance with therapy, to reflect routine clinical practice. Primary outcomes included incidence of NVFX and HPFX. To control for differences in baseline fracture risk, patients were their own controls: the ratio of fracture rate in the late treatment period (12 months after the first 90 days of antiresorptive therapy) to fracture rate in early treatment period (first 90 days of therapy, during which medication effect is assumed absent) was calculated for each treatment.

Results

A total of 213 102 patients were included: denosumab (DMAB; 17 561 women), intravenous (IV) zoledronic acid (ZA; 20 223), IV ibandronate (IBAN; 1230), oral IBAN (40 739), risedronate (RIS; 31 651) and alendronate (ALN; 101 698). Women who initiated DMAB, IV ZA and IV IBAN were older (mean age 67.1-69.2 vs 63.6-65.2 years) and more likely to have had a prior fracture (5.9-7.5% vs 3.2-4.7%) than those receiving oral agents. Despite DMAB patients having the highest fracture risk in the early treatment period (3.1 NVFX and 0.8 HPFX per 100 patient-years), in the year following the early treatment period DMAB reduced NVFX by 25% compared with the early treatment period (Fig). ALN was the only other agent to reduce NVFX incidence (11%). These agents prevented 8 and 2 NVFX per 1000 patient-years, respectively. No agent reduced HPFX incidence in this assessment. Sensitivity analyses showed that changing the length of the early and late treatment periods and censoring patients at first fracture during follow-up did not affect the results.

Conclusions

DMAB produced the greatest reduction in NVFX in this large, community cohort, although the fracture rate remained high, reflecting the baseline characteristics of patients initiating DMAB. The results for ALN and IBAN are consistent with Abelson *et al.* (Osteoporos Int 2010). The lack of effect of RIS is surprising and warrants further research.

IV ibandronate not included because of small sample size
 Numbers annotated are fracture rate ratio between late and early treatment periods and 95% confidence interval

Incidence of non-vertebral fractures after starting therapy

Denosumab Compared to Other Treatments to Prevent or Treat Osteoporosis: a Systematic Review and Meta-analysis. Claudia Beaudoin*¹, Sonia Jean², Louis Bessette³, Louis-Georges Ste-Marie⁴, Jacques P. Brown³.¹CHU de Québec Research Centre, Canada, ²Institut national de santé publique du Québec, Canada, ³CHU de Québec Research Centre, Canada, ⁴Université de Montréal, Canada

Background: Denosumab is a new pharmacological treatment for osteoporosis which acts by a different mechanism than bisphosphonates, the most commonly used drugs. **Objective:** To compare the efficacy and safety of denosumab over other pharmacological treatments for osteoporosis in individuals at high risk of fracture or suffering from osteoporosis. **Methods:** Randomized controlled trials comparing the effect of denosumab with another pharmacological treatment for osteoporosis were searched in MEDLINE, EMBASE and CENTRAL. Identified articles (1763) were screened by two independent reviewers and assessed for inclusion. Studies including only individuals with a specific condition other than osteoporosis were excluded. Data from included studies were extracted and meta-analyses were conducted using Mantel-Haenszel, generic inverse variance or Peto method. Results (preliminary): Nine studies conducted on a maximum follow-up period of 24 months were found and included 4339 participants (Table 1). All participants were post-menopausal women. None of the individual studies were powered and designed to evaluate the comparative effectiveness of denosumab to decrease the fracture risk. There was no statistically significant difference between patients receiving denosumab and those receiving another treatment in terms of fracture risk (RR [95% CI] = 1.31 [0.94; 1.84]), number of adverse events (RR [95% CI] = 0.98 [0.95; 1.02]), withdrawals due to adverse events (OR [95% CI] = 0.73 [0.47; 1.16]) or deaths (OR [95% CI] = 0.75 [0.14; 4.05]). The percent change in bone mineral density was higher in participants who received denosumab (mean difference [95% CI] at the total hip: 1.12[0.88;1.36], lumbar spine: 1.34[0.79;1.89], femoral neck: 0.99[0.71;1.28], one-third radius: 1.31[0.31;2.31]). **Conclusion:** The results of this meta-analysis suggest that the safety and efficacy of denosumab to reduce fractures is not significantly different from other osteoporosis medications. A recent review from Institut national d'excellence en santé et en services sociaux (INESSS, Quebec, Canada) has shown that, in a clinical setting, persistence and compliance with denosumab is significantly better than with oral bisphosphonate. In the real-world clinical practice, denosumab may have an increased effectiveness. Other studies conducted over a longer period and specifically designed to evaluate the comparative effectiveness of denosumab to decrease the incidence of fractures should be performed.

Difference and similarity between alendronate oral jelly therapy and alendronate weekly tablet therapy in the treatment of osteoporosis in Japanese clinical settings. Nobukazu Okimoto*¹, Satoshi IKeda², Hidehiro Matsumoto³, Akinori Sakai⁴. ¹Okimoto Clinic, Japan, ²Ken-Ai memorial Hospital, Japan, ³Sanzai Hospital, Japan, ⁴University of Occupational & Environmental Health Japan, Japan

Purpose: We conducted the comparative trial of alendronate oral jelly (ALN-J, 35mg) versus alendronate weekly tablet (ALN-T, 35mg) to clarify the effect of

alendronate oral jelly in the treatment of osteoporosis in Japanese clinical settings. **Methods:** We allocated ALN-J or ALN-T to the patients in accordance with their preferences in each institution. The patients took ALN-J or ALN-T weekly and were observed for 6 months. Bone turnover marker (TRACP-5b, PINP) was measured at baseline, 3 months and 6 months and bone mineral density was measured at baseline and 6 months. Upper gastrointestinal symptoms were assessed using Izumo scale questionnaire with nine questions in three domains. Compliance with medical treatment and intention of continuing allocated therapy were periodically confirmed. **Results:** A total of 94 patients were enrolled in this trial from ten institutions. Of 94 patients, 65 patients (female, 62; male, 3) assigned to the ALN-J group and 29 patients (female, 27; male, 2) to the ALN-T group. Mean [SD] of age was 77.5 [7.6] in the ALN-J group and 76.0 [6.6] in ALN-T group, and proportion of history of fracture was over 70 % in each group. TRACP-5 decreased by 38.8 % in the ALN-J group and 36.8 % in the ALN-T group at 3 months and 44.0 % in both groups at 6 months. PINP decreased by 44.2 % in the ALN-J group and 45.9 % in the ALN-T group at 3 months, and 51.6 % and 57.8 % at 6 months, respectively. The scores of upper gastrointestinal symptoms such as heartburn, epigastralgia and epigastric fullness increased in ALN-T therapy group during the period of treatment, however, that of ALN-J group was stable. The compliance of medical treatment was similar and good in both groups. **Conclusions:** The patients preferred ALN-J to ALN-T therapy. ALN-J has equal effectiveness to ALN-T, however, ALN-J therapy has the potential to alleviate upper gastrointestinal symptoms compared with ALN-T therapy.

MO0340

Difference in Bone Mineral Density Change at the Lateral Femoral Cortices According to Administration of Different Bisphosphonate Agents. Kyu Hyun Yang*¹, Sungjun Kim¹, IL Hyung Park². ¹Gangnam Severance Hospital, South Korea, ²Kyungbook National University, South Korea

Purpose: Even though the effect of bisphosphonate (BP) agents in preventing osteoporotic fracture is eminent, their strong association with atypical femoral fracture (AFF) has recently been suspected after long-term administration. The purpose of this study was to retrospectively assess whether the response in the subtrochanteric lateral cortex (STLC) was different in BPs. **Material and Methods:** 1) Subject collection: A total of 149 individuals who underwent serial DXA examinations during the 2 or more years to trace bone mineral density during bisphosphonate administration (alendronate or risedronate) as naïve users or who simply underwent health check-up were included. Among them, 48 were naïve alendronate users (alendronate group), 63 were naïve risedronate users (risedronate group) and 38 did not take bisphosphonate medications (control group). 2) DXA examination and BMD measurement: For each subject, serial DXA examinations were performed by a technician at the same scanner of Lunar Prodigy (GE-healthcare Lunar, Madison, WI) without system change of the DXA scanner during the study interval. The PA spine and unilateral hip (right hip in all patients) DXA examination were performed. To validate whether the medication compliance was acceptable, BMD measurement for spine and hip was performed. BMD was measured at STLC and subtrochanteric medial cortex (STMC) for each patient at the level just distal to the lesser trochanter. Rectangular region of interest (ROI) was drawn at the cortex. As for the width, ROIs were drawn not violating the boundary of the cortices. The proximal to distal length of the ROI was unified as 1 cm. All measured BMD data were recorded as g/cm². 3) Measurement of BMD change and its assessment: Percent change (% change) = (BMD from the second DXA examination - BMD from the first DXA examination) x 100 / BMD from the first DXA examination. The % changes were calculated for STLC, STMC, spine, and total hip and were assessed statistically as stated below in the following two aspects: 1) to compare % change of total hip and spine BMD between medication and control groups to test the compliance of the patients who took the medication; 2) to test difference of later cortex % change according to agents. 4) Statistical analysis: To test whether there is difference of % change of BMD in hip, spine, and STLC among the agents, ANCOVA (analysis of covariance) model was adopted to control five independent variables assessed in this study including age, BMI, STMC % change, hip axis length, time interval between DXA examinations concurrently assessing whether any of the variables other than medication affect the % change of BMD in hip, spine, and STLC. Using the ANCOVA model, the least square means of % change for hip BMD, spine BMD, and STLC BMD were obtained for each medication group, and multiple comparisons were done to assess between group differences. Subsequent post-hoc comparison t-tests with Bonferroni correction were used. **Results:** Subject's age, interval between the first and the second DXA examinations, BMI, HAL, mean % change values of spine, hip, medial and lateral subtrochanteric cortices are summarized in Table 1. Difference of BMD % change among the medication groups in the analysis of covariance, % change of spine BMD was affected by medication (p<0.001) and time interval between DXA examination (=0.026). Similarly, % change of hip BMD was affected by medication (p<0.001) and time interval between DXA examination (=0.029). In the assessment of difference of BMD % change of STLC according to the given medication after controlling of the dependent variables, risedronate group showed higher % change with statistical significance than did control (adjusted p=0.012) and alendronate (adjusted p=0.016) groups (Figure 1). **Conclusion:** We traced and confirmed that increase in BMD on the STLC was significant after risedronate administration even though the implication of these changes must be qualified in the future.

| | Control | Risedronate | Alendronate |
|--|-----------------------|----------------------|-----------------------|
| Age (years) at the first DXA examination | 67.9±3.0 (63-74) | 69.9±2.9 (65-75) | 69.8±3.1 (62-75) |

Different BMD gains after denosumab compared to zoledronate following teriparatide in women with postmenopausal osteoporosis – a case-control study. Albrecht Popp*, Schaefer Silke, Helene Buffat, Piera Rossi, Christoph Senn, Kurt Lippuner. Department of Osteoporosis, University Hospital Bern, Switzerland

Background: Treatment with parathyroid hormone (PTH) or its 1-34 derivate teriparatide (TPTD) increases bone mineral density (BMD) and reduces fracture risk by anabolic mode of action. Antiresorptives after PTH preserve the gains in BMD achieved with PTH (Black DM 2005). It is unknown whether highly potent antiresorptives such as the bisphosphonate zoledronate (ZOL) or the monoclonal antibody denosumab (Dmab) lead to different BMD changes after TPTD.

Methods: A case-control study was performed in women with postmenopausal osteoporosis who were treated with TPTD at the Department of Osteoporosis, University Hospital Bern, Switzerland. Baseline BMD was measured at the end of the treatment period with TPTD at the lumbar spine (LS), femoral neck (FN), total hip (TH) as well as distal tibial epiphysis (T-EPI) and diaphysis (T-DIA), the last two according to a previously validated method (Casez JP1994; Popp AW 2009) using cross calibrated Hologic QDR 4500 A und Discovery™ scanner. Antiresorptive therapy was initiated with either ZOL (control group) or Dmab (cases). Follow-up BMD was measured 24 months later. Of ninety-two women, 23 pairs could be matched for age, TH T-scores, and treatment duration with TPTD. Changes in BMD were compared using Mann-Whitney U test. Values are indicated as means ± SEM.

Results: Baseline characteristics (mean ± SD) were similar between groups in terms of age, 74.7 ± 8.5 years; TH T-score, -1.8 ± 1.0 and treatment duration with TPTD 21.4 ± 3.1 months. Consistent with reimbursement restrictions for the usage of TPTD in Switzerland, almost all women were treated with bisphosphonates and switched to TPTD. The percentual changes in BMD vs. baseline after 24 months of ZOL or Dmab following TPTD were:

| | Dmab | ZOL | p |
|----|-------------|-------------|-------|
| LS | +6.8 ± 0.8% | +2.3 ± 0.9% | 0.001 |
| FN | +5.7 ± 1.5% | +1.3 ± 1.0% | 0.024 |

| | | | |
|-------|-------------|-------------|-------|
| TH | +3.2 ± 1.1% | +2.0 ± 0.9% | 0.69 |
| T-DIA | +2.2 ± 1.1% | +0.7 ± 0.9% | 0.337 |
| T-EPI | +2.9 ± 0.9% | +3.0 ± 1.2% | 0.663 |

Conclusion: In this case-control study, Dmab led to significantly higher gains in LS and FN BMD in women previously treated with TPTD compared to ZOL, while differences at the total hip and the tibial sites did not reach statistical significance.

MO0342

Discontinuation of Denosumab is associated with a severe increase risk of spontaneous vertebral fractures: 3 case reports. Olivier Lamy¹, Delphine Stoll², Elena Gonzalez Rodriguez³, Didier Hans², Bérengrère Aubry-Rozier^{*2}. ¹Chief of the Bone Unit, Switzerland, ²Center of Bone Diseases, Lausanne University Hospital, Switzerland, ³Center of Bone Disease, Lausanne University Hospital, Switzerland

Introduction : The discontinuation of bisphosphonates is associated with a prolonged reduction in bone turnover markers (BTMs), a slow decrease of bone mineral density (BMD) and no increase of fracture risk (FxR). In contrast, the discontinuation of other antiresorptive agents, is associated with a BTMs rebound and a rapid decrease of BMD to above pretreatment values. FxR is increased after the discontinuation of oestrogens. The discontinuation of Denosumab (Dmab) is associated with a severe rebound effect on BTMs and BMD. It is not known whether this rebound effect is associated with an increase of FxR. Method: We report the cases of 3 women with postmenopausal osteoporosis without any prior fracture. They received Dmab 60mg every 6 months for 4 to 6 doses. The 3 women were on calcium and vitamin D during and after the discontinuation of Dmab. A wide biological assessment, performed at the time of fracture, was strictly normal. A secondary cause of osteoporosis was excluded.

Results : A 77y old women (BMD -4.1 DS at lumbar spine (LS) and -3.4 DS at total hip (TH)) received 5 doses of Dmab between Feb. 2011 and June 2013. The BMD changes were +6.7% and -5.0%, respectively. At the end of 2014, She presented 9 symptomatic spontaneous vertebral fractures (SSVFx) (D5, D6, D7, D8, D9, D11, D12, L1, L2) and one costal Fx.

A 56y old women (BMD -3.1 DS at LS and -2.5 DS at TH) received 4 doses of Dmab between Oct. 2011 and Nov. 2013. The BMD changes were +12% and +6.5%, respectively. She presented 5 SSVFx (D11, D12, L2, L3, L4) between August and Sept. 2014.

A 55y old women (BMD -3.1 DS at LS and -2.0 DS at TH) received 6 doses of Dmab between Dec. 2010 and Nov. 2013. The BMD changes were +11.1% and +13.5% respectively. She presented 1 SSVFx (D12) in Sept. 2014

Conclusion : These 3 cases show an increased risk of vertebral fractures in the 9 to 16 months after the last injection of Dmab. This raises several questions. Can we identify patients at risk of fracture after discontinuation of Dmab? Can we reduce this risk with a bisphosphonate for 6 to 12 months after Dmab discontinuation?

Ectosteric inhibitors of cathepsin K from *Salvia miltiorrhiza*. Simon Law*, Preeti Panwar, Nham Nguyen, Gary Braver, Dieter Bromme. University of British Columbia, Canada

Cathepsin K is a lysosomal cysteine protease highly expressed in osteoclasts and macrophages which has been implicated in musculoskeletal and cardiovascular diseases. It displays potent collagenase and elastase activity and has become a target for bone diseases. However, existing drugs are active-site inhibitors, which block the entire protease activity and have been implicated in side effects. Our strategy is to identify compounds that selectively block the collagenase activity without interfering with other regulatory functions of cathepsin K. We call these drugs ectosteric inhibitors which in contrast to allosteric inhibitors have no effect on the active site.

Natural products are a great source of chemical diversity and some have been used for millennia to treat diseases. *Salvia miltiorrhiza* is a widely used Chinese herb for the treatment of musculoskeletal and cardiovascular diseases and produces a unique pool of diterpenoids, called tanshinones. We identified these compounds as ectosteric inhibitors for cathepsin K. From 37 tanshinones about half of them revealed a selective anticollagenase activity without blocking the active site of cathepsin K. Some of the compounds can differentiate between the degradation of soluble and fibrous collagen and thus provide ideal tools for studying the mechanism of collagen degradation by osteoclasts. The most potent tanshinone identified was Tanshinone IIA Sulfonic Sodium with an IC₅₀ value of approximately 2µM for soluble collagen degradation and was highly potent in inhibiting insoluble collagen degradation at the same concentrations. Molecular modeling has identified an ectosteric site on cathepsin K which is required to form collagenolytically active protease oligomers. Crystallization experiments are in progress which will define the exact binding mode of Tanshinone IIA Sulfonic Sodium. The inhibitor-cathepsin K complex structure will provide structural information that will assist in designing high affine and selective ectosteric inhibitors of cathepsin K.

Factors Affecting Persistence With Denosumab (Prolia®) in Postmenopausal Women With Osteoporosis: Results From a Prospective Observational Study. SL Silverman*¹, E Siris², DL Kendler³, D Belazi⁴, JP Brown⁵, DT Gold⁶, EM Lewiecki⁷, A Papaioannou⁸, C Simonelli⁹, G Quinn¹⁰, S Yue¹¹, LI Cheng¹¹, B Stolshek¹¹, C Recknor¹². ¹Cedars-Sinai Medical Center, UCLA School of Medicine, & OMC Clinical Research, USA, ²Columbia University Medical Center, USA, ³University of British Columbia, Canada, ⁴AlchemiPharma LLC, USA, ⁵Laval University & CHU de Québec (CHUL) Research Centre, Canada, ⁶Duke University Medical Center, USA, ⁷New Mexico Clinical Research & Osteoporosis Center & University of New Mexico School of Medicine, USA, ⁸McMaster University, Canada, ⁹Health East Osteoporosis Care, USA, ¹⁰Sarnia Statistics Ltd, United Kingdom, ¹¹Amgen Inc., USA, ¹²United Osteoporosis Centers, USA

Purpose
Osteoporosis therapy is effective in reducing fracture risk. Evidence has shown that low persistence with therapy in the community setting is associated with suboptimal patient outcomes. This analysis evaluated whether factors affecting persistence with denosumab at 24 months were different from those at 12 months in the United States (US).

Methods
In this multicenter, single-arm study, postmenopausal women were enrolled within 4 weeks of initiating treatment with denosumab for osteoporosis. No clinical procedures, assessments, or changes in routine management of patients were required. Persistence with denosumab was assessed at 12 and 24 months, defined as receiving ≥2 injections and ≥4 injections, respectively, and no 2 consecutive injections more than 6 months + 8 weeks apart. Persistence rates were based on total patient count at enrollment. Univariate analysis was performed to assess factors associated with persistence with no adjustment for multiplicity, and we report the US results.

Results
Of the 935 patients enrolled, 632 were from the US. These patients had a mean (SD) age of 72 (10) years, mean (SD) lumbar spine BMD T-score of -1.9 (1.4), and 95% were white. Persistence with denosumab was 81% at 12 months and 50% at 24 months. Of >60 factors assessed, 23 were associated with persistence at either time point (Table). Six factors were associated with persistence at both time points, including geographic, socioeconomic, patient, and healthcare system-related factors. Differences were observed in factors associated with persistence at 12 and 24 months. Of the additional 17 factors identified as associated with persistence, 3 factors influenced persistence at 12 months only: patients' beliefs about medication (assessed using the Beliefs and Medicines Questionnaire), intolerance to previous osteoporosis therapies, and prior insurance authorization required for denosumab treatment. Considerably more factors (n=14) affected persistence at 24 months than at 12 months; several of these factors were patient related (Table).

Conclusions
Many factors influenced persistence with denosumab at 12 and 24 months, although several factors that influenced persistence at 24 months did not affect persistence at 12 months. Awareness of these factors may assist in the identification of patients who may become nonpersistent with therapy, and some factors may be modifiable, such as the use of a reminder program, and could be incorporated in clinical practice.

MO0345

Incidence Rate of Osteonecrosis of the Jaw among Women with Postmenopausal Osteoporosis Treated with Prolia or Bisphosphonate. Fei Xue*¹, Rachel Wagman², Susan Yue², Shawna Smith³, Violeta Hennessey⁴, Tarun Arora⁵, Jeffrey Curtis⁵, Vera Ehrenstein⁶, Henrik Sorensen⁶, Grethe Tell⁷, Helle Kieler⁸, Florence Wang⁹, David Dore⁹, J. Michael Sprafka¹⁰. ¹Amgen Inc., USA, ²Global Development, Amgen Inc., USA, ³Global Safety, Amgen Inc., USA, ⁴Global Biostatistics, Amgen Inc., USA, ⁵Division of Clinical Immunology & Rheumatology, University of Alabama at Birmingham, USA, ⁶Department of Clinical Epidemiology, Aarhus University, Denmark, ⁷Department of Global Public Health & Primary Care, University of Bergen, Norway, ⁸Center for Pharmacoepidemiology, Karolinska Institute, Sweden, ⁹Optum Epidemiology, USA, ¹⁰Center for Observational Research, Amgen Inc., USA

Purpose: To estimate the incidence rate (IR) of osteonecrosis of the jaw (ONJ) in recipients of Prolia (denosumab 60 mg) or bisphosphonate (BP) for postmenopausal osteoporosis (PMO) in multiple administrative databases.

Methods: Using administrative data from US Medicare, Optum and Scandinavian national medical registries (Denmark, Norway and Sweden), postmenopausal women with a diagnosis of osteoporosis or osteoporotic fracture, or osteoporosis medications were identified from May 2010 to Dec 2011 (Medicare and Scandinavian national registries) or Mar 2013 (Optum). The women were followed for incident event of potential ONJ defined by ICD codes. Prolia and BP (oral and IV) exposure was updated in a time-varying manner and characterized "as treated", with and without a 1 year extension following the on-treatment period defined as the days supplied plus 60 days. The age-standardized IR of ONJ was computed for each exposure cohort.

Results: A total of 2,561,119 women with PMO were identified from Medicare (1,995,915), Optum (193,003), Denmark (106,691), Norway (95,628) and Sweden (169,882). The IR (95% CI) per 100,000 person-years of ONJ in women with PMO was 40 (38 - 42) in Medicare, 27 (20 - 34) in Optum, 37 (27 - 50) in Denmark, 17 (11 - 26) in Norway and 25 (17 - 38) in Sweden. In Medicare, when exposure cohorts were classified only by the on-treatment period, the IR (95% CI) was 70 (28 - 145) in the Prolia only cohort and 90 (11 - 328) in the Prolia + BP cohort, and ranged from 45 (41 - 49) to 77 (7 - 310) in cohorts exposed to BP only (Table 1). When exposure cohorts were classified by on-treatment + 1-year post-treatment period, the IR (95% CI) was numerically lower in the Prolia only cohort [59 (11 - 180)] and the Prolia + BP cohort [76 (30 - 160)], and remained similar in cohorts exposed to BP only [ranging from 45 (42 - 48) to 84 (53 - 125)] relative to the corresponding on-treatment only cohorts (Table 2). The number of ONJ cases in the other data systems was too low (0 - 2) in Prolia recipients to allow a robust estimation of the IR.

Conclusion: The descriptive analysis based on Medicare suggested the IR of ONJ was low in the PMO population and did not differ substantially by treatment. The number of cases in other data systems was low and precluded meaningful interpretation of the ONJ IR, especially in Prolia recipients. To confirm these results, further analysis based on medically confirmed cases and adjustment for confounders is warranted.

Relationship Between Suppression of Bone Turnover Markers (TRACP-5b, BAP) and Future Increases in Bone Mineral Density in Risedronate Treatment- Sub-analysis of Japanese Phase III Study of Risedronate 75 mg - Taro Mawatari¹, Ryoichi Muraoka², Yukihide Iwamoto³.
¹Hamanomachi Hospital, Japan, ²Ajinomoto Pharmaceuticals Co., Ltd., Japan, ³Department of Orthopaedic Surgery, Graduate School of Medical Sciences, Kyushu University, Japan

While bone turnover markers (BTMs) are useful to monitor response and adherence to osteoporosis treatment, the relationship between risedronate-related suppression of BTMs and future increase in bone mineral density (BMD) is not fully established. This study further explored the nature of this relationship.

Sub-analysis included 800 subjects included in the Japanese phase III study of patients treated with risedronate 75 mg once a month for 12 months, whose vertebral BMD, serum TRACP-5b (tartrate-resistant acid phosphatase 5b), and serum BAP (bone alkaline phosphatase) were measured sequentially. The minimal significant change (MSC) was defined as 12.4% for TRACP-5b, and 23.1% for BAP. The upper limit of normal (ULN) was defined as 420 mU/dL for TRACP-5b, and 29.0 U/L for BAP. The subjects were divided into three subgroups according to the change in BTMs at 3 months: Group L (reduction more than MSC), Group N (change within MSC), and Group H (elevation more than MSC). Alternatively, the subjects were divided into two groups, depending on whether the BTMs at 3 months were less than ULN. Percent change in BMD at 12 months was compared among these subgroups.

Vertebral BMD gain in Group L was significantly greater than that in the other groups, for both TRACP-5b and BAP analyses (TRACP-5b: Group L [N = 661] 6.24 ± 4.11%, Group N [N = 99] 4.38 ± 4.50%, Group H [N = 33] 2.15 ± 4.21%, one-way analysis of variance (ANOVA): P < 0.0001; BAP: Group L [N = 463] 6.52 ± 4.02%, Group N [N = 332] 4.97 ± 4.47%, Group H [N = 7] 2.26 ± 3.13%, one-way ANOVA: P < 0.0001). With regard to suppression in BTMs less than ULN, TRACP-5b at 3 months was related to a future increase in BMD (TRACP-5b ≤ ULN [N = 678] 5.99 ± 4.03%, TRACP-5b > ULN [N = 115] 4.94 ± 5.43%, P < 0.0150), but this was not seen in BAP.

In summary, BMD gain at 12 months was greater (more than 6% on average) in the subgroups showing reduction more than MSC in serum TRACP-5b or BAP at 3 months, while BMD gain was attenuated when reduction in BTMs was less than MSC. Furthermore, BMD gain at 12 months was greater when the value of serum TRACP-5b at 3 months was less than ULN, compared with cases with a value higher than ULN. These results suggest that monitoring patients with BTMs may be useful in predicting future BMD gain with risedronate treatment.

Disclosures: Taro Mawatari, None.

Spaceflight Bone Atrophy-Problem Solved?. Adrian LeBlanc¹, Toshio Matsumoto², Jeffrey Jones³, Jay Shapiro⁴, Thomas Lang⁵, Linda Shackelford⁶, Scott M. Smith⁶, Scott M. Smith⁶, Harlan Evans⁷, Elisabeth Spector⁸, Robert Ploutz-Snyder⁹, Jean Sibonga⁶, Joyce Kevak¹⁰, Toshitaka Nakamura¹¹, Kenjiro Kohri¹², Hiroshi Ohshima¹³, Gilbert Moralez¹⁴.
¹Universities Space Research Association (USRA), USA, ²Fujii Memorial Institute of Medical Sciences, University of Tokushima, Japan, ³Baylor College of Medicine- Center for Space Medicine, USA, ⁴Kennedy Krieger Institute, USA, ⁵UC San Francisco, USA, ⁶NASA, USA, ⁷Wyle Houston, USA, ⁸Wyle Science, Technology & Engineering Group, USA, ⁹USRA, USA, ¹⁰UC Irvine, USA, ¹¹National Center for Global Health & Medicine Center Hospital, Japan, ¹²Nagoya City U, Japan, ¹³Space Biomedical Research Group, JAXA, Japan, ¹⁴The University of North Texas Health Science Center (UNTHSC), USA

The NASA Human Research Program (HRP) has explored bone loss countermeasures for long duration spaceflight since the 1970's. Three main strategies have emerged: exercise, nutrition, pharmacological. During Skylab and subsequent Soviet Mir and Shuttle/Mir missions, aerobic exercises with limited amounts of resistive exercise were employed. Following the Mir era, NASA and space partners (Russia, Japan, Europe Canada) launched the International Space Station (ISS) with a new resistive exercise device called the IRED (interim resistive exercise device). Implementation of this device met with limited success partly because of engineering problems. This was followed in 2008 by the Advanced Resistive Exercise Device (ARED) with significantly improved capability. In addition to exercise, the diet has been improved over the years with the use of Vitamin D and improved energy intake. Other dietary improvements are being explored, e.g., lowering Na content of the diet. A third option is pharmacological-an antiresorptive drug, oral alendronate, 70 mg/week, was tested on ISS. Current status: while the exercise protocol using the ARED device alone appears partially effective, BMD loss continues (fig1) and urinary Ca and resorption markers remain elevated (p<0.05). Still under investigation is whether bone strength is preserved or if there is a redistribution of bone targeted by resistive

exercise. Exercise plus an antiresorptive drug appears to preserve bone mass (fig1) and bone strength without elevation of bone resorption markers or urinary calcium excretion ($p > 0.05$). This third option allows for a more robust countermeasure for long duration flight in case exercise is precluded, e.g., equipment failure or crew injury. Related to this issue, bed rest studies have shown that antiresorptive treatment would be effective without exercise. The question posed: is the problem solved? Conclusion: NASA Human Systems Risk Board has changed the status of bone loss in space from high risk to manageable risk. Exercise or exercise plus a pharmacological intervention appear effective but additional investigations are needed to optimize the ultimate prescription. Newer medications such as RANKL, Sclerostin or Cathepsin-K inhibitors which might offer similar protection with a better tolerability profile should be investigated. The combination of various exercise prescriptions and drug combinations to improve countermeasure efficiency warrant further investigation.

The Effects of a Novel Selective Estrogen Receptor Modulator (SERM) pERD on Bone Health in Intact Female Rats. Jukka Morko¹, Arndt Schmitz², ZhiQi Peng¹, Katja M Fagerlund¹, Yvonne Konkol¹, Mari I Suominen¹, Jenni Bernoulli¹, Jukka P Rissanen¹, Jussi M Halleen¹, Andrea Wagenfeld². ¹Pharmatest Services Ltd, Finland, ²Bayer Pharma AG, Finland

Selective estrogen receptor modulators (SERMs) are a diverse class of compounds that bind to estrogen receptors (ERs) and agonize or antagonize estrogen action in different tissue types. Due to a broad spectrum of physiological and pathological processes contributed by ERs, SERMs provide a potential therapeutic benefit for a variety of diseases exhibiting modulated estrogen action. In this study, we characterized the effects of a novel SERM pERD on bone health in intact female rats, and we compared the effects of pERD treatment with the effects of ovariectomy (OVX), fulvestrant (FUL), raloxifene (RAL) and tamoxifen (TAM). FUL was used as a complete antagonist and RAL and TAM as reference SERMs exhibiting agonist activity on bone and being used in clinical practice. Treatment of female Sprague-Dawley rats was started at 3 months of age and continued once a day for 8 weeks. Intact rats were treated with pERD at 3, 10 and 30 mg/kg/d *p.o.*, FUL at 3 mg/kg/d *s.c.*, RAL at 1 mg/kg/d *p.o.*, TAM at 10 mg/kg/d *p.o.* or with vehicle, and OVX rats were treated with vehicle. Treatment effects on bone were studied by peripheral quantitative computed tomography (pQCT) and measuring serum levels of bone turnover biomarkers. In metaphyseal trabecular bone, treatment with pERD at 3 mg/kg/d decreased bone mineral density (BMD) and bone mineral content (BMC) slightly. These pERD effects were only minor when compared with the effects of OVX and FUL. In diaphyseal cortical bone, treatment with pERD at 3 mg/kg/d decreased cortical bone area and cortical thickness slightly as well. These pERD effects were opposite to the effects of OVX and similar with the effects of RAL. Treatment with pERD at 10 and 30 mg/kg/d did not affect metaphyseal trabecular bone and diaphyseal cortical bone significantly. In circulation, treatment with pERD decreased serum levels of N-terminal mid-fragment of osteocalcin (OC) at 30 mg/kg/d and serum activity of tartrate-resistant acid phosphatase isoform 5b (TRACP 5b) at 3, 10 and 30 mg/kg/d. These effects of pERD treatment indicate a minor antagonist activity in metaphyseal trabecular bone and an agonist activity in diaphyseal cortical bone at 3 mg/kg/d. Therefore, this study presents pERD as a novel mixed partial antagonist and agonist in bone at the dose of 3 mg/kg/d, and as novel SERM without agonist and antagonist activities in metaphyseal trabecular bone and diaphyseal cortical bone at the doses of 10-30 mg/kg/d in young adult female rats.

MO0349

The Effects of Teriparatide and Zoledronic Acid Differ Across Different Bones Sites. A Study at the Femoral Neck, Vertebra and Iliac Crest in Ewes. Nathalie R Portero-Muzy, Pascale Chavassieux*, Evelyne Gineyts, Roland D Chapurlat. INSERM UMR1033, Université de Lyon, France

Iliac crest (IC) bone biopsies are used to assess the mechanism of action of therapeutic agents, yet there is little data comparing this site to sites prone to fracture. Zoledronic acid (ZOL) and teriparatide (TPTD) have different mechanism of action. We have previously shown in ewes that the magnitude and time to response to ZOL and TPTD differed between the 1st lumbar vertebra (LV1) and iliac crest (1). In the present experimental study in ewes, we distinguish their respective effects on 2D-microarchitecture, collagen crosslinks composition and bone remodeling in the femoral neck (FN) compared to IC and LV1. Three groups of 24 aged ewes received either vehicle (CTRL; 8.4±0.4 yrs, n = 8) or a single injection of 10 mg of ZOL (8.1±0.4 yrs, n = 8) or daily injection of 20µg/d of TPTD (8.1±0.4 yrs, n = 8). After 3 months, ewes received a double tetracycline labeling before slaughtering and IC, LV1 and FN were collected. In CTRL, BV/TV was 2 times lower at IC than at FN and LV1 ($p < 0.0001$). FN was characterized by a significantly lower bone formation (OS/BS: 3.2±2.1, 17.8±12.7 and 5.9±3.8 % in FN, IC and LV1 respectively, $p < 0.0001$) and resorption (ES/BS: 0.5±0.1, 1.5±0.7 and 3.9±1.6% in FN, IC and LV1 respectively, $p < 0.0001$). The bone turnover was the lowest at FN: BFR/BS was 4 and 2.5 times lower in FN than in IC and LV1 respectively ($p < 0.0001$). This was associated with significantly lower pyridinoline (PYR) and deoxypyridinoline (DPD) contents at FN than at other sites ($p < 0.0001$). After 3 months, ZOL induced a marked decrease of bone turnover at all sites but the magnitude was the lowest at FN. MS/BS, BFR/BS and MAR were significantly decreased by 72.4, 93.3 and 97.8% ($p < 0.001$), 75, 93.2 and 95.3% ($p < 0.001$) and 13, 58.4 and 52.9% ($p < 0.05$) respectively at FN, LV1 and IC when compared to CTRL. This was associated with a lower PYR/DPD ratio at FN than at IC ($p < 0.02$). After 3 months of TPTD the augmentations of ES/BS and BFR/BS were significantly higher at FN than at the other sites ($p < 0.01$ and 0.03 respectively) but the crosslinks contents were not changed. In conclusion, in ewes, the early effects of ZOL and TPTD on bone are observed at FN, LV1 and IC, but with a different magnitude according to the skeletal site. To fully understand the mechanisms underlying the anti-fracture efficacy of osteoporosis therapies, the distinction of bone sites is important.1 - Portero-Muzy N.R. et al., Bone 51:714-719, 2012.

Utilization of osteoporosis medication after a fragility fracture among elderly Medicare beneficiaries. Akeem Yusuf¹, Tom Matlon¹, Andreas Grauer², Rich Barron², David Chandler², Yi Peng¹. ¹Chronic Disease Research Group, USA, ²Amgen Inc., USA

Osteoporosis (OP) medications are recommended for elderly patients after a fragility fracture, but under-treatment is common. In this study of elderly Medicare beneficiaries after a fragility fracture, we 1) determined the incidence of OP medication prescription, and 2) examined factors associated with OP medication use.

Our cohort included elderly (age ≥ 66 years) Medicare-enrolled patients who sustained a fragility fracture between January 1, 2008, and December 31, 2011. OP medication prescriptions were determined in the 12 months after the index fracture (follow-up period). Proportions of treated patients overall and by fracture site were examined. Using multivariate logistic models, we examined the association between post-fracture OP medication use and predictors (demographics, clinical conditions, bone mineral density [BMD] tests).

We identified 145,185 patients with fragility fractures (mean age 80.9 ± 7.8 years; 91.2% white; 81.3% female). Hip, vertebral, and non-hip-non-vertebral (NHNV) fractures accounted for 29.9%, 31.8%, and 38.3%, respectively, of identified index fracture events. Overall, 30.4% of the cohort received an OP medication in the follow-up period. Proportions receiving bisphosphonates, calcitonin, raloxifene, teriparatide, and denosumab were 25.3%, 4.1%, 2.0%, 1.3%, and 0.3%, respectively. Of patients on OP pharmacotherapy before an index fragility fracture, 23.8% did not receive an OP medication in the follow-up period. Of those with index hip, vertebral, and NHNV fractures, proportions receiving OP medications were 23.3%, 43.2%, and 25.4%, respectively ($P < 0.0001$). Odds of post-fracture OP medication use were 68% higher for women than for men. Osteoporosis diagnosis (odds ratio, 1.55; $P < 0.0001$) and BMD tests before an index fracture (odds ratio, 1.24; $P < 0.001$) were significantly associated with OP medication use after fracture.

In a large cohort of nearly 150,000 elderly US Medicare beneficiaries with a fragility fracture, less than a third received an OP medication in the year after the fracture, when risk of a second fragility fracture is highest. This study confirms results of previous smaller studies on a larger scale, and demonstrates dramatic under-treatment. These findings are a call to action for improved monitoring, patient identification, and treatment with OP therapy of elderly patients experiencing fragility fractures.

Bone Union rate of PLIF using local bone graft in long term bisphosphonates users. Si Young Park^{*1}, Seung Wo Suh², Jae Young Hong², Hyun Min Lee², Hwan Mo Lee³, Hwan Mo Lee². ¹Korea University, College of Medicine, South Korea, ²Korea University Hospital, South Korea, ³Yonsei University Severance Hospital, South Korea

Introduction

Bisphosphonates are the most popular drugs for treatment of postmenopausal osteoporosis. However, long-term use of bisphosphonates (BPs) may cause several complications such as atypical fracture of hip, osteonecrosis of jaw and delayed fracture healing. PLIF is a typical surgical technique for treatment of degenerative spinal disorders. Long-term use of BPs may also inhibit spinal fusion process after PLIF. We compared bony union rates of long-term BPs users and non-users after undergoing PLIF.

Methods

The subject were 81 postmenopausal women whose course could be observed for at least 2 years after surgery. Single interbody PLIF was done using local bone graft from laminectomy. Participants were divided into two groups; there were 46 patients in long-term BPs users group and 35 in non-users group. Serum C-terminal cross linking telopeptide levels were checked for bone resorption marker which could be extremely decreased in long-term BPs users. Bone fusion rates were calculated, 2 years after the surgery using plain radiographs and computed tomographic scans. Clinical outcomes were measured using ODI and VAS.

Results

Serum CTX level was extremely decreased in long-term BPs user group (p<.05). However, fusion rates turned out to be 82% in long-term BPs users group and 87% in non-users group (p>.05, not significant). There was no significant difference between two groups in ODI and VAS.

Discussion

At the two-year postoperative follow-up, there was no significant difference in bone fusion rate between two groups. Long-term BPs users showed fusion rates greater than 80% and clinical outcome improvement that were compatible to those in non-users. No significant effect was found after long-term BPs use on fusion rate of PLIF.

Can combined therapy with teriparatide and low-intensity pulsed ultrasound accelerate fracture healing with an Ilizarov external fixator?. Koji Nozaka^{*}, Yoichi Shimada, Naohisa Miyakoshi, Shin Yamada, Michio Hongo, Yuji Kasukawa, Hidetomo Saito, Hiroaki Kijima, Tsuchie Hiroyuki. Akita University Graduate School of Medicine, Japan

Background: Ilizarov external fixators have many advantages in the treatment of fractures. However, a disadvantage of the Ilizarov system is the relatively frequent incidence of pin infection. It is an advantage for orthopedic surgeons to remove an Ilizarov external fixator as early as possible after surgery. Although both teriparatide

and low-intensity pulsed ultrasound (LIPUS) have been found to accelerate fracture-healing processes, the effect of the combination of teriparatide and LIPUS in clinical bone fracture management remains unclear. Therefore, a retrospective study comparing the treatment effects of use of an Ilizarov external fixator alone and that of an Ilizarov external fixator combined with teriparatide and LIPUS was performed among elderly patients with lower limb fractures. Subjects: From among 721 patients with a lower limb fracture on admission to our department who underwent surgical treatment for a lower limb fracture with an Ilizarov external fixator, 38 patients >60 years old were investigated. Patients were either treated with an Ilizarov external fixator alone (IEF alone, n=20) or an Ilizarov external fixator combined with teriparatide and LIPUS (IEF combination, n=18). The patients' mean age was 64.1 years (range, 60-79 years) in the IEF alone group and 67.2 years (range, 60-83 years) in the IEF combination group. Teriparatide (20 µg subcutaneous injection daily or 56.5 µg subcutaneous injection once-weekly) and LIPUS (20 min/day) were started immediately after surgery for IEF combination group in an attempt to accelerate healing of the lower limb fracture with the Ilizarov external fixator. Results: The mean duration of union was 111.9 days (range, 94-175 days) for IEF alone and 72.1 days (range, 68-141 days) for the IEF combination; it was significantly shorter with the IEF combination (p<.05). Bone density (relative to young adult mean, YAM) was 61.3% (range, 38-82%) for IEF alone and 52.1% (range, 30-79%) for the IEF combination. The mean AOFAS score was 86.2 (range, 72-100) for IEF alone and 91.2 (range, 82-100) for the IEF combination. Discussion: In elderly patients with lower limb fractures, combined therapy (teriparatide and LIPUS) showed a shorter mean duration of union than the Ilizarov external fixator alone. Combined therapy with teriparatide and LIPUS may become a useful option in the treatment of elderly patients with lower limb fractures.

The bone union promoting effect of intermittent administrated Teriparatides daily or weekly in the treatment of vertebral fractures. Yoichi Kishikawa^{*}. Kishikawa Orthopedics, Japan

Background: Intermittent administrated teriparatide has an excellent bone formation promoting effect, but its bone union promoting effect in the treatment of vertebral fracture has not yet proven. Patient's rest level could be a major bias in the evaluation of therapeutic effect of drugs in the conservative management of vertebral fractures. In the past we reported the non-weight-bearing rest (: NWB rest, patient's are never allowed to sit up until the pain aboished when rolling on the bed) in the initial phase of treatment of vertebral fractures could prevent a vertebral collapse. We also reported the difference of changing in serum bone metabolism markers that took place after 4 months , between daily teriparatide (Forteo20µ/day : FOR) and weekly one (Teribone56.5µ/week : TRB, chemically synthesized and available only in Japan) in the treatment of vertebral fractures. We have found a difference in bone union promoting effect of the two teriparatides , when compaired under the same initial NWB rest level. Methods: 129 subjects (115female, 14male) who have recent vertebral fractures in thoracic or lumbar spine, all recieved conservative treatment with soft corset, then were divided into four subgroups, according to both the rest level and the administrated teriparatides, daily or weekly. Administrated teriparatides were as follows, FOR 73 (including 42 NWB rest), TRB 56 (including 26 NWB rest). Vertebral collapse rate was calculated as a ratio of anterior vertebral height to posterior vertebral height. We also measured the weight bearing change in anterior vertebral height by comparing the lateral X-ray examination standing and lying in supine position, this indicates the instability of the vertebral fracture. The bone union of vertebral fractures wre confirmed by comparing standing and lying in supine position as well. We also checked the number of previous vertebral fractures, posterior vertebral hight collapse score, local alignment score , and bone mineral density of proxymal femur . These are factors that may influence the bone union that would be found from X-ray examination. Results: Comparing in the same rest level , initial NWB rest subgroup (FOR 42, TRB 26), weekly teriparatide seemed to take a better advantage rather than the daily teriparatide with regard to fracture healing. The time it took for the bone union from the start of treatment were 12.4weeks in FOR subgroup and 9.2weeks in TRB subgroup . The time was statistically shorter in the later one (Student's T test P=0.034). In daily teriparatide subgroup, the vertebral collapse rate and the age might be major factors that influence to the time that was needed for the bone union. On the other hand, in weekly teriparatide no factor was found that prevent the bone union. Although there were no statistical difference between FOR and TRB subgroups in the vertebral collapse rate (Mann-Whitney U test P=0.148) and the age (Mann-Whitney U test P=0.071) at the baseline. Discussion: When teriparatide was used in the treatment of vertebral fracture, two types of teriparatides might have different effects on healing process of vertebral fracture according to their different change in bone metabolism. Daily teriparatide showed very high change in bone absorption as much as bone formation (4months after/ before: TRACP5b205%, uOC313%, uOC858%), while weekly teriparatide showed no change in bone absorption and mild changing in bone formation (4months after/ before: TRACP5b96%, OC129%, uOC237%) as we reported in ASBMR 2013.

MO0354**Effects of Mineralocorticoid Receptor Antagonism on Markers of Bone Turnover in Patients with Primary Hyperparathyroidism – the EPATH Trial.**

Nicolas Verheyen^{*1}, Astrid Fahrleitner-Pammer², Cristiana Catena³, Evgeny Belyavkiy⁴, Johann Martensen², Julia Wetzel², Martin Gaksch², Martin Grüber², Elisabeth Kraigher-Krainer⁵, Jakob Voelkl⁴, Florian Lang⁶, Andreas Meinitzer², Burkert Pieske⁵, Stefan Pilz², Andreas Tomaschitz². ¹Medical University Graz, Austria, ²Medical University of Graz, Austria, ³University of Udine, Italy, ⁴Medical University of Graz, Germany, ⁵Charite Universitaetsmedizin Berlin, Germany, ⁶University of Tübingen, Germany

Purpose

Animal and human studies indicated that mineralocorticoid receptor (MR) antagonism affects bone metabolism. We therefore aimed to test in a randomized, placebo-controlled trial whether the MR-blocker eplerenone affects markers of bone turnover in patients with primary hyperparathyroidism.

Methods

The present study analysed the pre-specified secondary endpoint change in levels of bone turnover markers of the “Effect of Eplerenone on Parathyroid Hormone Levels in Patients with Primary Hyperparathyroidism” (EPATH) Trial (ISCRN 33941607). Patients with primary hyperparathyroidism (pHPT; n=110), 25-hydroxy vitamin D >= 20ng/mL, GFR > 50mL/min/1.73m² and plasma potassium <= 5.0 mmol/L were randomly 1:1 assigned to treatment with 25mg eplerenone (escalation to 50mg after 4 weeks) or matching placebo for 8 weeks. Markers of bone formation (osteocalcin [OC], bone-specific alkaline phosphatase [BALP] and procollagen type 1 [P1NP]) and beta-crosslaps [beta-CTX]) from before and after 8 weeks of intervention were measured in serum that had been frozen and stored at -80°C immediately after blood sampling.

Results

The trial was completed by 97 (88.2%) participants (mean age 68 +/- 10 years, 76 (78%) females). Median PTH was 102 (83 – 127) pg/mL, mean calcium was 2.62 +/- 0.14 mmol/L and 48 (49.5%) had osteoporosis. Median OC at baseline was 22.5 (16.2 – 36.4) ng/mL, median BALP was 19.9 (15.5 – 26.5) µg/mL, median P1NP was 52.9 (34.7 – 75.6) ng/mL, median TRAP was 3.84 (3.25 – 4.74) U/L and median b-CTX was 0.435 (0.242 – 0.770) ng/mL. In analysis of covariance with adjustment for baseline values eplerenone had a mean treatment effect on OC of 1.507 ng/mL (95% CI (-1.205 – 4.219), P=0.38), on BALP of 0.775 µg/mL ((-0.627 – 2.177), P=0.32), on P1NP of -4.092 ng/mL (-9.879 – 1.796), P=0.21) and on beta-CTX of 0.003 ng/mL (-0.68 – 0.74), P=0.97).

Conclusions

MR antagonism for 8 weeks had no significant effects on serum levels of bone turnover markers in patients with pHPT. These data are contrasting previous observational studies. Further interventional trials should evaluate whether MR antagonism affects bone turnover after intermediate- or long-term treatment and in patients without PTH excess.

MO0355**Inhibition of Osteoclastogenesis by Poly - γ - glutamic acid. Tae-Hwan Kim^{*1}, Bitnara Lee¹, Eunji Kwon¹, Jong Dae Ji², Sang-Hyon Kim³.**

¹Hanyang University Hospital for Rheumatic Diseases, South Korea, ²College of Medicine, Korea University, South Korea, ³Keimyung University Dongsan Medical Center, South Korea

Background : We examined whether Poly - γ - glutamic acid(γ -PGA) inhibited RANKL-induced osteoclast differentiation via the Toll-like receptor 4(TLR4) signaling pathway in human and mice.

Methods : We tested the inhibitory effects of γ -PGA on osteoclastogenesis in healthy human peripheral blood monocytes and mice bone marrow macrophages (BMMs). The osteoclastogenesis was assessed by generation of *Tartrate-resistant acid phosphatase (TRAP)* + multinucleated cells and actin ring formation. Also we analyzed essential genes and proteins expression for osteoclast differentiation by real-time PCR and Western blot analysis. And we observed whether the treatment of mice with γ -PGA significantly reduce *in vivo* the TRAP-stained osteoclasts of the joint. To investigate the regulatory mechanism of γ -PGA through a *TLR4*-dependent pathway, we tested effects of LPS which is a *TLR4* ligand on osteoclastogenesis in human and mice. Also the inhibitory effects of γ -PGA was evaluated by osteoclast formation in BMMs which were obtained from *TLR4*^{-/-} mice, and compared with wild type (WT) mice.

Results : γ -PGA strongly inhibited human osteoclastogenesis as assessed by generation of TRAP+ multinucleated cells and suppressed expression of osteoclast specific gene such as cathepsin K, Integrin β 3, ATP6v0d2. Also primary transcript analysis showed that γ -PGA inhibited RANK gene expression but not protein. Treatment with γ -PGA acted on mouse osteoclast precursors to suppress differentiation of TRAP+ multinucleated cells. However, the expression of genes and proteins much less inhibited or did not show a significant change in BMMs compared with human.

In contrast to γ -PGA, we confirmed LPS suppressed osteoclast formation and expression of osteoclast specific genes, RANK mRNA and protein in both species. But we observed that many more TRAP+ single cells created by γ -PGA in

osteoclastogenesis than by LPS. TRAP staining of osteoclasts showed that the number of osteoclast was increased on osteoclast differentiation with γ -PGA in the *TLR4*^{-/-} mice compared to in the WT mice. γ -PGA in *IL-10*KO mice with arthritis decreased joint osteoclast in joint sections compared to controls *IL-10*KO with arthritis mice.

Conclusions : γ -PGA can be a good therapeutic approach to prevent selectively osteoclast differentiation and to reduce bony destruction and can be used to be a drug for prevention of chronic destructive joint disease like Rheumatoid arthritis.

MO0356**The importance of vitamin D on mineralization by the osteocyte in CKD subjects with renal hyperparathyroidism. Aiji Yajima^{*}. Otsuki Municipal Central Hospital, Japan**

The importance of vitamin D on mineralization by the osteocyte in CKD subjects with renal hyperparathyroidism

Aiji Yajima M.D., Ph.D.

Bone mineral recovery in Basic Multicellular Unit (BMU) and Bone Structural Unit (BSU) following the treatment of hyperparathyroid bone disease has not been discussed. Vitamin D receptor on the osteocyte is important in thinking about poorly mineralized bone area because the volume and texture of bone in both BMU and BSU depend on mineralization in the osteocytic perilacunar/canalicular system.

The patients with renal hyperparathyroidism were treated with cinacalcet hydrochloride, vitamin D sterols, and parathyroidectomy.

The eighteen hemodialysis (HD) patients underwent parathyroidectomy, followed by 2.0 µg/day of alfacalcidol administration (Group I). The four HD patients also underwent parathyroidectomy, without following vitamin D administration (Group II). Plasma 1.25(OH)₂D₃ level was significantly increased, but lower than the upper limit (Group I), however 1.25(OH)₂D₃ was below 10 pg/mL (Group II) after the surgery.

Poorly mineralized bone volume in BMU (PM.BV(BMU)/BV) and BSU (PM.BV(BSU)/BV) were evaluated before and after parathyroidectomy. PM.BV(BMU)/BV was significantly decreased from 20.2 ± 16.2 to 3.1 ± 4.2 %, and PM.BV(BSU)/BV was also decreased from 16.7 ± 15.2 to 2.6 ± 3.0 % at 4 weeks after the surgery (Group I), however both PM.BV(BMU)/BV and PM.BV(BSU)/BV were increased (Group II).

In addition, the seven HD patients were treated with cinacalcet hydrochloride and low doses (0.25 or 0.5 µg/day) of alfacalcidol (Group III) and the seven HD patients were treated with cinacalcet hydrochloride and low doses of alfacalcidol + low doses of intravenous maxacalcitol (Group IV). PM.BV(BMU)/BV and PM.BV(BSU)/BV were not changed (Group III), but both of them were decreased in Group IV after 1 year of the treatment.

As a conclusion, vitamin D plays an important role in mineralization by osteocytes, resulting in the reduction of poorly mineralized bone volume and improvement in bone stability.

MO0357**Patient Perspectives on Participating in the Effectiveness of Discontinuing Bisphosphonates (EDGE) Study. Nicole Wright^{*1}, Phillip Foster¹, Sally Fullman², Susan Randall³, Mary Melton¹, Wilson Pace⁴, Walter Calmbach⁵, Kenneth Saag¹.**

¹University of Alabama at Birmingham, USA, ²Project Healthy Bones, USA, ³National Osteoporosis Foundation, USA, ⁴University of Colorado Denver, USA, ⁵University of Texas Health Science Center at San Antonio, USA

Purpose: Patient engagement during the design of clinical trials is important, particularly to select outcomes of highest interest to patients and to identify issues affecting recruitment. We designed a web-based survey to gain patient insight on potential study outcomes, randomization, and consequences of participating in the EDGE study, a pragmatic clinical trial examining the long-term effectiveness and safety of alendronate (ALN).

Methods: Our survey, posted on the National Osteoporosis Foundation website, focused on: 1) optimal study outcomes, including quality of life, and physical and mental health, 2) willingness to be randomized either to discontinue or continue ALN, and 3) the effect of trial participation on physical activity.

Results: We received 311 survey responses from 12/30/14 to 02/26/15. Our sample included 215 women with 25% reporting current ALN use. The table below shows the outcome categories reported by patients from the entire population and ≥3 years ALN users (n=25). Overall, quality of life was the top category. Among those with ≥3 years of use, medication effectiveness, specifically fracture reduction, was the outcome category of greatest interest. Willingness to be randomized to discontinue ALN was indicated by 38% of respondents. An additional 11% were willing to discontinue ALN after a discussion with their doctor or if the study/physician provided additional monitoring. Nearly 22% reported concern about being randomized to discontinue ALN, and some patients were not willing to be randomized to discontinue ALN (Overall: 9%; ≥3 years ALN users: 22%). Willingness to be randomized to continue

ALN was indicated by 49% of patients, but 22% indicated they would not want to continue ALN. The majority of respondents indicated that they would continue their current level of physical activity, regardless of randomized study arm. Concern about physical activity was indicated by 13% of respondents when considering stopping ALN, and only 3% of respondents when considering continuing ALN.

Conclusion: Engaging patients during the design of EDGE provided insight into the outcomes patients are interested in and their willingness to participate in the study. Patients were equally interested in quality of life and effectiveness outcomes, such as fractures. The majority of patients were willing to be randomized, although a small number had concerns that would warrant additional attention during recruitment efforts.

Table. Proposed Study Outcomes Categories for the EDGE Study Indicated on the EDGE National Osteoporosis Foundation Patient Survey

| | Overall (N=215)* | | =3 Years ALN Use (N=25) | |
|---------------------------------|------------------|-------------|-------------------------|-------------|
| | | | | |
| Quality of life | 86 | 33.2 | 8 | 32.0 |
| Mental Health | 19 | 22.1 | 1 | 12.5 |
| Physical Health | 34 | 39.5 | 3 | 37.5 |
| Medication Effectiveness | 85 | 32.8 | 13 | 52.0 |
| Fractures | 35 | 41.2 | 8 | 61.5 |
| Retaining bone mass/strength | 12 | 14.1 | 3 | 23.1 |
| Safety | 67 | 25.9 | 4 | 16.0 |
| ONJ | 10 | 14.9 | - | - |
| Atypical Fractures | 5 | 7.5 | - | - |
| Medication duration | 12 | 4.6 | - | - |

ALN – alendronate; ONJ – osteonecrosis of the jaw
*Indicates totals study sample; however, each person may have contributed more than one response.

Accelerated tooth loss in HIV-infected women. Grace Kim^{*1}, Elizabeth Shane², Kyle Nishiyama², Sunil Wadhwa¹, Michael Yin². ¹Columbia College of Dental Medicine, USA, ²Columbia University Medical Center, USA

Introduction: The advent of effective antiretroviral therapy (ART) has dramatically increased the lifespan of HIV-infected individuals. However, the effect of ART on dentition is largely unknown. Initiation of ART is associated with decreased bone mineral density (BMD) at the spine and hip, and fracture rates are higher in HIV-infected than uninfected women especially after menopause. The goal of this study is to evaluate number of teeth in relation to mandibular cortical width in HIV-infected women before and after the menopausal transition.

Material and Methods: A retrospective chart review of existing panoramic dental x-rays and dental records was performed to compare number of teeth and inferior mandibular cortical width at the mental region in 40-60 year old HIV-infected women (n=39) and age and race/ethnicity matched uninfected controls (n=89) from the same dental clinic in New York City.

Results: HIV-infected and uninfected controls were similar in age (53+7 vs 53+7), race/ethnicity (41% black, 38% Hispanic), and history of diabetes (30% vs 20%, p=0.23). Cigarette use was greater among HIV-infected women (27% vs 12%, p=0.03). Mean CD4+ T cell count was 653 cells/ul and 87% of women were on ART. Number of teeth decreased in both groups after age 50 (Table). Although HIV-infected women had 2-3 less teeth than controls, the differences were not statistically significant. Further, the proportion of HIV-infected women who were edentulous increased from 5% to 18% after age 50. In comparison, the mean number of teeth in women age 50-64 from NHANES was 22, and only 10% were edentulous. Mandibular cortical width did not differ between HIV-infected women and controls before or after menopause. Conclusion: HIV-infected women appear to have accelerated age-related tooth loss, which is unrelated to mandibular cortical width. Further research using more sensitive imaging modalities such as cone beam CT is necessary to determine effects of HIV and ART on alveolar bone density and trabecular microarchitecture, and their associations with tooth loss.

| Table | Age 40-50 | | P value | Age 50-60 | | P value |
|--------------------------------|-------------|-----------------|---------|-------------|-----------------|---------|
| | HIV+ (N=22) | controls (N=48) | | HIV+ (N=17) | controls (N=41) | |
| Number of teeth | 18±4 | 20±7 | 0.34 | 13±9 | 16±8 | 0.16 |
| % edentulous | 5% | 0% | 0.31 | 18% | 5% | 0.13 |
| Mandibular cortical width (mm) | 4.5±1.0 | 4.4±1.0 | 0.82 | 4.7±1.1 | 4.3±1.0 | 0.15 |

MO0359

Age at first Major Osteoporotic Fracture in Danes aged 50 and over: Influence of diabetes on mean age at fracture and one year mortality. Bo Abrahamsen^{*1}, Björn Rosengren², Daniel Prieto-Alhambra³, Nicola Napoli⁴, Cooper Cyrus⁵. ¹University of Southern Denmark, Denmark, ²Clinical & Molecular Osteoporosis Research Unit, Department of Orthopedics, Sweden, ³Oxford NIHR Musculoskeletal Biomedical Research Unit, Nuffield Department of Orthopaedics, United Kingdom, ⁴Division of Endocrinology & Diabetes, Università Campus Bio-Medico di Roma, Italy, ⁵MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom

Diabetes mellitus (DM) is associated with an increased risk of fractures in excess of what would be expected from age and BMD. Further, DM is associated with increased risk of mortality in patients with hip fractures and possibly also other osteoporotic fractures. Study population and methods: Patients aged 50+ who were treated for fractures of the hip, forearm, humerus and spine over six years (2004-2009, N=146,256) not coded as road traffic accidents were tracked in national registers for one year post fracture mortality and for a history of DM by ICD-10 code, with a look-back to 1/1/2000. Results: Patients with DM sustained their first major osteoporotic fracture at a slightly younger age at the hip only (78.1 vs 80.5, p<0.001). By contrast, forearm (71.8 vs 69.8, p<0.001), and spine fractures (73.2 vs 72.0, p=0.005) occurred at a higher age in patients with DM, with no difference in age for humerus fractures (p=0.34). Patients with DM had poorer ly survival after fracture than fracture patients without DM, with the only exception being spine fractures in the very old (age 90-99), fig. Conclusions: The increased risk of fractures in patients with DM does not manifest itself in a clinically significant earlier age a first major osteoporotic fracture. Patients with DM have poorer short term post fracture survival than patients w/o DM irrespective of fracture site.

MO0360

Serum Sclerostin and Bone Turnover Markers in Patients with Type 2 Diabetes or LADA. Nicola Napoli¹, Rocky Strollo^{*1}, Giuseppe Defeudis¹, Mohammed Hawa², Gaetano Leto³, Luca D'Onofrio³, Andrea Palermo¹, Giuseppe Campagna³, Richard David Leslie⁴, Paolo Pozzilli¹, Raffaella Buzzetti³. ¹University Campus Bio-Medico, Italy, ²Queen Mary University of London, United Kingdom, ³University Sapienza of Rome, Italy, ⁴Queen Mary University of London, Italy

Diabetic patients may suffer of a low bone turnover condition. Several factors, including insulin deficiency and suppression of Wnt signaling may be involved. Sclerostin, a circulating Wnt antagonist, has been shown to be increased in patients with type 2 diabetes (T2D) but not in type 1 autoimmune diabetes (T1D). However, no data are available on bone turnover or sclerostin levels in patients with latent autoimmune diabetes of adults (LADA), an autoimmune type of diabetes often confused with T2D because of the late onset and the presence of metabolic syndrome (MS).

The aim of this study was to evaluate serum sclerostin levels and bone turnover in subjects with T2D or LADA in relation to MS. Subjects with LADA were defined as non-insulin-requiring patients with GAD-autoantibodies who had not received insulin therapy for at least 6 months after diagnosis.

This was a cross-sectional study including 95 subjects with T2D and 89 with LADA with similar age (51.08 ± 10.80 years), disease duration (2.65 ± 1.94 years) and BMI, recruited through the ACTION LADA and NIRAD cohorts and further

divided according to diagnosis of MS (NCEP criteria). Serum sclerostin, serum markers of bone formation (PINP) and bone resorption (serum CTx) were analyzed by ELISA.

Serum sclerostin was significantly higher in T2D compared with LADA (30.9 ± 1.8 vs 23.8 ± 1.8 pmol/l, $P < 0.001$) also after adjustment for age and BMI ($P = 0.008$). For each type of diabetes, there was no difference in serum sclerostin between patients with or without MS ($P > 0.139$) (Fig.1). T2D with MS had almost double levels of sclerostin in comparison with LADA without MS (33.6 ± 2.3 vs 19.7 ± 1.8 pmol/l, $P < 0.001$). In patients without MS, serum sclerostin was higher in T2D than LADA (29.4 ± 2.4 vs 19.7 ± 1.8 pmol/l, $P = 0.04$), but this difference was lost after adjustment for BMI. PINP levels were lower in T2D compared to LADA ($P = 0.038$) while CTx levels were similar between the two groups. In the all groups of subjects, sclerostin levels were significantly correlated with BMI ($r = 0.28$; $P = 0.003$).

In conclusion, our findings indicate that T2D patients present higher levels of sclerostin than LADA ones which may cause low bone formation. MS may not play a crucial role, but power to detect modest association was limited. Although T2D and LADA share similar clinical features, specific pathophysiological elements linked to the type of diabetes may determine differences in sclerostin levels and bone turnover.

Parkin, A link between Parkinson's disease and bone homeostasis. Thomas Mbimba^{*1}, Kimberly Novack², Fouad M. Moussa², Gregory Songdag², Li Lin³, Christine Dengler-Criss³, Werner J Geldenhuys³, Favez Safady⁴. ¹Kent State University, USA, ²Biomedical Science Department, Kent State University/ Anatomy & Neuroscience Department NEOMED, USA, ³NEOMED, USA, ⁴NEOMED - KENT STATE, USA

Parkinson's Disease (PD) is a neurodegenerative disease characterized by a loss of dopaminergic neurons in the nigrostriatal pathway, which causes movement disorder distinguished by resting tremor, bradykinesia, rigidity, postural instability and gait disturbance. PD patients show a high risk of fracture incidents compare to age- and gender-matched controls. Mutation in the Parkin (PARK2) gene has been associated patients with PD. PARK2 is an E3 ubiquitin protein ligase that plays a role in the regulation of mitochondrial function. To date, various models of PARK2 dysfunction have been generated in an effort to understand the underlying mechanism of the disease. Human mutation in Parkin showed mitochondrial dysfunction in dopamine-producing nerve cells that plays an important role in causing signs and symptoms of Parkinson disease. In this study, we sought to examine the relationship between PD and skeletogenesis. First, we examined the expression of PARK2 in bone cells and observed that PARK2 mRNA expression is increased during osteoclast and osteoblast differentiation. Next, we examined the skeletal phenotype of transgenic mice expressing the mutant form of PARK2. These mice are carrying the human Q311X truncation associated with Turkish early-onset Parkinson's disease. Micro-CT analysis of 6-month old Parkin mutant mice have decreased bone mass associated with decreased trabecular number and thickness. DEXA showed significant reduction in bone mineral density in Parkin mutants. qPCR analysis of bone related markers showed significant reduction in the Parkin mutants compared to WT mice. Next, we examined the effects of Parkin mutant on bone cell differentiation and function *ex vivo*. There was significant decrease in bone marrow-derived osteoblast differentiation associated with decreased matrix production and osteoblast-related gene expression. RANKL-induced osteoclast differentiation was dramatically reduced in Parkin mutants compared to controls. Osteoclast-mediated bone resorption

determined by Osteologic assays showed significant decrease in Parkin mutants compared to WT mice. Taken together, these data suggest possible relationship between PD-associated protein and bone loss. Currently, studies are underway to determine the mechanism of Parkin on bone cell differentiation and function. These studies are the first to report a link between PD and bone homeostasis.

A Testosterone Deficit Precedes Bone Loss in a Rodent Contusion Spinal Cord Injury Model. Joshua Yarrow^{*1}, Fan Ye¹, Christine Conover², Dana Otzel², Thomas Wronski³, J. Ignacio Aguirre³, Stephen Borst¹. ¹VA Medical Center, University of Florida, USA, ²VA Medical Center, USA, ³University of Florida, USA

Disuse resulting from a neurologic insult induces bone loss after spinal cord injury (SCI). However, SCI-induced bone loss occurs more quickly and is more severe than in other disuse models, suggesting that additional factors influence bone loss after SCI. Interestingly, a large proportion of men with SCI exhibit severe testosterone (T) deficits that persist for several years after injury, coinciding with the time frame of the most severe bone loss. Our purpose was to determine the time course for T deficits in relation to cancellous/cortical bone loss in a rodent SCI model. Forty-five 20-week old male Sprague-Dawley rats received SHAM surgery or T9 laminectomy plus moderate/severe contusion SCI and were euthanized 1-, 2-, or 3-months post-surgery. Expected sublesional functional deficits persisted in SCI animals throughout the study duration. Following SCI, T was reduced 40-45% at 1-week and 1-month post-SCI, 37% at 2-months, and restored to SHAM levels by 3-months. Cancellous bone deficits were observable 1-month post SCI at the distal femur (assessed via microCT) and proximal tibia (assessed via histology), but did not reach a level of significance due to high variability. At 2-months and 3-months post-SCI, cancellous bone mineral density was 32-35% lower than respective SHAMs, and was characterized by a 51-66% lower cancellous bone volume ($p < 0.05$, 2-month; $p < 0.01$, 3-month) that primarily resulted from reduced trabecular number. Trabecular pattern factor (an inverse measure of trabecular connectivity) and structure model index (a measure of plate-/rod-like trabecular structures) were also elevated by SCI at 2-months ($p < 0.05$) and 3-months ($p < 0.01$). At the femoral diaphysis, 2- and 3-month SCI animals exhibited 10% lower cortical thickness ($p < 0.01$), 8% lower total bone area ($p < 0.05$, 3-month only), 12-13% lower cortical area ($p < 0.01$), and 5-6% lower cortical bone volume ($p < 0.05$) compared with SHAMs. Our data indicates that T deficits occur early after SCI in our rodent model, preceding the time frame in which the vast majority of bone losses occur, and persist for 2 month after SCI. The deleterious morphological and microarchitectural alterations we observed indicate compromised lower-limb skeletal integrity exists, similar to what is observed clinically. These findings suggest that our rodent model is clinically-relevant and can be used to test therapeutic interventions designed to prevent bone loss and/or regenerate bone after SCI.

Denosumab Increases Sublesional Bone Mass In Osteoporotic Patients With Recent Spinal Cord Injury. Laia Gifre^{*1}, Joan Vidal², Josep Lluís Carrasco³, Africa Muxi⁴, Enric Portell², Ana Monegal⁵, Núria Guañabens⁵, Pilar Peris⁵. ¹Hospital Clinic Barcelona, Spain, ²Guttmann Neurorehabilitation Institute, Universitat Autònoma de Barcelona, Spain, ³Public Health Department, University of Barcelona, Spain, ⁴Nuclear Medicine Department, Hospital Clínic of Barcelona, Spain, ⁵Rheumatology Department, Hospital Clinic of Barcelona, Spain

Background: Osteoporosis development is a frequent complication related to spinal cord injury (SCI), especially at the sublesional level. However, although treatment with bisphosphonates may attenuate bone loss after SCI, no effective treatment has been reported to treat this clinical complication. Thus, the aim of this study was to analyze the efficacy of denosumab, a potent antiresorptive agent, in the treatment of patients with SCI-related osteoporosis. Methods: 14 patients aged 39-75 years with osteoporosis secondary to recent complete SCI (13 ASIA A-B; mean injury duration: 15.4 months) were treated with denosumab 60mg every 6 months for 12 months. Bone turnover markers (BTMs) (PINP, bone ALP and sCTX), 25-OH vitamin D (25OHD) levels and bone mineral density (BMD) at lumbar spine (LS), total hip (TH) and femoral neck (FN) were assessed at baseline and at 12 months. Results were compared with a control group of 9 SCI-patients with similar clinical characteristics (age, gender, duration and severity of SCI) without osteoporosis. All patients received calcium and vitamin D supplementation. Results: At 12 months, SCI patients treated with denosumab showed a significant increase in BMD at TH (+2.4-3.6%, $p = 0.042$), FN (+3.3.6%, $p = 0.006$) and LS (+7.8-3.7%, $p < 0.001$) compared to baseline values, whereas non-treated SCI patients showed a significant maintained BMD decrease at sublesional sites (TH: -8.6-7.4%, $p = 0.013$; FN: -5.9-6.2%, $p = 0.03$). In addition, denosumab treatment was associated with a significant decrease in BTMs (bone ALP -42%, $p < 0.001$; PINP -58%, $p < 0.001$, sCTX -57%, $p = 0.002$) at 12 months, with significantly greater changes compared to non-treated patients. BMD evolution was not related to BTM changes or to 25OHD

serum levels. No skeletal fractures were observed during follow-up and no treatment-related adverse events were noted. Conclusions: Treatment with denosumab increases lumbar and femoral BMD and decreases bone turnover markers in SCI-patients with secondary osteoporosis. This drug may be a promising therapeutic option in patients with SCI-related osteoporosis.

A semi-automatic algorithm to assess bone attenuation and thoracic kyphosis on chest CT scans of patients with chronic obstructive pulmonary disease.

Mayke J. van Dort^{*1}, Erica P.A. Rutten², Bert van Rietbergen³, Elisabeth A.P.M. Romme⁴, Frank W.J.M. Smeenk⁴, Piet P.M.M. Geusens⁵, Emiel F.M. Wouters⁶, Joop P.W. van den Bergh⁷. ¹Department of Internal Medicine, NUTRIM School of Nutrition & Translational Research in Metabolism, Maastricht University Medical Center+ (MUMC+), Netherlands, ²Research & Education, Centre of expertise for chronic organ failure + (CIRO+), Netherlands, ³Department of Medical Engineering, Eindhoven University of Technology, Netherlands, ⁴Department of Respiratory Medicine, Catharina Hospital, Netherlands, ⁵Department of Internal Medicine, Rheumatology, Maastricht University Medical Center+ (MUMC+), Netherlands, ⁶Department of Respiratory Medicine, Maastricht University Medical Centre + (MUMC+), Netherlands, ⁷Department of Internal Medicine, VieCuri Medical Centre, Venlo & Department of Internal Medicine, NUTRIM School of Nutrition & Translational Research in Metabolism, Maastricht University Medical Center+ (MUMC+), Netherlands

Chronic obstructive pulmonary disease (COPD) is associated with osteoporosis and vertebral fractures (VFs). We developed a semi-automatic algorithm to assess bone attenuation (a measure of bone density) and kyphosis on regular chest CT scans in a pilot study in COPD patients and control subjects.

We investigated chest CT scans of a subgroup of the ECLIPSE cohort (a non-interventional, observational, multicenter, three-year study): 25 COPD subjects (COPDs), 25 non-COPD smoking (SC) and 25 non-smoking controls (NSC). A semi-automatic algorithm was created in Matlab (MathWorks) to assess thoracic kyphosis and 3D bone attenuation. Bone attenuation was measured in a region of 275 mm³ centered in T4, T7 and T10. Kyphosis was measured calculating the angle between two lines (above T4 and below T12) perpendicular to the tangents to a 3rd order polynomial fit through the spine. VFs were evaluated according Genant's method using SpineAnalyzerTM (OptasiaMedical) software. Age, gender and body mass index (BMI, kg/m²) were available.

Intraclass correlation coefficients (ICC) and coefficients of variation (CV) were calculated to examine reproducibility of the algorithm based on triple measurements of 25 scans by one reader.

We calculated ICCs and CVs of the semi-automatic assessment of bone attenuation (ICC: 0.994, CI [0.988;0.997], p<0.001; CV: 2.21%) and kyphosis angle measurements (ICC: 0.994, CI [0.988;0.997], p<0.001; CV: 3.21%).

A significant difference in bone attenuation was found between COPDs and NSC (172 and 228 Hounsfield Units resp., p=0.005) but not between COPDs and SC (p=0.815), and SC and NSC (p=0.104). However, after correction for age the difference was no longer significant. Gender nor BMI influenced the model significantly.

The prevalence of VFs and degree of thoracic kyphosis were not significantly different between the groups. Thoracic kyphosis was significantly related to the presence of VFs (p=0.001), but bone attenuation was not.

Our semi-automatic algorithm for assessment of bone attenuation and kyphosis angle on chest CT has a high reproducibility and CV of 2.21% and 3.21%, respectively.

In this pilot study, bone attenuation (after correction for age), thoracic kyphosis and presence of VFs were not significantly different between COPDs, SC and NSC. ICCs and CVs showed that our algorithm is reproducible and allow further investigation of associations between COPD, bone attenuation, thoracic kyphosis and VFs in larger and longitudinal studies.

Arterial Stiffness is Associated with Low Bone Mineral Density in Women Living with Human Immunodeficiency Virus. Zoraya Barros¹, Francisco Bandeira², Érico Carvalho³, Democrito Miranda Filho⁴, Heloisa Melo¹, Nathalia Brito³, Maria Albuquerque⁶, Ulisses Montarroyos⁷, Ricardo Ximenes⁷. ¹Departamento de Medicina Clínica, Universidade de Pernambuco, Brazil, ²Serviço de Endocrinologia, Hospital Agamenon Magalhães, SUS/Universidade de Pernambuco, Brazil, ³Serviço de Infectologia, Universidade de Pernambuco, Brazil, ⁴Departamento de Medicina Clínica, Universidade de Pernambuco, Brazil, ⁵Hospital Maternidade Sao Vicente De Paulo, Brazil, ⁶Centro de Pesquisa Aggeu Magalhães, Brazil, ⁷Departamento de Medicina Tropical, Universidade Federal de Pernambuco, Brazil

Introduction: Osteoporosis and cardiovascular disease are major causes of morbidity and mortality in people living with the human immunodeficiency virus (PLHIV). An independent relationship was found between the BMD, which represents the low BMD values and vascular calcification, as a risk factor for cardiovascular disease, but most data so far are derived from the male population and the link between those two conditions remains elusive. **Methods:** We investigated the association between BMD and aortic stiffness in 254 women living with HIV, aged 37-55 years; mean 45,8 ± 9,0; BMI (kg/m²) 25,0 ± 6,7; WC (cm) 89,1 ± 11,5; SBP(mmHg) 131 ± 22,2; DBP(mmHg) 83,2 ± 13,9. BMD was measured by dual energy x-ray absorptiometry (DXA) in the lumbar spine, femoral neck and total femur, and aortic stiffness was measured by aortic pulse wave velocity (aPWV). **Results:** There was a high frequency of low bone mass (63,4%), arterial hypertension (50%), and metabolic syndrome (43,2%). In multiple linear regression analysis there was a negative correlation between femoral neck BMD (Coefficient β=-2,191, p = 0,001), total femur (Coefficient β=-1,940, p = 0,004) and the aPWV, which remained significant after adjustment for age, long menstrual intervals, body mass index (BMI), metabolic syndrome, non-HDL cholesterol, mean arterial pressure and heart rate. **Conclusion:** Our data demonstrate an independent association between arterial stiffness and low BMD in women living with HIV suggesting common mechanisms on the development of both atherosclerosis and bone fragility. **Keyword:** osteoporosis, aortic stiffness, aortic pulse wave velocity, HIV.

Effects of Gastric Bypass Surgery on Bone Mass and Microarchitecture Occur Early and Particularly Impact Postmenopausal Women. Anne Schafer^{*1}, Galateia Kazakia², Lygia Stewart³, Stanley Rogers², Jonathan Carter², Andrew Posselt², Courtney Pasco², Dolores Shoback³, Dennis Black². ¹University of California, San Francisco & the San Francisco VA Medical Center, USA, ²University of California, San Francisco, USA, ³San Francisco VA Medical Center & University of California, San Francisco, USA

Roux-en-Y gastric bypass (RYGB) surgery has negative effects on the skeleton. Skeletal effects may begin very early in the postoperative period, but no studies using advanced quantitative computed tomography (QCT) in addition to standard dual-energy X-ray absorptiometry (DXA) have included that imaging as early as 6 months after surgery. Also, as a result of modestly sized samples of mostly premenopausal women and very few men, the relative skeletal effects of RYGB by sex and menopausal status are uncertain. We conducted a prospective cohort study of RYGB and skeletal health, the largest to date to examine changes in axial and appendicular volumetric bone mineral density (vBMD) and appendicular bone microarchitecture.

Obese adults (N=47; 37 premenopausal and 10 postmenopausal women, 10 men) with BMI 44 ± 7 kg/m² were assessed before and 6 and 12 months after RYGB. Participants underwent hip and spine DXA, spine QCT, and high-resolution peripheral QCT (HR-pQCT) (radius and tibia).

Mean weight loss 6 and 12 months postoperatively was 31 and 37 kg. Femoral neck BMD by DXA decreased by mean 5.0% and 8.0% at 6 and 12 months postoperatively. Spine vBMD by QCT declined 6.6% and 8.1% after 6 and 12 months; declines were statistically significant among premenopausal and postmenopausal women and men, with a greater decline among postmenopausal vs. premenopausal women (-11.6% vs. -6.0% at 12 months, p=0.02). At the tibia, detrimental changes in trabecular (Tb) microarchitecture (decreased number, increased spacing and heterogeneity) occurred at 6 and 12 months. At the radius, changes in Tb number and spacing were not significant vs. baseline but were more detrimental for women than men (p≤0.03 for difference). Cortical porosity increased at the radius and tibia, with more dramatic 12-month increases among postmenopausal than premenopausal women at the tibia (+51.4% vs. +18.0%, p<0.01, Figure); increases among men were not detected (p≤0.02 for difference vs. the other groups). At 12 months, decline in Tb vBMD was larger at radius than tibia, while decline in cortical vBMD was larger at tibia than radius (p=0.02 for site comparisons). Cortical vBMD decline was greater in postmenopausal than premenopausal women (-4.4% vs. -0.7%, p<0.01).

Detrimental effects of RYGB on axial and appendicular vBMD and on bone microarchitecture are detectable as early as 6 months postoperatively and progress thereafter. Postmenopausal women are at highest risk for skeletal complications.

MO0367

Osteoporosis: What Is the Burden of Disease in Psoriatic Arthritis?. Glenn Haugeberg^{*1}, Berit Helen Grandaunet², Hege Høiberg³, Andreas P Diamantopoulos⁴, Arthur Kavanaugh⁵. ¹Hospital of Southern Norway, Norway, ²St. Olavs Hospital, Norway, ³Sørlandet sykehus, Norway, ⁴Sshf Kristiansand, Norway, ⁵UC San Diego School of Medicine, USA

Bone damage, including localized as well as generalized osteoporosis is a well known consequence of the inflammatory arthritides such as rheumatoid arthritis (RA). Psoriatic arthritis (PsA) can be characterized by bone destruction but also new bone formation. In PsA, the literature on osteoporosis is inconclusive and scarcer than in RA. The aim of the study was to explore if PsA patients are at increased risk of having reduced bone mineral density (BMD) at hip and/or lumbar spine. Consecutive patients from an outpatient clinic fulfilling CASPAR criteria for PsA were enrolled. We excluded PsA patients with only axial manifestation without peripheral arthritis. All patients underwent a thorough examination according to an extensive protocol. Data collection included demographics, clinical and laboratory disease measures, treatments, and previous fracture history. BMD was measured at spine (L1-4) and hip (femoral neck and total hip) by dual energy X-ray absorptiometry (DXA, Lunar Prodigy). Calibration of the DXA machine was stable during the whole measurement period. BMD was expressed as g/cm², Z-score and T-score. The percentage of patients with T-score = -2.5 SD (WHO osteoporosis definition) and with Z-score = -1.0 SD was calculated. Appropriate descriptive statistics was applied for continuous and categorical variables. Patient characteristics among the 141 examined PsA patients (men 50.4%): mean (SD) age 52.5 (9.9) years, body mass index (BMI) 28.3 (4.4) kg/m², disease duration 8.9 years (6.8) and current smoker 17.0%. Median (range) 68 tender joint count was 6.0 [0-55], 66 swollen joint count 0 [0-6] and CRP 2.0 [0-63] mg/dl. Mean (SD) DAS28 was 3.2 (1.2), ESR 15.9 (11.9) mm/hr, MHAQ 0.44 (0.40) and pain and fatigue on visual analogue scale 35.1 (23.5) and 45.7 (32.4) mm respectively. Biologic DMARDs were used by 33.3%, synthetic DMARDs by 56.7% and glucocorticosteroids by 9.9%. Only 11.3% of patients were using calcium and vitamin D supplementation and 2.1 % antiresorptive osteoporosis treatment. Low energy fracture was reported in 8.9% of the patients. In the table below mean (SD or 95%CI) bone density values expressed as BMD, Z-score and T-score and percentage of patients with T-score = -2.5 SD and Z-score = -1.0 SD (by definition 16% in the reference population) is displayed. As shown the proportion of patients with Z-score = -1.0 SD was comparable with the 16% seen in the reference population database. In conclusion the proportion of PsA patients with osteoporosis in our study was low. Overall BMD was comparable to that from normative bone density reference values.

| | Femoral neck left | Femoral neck right | Total hip left | Total hip right | Spine L1-4 |
|-------------------------------|-------------------------|-------------------------|-------------------------|-------------------------|-----------------------|
| BMD (g/cm²) | 0.97 (0.14) | 0.97 (0.14) | 1.02 (0.15) | 1.01 (0.15) | 1.21 (0.17) |

Serum carboxy-terminal telopeptide of type 1 collagen (ICTP) is a prognostic factor in a cohort of Japanese male patients undergoing coronary angiography: CHIBA (Coronary Heart Disease of Ischemia and Bone Association) Study. Nobuyuki Tai^{*1}, Reiko Watanabe², Junko Hirano², Hiroaki Masaki², Toshihiro Amaki², Fumitaka Nakamura², Ryo Okazaki², Daisuke Inoue². ¹Teikyo University School of Medicine, Japan, ²Third Department of Medicine, Teikyo University School of Medicine, Japan

Background: Evidence suggests a link between atherosclerotic diseases and osteoporosis. Some resorption markers have been shown to be associated with cardiovascular diseases and related mortality, but relationship between bone metabolic abnormalities and such events has not been established. We previously reported that an MMP-dependent marker, ICTP, was strongly correlated with cardiac dysfunction in a cross-sectional study.

Aim: To evaluate the ability for bone metabolic markers to predict cardiovascular events and mortality.

Methods: Subjects undergoing coronary angiography (CAG) was consecutively recruited to this cohort study in our hospital. Baseline levels of various parameters of bone, heart, glucose and lipid metabolism were measured. A survey using mail questionnaires and medical records was conducted in 2014 targeting 577 subjects recruited from Jan 2006-Jan 2007, excluding females and those with serum Cr level of 2 mg/dl or more. Primary end points are cerebro-cardiovascular events and all-cause deaths.

Results: Out of 362 eligible subjects, 215 responded and were included in the analysis. Mean age and observation period were 65.3 ± 10.7 years old and 78.8 ± 20.6 months. Ninety patients had the history of intervention (PCI or CABG). Cerebro-cardiovascular events and all cause deaths occurred 17.1 % and 19.0 %, respectively. At baseline, ICTP was correlated with NT-proBNP and left ventricular ejection fraction. Kaplan-Meier analysis showed that the survival was significantly shorter in the highest ICTP quartile (log-rank, p<0.001). Cox regression analysis revealed that age, ICTP, NTX and NT-proBNP were independent predictors of all-cause death after correction for eGFR and the past history of PCI or CABG. Interestingly, TRACP-5b, a non-collagen resorption marker, was also an independent determinant of survival together with age and NT-proBNP, demonstrating a definite link to bone metabolic abnormalities, not just an abnormal collagen metabolism in the cardiovascular tissues. As for cerebro-cardiovascular events, age, 25(OH)D and the number of significant coronary artery stenosis were independent predictors.

Conclusions: ICTP was found to be a strong predictor of all-cause death in male subjects undergoing CAG, and thus may be a useful prognostic marker in the context of coexistent cardiovascular and bone metabolic abnormalities.

MO0369

Using electronic health records and machine learning to develop a fracture prediction tool in end stage renal disease patients. Kyle Nishiyama^{*1}, Chengchen Zhang¹, Jianhua Li¹, Donald McMahon¹, Jonathan Lorch², Elizabeth Shane¹, Jeri Nieves¹, Herbert Chase¹, Thomas Nickolas¹. ¹Columbia University, USA, ²Rogosin Institute, USA

Fractures in end stage renal disease (ESRD) patients are 14-fold greater than in the general population. Unfortunately we lack tools to adequately identify these individual ESRD patients who are at risk. Only recently was bone mineral density (BMD) shown to predict fractures, and the World Health Organization's Fracture Risk Assessment (FRAX) tool was shown to have no predictive value in ESRD. Thus, while tools to predict fracture in ESRD are needed, their development has been impeded by the lack of large prospective ESRD cohorts with fracture outcomes. To address these significant limitations, we leveraged the data-rich content of electronic health records (EHR) to build a cohort of ESRD patients and then used machine-learning methods to develop an ESRD-specific fracture prediction models. We

evaluated the ability of clinical risk factors available to clinicians on the first day of dialysis to predict fracture. This retrospective study with prospective follow-up included 7191 ESRD patients with (n=809) and without (n=6382) fracture from New York-Presbyterian Hospital. Clinical predictors included, but were not limited to, demographics (age, sex, race), labs (serum creatinine, PTH, hemoglobin, total alkaline phosphatase, phosphate), secondary causes of osteoporosis (glucocorticoids, diabetes) and BMD. We used feature selection and machine learning (Naïve Bayes) to classify fracture cases and controls. To determine whether BMD contributed to fracture prediction above clinical risk factors, we repeated these analyses in a subset of subjects with BMD (cases n=173; controls n=589) representative of the full dataset. Sensitivity, specificity, accuracy and area under the ROC curve (AUC) are presented (Table). In the full dataset, we achieved moderate prediction (AUC=0.67) with clinical data alone. In patients with BMD, performance significantly improved in models with BMD compared to without BMD (AUC=0.67 vs. AUC=0.59, $p<0.05$). These preliminary findings suggest that using large-scale datasets from EHR combined with machine learning methods has potential to build fracture risk prediction tools in understudied populations. They suggest that BMD, which is not assessed routinely in ESRD patients, may improve fracture prediction above that of clinical risk factors. Future work will include model refinement using other machine learning methods as well as using natural language processing to extract additional information from text written notes in the EHR.

Table: Results using machine learning to classify subjects with and without fractures.

| | Model | AUC | Accuracy (%) | Sensitivity (%) | Specificity (%) |
|----------------------------|-------------|------|--------------|-----------------|-----------------|
| Full Dataset (n=7179) | Naïve Bayes | 0.67 | 85 | 24 | 90 |
| Subset with DXA (n=762) | Naïve Bayes | 0.67 | 69 | 32 | 80 |
| Subset without DXA (n=762) | Naïve Bayes | 0.59 | 74 | 30 | 78 |

Advanced Glycation End-products are Higher in Trabecular Bone from Premenopausal Women with Idiopathic Osteoporosis. Timothy Cleland¹, Adi Cohen², David Dempster², Robert Recker³, Joan Lappe³, Hua Zhou⁴, Elizabeth Shane², Deepak Vashishth¹. ¹Rensselaer Polytechnic Institute, USA, ²Columbia University, USA, ³Creighton University, USA, ⁴Helen Hayes Hospital, USA

The pathogenesis of fragility fractures (FX) in premenopausal women with idiopathic osteoporosis (IOP) is unclear. Our prior studies found no differences in clinical characteristics, key hormones, turnover markers, and bone microarchitecture in women with IOP who have had fragility FX (IOP-FX) and those with idiopathic low bone mineral density (ILBMD) but no FX [1]. IOP-FX and ILBMD have differences in matrix mineralization compared to age-matched controls with normal BMD (CON), but also show significant between-groups differences in newly formed organic matrix suggesting osteoblast dysfunction as one possible reason for fragility fracture [2]. Because accumulation of Advanced Glycation End-products (AGEs) in the organic matrix has been shown to reduce osteoblastic differentiation and activity, osteoclastic resorption, and material properties of cancellous bone tissue [3], we measured fluorescent AGE content in cortical and cancellous bone in transiliac biopsies from premenopausal women with IOP, 45 IOP-FX, 19 ILBMD, and 40 CON, using a fluorescent AGE assay. By Student-Newman-Keuls one-way ANOVA, we found trabecular AGE concentrations were higher in the ILBMD than the CON group (228.14 ± 415.08 versus 52.48 ± 97.44 ng quinine/mg collagen; $p<0.05$), a non-significant trend for higher AGE concentrations in the ILBMD than the IOP-FX group (228.14 ± 415.08 versus 99.42 ± 255.74 ng quinine/mg collagen; $p=0.064$) and no difference between CON and IOP groups ($p>0.05$). In contrast to trabecular bone, we detected no group differences in cortical bone ($p > 0.05$ for ANOVA). A trend for presence of higher AGEs between the combined IOP-FX and ILBMD groups than CON ($p=0.099$) may translate into higher risk of fragility fracture, as accumulation of AGEs is associated with poorer material properties of bone. Furthermore, these results suggest that IOP in premenopausal women is associated with more glycated and, hence, older tissue that is resistant to complete resorption and promotes osteoblast dysfunction. Alteration in both these key processes would render bone deficient in key matrix proteins and modify the proteins that are present. Analyzing the proteomic profile of tissue from the IOP-FX and ILBMD groups may further elucidate the pathogenesis of fragility fractures associated with IOP.

Pregnancy and Lactation Associated Osteoporosis (PLO): Similar Bone Structure and Lower Bone Remodeling than Idiopathic Osteoporosis. Adi Cohen¹, Mafo Kamanda-Kosse², Hua Zhou³, David Dempster², Mariana Bucovsky², Julie Stubby⁴, Robert Recker⁴, Joan Lappe⁴, Elizabeth Shane². ¹Columbia University Medical Center, USA, ²Columbia University, USA, ³Helen Hayes Hospital, USA, ⁴Creighton University, USA

Pregnancy and lactation (P/L) are associated with rapid decreases in lumbar spine (LS) and femoral neck (FN) BMD followed by recovery. Rarely, young women present with fragility fractures that occur during P/L, and, in the absence of a secondary cause, are said to have P/L associated osteoporosis (PLO). Whether clinical, structural or metabolic characteristics of women with PLO differ from those with premenopausal idiopathic osteoporosis (IOP) is unknown and bone biopsy data are lacking in PLO. We compared 10 women with PLO to 56 women with IOP and 40 premenopausal normal controls. All women were otherwise healthy, and normally menstruating at the time of the evaluation. All had a complete history, physical exam, biochemistries to exclude secondary osteoporosis, BMD by DXA and transiliac crest bone biopsy after double tetracycline labeling. Subjects were evaluated ≥ 12 months after delivery or weaning and > 3 months after fracture. Two with PLO, 7 with IOP, and 0 Controls were using estrogen-based hormonal contraception. Parity, months of breastfeeding, and age at first pregnancy did not differ between the groups. Vertebral fractures were more common in PLO than IOP (70% versus 25%; $p = 0.005$). Non-vertebral fractures were comparable; PLO: 2 had rib, 3 had hip and 8 had extremity fractures. IOP: 12 had rib, 12 had hip and 41 had extremity fractures. A family history of osteoporosis was similar in both groups ($\sim 50\%$). More PLO women had a history of multiple fractures (100% vs 75%) and of childhood fracture (70% vs 30%), suggesting that bone fragility may antedate the presentation with PLO. PLO women tended to be younger (33 ± 6 vs 37 ± 8 yrs; $p=0.1$). Height, weight, BMI and DXA body fat did not differ between IOP and PLO. Serum and urine calcium, PTH and 25-OHD were normal in all and did not differ between groups. LS BMD tended to be lower in PLO than IOP, but trabecular microstructure did not differ on biopsies. Cortical width tended to be lower in PLO than IOP, but cortical porosity was similar. Cancellous bone remodeling was lower in those with PLO vs both IOP and Controls, tended to be lower at the endocortical surface, but did not differ in cortical bone (data not shown); 56% of women with PLO had cancellous bone formation rate (BFR) < 0.006 mm³/mm²/yr, a cutoff we previously used to define low turnover IOP, compared to 29% with IOP. Further research is needed to determine whether low bone formation contributes to the risk of PLO.

| Table: Bone Structure and Remodeling in PLO and IOP | PLO N=10 | IOP N=56 | Controls N=40 | P: PLO vs IOP | P: PLO vs Control |
|---|---------------|---------------|---------------|---------------|-------------------|

Are fractures and bone loss to be inevitably expected after renal transplantation? Results of up to 5 year follow up in a South East Asian population of renal transplant patients. Manju Chandran¹, Matthew Tan². ¹Singapore General Hospital, Singapore, ²Osteoporosis & Bone Metabolism Unit, Department of Endocrinology, Singapore General Hospital, Singapore

Introduction: The risk of bone loss and fractures is reportedly very high during the first year of follow-up after kidney transplantation and this risk apparently remains high even in the long term. We have previously reported on the prevalence and predictors of bone loss in the first year after renal transplantation amongst Singaporean patients¹. We now aimed to evaluate the baseline bone health

and to examine factors correlating with BMD changes and fractures if any in patients followed up to five years after renal transplantation.

Method: 164 patients who underwent renal transplant between 2008 and 2014 were studied retrospectively. Baseline bone parameters evaluated were BMD, parathyroid status, and 25(OH)D level. In post-menopausal women and in men over the age of 50, osteoporosis was diagnosed if the lowest T score at any axial site was ≤ -2.5 . In premenopausal women and in men under the age of 50, a diagnosis of low bone mass was made if the Z score was ≤ 2 . BMD changes at 6 months, 1 year, 2 years, and 5 years were compared using paired T-tests. $P < 0.05$ was considered significant. Pearson's correlation coefficient was used to measure correlations between changes in BMD and the different covariates.

Results: At baseline, 80.9% of patients had secondary and 4.5% had tertiary hyperparathyroidism. 14.5% had parathyroidectomy. The median 25(OH)D level was 14.6 ng/ml (11.7-22.8). 46% of the patients had osteoporosis or low bone mass. PTH level correlated negatively with the BMD at the femoral neck ($r = -0.169$, $p = 0.032$). BMD decreased significantly at 6 months compared to baseline at all 3 axial sites ($p = .000$). Subsequent to this there was no significant change in BMD in the patients who had follow-up over the next 4.5 years. During the 5 year follow up period, 6 patients had a low trauma metatarsal fracture each and 1 patient had an ankle fracture. No other atraumatic clinical fractures were noted in the patient population. BMD was not significantly correlated with the peripheral fractures.

Conclusion: Unlike reported in the western literature, we did not find an increased incidence of typical osteoporotic fractures during follow up, nor did we see a continued and significant bone mass loss after the first 6 months following transplant. This raises very intriguing questions about possible differences in the bone biology and genetic make up of SE Asian renal transplant patients as compared to Caucasian populations. Further studies are needed to elucidate these differences.

PDGF and BMP2 Enhance Proliferation, Migration and Differentiation of Periosteal Progenitor Cells. Xi Wang*, Brya Matthews, Ivo Kalajzic. University of Connecticut Health Center, USA

The periosteum contains multipotent skeletal progenitor cells and plays an essential role in bone repair. Understanding factors that regulate cell behavior and differentiation in the periosteum is important for future therapeutic applications. BMP2 has been widely used in orthopaedics but supraphysiological doses lead to side effects. A growth factor which could potentially reduce BMP2 doses is Platelet Derived Growth Factor-BB (PDGF-BB). It is involved in the early stages of bone repair but its effect on periosteal cells is unknown. We aimed to evaluate the effects of PDGF-BB and BMP2 on periosteal progenitor cells (PPCs).

To isolate PPCs, we scraped the periosteum from femurs and tibias of 6-8 week old mice and enzymatically digested for 1 hour. Primary cells were cultured in 5% oxygen for the first 4 days. For differentiation, cells were treated with 10ng/ml rhPDGF-BB and/or 100 ng/ml BMP2 beginning on Day 3, and cultured in osteogenic medium from Day 7-21. Gene expression and mineralized nodule formation was evaluated by expression of Col2.3GFP transgene and von Kossa staining. EdU and TUNEL assay was completed to evaluate the effects of PDGF-BB and BMP2 on the proliferation and apoptosis of PPCs. Migration was evaluated by measuring closure of a scratch wound.

Flow cytometric analysis showed that a large proportion of CD45- PPCs express mesenchymal stem cell markers: 81.3% are Sca-1+ and 75.6% express CD105. 30.5% PPCs express PDGF Receptor- α , 71.8% cells are PDGFR- β +. During osteogenic differentiation, continuous PDGF-BB treatment inhibited the formation of mineralized nodules while pretreatment with PDGF-BB at days 3-7 of culture promoted mineralization. Sequential combination of PDGF-BB and BMP2 resulted in the highest level of mineralization and expression of osteocalcin and bone sialoprotein. In addition, PDGF-BB significantly increased the proportion of EdU+ cells from 3.7% to 20.5% and prevented apoptosis of periosteal cells. PDGF also accelerated the migration of PPCs in a scratch assay, while the combination of PDGF-BB and BMP2 further increased speed of scratch healing in vitro.

In conclusion, our data show that under temporal control, PDGF-BB and BMP-2 can significantly promote osteogenic differentiation of PPCs. They also jointly accelerate in vitro wound healing, suggesting therapeutic potential for combination treatment. We are currently evaluating the effects of combinatorial treatment in models of bone repair in vivo.

Release of Titanium particle by Ultrasonic Cleaning of dental implants may aggravate the peri-implant inflammatory response. Yankel Gabet, Michal Eger*, Tamar Liron, Nir Sterer, David Kochavi. Tel Aviv University, Israel

Titanium (Ti) and its alloys are widely used as dental implants due to their biocompatibility, mechanical strength, corrosion resistance and osseointegration. To

date, virtually all-available implants undergo surface roughening in order to accelerate osseointegration and shorten healing time. Peri-implantitis is a major clinical concern and main cause of long term implant failure. Triggered by specific oral bacteria, it consists of an inflammatory process that leads to bone resorption around dental implants. Once the process starts it can hardly be controlled and often results in implant loss. Treatment includes mechanical cleaning of the surrounding oral flora by ultrasonic scaling (US). We hypothesize that the scaling process releases Ti particles into the implant microenvironment and that these particles aggravate or even trigger the inflammatory response. To test this hypothesis, we performed US of Ti discs with various surface types. The released particles were then added to bone marrow-derived mouse macrophages (BMDM) cultures. Bacterial lipopolysaccharides (LPS) were added to parallel cultures as positive control and in addition to Ti particles to assess additive/synergistic effects in the RNA expression of inflammatory cytokines. Atomic force microscopy and electron scanning microscopy were used for profilometry of the released particle and post-cleaning titanium surface. RT-qPCR indicated that Ti particles originating from sand-blasted/acid etched (SLA) implants stimulated gene expression of pro-inflammatory cytokines (TNF α , IL1 β , IL6) to a greater extent than LPS. Using SEM we then compared the profile, size and quantity of Ti particles obtained from all 3 different surface types, namely machined, SLA and sand-blasted (SB). BMDM were then cultured with the particles released from each surface type. In general, particles originating from SB implants yielded the most severe inflammatory response, while particles from machined implants induced the mildest response. Our results showed that both the amount and the shape of particles have an effect on the inflammatory response. These data suggest that scaling of Ti implants, intended at preventing peri-implantitis, may in fact aggravate the osteolytic inflammatory response by causing an accumulation of Ti particles in the peri-implant environment. This adverse reaction is likely to be even more severe around roughened Ti implants.

The Role of EphrinB2 Signaling during Endochondral Bone Formation. Yongmei Wang*¹, Alicia Menendez², Chak Fong³, Nicholas Heiniger³, Daniel Bikle⁴. ¹Endocrine Unit, University of California, San Francisco/VA Medical Center, USA, ²Endocrine Unit, University of California, San Francisco/ San Francisco VA Medical Center, USA, ³Endocrine Unit, University of California, San Francisco/San Francisco VA Medical Center, USA, ⁴Endocrine Unit, University of California, San Francisco/San Francisco VA Medical Center, USA

EphrinB2 (ENF2) and its receptor EphB4 are critical in regulating chondrocyte, osteoblast (OB), and osteoclast differentiation, the communication between these cells and the skeletal actions of parathyroid hormone and insulin-like growth factor (IGF-I). However, whether and how ENF2/EphB4 regulates endochondral bone formation remains unknown. To address these issues, we generated mice with specific ENF2 null mutation in their type II collagen (Col.II) expressing chondrocytes (Col.II.ENF2KO) (floxed ENF2 X Col.II promoter driven Cre-recombinase) to investigate the role of ENF2 during endochondral bone formation. The deletion of ENF2 was confirmed by immunohistochemistry in the proliferating chondrocytes and in the OBs of the trabecular bone surface in the Col.II.ENF2KO. At P7, the Col.II.ENF2KOs showed shorter proliferating zone and hypertrophic zone with fewer PCNA positive cells in the proliferating zone of the growth plate and the cells lining the trabecular bone surface when compared to the controls. As determined by μ CT, at 6 weeks, trabecular bone volume (BV/TV, 30%) and number (Tb.N, 28%) were significantly lower in the female Col.II.ENF2KOs than in the female controls. Quantitative PCR revealed that mRNA levels of Col.II and Indian Hedgehog were decreased by 56% and 40%, respectively in the Col.II.ENF2KOs compared to the controls. To determine the role of ENF2 in mediating skeletal stimulation of IGF-I during endochondral bone formation, metatarsals (MTs) from the P0 controls and the Col.II.ENF2KOs (KOs) were cultured with or without IGF-I treatment (100 ng/ml). At day 7, IGF-I treatment significantly increased the total bone (30%) and cartilage (32%) length in the control MTs, but not in the KO MTs. IGF-I increased the number of PCNA positive cells and phosphorylated ERK (pERK) expression in growth plate chondrocytes of the control MTs, but these effects were abolished in the KO MTs. Our data indicate that ENF2 in Col.II expressing cells promotes chondrocyte proliferation and differentiation and is required for IGF-I stimulated endochondral bone formation.

Localization of parathyroid hormone-related protein and its receptor in different pancreatic tumor types. Syu Mi Sam*¹, Kristi Milley¹, John Slavin², Peter Little¹, Mathis Grossmann³, Jeffrey Zajac³, Janine Danks¹. ¹School of Medical Sciences, RMIT University, Australia, ²Department of Pathology, St Vincent's Hospital, Melbourne, Australia, ³Department of Medicine, The University of Melbourne, Austin Health, Australia

PTHrP has been demonstrated to be involved in calcium homeostasis, smooth muscle relaxation and cellular proliferation, survival and differentiation in tissues such as skin, mammary gland and bone in physiological conditions. In pathological conditions, PTHrP has been shown to be expressed in common malignancies such as

breast and prostate cancer. There is limited data on the expression and secretion of PTHrP in pancreatic tumors, most literature has only focused on adenocarcinomas. Little is known about the role or presence of PTHrP in other pancreatic tumors such as in benign or premalignant tumors. To date no studies have examined the presence of PTHrP and PTH1R in other pancreatic tumor histopathological types. The aim of this study was to establish if PTHrP and PTH1R are present in different pancreatic tumor histopathological types. Using WHO classification, PTHrP and PTH1R was localized using immunohistochemistry in six benign, four premalignant and 27 malignant formalin-fixed paraffin-embedded archival samples. Slides were digitally scanned using Aperio ScanScope and both the tumor and adjacent normal tissue were analyzed using the ImageScope cytoplasmic algorithm. Cytoplasmic localization patterns were observed in the pancreatic islets and staining intensity was varied depending on their location to the tumor. Overall, the result of this study is the first to demonstrate both PTHrP and its receptor using immunohistochemistry in benign, premalignant and malignant pancreatic tumors.

PTH Stimulation of RANKL in Primary Osteoblasts Is Independent of PTH-Stimulated cAMP. Thomas Estus*, Shilpa Choudhary, Carol Pilbeam, University of Connecticut, USA

Parathyroid hormone (PTH) can stimulate both bone formation and resorption. When PTH is given continuously, resorption is greater than formation and bone is lost. We showed that the osteogenic actions of continuous PTH *in vitro* are suppressed by a factor that blocks PTH-stimulated cAMP production in osteoblastic cells. The production of this factor is dependent on the expression of cyclooxygenase 2 (Cox2), the major enzyme regulating prostaglandin production. When we treated wild type (WT) and Cox2 knockout (KO) mice with PTH infusion for 12-21 days, we found that anabolic actions of PTH were suppressed in WT, but not KO mice. However, the PTH stimulation of bone resorption was the same in both WT and KO mice. We have identified the inhibitory factor *in vitro* as serum amyloid A 3 (Saa3) and shown that Saa3 is secreted by bone marrow macrophages (BMMs) treated with RANKL. In this study we use the conditioned media (CM) from RANKL-treated WT BMMs or a recombinant, human-homolog of murine Saa3 (SAA) to study the involvement of cAMP-activated signaling in the PTH induction of *Rankl*. We cultured primary osteoblasts (POBs) from neonatal calvaria to confluence (5 days), treated with PTH (10 nM) in the presence or absence of CM or SAA (10 µg/mL) for 3 h and measured gene expression by qPCR. SAA concentration was determined by dose response as measured by cAMP signaling inhibition. As expected, both CM and SAA blocked the PTH-stimulated gene expression of cAMP-regulated receptor activity modifying protein 3 (*Ramp3*). However, PTH stimulated *Rankl* expression was not decreased by CM or SAA. The protein kinase A (PKA) inhibitor, H-89, blocked PTH-stimulated *Ramp3* expression but had no effect on PTH-stimulated *Rankl* expression. PTH has also been shown to activate the protein kinase C (PKC) pathway, which subsequently signals via extracellular-signal-regulated kinases (ERKs). The PKC inhibitor GF109203X and the ERK inhibitor PD98059 both blocked PTH-stimulated *Rankl* expression but did not decrease PTH-stimulated *Ramp3*. The calcium chelation agent BAPTA also blocked PTH-stimulated *Rankl* expression. In conclusion, our results indicate that PTH-stimulated *Rankl* in POBs is independent of cAMP signaling and likely to depend upon the PKC pathway. These data support our PTH infusion study, which indicated that the anabolic and catabolic effects of PTH occur via different signaling pathways.

Osteogenic potential of FOP iPSC cell-derived endothelial cells. Emilie Barruet*¹, Marcela Morales¹, Iris Pennings², Debby Gawlitta³, Hannah Kim¹, Ashley Urrutia¹, Wint Lwin¹, Mark P. White⁴, Christina Theodoris⁴, Deepak Srivastava⁴, Edward C Hsiao¹. ¹University of California, San Francisco, USA, ²Department of Orthopaedics, University Medical Center Utrecht, Netherlands, ³Department of Orthopaedics, University Medical Center Utrecht, Utrecht, The Netherlands, ⁴Gladstone Institute of Cardiovascular Disease & University of California, San Francisco, USA, USA

Patients with mutations in the Activin A Type I receptor (ACVR1), a bone morphogenetic protein (BMP) receptor, develop the debilitating disease fibrodysplasia ossificans progressiva (FOP) with massive heterotopic ossification. Several studies have suggested that stem cells or osteoprogenitors from different tissues may be responsible for the heterotopic ossification, and that human endothelial cells (ECs) carrying the ACVR1 R206H mutation may contribute to the formation of FOP lesions. Our overall hypothesis is that activated BMP signaling caused by the ACVR1 R206H mutation in ECs increases heterotopic bone formation by activating osteogenesis. The recent advent of human induced pluripotent stem cells (iPSCs) provides an ideal opportunity to create human-specific models for FOP, particularly as primary cells are extremely difficult to isolate from FOP patients. Using a series of human iPSCs created from normal control and FOP donors, we previously showed that FOP iPSCs demonstrated increased mineralization and enhanced chondrogenesis. Here we show that the mineralizing FOP cultures have increased numbers of ECs

but no differences in mesenchymal stem cells (MSCs). To determine if the ACVR1 R206H mutation could lead to increased ECs formation we created iPSC-derived endothelial progenitor cells (iECs). CD31⁺/KDR⁺ iECs formed at equal yields of 20% from both control and FOP iPSC lines in standard culture conditions. However, we found that FOP iPSCs could form iECs at lower BMP4 concentrations compared to control iPSCs, even in conditions lacking BMP4 (1% FOP vs 0.1% WT yield). FOP iECs also expressed increased level of fibroblastic (FSP-1), chondrogenic (COL1A1 and COL2A1), and osteogenic (ALPL) markers. When cultured in osteogenic conditions, FOP iECs showed significantly increased alkaline phosphatase staining. Despite these signs of increased early cell fates favoring osteogenesis, FOP iECs showed little difference in mineralization using 2D or 3D assays to recapitulate endochondral bone formation. These studies show that the FOP ACVR1 activating mutation can activate two potential mechanisms for inducing heterotopic ossification: increasing EC formation and increasing expression of early osteogenic genes. The insights gained from these studies will help identify cellular targets for treating FOP and related diseases, while potentially identifying endogenous skeletal stem cells that could be activated for regenerative medicine.

Response to treatment with bisphosphonates in McCune-Albright Syndrome: A case series. Natasha Appelman-Dijkstra*¹, Bas Majoor², Sander Dijkstra³, Neveen Hamdy³. ¹Leiden University Medical Center Netherlands, Netherlands, ²Leiden University Medical Center in the Netherlands, , ³Leiden University Medical Center, Netherlands

Introduction McCune-Albright syndrome (MAS) is a rare bone dysplasia due to a postzygotic mutation of the GNAS1-gene, characterized by a classical triad of polyostotic fibrous dysplasia (FD), café-au-lait patches and precocious puberty. Other endocrinopathies may be present. Patients with FD favourably respond to treatment with bisphosphonates, with decrease in bone pain associated with decreases in bone turnover and arrest of progression of bone lesions. Whether patients with MAS respond similarly to treatment with these agents remains to be established.

Patients & Methods We studied the effect of treatment with bisphosphonates in twelve patients with MAS (10 female) and aged 7-51 yrs, all of whom had precocious puberty (mean age 4.6yrs ± 3.6 SD) & 9 had café-au-lait patches. Mean duration of follow-up was 11.8 yrs (0.3-22yrs). Therapeutic objective was normalization of bone turnover and evaluation of the effect of this on pain symptoms.

Results Median age at time of diagnosis was 3.5 years ± 13.8 SD. Endocrinopathies included hyperthyroidism (n=3), growth hormone (GH) excess (n=3) and hyperprolactinemia (n=3). Ten patients (83%) had hypophosphatemia. Nine patients (75%) had at least one fracture (median 2/patient). GH-excess was adequately controlled before starting treatment. Dimethyl-APD (olpadronate) was administered in 11 patients (maximum dose 200 mg/d po or iv 4-8 mg for 3-5 days 3 monthly), and intermittent iv zoledronate in one patient, for variable duration of time aiming at normalization of bone turnover. After longer duration of treatment and use of higher cumulative doses of bisphosphonates, this was achieved in 7 patients (58%), 2 (17%) demonstrated a moderate decrease in bone-turnover, and there was no significant effect on bone-turnover in the 3 patients with GH-excess (27%). There was no adverse effect of treatment, and decreases in bone turnover were associated with corresponding improvement in bone pain.

Conclusion Our data demonstrate that patients with MAS require higher cumulative doses of bisphosphonates to achieve a clinical and biochemical response, and that those with GH-excess respond poorly to treatment, possibly because of the effect of GH-excess on the extent and severity of the skeletal manifestations. These findings suggest that GH-excess should be identified and treated early after the disease is diagnosed, and that bone-modifying treatment other than bisphosphonates may be required to control disease activity in these patients.

Clinical, Biochemical and Radiographic Spectrum of gene diagnosed X-linked Hypophosphatemia in Adults. Bo Wu*, Yan Jiang, Lijun Xu, Zhen Zhao, Ou Wang, Mei Li, Xiaoping Xing, Wei Yu, Weibo Xia. Peking Union Medical College Hospital Department of Endocrinology, China

X-linked hypophosphatemic rickets or osteomalacia (XLH) is congenital disease, characterized by renal phosphate wasting induced hypophosphatemia and defective mineralization of bones. Few studies focus on phenotype of XLH in adulthood. Therefore, this cross-sectional study systematically described anthropometric, clinical, biochemical and radiological features in 47 adult XLH patients. Similar to previous studies, adult XLH patients were characterized by short stature and disproportioned body proportion, as well as hypophosphatemia, elevated ALP, increased PTH concentration. The radiological spectrum illustrated more severe, prevalent and influential degenerative joint disease in hip than knee, the distribution of vertebral fracture and enthesopathy, both were rarely mentioned in previous study. Patients also showed elevated vertebra BMD, negatively affect by OPG and PTH, and decreased femur BMD, positively impacted by serum phosphate, and negatively affected by ALP and PTH. There is no genotype and phenotype association in adult XLH patients. Male patients presented with less osteoarthritis, higher calcium, ALP

and sclerostin than female. Lower upper body measurements and sitting height, higher PTH may indicate higher fracture risk. In a word, this is the largest study investigating clinical spectrum of adult XLH patients, proposed rarely reported radiologic characters and the biochemical factors affect BMD.

Disclosures: Bo Wu, None.

Searching for Hypophosphatasia: Conditions Associated with Low Serum Alkaline Phosphatase in Children. Linda Dimeglio¹, Erik Imel², Marc Rosenman². ¹Indiana University School of Medicine, USA, ²Indiana University, USA

Hypophosphatasia (HPP) is a rare, inherited metabolic bone disorder caused by mutations in the *ALPL* gene and characterized by low serum alkaline phosphatase (ALP) activity. HPP can present clinically as mild to severe forms and is associated with five recognized phenotypes: perinatal, infantile, childhood, adult, and odontohypophosphatasia. The variety of phenotypic expression as well as low awareness of the disease among physicians can make diagnosing HPP difficult and nosology relatively subjective. Given the wide variety of presentations of HPP, many cases may be missed or misdiagnosed. We used a large multi-health system electronic medical record (EMR) database (through the Indiana Network for Patient Care) to identify children with low serum ALP values, in order to examine causes of persistent low ALP and to search for undiagnosed cases of HPP.

After IRB approval, we queried the database for children aged ≤ 18 years with available records from 1/1980-12/2012. 896,473 children had at least one ALP result. We then looked for those who had at least 2 low ALP levels (>10 U/L below the lower normal limit for age) separated by at least 6 months with records at our children's hospital or county hospital. 50 subjects met these criteria. 34 subjects (85% female, mean age 12.2 years, range 0-18 years) had EMRs with ICD-9 codes available for review. Four of these children had been diagnosed with HPP. Two additional cases had clinical characteristics suggestive of HPP (hypercalcemia, fracture, scoliosis) without evidence of prior or subsequent normal ALP values. The remaining 28 had other identifiable associated medical conditions including congenital heart disease (N=5, 1 post-transplant); gastrointestinal disease (N=3); end-stage renal disease (N=3, 2 post-transplant); acute lymphocytic leukemia (N=3); lupus (N=3), pregnancy (N=2, 1 with hyperemesis), cerebral palsy (N=2), anorexia (N=2), fatigue (N=1), Behcet's (N=1), histiocytosis (N=1, post-transplant), Marfan's (N=1), and hepatitis C (1). Several of these children had documentation of steroid use at the time the ALP was obtained.

When age-specific normal ranges are used, persistently low ALP is a relatively uncommon finding in the pediatric setting. Prior reports have identified early puberty, hypothyroidism, malnutrition, pernicious anemia, vitamin D toxicity, Wilson disease and zinc deficiency as causes of low ALP in addition to the diagnoses of HPP and malnutrition which we identified. Our investigation, therefore, adds to the list of conditions associated with persistently low serum ALP in children.

Validation of a Novel Scoring System, the Radiographic Global Impression of Change (RGI-C) Scale, for Assessing Skeletal Manifestations of Hypophosphatasia in Infants and Children. Michael P Whyte¹, Kenji P Fujita², Scott Moseley², David Thompson², William H McAlister³. ¹Shriners Hospital for Children, USA, ²Alexion Pharmaceuticals, USA, ³Department of Pediatric Radiology, Mallinckrodt Institute of Radiology, St. Louis Children's Hospital, USA

Purpose: Hypophosphatasia (HPP) is the rare inherited metabolic bone disease caused by loss-of-function mutations in the tissue nonspecific alkaline phosphatase (TNSALP) gene. Resultant TNSALP deficiency leads to extracellular excess of inorganic pyrophosphate, an inhibitor of bone mineralization. The rickets in infants and children has distinctive radiographic features. Here, we report the validity and reproducibility of a novel scoring system to quantify HPP-specific radiographic changes in pediatric patients (pts).

Methods: The Radiographic Global Impression of Change (RGI-C) is a 7-point ordinal scale (-3=severe worsening; 0=no change; +3=near/complete healing) designed to provide a comprehensive evaluation of skeletal health in pediatric pts with HPP. Sequential radiographic studies (chest [<5 years only], knees, and wrists) are assessed for improvement or worsening using age-specific ($<$ or ≥ 5 years of age) hallmarks of HPP developed by expert consensus. Features common to both age groups include metadiaphyseal sclerosis, apparent physeal widening, and metaphyseal radiolucencies and/or fraying. Age-specific features include gracile and/or absent bones and chest deformity for pts <5 years, and osteopenia, "popcorn calcification", and physeal corner defects for pts ≥ 5 years. Inter- and intra-rater agreements for 6 raters across 3 treatment studies were assessed using intraclass correlation coefficients (ICC) and weighted kappa coefficients (KC). Concurrent validity was assessed via correlation between RGI-C scores and simultaneous changes from baseline in: 1) Rickets Severity Scale (RSS)¹; 2) Pediatric Outcomes Data Collection Instrument (PODCI) Global Function scale; 3) Child Health Assessment Questionnaire (CHAQ)

Disability Index; 4) 6 Minute Walk Test (6MWT); and 5) height z-scores, in children ≥ 5 years.

Results: ICC revealed moderate-to-good inter-rater agreement for pts <5 years (0.65, 227 radiographs; $p<0.0001$) and pts ≥ 5 years (0.57, 136 radiographs; $p<0.0001$). Most raters achieved substantial ($n=4$, KC >0.6) or almost perfect ($n=4$, KC >0.8) intra-rater agreement ($n=1$, moderate agreement, KC >0.5). The linear regressions revealed significant correlations with RSS, PODCI Global Function, CHAQ Disability Index, 6MWT, and height z-scores (Table 1).

Conclusion: The RGI-C scale is a reproducible and valid measure for assessing over time clinically important changes in skeletal manifestations of HPP in pediatric patients.1. Thacher, *J Trop Ped* 2000

Table 1. Correlations between RGI-C and changes from baseline in other clinical outcomes in patients with HPP

| Measure | Number of data points | Pearson correlation (r) | p-value |
|------------------------|-----------------------|-------------------------|-----------|
| Rickets Severity Scale | 135 | -0.664 | <0.0001 |
| PODCI Global Function | 84 | 0.595 | <0.0001 |
| CHAQ Disability Index | 84 | -0.589 | <0.0001 |
| 6-Minute Walk Test | 100 | 0.284 | 0.0043 |
| Height Z-score | 108 | 0.261 | 0.0065 |

⁶⁸Ga-DOTATATE for tumor localization in Tumor-induced Osteomalacia. Diala El-Maouche¹, Samira Sadowski², Lori Guthrie³, Candice Cottle-Delisle², Roxanne Merkel², Corina Millo⁴, Clara Chen⁴, Electron Kebebew², Michael Collins⁵. ¹University of Miami/ National Institutes of Health/NIDCR, USA, ²NIH/NCI, USA, ³NIH/NIDCR, USA, ⁴NIH/CC, USA, ⁵NIH/NIDCR, USA

Purpose:

Evaluate the use of ⁶⁸Ga-DOTATATE for tumor localization in Tumor-induced osteomalacia (TIO).

Background:

Tumor-induced osteomalacia (TIO) is a paraneoplastic disorder caused by small mesenchymal tumors that produce high levels of the hormone fibroblast-growth-factor 23 (FGF23). Complete surgical resection leads to cure, however these tumors are notoriously difficult to locate, often due to their small size.

In a recent NIH series, successful localization was achieved in only 61% of patients even with a combination of localization studies that included two functional imaging modalities (¹¹¹In- pentetreotide -SPECT/CT (octreotide) and FDG-PET/CT), anatomical localization studies, and as needed, selective venous sampling¹. Recent case reports and a small series suggest ⁶⁸Ga-DOTANOC or DOTATATE may be useful at identifying tumors, but these have not been compared to conventional studies^{2,3}. In this series, we compared ⁶⁸Ga-DOTATATE PET/CT vs. octreotide SPECT/CT and FDG-PET/CT scan in a series of 12 patients with presumed TIO.

Methods and Results:

Twelve patients (7 female, 5 males) with TIO diagnosed on clinical and biochemical presentation and who had previously failed localization elsewhere were enrolled in an NIH IRB-approved study and underwent imaging for tumor localization (Table 1). The tumor was successfully localized and resected in 4/12 (33.3%) patients, not localized in 6/12 (50%), localized and pending surgical resection in 1/12, and found to be metastatic in 1/12. ⁶⁸Ga-DOTATATE imaging correlated with octreotide imaging in 10/12 (83.3%), and was more sensitive than octreotide in 2/12. However in these 2 subjects in whom results were confirmed upon surgical resection, the tumors were visualized on FDG-PET.

Conclusion:

In two cases, ⁶⁸Ga-DOTATATE found the lesions not seen on octreotide, but no tumors were localized on ⁶⁸Ga-DOTATATE scanning that were not localized on a combination of octreotide and FDG-PET scans. Limitations of this study include small sample size. Future studies, including larger patient sample, and possibly DOTANOC, are needed to assess the utility of DOTATATE or DOTANOC compared to existing imaging modalities.

Muscle Function in Osteogenesis Imperfecta Type IV. Louis-Nicolas Veilleux*¹, Francis H. Glorieux², Frank Rauch². ¹McGill University/Shriners Hospital for Children-Canada, Canada, ²Shriners Hospital for Children-Canada, Canada

Context: Osteogenesis imperfecta (OI) is a heritable bone fragility disorder that is caused by mutations affecting collagen type I. In addition to bone fragility, we recently showed that patients with the mildest form of OI (OI type I) have muscle weakness. However, there is presently little information on muscle function in more severe forms of OI, such as OI type IV. Objective: The objective of the current study was to investigate upper- and lower-limbs muscle function in children and adolescents with OI type IV and to compare it to OI type I and healthy age- and sex-matched controls. Patients and Other Participants: Forty-four patients with OI type IV (21 females; mean age [SD]: 12.7 years [3.8]) were compared to 42 patients with OI type I (mean age [SD]: 12.6 years [3.8]) and 42 healthy age- and gender-matched controls (mean age [SD]: 12.6 years [3.9]). Main Outcome Measures: Upper-limbs muscle force was tested with grip strength dynamometer. Lower extremity muscle force and power were measured by five mechanography tests. Results: Patients with OI type IV had an average grip strength Z-score of -1.2 for the left hand and -1.6 for the right hand, compared to healthy age and sex reference data. Lower limb muscle power was 20% lower in patients with OI type IV compared to patients with OI type I ($p < 0.001$) and 25% lower compared to age- and sex-matched controls ($p < 0.001$). Lower limb muscle force was 5% lower in patients with OI type IV compared to patients with OI type I ($p = 0.45$) and 25% lower compared to age- and sex-matched controls ($p = 0.01$). Conclusions: Patients with OI type IV have a generalized muscle function deficit compared to healthy controls. Such patients might benefit from a physical training intervention as an adjunct therapy.

A heterozygous missense mutation p.His381Arg identified in a patient with a childhood form of hypophosphatasia. Anna Petryk*¹, Lynda Polgreen², Kenneth Beckman³, Amy Calhoun⁴. ¹University of Minnesota, USA, ²Division of Pediatric Endocrinology & Metabolism, Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, USA, ³University of Minnesota Genomics Center, USA, ⁴Department of Pediatrics, Division of Genetics & Metabolism, University of Minnesota Masonic Children's Hospital, USA

Background: Hypophosphatasia (HPP) is a rare inherited disorder characterized by low level of tissue-nonspecific alkaline phosphatase (ALP) due to loss-of-function mutations in the ALPL gene. The disease has a wide spectrum of clinical presentation, including the perinatal (usually lethal), infantile, childhood and adult forms. Much remains to be learned about the types of pathogenic mutations in patients with various forms of HPP and their clinical implications. Objective: To describe the clinical course in a patient with childhood HPP and to identify the underlying mutation. Methods: Targeted next generation sequencing of ALPL was performed. Genomic DNA was extracted from the blood sample. Sequencing libraries were prepared and sequence capture performed according to Illumina protocols utilizing the TruSight One Sequencing Panel. The enriched DNA libraries were sequenced on an Illumina HiSeq 2500 instrument. Raw sequencing reads were mapped to the reference genome using Burrows-Wheeler Alignment. Point mutation and indel calls in exons and adjoining intronic regions were made using the GATK Unified Genotyper. Results: The patient is a 3.9 years old boy who presented with premature loss of primary teeth starting at 2.5 years of age. His growth has been normal (height and growth velocity at the 49th percentile). He began walking at 14 months; has had no history of fractures, gait abnormalities, bone pain, or poor muscle tone. His mother also has a low ALP level, but has no history of fractures, bone pain, or premature loss of teeth. His father has a normal ALP level. Maternal great-grandmother had rickets in her youth. Paternal grandmother started wearing dentures in her 40s. He had low ALP level (59 U/L, normal range 110-320), elevated urine phosphoethanolamine, markedly elevated vitamin B6, normal calcium, phosphorus, and vitamin D levels, low PTH level, and no evidence of rickets on a hand radiograph. A heterozygous missense mutation c.1142A>G (p.His381Arg) was identified in ALPL. This mutation (previously reported as p.H364R) has been reported in conjunction with a second missense ALPL mutation in one case of a lethal autosomal recessive hypophosphatasia. Conclusion: p.His381Arg mutation can occur not only in a lethal autosomal recessive HPP, but also a mild, presumably autosomal dominant, form due to haploinsufficiency. Molecular analysis of other family members may help to clarify the inheritance pattern and clinical presentation of this mutation.

Pain Resulting from Unresolved Skeletal Disease has a Significant Impact on the Daily Function of Adults with X-linked Hypophosphatemia (XLH). Alison Skrinar, PhD*¹, Ayla Marshall², Javier San Martin, MD², Melita Dvorak-Ewell, PhD², Carolyn Macica, M.S., PhD³. ¹Ultragenyx Pharmaceutical, USA, ²Ultragenyx Pharmaceutical Inc., USA, ³Frank H. Netter School of Medicine Quinnipiac University, USA

Background: X-linked Hypophosphatemia (XLH) is a disorder of renal phosphate wasting and defective bone mineralization caused by high circulating levels of fibroblast growth factor 23 that impair normal phosphate reabsorption in the kidney. The disorder presents in childhood with hypophosphatemia leading to rickets and bowing of the legs that is treated with oral phosphate and vitamin D metabolites. Despite treatment, many skeletal defects remain unresolved and lead to significant complications in adulthood. Progressive osteomalacia with associated pseudofractures and bone and joint pain are common, particularly in the lower extremities. Objective: The primary objective of the study was to characterize disease burden in adults with XLH. Methods: An IRB-approved, web-based questionnaire was completed by adults with XLH to evaluate disease history, current clinical conditions and resulting symptoms and complications. Patient-reported pain and disability were assessed using the Brief Pain Inventory (BPI), Western Ontario and McMaster Osteoarthritis Index (WOMAC), and SF-36v2 Health Survey. Results: 195 responders from 16 countries, primarily the US (70%), with a mean age of 46 years (range: 18 – 74) completed the survey. Gait disturbance was common (86%) with 31% using a walking device. A history of fractures was reported by 86/195 (44%) of responders with the most common fracture locations being the femur (18%), feet (14%) and tibia/fibula (14%), which is likely due to the stress of weight bearing. The majority of responders had experienced joint pain (89%) and bone pain (73%) in the lower extremities in the past year that led to regular pain medication use by 69%, including 20% taking opiates. BPI Pain Severity and Pain Interference were measured using an 11-point VAS with 10 as the maximum possible score. Mean BPI Pain Severity and Pain Interference scores were 3.6 and 4.1, respectively, indicating bone pain in the moderate range that interferes with daily activities, such as walking and working. BPI findings were supported by WOMAC Pain and Physical Function scores, as well as SF-36 Physical Component Summary (PCS) and Bodily Pain (BP) scores which indicated significant pain and burden relative to US general population norms. Conclusion: Adults with XLH experience lower extremity bone and joint pain that is readily detectable on various validated measures and significant enough to interfere with daily function.

MO0387

Analysis of classical and non-classical Fibrodysplasia Ossificans Progressiva mutations using human induced pluripotent stem cells. Laura Hildebrand^{*1}, Bella Rossbach², Andreas Kurtz³, Manfred Gossen⁴, Harald Stachelscheid⁵, Petra Seemann². ¹Charité - Universitätsmedizin Berlin, Germany, ²Charité- Universitätsmedizin Berlin, Berlin-Brandenburg Center for Regenerative Therapies (BCRT), Berlin, Germany, Germany, ³Seoul National University, College of Veterinary Medicine & Research Institute for Veterinary Science, Seoul, Republic of Korea, Charité – Universitätsmedizin Berlin, Berlin-Brandenburg Center for Regenerative Therapies (BCRT), Berlin, Germany, Germany, ⁴Berlin-Brandenburg Center for Regenerative Therapies (BCRT) Berlin, Helmholtz-Zentrum Geesthacht (HZG), Institute of Biomaterial Science, Teltow, Germany, Germany, ⁵Charité- Universitätsmedizin Berlin, Berlin-Brandenburg Center for Regenerative Therapies (BCRT), Berlin, Germany, Berlin Institute of Health, Berlin, Germany, Germany

Fibrodysplasia Ossificans Progressiva (FOP) is a rare autosomal dominant disorder. Patients appear to be healthy at birth, except for malformed big toes. Starting in childhood, they develop endochondral bone replacing skeletal muscles, tendons and ligaments. This heterotopic ossification can be triggered by viral illnesses, accidents, surgical interventions or even might start spontaneously.

FOP is caused by different gain-of-function mutations in the Bone Morphogenetic Protein (BMP) receptor ACVR1, which lead to constant downstream signaling. The majority of FOP patients carry the R206H mutation located in the GS domain of the receptor. But also other FOP mutations in ACVR1 are described that are predominantly located in the kinase domain. It seems that the different mutations have distinct activation mechanisms. Establishing induced pluripotent stem cells (iPSC) for every FOP mutation is difficult, as some mutations are very rare and patient samples are not always readily available. Furthermore, the genetic backgrounds vary, complicating a direct comparison.

In this study, we apply a newly established stem cell tool, which uses an avian receptor to transduce iPSC with an avian leucosis virus carrying the ACVR1 variants. The avian receptor was introduced via a PiggyBac transposon, leading to a new hiPSC line stably expressing the avian receptor gene, while retaining pluripotency. These iPSC⁺ are infected with ACVR1 variants, carrying FOP mutations in the GS domain (R206H, Q207D) and kinase domain (G356D, G328E, G328W, G328R), respectively. This strategy allows the analysis and comparison of different ACVR1 mutations on the common genetic background of hiPSC⁺.

The functionality of this new stem cell tool will be validated with two FOP patient derived iPSC cell lines, carrying the classical R206H mutation, generated in our laboratory. To this end, a primary cell culture isolated from urine was reprogrammed using Sendai virus technology. We conclude that our iPSC⁺ tool will enable a more reliable biochemical characterization and comparison of different disease-causing mutations in ACVR1. Notably, this novel strategy can also be applied to other monogenetic diseases, as the viral gene delivery system enables an efficient overexpression of the genes of interest generating pluripotent cells with a common genetic background.

MO0388

Cranial base defects in a mouse model of Hereditary Multiple Exostoses are associated with ectopic hedgehog signaling. Federica Sgariglia^{*1}, Paul Billings², Hyo-Bin Um², Kevin Jones³, Eiki Koyama², Maurizio Pacifici². ¹Children's Hospital of Philadelphia, USA, ²CHOP, USA, ³University of Utah, USA

Hereditary Multiple Exostoses (HME) is a pediatric autosomal-dominant disorder caused by mutations in the heparan sulfate (HS) synthesizing enzymes EXT1 or EXT2. Thus, HME patients are HS-deficient and characterized by the presence of numerous benign cartilaginous tumors –exostoses- forming next to the growth plates of axial and appendicular skeletal elements, including long bones and ribs. However, exostoses have not been described in the craniofacial skeleton, despite the fact that it contains several endochondral structures. Hence, we focused on the cranial base and in particular its synchondroses. These structures contain dual mirror-image growth plates, responsible for antero-posterior cranial base elongation and are flanked by intracranial and sub-cranial perichondrium. Indeed, several exostosis-like masses formed along the sphenoidal and occipital synchondroses of conditional Ext1-deficient mice (Ext1^{fl/fl};Col2CreER) injected with tamoxifen at P10. In the mutants, the occipital bone also was deformed, the cranial base was shorter and thinner, and the synchondrosis growth plates exhibited fewer resting and proliferative chondrocytes and an irregular columnar organization. These events were accompanied by deranged expression of typical growth plate chondrocyte markers including Sox9 and aggrecan as well as reduced expression of two HS-rich proteoglycans: Perlecan and Syndecan 3. To uncover additional mechanisms, we examined hedgehog signaling in Ext1-deficient mice in a Gli1LacZ reporter background. LacZ activity was stronger and widespread along mutant synchondrosis perichondrium and within growth plate at early stages and thus, preceded exostosis formation at later time points. Ectopic hedgehog signaling occurred also in mutant growth plates of limb and trunk elements

and was thus systemic. Treatment with a Smoothed inhibitor partially rescued the mutant phenotype, confirming involvement and active role of Hh signaling. Levels of immuno-detectable Noggin were significantly decreased in mutant perichondrium and growth plates as well, particularly in perichondrial cells facing the intracranial space. In sum, our data reveal that the skull is also affected by Ext1 deficiency and displays large exostosis-like masses whose formation appears to be linked to aberrant Hh and BMP signaling. We are currently re-examining radiographic skull scans from HME patients to determine whether analogous craniofacial skeletal defects are present.

MO0389

Deformed cranial morphologies are caused by the combined roles of the maldevelopment of calvarias, cranial base and brain in FGFR2-P253R mice. Yangli Xie¹, Xiaolan Du^{*2}, Fengtao Luo², Wei Xu², Junlan Huang², Siru Zhou², Zuqiang Wang², Wanling Jiang², Lin Chen². ¹Third Military Medical University, Peoples republic of china, ²Center of Bone Metabolism & Repair, Department of Rehabilitation Medicine, State Key Laboratory of Trauma, Burns & Combined Injury, Trauma Center, Institute of Surgery Research, Daping Hospital, Third Military Medical University, China

Apert syndrome(AS) is a most common genetic craniosynostosis syndrome in humans. Apert mouse model (Fgfr2+P253R) showed abnormalities in sutures, cranial base synchondroses and cerebrum. They may all be involved in the pathogenesis of skull malformation in AS. In this study, to distinguish the differential roles of these components of head in the pathogenesis of abnormal skull morphology of AS, we generated mouse models with specific expression of mutant FGFR2 in chondrocytes, osteoblasts, and central nerve cells by breeding FGFR2-P253R-neo mice with Col2a1-Cre, Osteocalcin-Cre (OC-Cre), and Nestin-Cre mice, and quantitatively compared the skull morphologies of these mutant mice with their littermates using EDMA (Euclidean distance matrix analysis) analysis. Col2a1-Fgfr2+/P253R mouse skulls showed shortened skull dimensions along the rostrocaudal axis, and craniofacial malformation with shortened nasal, as well as evidently advanced ossification of cranial base synchondroses. In OC-Fgfr2+/P253R mice, their skulls showed malformation in orbit and front of face. Nestin-Fgfr2+/P253R mice showed increased height on the posterior of neurocranium. Our study indicates that the abnormal skull morphologies of AS are caused by the combined results of the maldevelopment in cranial sutures, and the endochondral growth of cranial base, and central nervous system. These findings further deepen our knowledge about the pathogenesis of skull morphologies of AS, and provide some new clues for the future analyses of skull phenotypes and clinical management of AS.

MO0390

Evaluation of FGF23 Levels and Related Factors in a Patient with Hereditary Vitamin D Resistant Rickets. Keiko Yamamoto^{*1}, Makoto Fujiwara², Yasuhisa Ohata², Taichi Kitaoka², Takuo Kubota², Noriyuki Namba², Toshimi Michigami³, Sachiko Kitanaka⁴, Takehisa Yamamoto⁵, Keiichi Ozono². ¹Osaka University, Japan, ²Department of Pediatrics, Osaka University Graduate School of Medicine, Japan, ³Department of Bone & Mineral Research, Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, ⁴Department of Pediatrics, The University of Tokyo, Japan, ⁵Department of Pediatrics, Minoh City Hospital, Japan

1, 25(OH)₂D is a critical inducer of FGF23 expression, but several other factors such as serum Ca and intact PTH are also suggested to have effects on FGF23 levels. Hereditary vitamin D resistant rickets (HVDRR) is a rare disease caused by loss-of-function mutations in the VDR gene. Here we evaluated the change in levels of FGF23 and the other factors in a HVDRR patient with no functional VDR. The patient was a two-year-old girl, when her serum alkaline phosphatase was found to be elevated by chance. The further examination revealed hypocalcemia and secondary hyperparathyroidism without vitamin D deficiency: serum calcium (Ca) 7.7 mg/dl, phosphate (P) 3.0 mg/dl, intact PTH 576 pg/ml, 25(OH)₂D 20.1 ng/ml, 1, 25(OH)₂D 137 pg/ml. She had alopecia and radiographical signs of rickets. A homozygous p.R73X mutation in the DNA-binding domain of the VDR was detected. Initial treatment with oral active vitamin D and calcium had little effects. By increasing the dose of oral calcium without vitamin D, first her serum Ca became normal, and then intact PTH and Pi levels became normal and intact FGF23 levels started to increase. Rachitic change was improved and her IGF-1 level increased with accelerated height velocity. Her renal function was normal throughout our observation. We analyzed the correlation of intact FGF23 with serum Ca, Pi, intact PTH, 1, 25(OH)₂D, IGF-1 (evaluated by standard deviation score), Kaup index and uremic acid because their correlation were previously reported. We analyzed the data from 3y3m to 4y4m using the intact FGF23 level of 3y3m as 10 pg/ml, which is the resolution threshold. We evaluated the correlation of intact FGF23 with the parameters by parametric analysis (Pearson correlation test) and non-parametric analysis (Spearman's rank correlation coefficient), and found significant correlation with IGF1 (SD) and Kaup index (p<0.05). Then, we performed multiple regression analysis by the stepwise procedure

to evaluate the association of intact FGF23 with them, using IGF1, Kaup index and one more parameter; serum Ca, P, intact PTH, 1,25(OH)₂D and uremic acid. The result showed that IGF1 and serum P were the significant parameter (p=0.043, p=0.0384, respectively) and their partial regression coefficient levels were 0.932 and 0.304, respectively. These results suggested that FGF23 can be produced without VDR function and that IGF1 has some correlation with intact FGF23 as well as serum P.

Fracturing Without Apparent Skeletal Pathobiology In Congenital Insensitivity to Pain Caused By A Second Heterozygous Mutation in *SCN11A*. Voraluck Phatarakijirund*¹, Steven Mumm¹, William H McAlister², Deborah Novack¹, Deborah Wenkert³, Karen L. Clements³, Michael P Whyte³. ¹Washington University School of Medicine, USA, ²Department of Pediatric Radiology, Mallinckrodt Institute of Radiology at St. Louis Children's Hospital, Washington University School of Medicine, USA, ³Center for Metabolic Bone Disease & Molecular Research Shriners Hospitals for Children - St Louis, USA

Congenital insensitivity to pain (CIP) refers to the rare heritable disorders that feature inability to feel pain and no evidence of peripheral neuropathy. Although bone and joint complications are common in CIP, detailed biochemical studies of mineral and skeletal homeostasis and bone histopathology have not been reported. In 2013, a first and specific heterozygous gain-of-function mutation in *SCN11A* encoding voltage-gated sodium channel 1.9 (Nav1.9) was identified in three unrelated sporadic cases, thereby establishing a distinctive type of CIP. Each individual suffered multiple painless fractures, self-inflicted injuries, repeated self-mutilation causing un-healing wounds, chronic diarrhea, and hyperhidrosis. We studied CIP in a family (mother and her two children) including physical examination, biochemical studies, and radiological imaging with dual-energy X-ray absorptiometry (DXA). Genomic DNA from whole blood was PCR-amplified and sequenced in the children (mother's DNA unavailable) at each of the 26 coding exons and adjacent mRNA splice sites of *SCN11A*. The mother, first evaluated at age 10 years, had multiple fractures (primarily of her lower extremities) beginning at age two years, Charcot deformity of both ankles, and hypermobility of all joints. Her nerve conduction velocity and electromyography were normal. Her children were first studied at 1.5 and 3.5 years-of-age for recurrent major fractures and joint hypermobility. All three individuals had chronic diarrhea. The mother had excoriated right external nares, and both children had severe excoriation and hypertrophic scars of the posterior neck from repeated scratching. The daughter had hyperhidrosis. Skin collagen studies of the son showed normal results. Radiographs of each person revealed old fractures and deformities. However, BMD Z-scores for lumbar spine and total hip, biochemical parameters of mineral and skeletal homeostasis, and iliac crest histopathology of the mother (after *in vivo* tetracycline labeling) all were normal. Mutation analysis revealed a unique heterozygous missense mutation in exon 23 (c.3904C>T, p.Leu1302Phe) of *SCN11A*. This variant was absent in the SNP database, and is evolutionarily conserved. Our report is the first autosomal dominant CIP confirmed by mutation analysis. We discovered in the family the second mutation in *SCN11A*. Joint hypermobility is a novel manifestation. How mutation of Nav1.9 leads to significant skeletal disease remains unexplained. Lack of awareness of injury is typically offered as an explanation for the fractures. Indeed, normal biochemical, radiological, and histological studies in this family fail to indicate intrinsic skeletal pathobiology. We, however, hold open the possibility for intrinsic skeletal disease with poor bone quality underlying the skeletal complications of CIP.

MO0392

Induced Pluripotent Stem Cell (iPSC) Derived Mesenchymal Stem Cells (MSCs) for Studying Pathogenic Bone Formation in Spondyloarthritis (SpA). Gerlinde Layh-Schmitt*¹, Shajia Lu², Stephen R. Brooks², Emily Lazowick³, Massimo Gadinà², Robert A. Colbert³. ¹National Institutes of Health, USA, ²Translational Immunology Section, Office of Science & Technology, NIAMS, NIH, USA, ³Pediatric Translational Research Branch, NIAMS, NIH, USA

Many genes and cell types contribute to the axial inflammation, trabecular bone loss, and aberrant bone formation that result in ankylosing spondylitis (AS). However, the functional consequences of genetic variants may be manifest in certain cell types that are not readily accessible. Therefore, we generated iPSCs by reprogramming fibroblasts from SpA patients and healthy controls (HC) and differentiated them into MSCs and osteoblasts (OB) with the goal of identifying disease-related differences. MSCs were generated from iPSCs using a TGFB inhibitor. Gene expression patterns and expression of AS risk genes were compared by RNA-Seq in iPSCs, MSCs and blood. Expression of selected genes involved in bone formation and inflammation was determined in MSCs after treatment with IFN γ (I), TNF α (T) or both (I&T) using Nanostring. Expression of osteogenic genes during OB differentiation was also measured by Nanostring, while mineralizing capacity was determined by Alizarin staining. iPSCs, MSCs and blood cells showed cell type-specific gene expression patterns. Many AS risk genes were robustly expressed in blood (e.g. HLA-B, ERAP1 and ERAP2) and MSCs (e.g. ANTXR2, EDIL3). Patient derived MSCs exhibited up to 10 fold higher expression levels of IL-1 α and IL-6 at baseline compared to HC. MSCs were treated with pro-inflammatory cytokines known to be involved in AS pathogenesis. After T or I&T treatments, IL-1 α was 10-16-fold higher, and IL-1 β and IL-6 5-10-fold higher in patient cells compared to HC. OBs from patients exhibited a 3-fold higher mineralization capacity than the HC and 10-20 times higher expression levels of alkaline phosphatase (ALP) during osteoblastogenesis.

In summary, we have differentiated SpA-patient-derived MSCs, and OBs from iPSCs. Notably, MSCs from patients expressed higher levels of IL-1, IL-6 and ALP mRNA at baseline and in response to T or I&T compared to HC. Patient OBs demonstrated greater mineralization capacity, correlating with higher levels of ALP. These experiments were conducted with two patient derived lines (one derived twice in two independent laboratories) and one healthy control (derived twice). We are presently generating more lines in order to determine if this effect is generalizable, and can be used to unravel the underlying mechanisms. Expression of certain AS risk genes predominantly in MSCs underscores the potential for iPSC-derived cells as a powerful system to examine functional consequences of predisposing genes in AS.

Inflammatory Cytokines are Potent Mediators of Ectopic Ossification Caused by a Novel Sca-1+CD73+ Cell Type in Tissue Engineered Skeletal Muscle. Owen Davies*¹, Mark Lewis¹, Liam Grover², Yang Liu¹. ¹Loughborough University, United Kingdom, ²University of Birmingham, United Kingdom

Heterotopic ossification (HO) is a debilitating condition defined by the de novo formation of bone within non-osseous soft tissues following trauma. Currently, the underlying mechanisms of pathogenesis remain elusive. However, identifying the role of cytokines up-regulated during the initial stages of trauma is likely to be important for HO prediction and the development of future therapies. Our study utilised a novel *in vitro* model of skeletal muscle to define the relationship between post-traumatic inflammation and ectopic ossification. A muscle model was developed by seeding C2C12 myoblasts within a type-I collagen gel. Uniaxial tension was produced by anchoring the gel at opposing ends of a well plate using polyethylene flotation bars. The model was cultured with high glucose DMEM and 20% FBS for 4 days, after which FBS was replaced with 2% horse serum to facilitate myoblast fusion along the axis of tension. After myotube formation the model was exposed to combinations of osteogenic factors and inflammatory cytokines previously identified following trauma. Cytokine combinations were established using Minitab design of experiment. Cells were released from constructs using 0.1% collagenase, and phenotypic reversion analysed using flow cytometry for stem/progenitor markers Sca-1, CD73, CD90 and CD105. Cells were plated at 10x10⁵ per cm² in growth medium, and ossification visualised using alizarin red staining. We identified a population of skeletal muscle cells that did not contribute to myogenesis, and showed that exposure of these cells to PDGF led to ectopic ossification. In fact, exposure to PDGF led to significantly (P<0.05) more mineral deposition than BMP-2. The presence of osteogenic inducers caused phenotypic reversion to a novel Sca-1+CD73+ cell type capable of ossification after just 24hrs. However, we present novel data showing that ectopic ossification was mediated in the presence of an inflammatory environment. In conclusion, our study identified the presence of a novel osteogenic/non-myogenic population of skeletal muscle cells. This cell type has never before been identified, and may have a pathological role in HO. Additionally, we identified that the local inflammatory environment may act to modulate the response of this particular cell population in

skeletal muscle in the presence of osteogenic inducers. This has highly important implications when considering the current use of non-steroidal anti-inflammatories in HO prophylaxis.

MO0394

Next Generation Sequencing for Hypophosphatasia and X-Linked Hypophosphatemia. Steven Mumm^{*1}, Margaret Huskey¹, Shenghui Duan¹, Valerie Wollberg², Karen E Mack², C. Charles Gu¹, Katherine L Madson², Gary Gottesman², Michael P Whyte². ¹Washington University School of Medicine, USA, ²Center for Metabolic Bone Disease & Molecular Research Shriners Hospitals for Children - St Louis, USA

Hypophosphatasia (HPP) and X-linked hypophosphatemia (XLH), heritable disorders that typically manifest as rickets, are caused by mutations in the tissue non-specific alkaline phosphatase (*TNSALP*) gene and phosphate-regulating gene with homologies to endopeptidases on the X chromosome (*PHEX*), respectively. Both diseases feature a wide range of severity, sometimes with considerable variation among affected family members. We are taking a next generation sequencing (NGS) approach to fully understand the variable expressivity of HPP and XLH encountered among our ~ 200 HPP and ~ 300 XLH patients. We have designed an NGS gene panel, using the Life Technologies Ion Torrent platform, to identify in these patients the primary defects in *TNSALP* and *PHEX*, but also secondary changes in a total of 13 potential modifier genes that regulate pyrophosphate and phosphate homeostasis. All coding exons plus the 5' and 3' UTRs of *TNSALP* and *PHEX* are included. To date, mutations in *TNSALP* were identified in all 5 probands sequenced; 3 were heterozygous for missense mutations, and 2 were compound heterozygous for missense defects. *PHEX* defects were identified in 26 of 52 XLH probands. Mutations (all heterozygous or hemizygous) included missense, nonsense, and

splice-site defects. For the XLH probands, including sporadic and familial cases, without identified *PHEX* mutations, further defects were not detected in *DMP1*, *FGF23*, or the multiple other genes involved in Mendelian hypophosphatemic rickets (e.g. *SLC34A3*). To identify modifier gene effects, we have studied 5 XLH sibling pairs with known *PHEX* mutations and variable clinical severity by looking at SNPs and rare variants in all 15 genes. One sibling pair harbors different heterozygous, non-synonymous, *DMP1* SNPs. Another pair is discordant for *SLC34A3* non-synonymous SNPs. A third sib pair is discordant for non-synonymous SNPs in both *DMP1* and *MEPE*. Thus, identification of modifier gene effects in HPP and XLH may help to explain their variation in disease severity and to guide treatment.

MO0395

Twist and Turns in Anthrax 1-Dependent Regulation of Bone Tissue Maintenance. Tatiana Besschetnova^{*1}, Negin Katebi². ¹Harvard School of dental Medicine, USA, ²HSDM, USA

The GAPO syndrome is a progressive condition with dramatically reduced quality of life and reduced life expectancy. The main manifestations of the syndrome include growth retardation, alopecia and failure of primary and permanent tooth eruption. In addition to excessive extracellular matrix accumulation in all organs and interstitial tissues, skeletal tissues are severely affected. Reduced bone density, osteolysis, and delayed osteoid maturation in long bones are other hallmarks of this painful and devastating disease. Recent genetic studies of GAPO patients identified loss of function causative mutations in the surface receptor Anthrax 1 (ANTXR1), also known as TEM8. Expression in different cell types and the existence of at least 5 different splice variants, both with and without transmembrane domains, suggest flexible regulatory functions in different tissues. However, little is known about the mechanisms of TEM8 functions. Our studies of Antxr1 knockout mice provide mechanistic explanations for skin and vascular abnormalities in GAPO syndrome and suggest that fibrotic skin abnormalities in the syndrome are, at least partly, the consequence of increased VEGF signaling. The Antxr1 null mouse phenocopies the human GAPO syndrome. A remarkable feature of the bone phenotype in GAPO patients and Antxr1 null mice is progressive postnatal bone loss. Tem8 is widely expressed both during embryonic development and postnatally, including strong expression in osteoblasts/osteocytes, osteoclasts and in blood vessels. The osteoclast number is dramatically increased in mutant mice. Furthermore, loss of TEM8 results in failure of osteoclast reversal and uncouples bone resorption from bone formation. The increased levels of non-collagenous components, osteocalcin, osteopontin and bone sialoprotein are contrasted with reduced bone mineralization. In addition, MMP2 activity, shown to be an important factor in osteoid mineralization, is reduced in mutants. TEM8-dependent reduction of MMP2 activity suggests that some phenotypic characteristics of GAPO may be the result of pathophysiological mechanisms similar to those underlying syndromes with Multicentric skin Nodulosis and Osteolysis and Arthropathy (MONA) caused by homozygous loss-of-function mutations in MMP2. The results of the work are providing understanding of cellular and molecular regulatory mechanisms of TEM8-dependent bone maintenance. Furthermore, the studies provide novel insights into the reversal phase of bone remodeling. Deeper understanding of this process will help to advance the development of strategies to treat rare (GAPO, MONA) and common (osteoporosis) diseases.

MO0396

Calciphylaxis In a Patient with Liver disease and Prior Gastric bypass: Case Report of an unusual combination. Goral Panchal^{*1}, Catherine Anastasopoulou². ¹Albert Einstein Medical Center, USA, ²Division of Endocrinology, Albert Einstein Medical Center, USA

Background: Calciphylaxis is a microvascular occlusion syndrome of mural calcification, intimal proliferation, fibrosis and thrombosis leading to target organ hypoperfusion. It is mostly known as an important manifestation of disordered calcium homeostasis in end stage renal disease (ESRD) patients. Calciphylaxis in non-ESRD patients is a case reportable phenomenon with only 36 cases described so far. Risk factors associated include hypoalbuminemia, corticosteroid use, neoplasms, anticoagulation, chemotherapy, systemic inflammation, protein C & S deficiency, alcoholic liver disease, obesity and rapid weight loss.

Clinical Case: 37 year old Caucasian female presented with worsening rash on both lower extremities, mainly thighs and buttocks. The lesions initially started as a small nodule about 2 months ago, which gradually progressed to large lesions on both lower limbs with uncontrolled pain and skin discoloration. Her past medical history included alcoholic hepatitis, morbid obesity with gastric bypass surgery in 2003 and chronic thrombocytopenia.

The patient was on spironolactone, rifaximin, furosemide, gabapentin, pantoprazole and multivitamin. On admission Ca 9.7 mg/dL(8.4-10.3), albumin 2.4 gm/dL(3.5-5), Corrected Ca 11.0 mg/dL, PO4 5.2 mg/dL(2.3-4.7), Mg 1.4 mg/dL(1.6-2.6), PTH 19.2 pg/ml(9-73), 25 OH Vit D 16.6 ng/ml, TSH 5.99 mIU/ml(0.35-4.94), Free T4 0.93 ng/dL(0.78-1.48), ALP 167 U/L(40-150), ALT 42 U/L(0-55), AST 129 U/L(5-34), Creat 0.7 mg/dL(0.6-1.0).

Punch biopsy of the lesions revealed calciphylaxis and thrombotic vasculopathy. She was started on Sevelamer, Vit D 1000 U/day and given 30 mg IV Pamidronate once. Repeat chemistries after 3 weeks showed Corrected Ca 9.64, PO4 3 mg/dL, Mg 2.0 mg/dL.

Conclusion: Our patient's risk factors for development of calciphylaxis were liver disease and prior gastric bypass surgery- of which only 2 prior cases have been reported. Some of the proposed mechanisms include osteochondrogenic differentiation of vascular cells in presence of cytokines and inflammation, failed anticalcific process due to loss of inhibitors like cMGP, pOPN, fetuin, pyrophosphate, and also apoptosis induced by altered phosphorus metabolism and remodeling of bone due to above mechanisms causing altered calcium homeostasis in presence of normal parathyroid function.

Purpose: As the exact mechanism of calciphylaxis in such patients have yet to be determined, presentation of these cases will help in future research.

MO0397

Dietary Protein Intake is Associated with Better Physical Function and Muscle Strength Among Elderly Women. Masoud Isanejad^{*1}, Arja Erkkilä², Joonas Sirola³, Jaakko Mursu⁴, Heikki Kröger³, Toni Rikkinen³, Marjo Tuppurainen⁵. ¹University of Eastern Finland, Finland, ²Institute of Public Health & Clinical Nutrition, Finland, ³Department of Orthopaedics & Traumatology, Kuopio University Hospital, Kuopio Finland, Finland, ⁴Institute of Public Health & Clinical Nutrition, University of Eastern Finland, Finland, ⁵Department of Obstetrics & Gynaecology, Kuopio University Hospital, Kuopio, Finland

Higher protein intake than RDA (0.8 g/kg/body weight (BW)) might be beneficial to physical performance in elderly. This study evaluated the association of protein intake (g/kg BW) with physical function in non-sarcopenic and sarcopenic elderly women. In total 554 women aged 65.3- 71.6 yr in the OSTPRE-FPS study, filled a questionnaire on lifestyle factors and 3-d food record in 2002. Body composition was measured by dual energy X-ray absorptiometry and physical function tests were performed at baseline and in a 3 yr follow-up. A sarcopenic woman were belonged to lowest quartile of relative skeletal muscle index (RSMI) (5.3-6.3 kg/m²) and the lowest quartile of either grip strength (9-22.3 kPa) or gait speed 10 m (<0.51 m/s) or lowest quartile of RSMI but not the lowest quartile of any other measurement. A non-sarcopenic woman did not belong to the lowest quartile of any measurement (RSMI, grip strength or gait speed 10 m) or lowest quartile of either grip strength or walking speed or both, but not to that of RSMI. At baseline the women with higher protein intake (comparing categories of = 0.8 vs. 0.81-1.19 vs. = 1.2 g/ kg BW) had better performance in one leg stance (P<0.001), chair rise (P=0.042), standing with eyes closed for 10 s (P=0.050) and squat (P=0.027) and squat to the ground tests (P<0.001). They had also faster gait speed 10 m (P<0.001) and greater short physical performance battery score (SPPB) (P<0.001) at the baseline (Table 1). Prospective results showed that higher protein intake was associated with less decline in one leg stance (P=0.007) and squat test (P=0.012) as well as increased chair rises (P=0.001) over 3 yr of follow-up. Aforementioned results were attenuated but remained significant after adjustment for confounders, including age, energy intake, smoking status, alcohol consumption (portions/week), reported physical activity (hours/ week), hormone therapy use, diagnosed osteoporosis, baseline height and lean mass.

However, after controlling for fat mass significances were lost. Further, in non-sarcopenic women the associations between high protein intake and physical performance tests were detected but in sarcopenic women only the grip strength and high protein intake was significantly associated ($\beta=0.06$ and $P=0.043$) (Table 2). In conclusion higher protein intake than current RDA was positively associated with physical function measures in elderly women (namely in non-sarcopenic women as compared to their sarcopenic counterparts).

Table 1. Association of protein intake categories (g/kg body weight) with physical function tests.

MO0398

Focal cortical thinning is associated with lower thigh muscle area in hip fractures and controls. Toni Rikkinen¹, Graham Treece², Fjola Johannesdottir³, Kenneth Poole³. ¹Department of Medicine, University of Cambridge, Finland, ²Engineering Division of the Department of Engineering, University of Cambridge, United Kingdom, ³Department of Medicine, United Kingdom

Low muscle strength and focal osteoporosis are known risk factors for hip fracture. However, associations between thigh muscle compartment size and proximal femur 3D bone mass distribution in hip fracture are less clear. SUBJECTS AND METHODS. A total of 84 CT scans consisting of age matched hip fractured patients (n=40) and non-hip fracture controls (n=43) were analyzed (Mean age 78 years, range 61-92). Fracture cases were age matched with patients undergoing routine CT. Age, height and weight were recorded. The thigh muscle compartment was determined just below lesser trochanter using 10 x 1mm slice mean tissue values. Muscle and fat tissue separation and areal bone density (BMD) analysis were done using QCT Pro (5.1.3). Proximal femur bone mass characteristics were measured with Stradwin 5.0 software. Significant associations between muscle cross sectional area and bone parameters, including cortical mass (CM) and endocortical trabecular density (ECTD), were color mapped using SurfStat Matlab toolbox. An independent-samples t-test was conducted to compare the groups. RESULTS. A lower thigh muscle cross-sectional area (cm²) was seen in fractures (Mean=91.7, Standard deviation=13.9) compared to controls (97.8, 12.7); t(81)=-2.1, p<0.05. Across all patients, higher thigh muscle area was

associated with more cortical mass in patches of bone known to associate with hip fracture (Picture). Fracture patients had lower body mass index (22.8, 4.4) than control (26.1, 4.9) group; t(81)=-3.21, p<0.01. A lower areal BMD (g/cm²) was seen in fractures (0.624, 0.162) versus controls (0.698, 0.10) in total hip; t(81)=-2.57, p=0.01 and in femoral neck ((0.539, 0.120) vs. (0.651, 0.81)), respectively; t(81)=-5.0, p<0.001. There was no difference in the amount of intramuscular fat between the groups. Adjusting muscle and fat areas for height², did not change the results. The association persisted after adjusting for age and volumetric bone size. CONCLUSION. Femoral cortical bone distribution is associated with thigh muscle cross-sectional area, in fracture critical zones. In addition, the muscle compartment size and bone mass are significantly lower in hip fracture patients. Smaller muscle area is a modifiable risk factor suggested to contribute towards weaker bone characteristics and hip fractures.

Percentage increase in cortical mass (CM)

Higher Amounts of Calf Inter- and Intra-muscular Adipose Tissue Determined by pQCT are Associated with Poorer Musculoskeletal Health in Older Adults. David Scott¹, Elizabeth Skinner², Ross Clark³, Pazit Levinger⁴, Terry Haines¹, Kerrie Sanders³, Peter Ebeling¹. ¹Monash University, Australia, ²Western Health, Australia, ³Australian Catholic University, Australia, ⁴Victoria University, Australia

Purpose: Age-related increases in inter- and intra-muscular adipose tissue (IMAT) occur concurrently with declines in skeletal muscle mass (sarcopenia). Peripheral quantitative computed tomography (pQCT) can quantify IMAT non-invasively with low radiation doses. We investigated associations of pQCT-determined calf IMAT with indicators of musculoskeletal health in community-dwelling older adults. Methods: 48 volunteers aged 65 years and older (mean 71.6±4.8 years; 52% female) underwent pQCT at 66% tibial length of the dominant leg to assess cortical volumetric bone mineral density (cBMD; mg/cm³), area (mm²), and thickness (mm), and calf muscle IMAT area (cm²). Whole-body DXA determined appendicular lean mass (ALM), and fasting serum samples for glucose, lipids, and wide-range C-reactive protein (wr-CRP), were obtained. Knee extension strength (KES; dominant leg), sit-to-stand (STS), timed up-and-go (TUG), postural sway (computerized posturography; N=41), and gait (GAITrite System; N=40) were assessed. Recurrent falls status in the past 12 months was self-reported. Results: Calf IMAT was negatively associated with high-density lipoprotein cholesterol, and positively associated with glucose and wr-CRP (all P<0.03), but only wr-CRP remained significantly associated with IMAT, after adjusting for age, sex and ALM normalised to BMI. Absolute IMAT levels were not associated with cortical bone parameters, but IMAT normalised to leg lean mass had a borderline negative association with cBMD (r=-0.29, P=0.06). Higher IMAT was not associated with KES (P>0.05), but was significantly associated with slower performance of the STS and TUG (both P<0.05), greater postural sway (anteroposterior amplitude r=0.55, P<0.01; mediolateral amplitude r=0.33, P=0.04), slower gait speed (r=-0.36, P=0.03) and cadence (r=-0.39, P=0.02), and greater step time (r=0.42, P=0.01) and width (r=0.37, P=0.02), after adjusting for confounders. There was a significantly higher likelihood of self-reported falls in the previous 12 months per unit increase in IMAT (OR 1.08, 95%CI 1.02-1.14). Conclusions: pQCT-determined calf IMAT is associated with poorer balance and mobility in community-dwelling older adults, independent of muscle mass, and this may contribute to an increased likelihood of recurrent falls. A trend towards poorer tibial cBMD in participants with high IMAT relative to muscle mass was observed, suggesting IMAT may also influence age-related declines in bone health.

HPLC-MS-MS 25OHvitaminD levels are associated with prognosis markers of Heart Failure. Federica Saponaro^{*1}, Claudio Passino², Alessandro Saba³, Riccardo Zucchi⁴, Elena Pardi⁵, Simona Borsari⁶, Filomena Cetani⁵, Claudio Marcocci⁵. ¹University of Pisa, Italy, ²Unit of Cardiology, Fondazione Toscana Gabriele Monasterio, Italy, ³ Unit of Biochemistry, University of Pisa, Italy, ⁴Unit of Biochemistry, University of Pisa, Italy, ⁵Unit of Endocrinology 2, Pisa, Italy, ⁶U.O. Endocrinology 2, Pisa, Italy

Introduction

Heart failure (HF) is a health problem with poor prognosis, despite many treatments available. Vitamin D is the prehormone of the active calcitriol (1,25(OH)₂D₃). It is involved in bone homeostasis, but recent studies suggest extraskeletal functions, including pleiotropic effects on cardiovascular system and a relationship between low levels of 25OHvitamin D and worse HF prognosis. The aim of this study was to detect 25OHvitaminD in HF patients and correlate with HF instrumental markers.

Materials and Methods

We performed a retrospective study on 70 consecutive HF patients (NHYA 1-3), collecting clinical, biochemical and instrumental data (echocardiography and cardiopulmonary exercise test – CPET). We retrieved stored blood samples collected at the baseline and developed a fast isotope dilution Mass Spectrometry coupled with Liquid Chromatography (HPLC-MS-MS) method for accurate measurement of 25OHvitaminD levels.

Results

Patients (13 females and 57 males) had stable HF disease (prevalent NYHA 2), with age of 65 ± 11 years, FE of 32 ± 8% and mild kidney failure (creatinine 1.3 ± 0.5 mg/dl). Levels of 25OHvitaminD ranged 2-45 ng/ml with mean of 17 ± 9 ng/ml: 23% (n=16) patients had vitamin D deficiency (<10ng/ml), 67% (n=47) had vitamin insufficiency (between 10 and 20 ng/ml) and 10% (n=7) had vitamin >30 ng/ml, without any supplementation. The linear regression analysis showed that 25OHvitaminD levels were positively correlated with CPET parameters VO₂ peak and VO₂/HR (p<0.01) and negatively mortality Meckel score (p<0.1).

Conclusion

Our study revealed a strong association between variables from CPET, a well recognized valuable tool for HF prognosis and 25OHvitaminD levels, detected with a new and accurate method HPLC-MS-MS.

Increased Body Weight and Sarcopenic Obesity: Causes of Intertrochanteric Fracture in Non-Osteoporotic Female Patients. Hyung Min Ji^{*1}, Jun Han², Dong San Jin³, Ye-Yeon Won¹. ¹Ajou University Hospital, South Korea, ²Naver Corporation, South Korea, ³Mary Orthopedic Hospital of Beijing, China

Purpose

The purpose of this study was to determine if there were any differences between women diagnosed with an intertrochanteric fracture who were categorized into a low BMD group (T-score ≤ -2.5) and a high BMD group (T-score > -2.5). Additionally, we examined the correlation between T-score and intermuscular adipose tissue (IMAT) in different thigh muscles.

Methods

This cross-sectional study identified 117 women with intertrochanteric fracture in whom both preoperative computed tomography (CT) scan of the pelvis and dual-energy x-ray absorptiometry (DEXA) were obtained. The patients were divided into high BMD (49 patients) and a low BMD (68 patients) groups. Attenuation of the gluteus maximus, abductor, quadriceps, and hamstring muscles were measured from CT scans of the hip and thigh cross-sectional area. The cross-sectional area of normalized IMAT of the muscles was also measured. All variables were compared between the two groups.

Results

Patients with a high BMD were significantly younger, taller, and heavier. IMAT of the quadriceps was significantly higher in these patients (Table 1). A moderate correlation was observed between T-score and weight and a weak correlation was detected between T-score and the IMAT ratio of the quadriceps. Body mass index (BMI) was moderately correlated with IMAT of all muscles (Table 1). T-score was moderately correlated with abductor and quadriceps IMAT ratios in 55–60 kg patients.

Conclusion

BMI and body weight were higher and IMAT of the quadriceps increased in non-osteoporotic women with a T-score > -2.5 who sustained an intertrochanteric fracture when compared with those of patients with osteoporosis. This result indicates that increases in body weight and sarcopenic obesity play a role generating fractures in this population.

Prevalence of Sarcopenia and Classification Agreement According to Different Operational Definitions. Andrea Trombetti^{*}, Mélany Hars, Emmanuel Biver, Thierry Chevalley, Serge Ferrari, René Rizzoli. Division of Bone Diseases, Geneva University Hospitals & Faculty of Medicine, Switzerland

Sarcopenia is a devastating feature of aging associated with extensive burden. However, consensus on an operational definition, combining or not muscle mass and function diagnostic criteria, has not been reached yet. Indeed, markedly different criteria and cutpoints for low muscle mass and function have been proposed, with potential different disease prevalence and outcomes. In a homogenous cohort of 68-year old community-dwellers, we applied different criteria and cutpoints to evaluate disease prevalence and classification agreement according to various operational diagnostic criteria, as proposed by the European Working Group on Sarcopenia in Older People (EWGSOP), the International Working Group on Sarcopenia (IWG), and the Foundation for the National Institutes of Health Sarcopenia Project (FNIH). Seven hundred sixty-seven subjects (608 women; age 67.9 ± 1.5 years), enrolled in the Geneva Retirees Cohort (GERICO), were studied. Appendicular lean mass (ALM), ALM/height² and ALM/BMI ratios were determined by DXA (Hologic Discovery W). Gait speed was measured over a 4-m distance and grip strength using a digital handheld dynamometer. Sarcopenia prevalence was estimated using EWGSOP, IWG and FNIH proposed criteria, and degree of agreement assessed using kappa statistics. Low lean mass prevalence ranged from 3.8% (FNIH) to 16.0% (EWGSOP). Weakness (i.e., low grip strength) prevalence ranged from 0.7% (FNIH) to 3.9% (EWGSOP). Prevalence of low lean mass combined with either weakness or low gait speed fulfilling various proposed sarcopenia definitions was the lowest for FNIH (0.3%) compared with IWG (1.2%) and EWGSOP (1.6%) criteria, with higher prevalence in women across all definitions. There was poor agreement between the groups identified according to the different definitions, with kappa values below 0.3. Our results obtained in a large cohort of healthy 68-year old subjects indicate that the prevalence of sarcopenia is low at that age independently of the definition. They also suggest that muscle weakness, slowness and low lean mass prevalence widely vary depending on the criteria and cutpoints applied. Similarly, sarcopenia prevalence considerably varies according to the definitions, with poor agreement between classifications. Further studies should compare the predictive ability of candidate sarcopenia criteria for hard outcomes, like incident falls, fractures, activities of daily living and quality of life.

MO0403

Prevalence of Sarcopenia and Sarcopenic Obesity in Germany using established definitions: Baseline data of the FORMOSA-study. Wolfgang Kemmler, Klaus Engelke^{*}, Simon von Stengel, Ellen Freiburger. University of Erlangen-Nuremberg, Germany

Purpose: The primary aim of the study was to determine the prevalence of Sarcopenia and Sarcopenic Obesity in community-dwelling (CD) older females in Germany. The secondary aim was to assess whether these females really live independently and autonomously.

Methods: 1325 CD females 70 years and older living in the area of Northern Bavaria, Germany were assessed. Sarcopenia as defined by (a) the European Working Group on Sarcopenia in older people (EWGSOP) and (b) the International working group on Sarcopenia (IWGS) were identified. In order to determine Sarcopenic Obesity additionally Obesity defined as (a) BMI ≥ 30 kg/m² (according to NIH) or (b) body-fat ≥ 35% (according to WHO) was determined. In participants with Sarcopenia, Barthel Index, care level, and social network were retrospectively evaluated via personal interview.

Results: Based on anthropometric data, family, education and social status, lifestyle, number and distribution of diseases and medication the present cohort can be considered as representative for the corresponding German population. Sarcopenia prevalence was 4.5% according to EWGSOP (Fig. 1) and 3.3% according to the IWGS criteria.

Obesity prevalence in our cohort averaged 19.8% (BMI ≥ 30 kg/m², NIH) and 63.8% (total body-fat ≥ 35%, WHO). The overlap between both factors (i.e. SO) range from 0% (EWGSOP+NIH criteria) to 2.3% (EWGSOP+WHO criteria). Factors that may represent limited autonomy or independence were very rarely identified in subjects with Sarcopenia.

Conclusion: The prevalence of Sarcopenic Obesity in the CD (female) German population 70 years and older is relatively low. With respect to our second research aim, the hypothesis that Sarcopenia and Sarcopenic Obesity was incompatible with independent life was rejected. However, the latter finding should be addressed with more dedicated study designs.

Hydroxytyrosol Relieves Age-related Bone Formation Reduction Through Reversing of Adipogenesis Towards Osteogenesis. [Fan Zhao](#)^{*1}, [Zhihao Chen](#)², [Peihong Su](#)², [Wuxia Qiu](#)², [Xiaoli Ma](#)², [Dijie Li](#)², [Airong Qian](#)².
¹Northwestern Polytechnical University, Peoples republic of china, ²Key Laboratory for Space Bioscience & Biotechnology, Institute of Special Environmental Biophysics, School of Life Sciences, Northwestern Polytechnical University, China

Mediterranean diets have been long reported in disease prevention. Hydroxytyrosol, a kind of polyphenol compound highly abundant in such diets, has significant biological effects on some age-related degenerative diseases like cardiovascular diseases and cancer. However, the effects of hydroxytyrosol on skeletal aging were less understood and required deep-going researches. In order to study the effects of hydroxytyrosol on age-related bone loss and bone formation reduction, and to investigate the biological mechanisms, we used two groups of 3-month old C57BL/6 male mice (Young groups, n=15, respectively) and two groups of 16-month old natural aged C57BL/6 male mice (Aged groups, n=17, respectively), and treated them with Hydroxytyrosol Acetate solution (50mg/kg) or distilled water respectively for consecutively 3 months by intragastric administration. Results showed that after gavage for 3 months, aged mice administered with Hydroxytyrosol Acetate solution showed higher femur BMD and improved trabecular microarchitecture as compared to same age untreated mice, while no significant effect was detected between treated and untreated young mice. Red oil O stained femur FFPE sections showed that in aged mice, less fat was deposited in Hydroxytyrosol Acetate treated group than that in untreated group. Moreover, protein carbonylation level, tissue oxidation/anti-oxidation level, senescence-related gene expression, and some microRNAs expression changed as well, suggesting its antioxidant and anti-senescence role during aging. *In vitro* culture of mouse BMSCs (B6-msc) under induction medium supplemented with Hydroxytyrosol Acetate showed that adipogenesis was inhibited while osteogenesis was promoted in regard to cell proliferation, differentiation, and PPAR γ 2, Adiponectin, FABP4, ALP, Osteocalcin, Runx2 gene expression. Taken together all results reached so far, we have successfully recorded an anti-aging effect of hydroxytyrosol during skeletal aging. Fat accumulation in bone tissue and *in vitro* osteogenesis/adipogenesis induction experiments indicated its role to reverse adipogenesis towards osteogenesis. The results suggest hydroxytyrosol as an effective precaution countermeasure for age-related osteoporosis and bone metabolic diseases.

Modification of Systemic SDF-1 Levels or CXCR4 Signaling Alters Bone Formation with Age. [Alexandra Aguilar](#)^{*1}, [Sudharsan Periyasamy-Thandavan](#)², [Samuel Herberg](#)³, [Brian Volkman](#)⁴, [Galina Kondrikova](#)², [Mark Hamrick](#)², [Carlos Isales](#)², [William Hil](#)².

The rapid increase in the ageing of the population creates new challenges to battle aging-related bone loss. In the United States, there are more than 40 million individuals with low bone mass, or frank osteoporosis. Mechanisms involved in aging-related bone loss and osteoporosis remain poorly understood, but are thought to be mediated, in large part, by the fate of bone marrow mesenchymal stem cells (BMSCs). We demonstrate that bone marrow cell expression, and microenvironmental levels, of SDF-1 change with age and alterations of its signaling pathway leads to bone loss. We hypothesize that with aged there is an increased of SDF-1/CXCL-12 in circulation and a decrease in bone marrow, causing changes in MSC survival, migration and bone formation. Osmotic minipumps with saline, human-SDF-1a, AMD3100 (SDF-1/CXCL12 receptor CXCR4 inhibitor, but a CXCR7 (ACKR3) agonist), 5uM or 100uM human-SDF-1a locked ligand dimers were implanted subcutaneously in three and twenty two month old C57BL/6 mice for 28 days. SDF-1a levels in plasma and bone marrow interstitial fluid were analyzed by ELISA. We performed transwell BMSC migration assays to assess the bioactivity of SDF-1 in BM interstitial fluid. Proximal tibia bone mass content (BMC) and density (BMD) was measured using mCT. Young mice treated with AMD3100 and SDF-1a significantly (p<0.0001) decreased proximal tibia BMC/D. Levels of SDF-1a in three-month-old mice interstitial fluid and bone marrow cells were comparable. In contrast, twenty two month old groups treated with SDF-1a significantly (p<0.001) increased SDF-1a in plasma. Both, AMD3100 and SDF-1a groups decreased SDF-1a levels in bone marrow interstitial fluid. Low dose (5uM) of human-SDF-1a dimer significantly (p<0.05) increased SDF-1a levels in bone marrow cells. Migration of bone marrow cells increased toward interstitial fluid of mice treated with systemic AMD3100 and SDF-1a suggesting increased SDF-1 bioactivity and mediation of bone formation by the alternative SDF-1 receptor CXCR7 (ACKR3). Proximal tibia BMC/D significantly (p<0.0052) increased with AMD3100, SDF-1a, 5uM and 100uM human-SDF-1a dimers. This suggests that MSC engraftment and survival may also be mediated by biased switching of the CXCR4 signaling pathway from G-coupled receptor signaling to b-Arrestin mediated signaling of CXCR4 and possibly CXCR7 (ACKR3). Our data suggest that SDF-1 has a distinct role of in MSC mediated bone homeostasis with age.

Sarcopenia is independently associated with knee pain. [Shigeyuki Muraki](#)^{*1}, [Toru Akune](#)², [Hiroyuki Oka](#)³, [Sakae Tanaka](#)⁴, [Hiroshi Kawaguchi](#)⁵, [Kozo Nakamura](#)², [Noriko Yoshimura](#)⁶.
¹22nd Century Medical & Research Center, University of Tokyo, Japan, ²National Rehabilitation Center for Persons with Disabilities, Japan, ³22nd Century Medical & Research Center, Faculty of Medicine, The University of Tokyo, Japan, ⁴Department of Orthopaedic Surgery, Faculty of Medicine, The University of Tokyo, Japan, ⁵Department of Orthopaedic Surgery, Japan Community Health care Organization Tokyo Shinjuku Medical Center, Japan, ⁶22nd Century Medical & Research Center, The University of Tokyo, Japan

To clarify the effect of sarcopenia in knee pain by using data from the large-scale population-based cohort ROAD study. Among the 2,566 subjects who participated in the third visit of the ROAD study, 2,152 subjects who underwent X-ray examination of the knee and measurement of muscle strength and mass were enrolled in the present study. Knee osteoarthritis (OA) was graded according to the Kellgren-Lawrence (KL) grade. Knee pain was assessed by well experienced orthopedists. Grip strength was measured on the right and left sides using a TOEI LIGHT handgrip dynamometer (TOEI LIGHT CO. LTD., Saitama, Japan). Isometric knee extension muscle was estimated by using a quadriceps training machine (QTM) (QTM-05F; Alcare Co., Ltd., Tokyo, Japan). Skeletal muscle mass was measured via bioimpedance analysis by using a body composition analyzer (MC-190; Tanita Corp., Tokyo, Japan). The QTM and MC-190 have been validated. Grip strength and quadriceps muscle strength were significantly different between subjects with and without pain in men (grip strength, 37.5 ± 9.5 kgf and 35.1 ± 9.0 kgf, respectively, p < 0.05; quadriceps muscle strength, 32.9 ± 12.5 kgf and 26.4 ± 12.0 kgf, respectively, p < 0.05) and women (grip strength, 24.1 ± 5.8 kgf and 22.5 ± 5.8 kgf, respectively, p < 0.05; quadriceps muscle strength, 27.2 ± 9.9 kgf and 23.2 ± 9.5 kgf, respectively, p < 0.05). After adjustment for age, sex, and BMI, the significant association with quadriceps muscle strength remained (p < 0.05), while that of grip strength disappeared (p = 0.31 and 0.10 in men and women, respectively). Muscle mass (kg)/height (m²) at the lower limbs was not significantly associated with knee pain (men: 2.95 ± 0.44 kg/m² and 3.03 ± 0.47 kg/m², respectively, p = 0.89; women: 2.41 ± 0.27 kg/m² and 2.45 ± 0.32 kg/m², respectively, p = 0.14). After adjustment for age, BMI, sex and KL grade, quadriceps muscle strength were significantly associated with knee pain (5 kgf increase; OR, 0.87; 95% CI, 0.82–0.92), indicating that the significant association of quadriceps muscle strength with knee pain is independent of obesity and knee OA. Next, to determine the prevalence of knee pain according to muscle strength, subjects were classified by quadriceps muscle strength (<10 kgf, =10 to <20 kgf, =20 to <30 kgf, =30 to <40 kgf, and =40 kgf). The prevalence of knee pain was 53.9%, 27.0%, 14.4%, 11.6%, and 9.8% in men and 41.0%, 31.0%, 23.7%, 16.3%, and 12.5% in women with muscle strength <10 kgf, =10 to <20 kgf, =20 to <30 kgf, =30 to <40 kgf, and =40 kgf, respectively. After the adjustment for age, BMI, and KL grade, the prevalence of knee pain was significantly higher in subjects with muscle strength < 10 kgf and =10 to <20 kgf (p<0.05) compared to those with muscle strength = 40 kgf. The present study revealed that muscle strength had a stronger association with knee pain than grip strength or muscle mass.

Hyperkyphosis and mortality risk in older men: the Osteoporotic Fractures in Men Study. Deborah Kado*¹, Mei-Hua Huang², Peggy Cawthon³, Kristine Ensrud⁴, Wendy Katzman⁵, Nancy Lane⁶, Diane Schneider⁷, John Schousboe⁸, Eric Orwoll⁹. ¹University of California, San Diego, USA, ²UCLA, USA, ³CPMC, USA, ⁴U. Minnesota, USA, ⁵UCSF, USA, ⁶UC Davis, USA, ⁷4BoneHealth, USA, ⁸Univ Minnesota, USA, ⁹OHSU, USA

Background: Hyperkyphosis (HK), or increased thoracic curvature, commonly affects older people and is associated with poor health. A few studies suggest that older persons with worse kyphosis are at risk of earlier mortality, but most have not accounted for underlying vertebral fractures that are also associated with shortened survival.

Methods: Using data from the Osteoporotic Fractures in Men Study, we evaluated the association between worse kyphosis (measured both clinically and via x-rays) and mortality risk. During the 1st clinic visit in 2000-2, 2,320 men aged ≥ 65 years (mean age 72.7) had supine lateral spine x-rays from which the Cobb angle of kyphosis was calculated from the superior edge of T4 and inferior edge of T12. During the 3rd clinic visit in 2007-09, 2,892 men had a clinical measure of kyphosis measured while lying on the DXA table, where 1.7 cm blocks were placed underneath the participant's neck until he achieved a neutral head position (range 0 to 10). For the Cobb angle analyses, average follow-up was 10.2 years (SD = 3.5) during which 931 died. For the blocks analyses, the average follow-up was 5 years (SD = 1.5) during which 607 died.

Results: The mean Cobb angle was 38.6° (SD = 11.4). In crude analyses, per SD increase in Cobb angle, there was an 8% risk of mortality that was no longer significant after adjustment for age and clinic (RH: 0.98; 95% CI: 0.92, 1.05). Using the top quartile or quintile of kyphosis to define HK did not change the results. For the clinical measure, in age and clinic adjusted models, men who required ≥ 2 blocks were 1.38 times more likely to die than men with 0-1 blocks (95% CI: 1.09 – 1.76). In a model adjusted for baseline prevalent vertebral fracture, hip BMD, BMI, weight, weight loss between the 1st & 3rd visit, smoking and history of stroke, the relative hazard was 1.44 (95% CI: 1.06 – 1.97). However, further adjustment for either timed chair stand (RH: 1.21, 95% CI: 0.93, 1.58) or self-reported physical activity (RH: 1.18, 95% CI: 0.90, 1.53) significantly diminished the effect of blocks kyphosis on mortality.

Conclusions: We found that a clinical assessment of kyphosis using the blocks method was associated with mortality risk while the radiologic measure of Cobb angle kyphosis was not once adjusted for age. In summary, our study confirms previous reports that a clinical measure of kyphosis is associated with mortality risk, yet this association is largely confounded by poor physical function.

Disclosures: Deborah Kado, None.

MO0408

Diffuse Idiopathic Skeletal Hyperostosis (DISH) as a Predictor of Kyphosis in the Osteoporotic Fractures in Men Study (MrOS). Wendy Katzman*¹, Neeta Parimi², Ziba Mansoori³, Lorenzo Nardo³, Deborah Kado⁴, Peggy Cawthon², Lynn Marshall⁵, John Schousboe⁶, Nancy Lane⁷. ¹University of California, San Francisco, USA, ²San Francisco Coordinating Center, USA, ³University of California, USA, ⁴University of California San Diego, USA, ⁵Oregon Health Science University, USA, ⁶University of Minnesota, USA, ⁷University of California Davis, USA

Background. DISH and thoracic kyphosis are well-defined radiographic findings in the spines of older individuals. Characteristics of DISH (ossifications between vertebral segments) reflect changes in spine anatomy and physiology that have previously been associated with Cobb angle of kyphosis. Since the prevalence of these two disorders is high in older adults and can lead to physical disabilities, this study examined the association of DISH with prevalent and worsening kyphosis in older men. **Methods.** 1500 subjects from the MrOS cohort of community-dwelling, ambulatory men aged ≥ 65 years, mean age 72 (5.5 SD), with Cobb angle measurements of kyphosis obtained at year 1 and 4.7 years, measured from supine lateral spine radiographs, were selected for the study. DISH was assessed in the baseline radiographs using the Resnick criteria requiring the presence of ossification of the anterior longitudinal ligament of at least 4 contiguous vertebral bodies (3 intervertebral disc levels) and the absence of severe degenerative disc disease in the involved vertebral segment(s). Characteristics of participants with and without DISH were assessed using chi-square and t tests. Linear regression was used to analyze the association between prevalent DISH and Cobb angle at baseline and percent annualized change in Cobb angle. **Results.** DISH was identified on baseline radiographs in 222 (15%) participants. Participants with DISH were older, had higher BMI and total hip BMD, and higher baseline Cobb angle compared to those without DISH ($p < 0.05$). DISH was not associated with morphometric prevalent vertebral fractures, history of gout or diabetes ($p > 0.1$). The mean baseline Cobb angle in the analytic sample was 38.5 degrees (SD=11.3). There was a 7.9% greater baseline Cobb angle (95% CI: 3.7-12.2) in those with DISH compared to those with no DISH adjusted for age, race, clinic site, and BMI. Further adjustment for total hip BMD and prevalent vertebral fractures slightly strengthened the association (9%, 95%CI: 4.4-13.0). The percent change in Cobb angle from baseline to 4.7 years later was 3.2% with DISH and 4.8% without DISH ($p = 0.2$). There was no association of annualized percent change in Cobb angle with prevalent DISH in age-adjusted models. **Conclusions.** Greater Cobb angle of kyphosis is associated with DISH, and the presence of DISH did not worsen the kyphosis over this 4.7-year interval in older men.

Disclosures: Wendy Katzman, None.

Sedentary Behaviour, Sitting and Mortality in the Canadian Multicentre Osteoporosis Study (CaMOS)—cross-sectional and 10-year prospective data. Jerilynn Prior*¹, Adrian Bauman², Ding Ding², Sarah Pont², Claudie Berger³, Heather Macdonald⁴, Jonathan D. Adachi⁵, Wilma M. Hopman⁶, Stephanie M. Kaiser⁷, Christopher S. Kovacs⁸, K. Shawn Davison⁹, Lisa Langsetmo³, David Goltzman¹⁰, CaMOS Research Group¹¹. ¹University of British Columbia, Canada, ²University of Sydney, Epidemiology, Australia, ³CaMOS Methods Centre, Canada, ⁴Orthopedics, University of British Columbia, Canada, ⁵Rheumatology, McMaster University, Canada, ⁶Queens University, Canada, ⁷Endocrinology, Dalhousie University, Canada, ⁸Endocrinology, Memorial University, Canada, ⁹University of Victoria, Canada, ¹⁰Medicine/Endocrinology, McGill University, Canada, ¹¹McGill University, Canada

Prolonged sitting during leisure and work may relate to increased risks for cardiovascular diseases and osteoporosis. This sedentary behaviour, despite moderate-to-high physical activity, is also postulated to cause an increase in mortality. Since baseline, CaMOS has collected detailed sitting data. To date there are no published prospective data on multivariate adjusted changes in sitting over time. Thus, we aimed to describe baseline and longitudinal (baseline to 10 year) sitting behaviour, its predictors and adjusted mortality risks. We used multivariate logistic regression for this preliminary analysis; all-cause mortality was the primary outcome. We adjusted for baseline age (continuous), and categorical data on sex, current smoking, BMI, education, employment, living with an adult, general self-rated health, physical activity and sleep. Low sitting (< 7 hrs/day) and high sitting (≥ 7 hrs/day) were categories used for descriptive outputs. Odds ratios (OR) and their 95% confidence intervals (95%CI) were calculated. The CaMOS sitting analysis cohort included 5,406 women and men with 10-year data (Figure). Those analyzed vs excluded did not differ in categorical sitting ($P = 0.639$). At baseline, women versus (vs) men and those who were part-time/retired vs fulltime were less likely to be high sitters after adjustment for age, BMI, education, and physical activity. Those with a university education vs only high school, those with low vs high physical activity and who were obese vs normal weight were more likely to be high sitters. In 10-year follow-up, those who changed from obese to non-obese (vs always non-obese) or whose physical activity went from low to high still remained higher sitters. But those who changed from full-time to retired became less likely to be high sitters. Mortality considered exposures to total sitting as well as sitting related to work, transit/car, eating and TV-watching. Work-related sitting of 5-6 hrs/day was associated with a decreased mortality, OR 0.51 (0.27 to 0.95), but TV watching of > 10 hours/day related to markedly increased, OR 5.81 (1.96 to 17.26), mortality. Prolonged total sitting of 12-13.5 hrs/day related to increased mortality risk, OR 1.96 (1.30 to 2.95). In summary, these population-based prospective, preliminary Canadian data suggest that normal work-related sitting is not a risk but that prolonged hours of TV-related or total sitting are independently associated with risks for higher adjusted mortality.

Partial Tail Amputation in Zebrafish: A Model of Chondral Bone Regeneration? Yael Govezensky*, Dalia David, Dafna Ben-Yosef, Chen Shochat, David Karasik. Faculty of Medicine in the Galilee, Bar Ilan University, Israel

Purpose: The aim of this research was to develop an *in vivo* platform for conveniently examining the potential of various factors to augment chondral bone regeneration. For this purpose, we have established a *de novo* partial tail amputation model in adult zebrafish, which includes the resection of cartilage-temple based bones from the endoskeletal caudal complex. Endoskeletal amputations were rarely studied, as opposed to those of the distal caudal fin rays, which are a well-established regenerative model of membranous bone regeneration.

Methods: Dorsal (D) hemi-amputations were performed with a sterile scalpel from the proximal 2–3mm of the tail that has scales and musculature, and proceeded distally towards the fin rays (Fig.1). In order to observe regenerative properties, fish skeletons were vitally labeled with two Ca^{2+} -binding chromophores: calcein, and 20 days later, alizarin red s. In order to overcome the potential artifacts of autofluorescence, and the spectral overlap between both chromophores, we employed spectral imaging coupled with image analysis using the linear unmixing algorithm.

Results: After the caudal complex' partial amputation fish were vital, and normal activities such as eating and swimming were not compromised. The labeling method, which was validated in the distal caudal fin model, exhibited newly formed bone (Fig. 2), mainly some broadening at the tip of the stump in neural spines (A), but hypurals (B) did not regenerate. Interestingly, unamputated ventral hypurals (C) showed signs of active bone remodeling, which most probably can be attributed to increased muscle activity. None of the caudal complex bones regrew to form a structure similar to the original one, even 7 months post amputation.

Conclusions: We have acquired the ability to distinguish newly formed and pre-existing bone in our new model. We suggest that neural spines undergo a progressive widening at the tip of the stump, which resembles hypertrophic nonunion fracture in humans. However, hypurals do not seem to regenerate. Thus, our model is appropriate for the investigation of potential therapeutic factors for augmenting chondral bone regeneration, either for the induction of *de-novo* regeneration or for examination of treatments for abnormal regrowth: both of major importance in several clinical conditions and aspects of regenerative medicine.

A network connecting KAT6A and the miR-665 regulates the odontoblast differentiation program. Mohammad Hassan*. University of Alabama, USA

Dentinogenesis is the process by which dentin, the major mineralized tissue of teeth, is formed through progressive cytodifferentiation of progenitor cells to mature odontoblasts. Multiple layers of gene regulation, including those by microRNA (miRNA or miR), orchestrate the physiologic process of dentinogenesis in a stage-specific manner. Studies of proteins involved in microRNA (miRNA) processing, maturation, and silencing have indicated the importance of miRNAs in skeletogenesis, but the specific miRNAs involved in this process are incompletely defined. Here, we identified miRNA-665 (miR-665) as a potential repressor of odontoblast maturation. Studies with cultured cell lines and primary embryonic cells showed that miR-665 represses the expression of early and late odontoblast marker genes and stage-specific proteases involved in dentin maturation. K (lysine) acetyltransferase 6a (KAT6A) is a founding member of the MYST family of lysine acetyltransferases, acetylates lysine

residues on histones H2B, H3, and H4. Kat6a deletion is embryonic lethal and haploinsufficiency for Kat6a demonstrated craniofacial abnormalities. RISC-complex-immunoprecipitation studies identified Kat6a as a potential target of miR-665. Notably, miR-665 directly targeted Kat6a mRNA, repressed Kat6a translation and increased mRNA degradation. The expression of miR-665 is temporal and reciprocal to KAT6A and RUNX2 during in vitro odontoblast differentiation. KAT6A interacted physically and functionally with RUNX2, activating tissue-specific promoter activity and prompting odontoblast differentiation. MiR-665 prevents KAT6A-induced chromatin remodeling, and promotes the switch from acetylation to methylation of histone H3K9 in the tooth-specific Dsp and Dmp1 promoters. By reducing KAT6A expression, miR-665 hinders the formation of activating complexes to promote epigenetic activation of Dsp and Dmp1 chromatin, impairing odontoblast differentiation. Overall, the linkage of miR-665 to epigenetic factor KAT6A, and transcription factor RUNX2, all of which regulate tooth biology supports the developing concept that miRNAs link genetic and epigenetic events that are requisite for maintaining a normal tissue environment. The involvement of miR-665 at multiple levels of odontoblast differentiation suggests diverse functions for miR-665 that include physiologic tooth formation and homeostasis, and may inform the design of therapeutics for dental disorders.

miR-665 mediated epigenetic mechanism

Correlation between the Mineral Compositions and Bone Strength of Tibia bone in poultry. Tengfei Dou¹, Lixian Liu¹, Hua Rong¹, Qihua Li¹, Dahai Gu¹, Zhiqiang Xu¹, Limei Huang¹, Ying Huang², Sumei Zhao¹, Hongyong Zhang³, Marinus F.W.te Pas⁴, Changrong Ge^{*5}, Junjing Jia¹. ¹Yunnan Provincial Key Laboratory of Animal Nutrition & Feed Technology, Yunnan Agricultural University, China, ²Yunnan Provincial Key Laboratory of Animal Nutrition & Feed Technology, China, ³Department of Medicine, University of California at Davis Medical Center Sacramento, USA, ⁴Animal Breeding & Genetics Centre, Wageningen UR Livestock Science, Netherlands, ⁵Yunnan Agricultural University, China, Cn

The bone growth and development are most important factors affecting on the broilers and layer production in poultry. Indigenous Chinese chicken breeds comprise a wide variety of phenotypes, including large and small, and fast and slow growing chicken. Compare with commercial broilers, Wuding chicken breed is a slow growing large chicken breed with 2.5 kg of average body weight in 4 months old and the Daweishan mini chicken breed is a slow growing small chicken breed with 0.8-1.0 kg of average body weight in 4 months old. We had demonstrated that the Daweishan mini chicken showed higher bone strength compared with other local breeds and broilers. It has been hypothesized that the breed and age might affecting on the bone mineral composition and association with bone strength. The objective of this study was to investigate the effects of breed and age on the bone mineral compositions (BMC), and BMC association with bone strength in poultry.

A total of 180 1-day-old chicks from Daweishan mini chicken, Wuding chicken and Avian broilers were fed in an environmentally controlled room to 12 weeks. All chickens from 1-21 days were fed a starter diet, older chicken received a full diet. The chickens had free access to feed and water. Twenty chickens from each group were sacrificed at 4, 8 and 12 weeks to measure tibia minerals composition using Inductively Coupled Plasma - Mass Spectrometry. A 3-point bending test was used to determine the mechanical properties of the left tibia bone in each time point. Results: Daweishan Mini chicken had significantly higher tibia bone strength parameters which are including modulus of elasticity, yield stress and bending stress ($P < 0.01$), and tibia bone strontium content at three time points ($P < 0.01$), and higher magnesium and copper contents ($P < 0.05$) from 8-12 weeks and lower phosphorus, potassium and sodium contents ($P < 0.05$) while converse case were observed for the broilers in all time points. No breed and age effect on the other mineral contents were observed in three time points ($P > 0.05$). The contents of strontium, magnesium and copper in tibia bone were positive correlation with bone strength ($P < 0.01$). In contrast, the contents of phosphorus, potassium and sodium in tibia bone were negative correlation with tibia bone strength ($P < 0.01$).

In conclusion, we found that slow growing small chicken breed had higher bone strength and association with higher tibia bone strontium, magnesium and copper content compare with other two breeds. Our results implicated that supplement appropriate strontium in diet may improve the bone strength and health in broiler and layer.

Deletion of the Prolyl Hydroxylase Domain-containing Protein 2 (Phd2) Gene in Chondrocytes but not Osteoblasts Promotes Secondary Ossification at the Epiphysis. Shaohong Cheng^{*1}, Chandrasekhar Kesavan², Sheila Pourteymoor³, Catrina Alarcon³, Subburaman Mohan³. ¹VA Loma Linda Health Care Systems, USA, ²Jerry L Pettis VA Medical Center, USA, ³Pourteymoor, USA

Hypoxia has been shown to induce survival and differentiation of chondrocytes via modulation of the hypoxia-inducible factor (HIF) signaling pathway. HIF signaling in osteoblasts has also been established to play an important role in bone formation. The hypoxia effect on HIF1a signaling is mainly mediated via a direct oxygen sensor, prolyl hydroxylase domain (Phd) enzyme, Phd2. We, therefore, evaluated the role of Phd2 expressed in chondrocytes and osteoblasts on secondary ossification of the epiphysis. The Phd2 gene was conditionally disrupted in osteoblasts or chondrocytes by two generations of breeding of Phd2 floxed mice crossed with Col1a2-Cre or Col2a1-Cre mice. The amount of bone in the proximal tibial epiphysis was quantitated by micro-CT analyses. There was no significant difference in trabecular BV/TV (98.4% of control mice) or any other trabecular parameter comparing osteoblast-specific Phd2 conditional knockout (cKO) and littermate control mice at 5 wks of age. By contrast, chondrocyte-specific disruption of the Phd2 gene caused a 20% ($P = 0.01$) increase in trabecular bone mass as a consequence of the increase in trabecular number (8%, $P < 0.05$) and reduction in trabecular separation (12%, $P < 0.05$). To determine the mechanism for increased bone formation, we measured expression levels of genes involved in osteoblast and chondrocyte differentiation using total RNA extracted from the proximal tibial epiphysis. As expected, Phd2 expression was decreased by 44% ($P < 0.05$) while expression levels of HIF1a target genes, VEGF (59%, $P < 0.05$) and EPO (141%, $P < 0.05$) were increased in the cKO mice compared to control mice. Expression levels of osterix but not ATF4 was significantly increased in the cKO epiphysis. Of the chondrocyte markers, expression level of Col10 was increased by 245% while Col2 was unaffected in the cKO mice. The expression levels of osteoblast specific markers, BSP and ALP were increased by 95% and 80% respectively (both $P < 0.05$) in the cKO tibial epiphyses. Conclusions: 1) Phd2 expressed in chondrocytes inhibits osteoblast formation and secondary ossification at the epiphysis via regulation of HIF1 signaling; 2) the role of Phd2 in chondrocytes and osteoblasts is different.

MO0414

Identifying growth factors for improving the healing of the tendon-bone interface. David Musson^{*1}, Mei Lin Tay², Karen Callon², Dorit Naoit², Jillian Cornish². ¹University of Auckland, New Zealand, New Zealand, ²University of Auckland, New Zealand

Purpose

Injuries to tendon-bone interfaces are a significant clinical problem occurring in otherwise healthy, active people. Primarily caused by overuse or trauma, these injuries significantly affect patient quality of life and are a substantial financial burden to the healthcare economy. While there are currently no clinically accepted biological treatments for improving healing of these soft-hard tissue interfaces, much research has attempted to identify growth factors capable of aiding this challenging process.

In this study, a number of factors (IGF-1, lactoferrin, PTH, TGF- β) that are known to be important in bone biology have been evaluated for their ability to be anabolic to tendon. We compare these factors to those that are important in tendon repair, such as PDGF.

Methods

Primary tenocytes harvested from rat tails or human bicep tendons were treated with a range of factors for 48 hours. Cell growth was determined using alamarBlue[®] assays and collagen deposition was measured by Sirius red dye release. Gene expression analysis using real-time PCR was used to study tenocyte differentiation.

Results

IGF-1 significantly increased tenocyte cell numbers ($< 30\%$, $p < 0.05$), while both IGF-1 and TGF- β increased collagen production *in vitro* ($p < 0.05$). IGF-1 increased the expression of tenascin-C and tenomodulin genes (both $p < 0.05$), both important factors in the early response to tendon healing. TGF- β meanwhile, increased the expression of tenomodulin and tenascin-C ($p < 0.05$) as well as scleraxis ($p < 0.05$), a transcription factor important in tendon development. Both lactoferrin and PTH slightly decreased tenocyte number ($\sim 10\%$, $p < 0.05$) and collagen production, but increased the expression of IGF-1 (lactoferrin ~ 2.5 -fold and PTH ~ 10 -fold). Interestingly, while PDGF greatly increased tenocyte cell number and collagen

production, it significantly decreased the expression of a number of genes important in tendon cell biology, such as decorin, biglycan, scleraxis and tenomodulin (all $p < 0.05$).

Conclusions

Here we have shown that both IGF-1 and TGF- β have the potential to improve healing outcomes of the tendon-bone interface, due to their role in bone biology and their anabolic effects on tendon cells, while it appears that lactoferrin and PTH hold less promise in this regard. Interestingly, it appears that although PDGF is much studied in tendon healing, it may actually result in a de-differentiation away from the tenocytic lineage.

Inactivation of the progesterone receptor in Mx1+ cells potentiates osteogenesis in vitro but not in vivo. Zhendong Zhong¹, Weihua Sun², Haiyan Chen¹, Hongliang Zhang², Nancy Lane², Wei Yao³. ¹University of California Davis Medical Center, USA, ²University of California Davis Medical Center, USA, ³University of California, Davis Medical Center, USA

Sex hormones are intricately involved in the regulation of bone turnover. The effect of progesterone on bone remains elusive. Global progesterone receptor (PR) knockout mice display high bone mass phenotype suggesting that PR influences bone growth and modeling. Recently, Mx1+ cells were reported to differentiate into osteoblastic lineages. The aim of this study was to evaluate whether the PR in Mx1+ cells regulates osteogenesis. Methods We first evaluated the specificity and induction efficacy of Mx1-Cre by crossing it with the mT/mG reporter mouse strain and characterizing the Cre activity by GFP expression in bone tissue and in primary osteoblast cultures. Next, Mx1-Cre was crossed with PR-flox to generate an inducible PR knockout mouse model. Calvarial cells and calvariae from the Mx1-Cre;PR-flox pups were treated with interferon alpha (IFN α) to activate the Cre expression and delete the PR gene in the Mx1+ cells, and the osteogenic potential was then evaluated. The in-vivo skeletal phenotype of Mx1-Cre;PR-flox mice was evaluated. Results Using the Mx1-Cre;mT/mG reporter mouse model, we found that the calvarial cells exhibited minimal background Mx1-Cre activity prior to Cre activation compared with the bone marrow stromal cells. IFN α treatment significantly activated Mx1-Cre in the calvarial cells. After the PR gene was deleted in the Mx1-Cre;PR-flox calvarial cells in vitro, significantly higher levels of expression of osteoblast maturation marker genes and osteogenic potential were detected. The PR-deficient calvariae also exhibited greater RUNX2 protein expression. Although Mx1-Cre activity could be induced on the bone surface in vivo, the Mx1+ cells did not differentiate into osteocytes in long bones. Bone volumes at the distal femurs and the bone turnover marker serum Osteocalcin were similar between the Mx1-Cre;PR-flox mutant mice and the corresponding wild types. Conclusions Blocking progesterone signaling via PRs in calvarial Mx1+ cells promoted osteoblast differentiation in vitro. Mx1+ progenitor cells did not contribute to osteocyte differentiations during long bone development in vivo. Selectively inactivating the PR gene in Mx1+ cells did not affect peripheral skeletal homeostasis.

Low Dose IGF-I Augments the Bone-Lengthening Effect of Targeted Heat in the Mouse Hindlimb. Maria Serrat^{*}, Gabriela Ion, Kaitlynn Hughes. Marshall University School of Medicine, USA

Introduction: Linear growth deficiencies can result from injury, illness or genetic disease. These conditions can lead to limb length inequality and chronic disability. Delivering therapeutics to avascular growth plates is challenging, and treatments are often limited to invasive surgeries that are only partially effective. We previously developed a unilateral heating model to increase extremity length in mice using targeted heat exposure on one side of the body. We demonstrated that femora were significantly longer and tibial elongation rate was >12% greater on the heat-treated side. The purpose of this study was to combine heat with the growth-stimulating drug IGF-I. We tested the hypothesis that low dose IGF-I augments the bone-lengthening effect of intermittent heat application on hindlimbs of growing mice.

Methods: 3-week old female C57BL/6 mice (N=6) were injected each morning with IGF-I (2.5mg/kg SQ) and treated with 40C unilateral heat for 40 minutes/day for 14 days. Non-injected, heat-treated mice from our prior study (N=14) served as controls for the temperature effect. Body mass and tail length were recorded. Mice were given oxytetracycline (7.5 mg/kg IP) to quantify growth rate. Bones were measured at the 5-week endpoint.

Results: Tibial elongation rate was ~19% greater on the heat-treated side (40C) of IGF-I injected mice compared to their non-treated contralateral side (30C) (Fig. 1). The growth acceleration averaged 18.5 μ m/day (paired $t = 4.89$, $p = 0.003$), 23% faster than mice that received heat alone (15 μ m/day). Femoral length increased over 1.7% ($t = 7.97$, $p < 0.001$). When compared to heat-treated controls (1.3% increase in femoral length), there was a significant heat by drug interaction (ANOVA, $F = 3.06$, $p = 0.05$), indicating that heat had greater lengthening effects when combined with IGF-I. Controlling for variation in starting mass and tail length, IGF-I mice were not significantly larger than controls ($F = 2.63$, $p = 0.123$), but they had longer tails ($F = 16.84$, $p < 0.001$), suggesting that IGF-I increased extremity size without affecting

overall body mass. **Conclusion:** These data support the hypothesis that low dose IGF-I enhances the bone-lengthening effects of heat in growing mice. This research has practical relevance for treating a spectrum of linear growth disorders in children. Results could lead to new, noninvasive approaches with better outcomes by reducing costs and side effects of surgeries and high-dose pharmaceuticals.

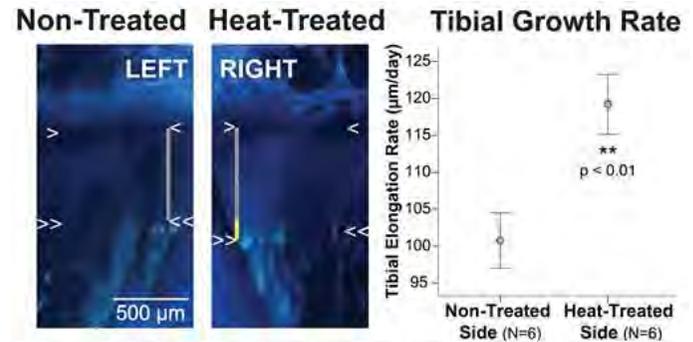

Figure 1. Left-right tibial slab sections from the same mouse labeled with oxytetracycline (OTC) show increased lengthening on the heat-treated side. The metaphyseal chondro-osseous junction is indicated by single arrowheads. Double arrowheads show OTC band in metaphyseal bone. Growth rate was measured as the vertical distance between the arrowheads (gray lines). Yellow segment of vertical line on the heat-treated side shows total difference in length measured over 7-days. Error bar plot (right) illustrates that growth rate was nearly 19% greater on the heat-treated side (18.5 μ m/day). Mean \pm 1 SE.

Motor Ability in Early Childhood is Positively Associated with Bone Strength in Late Adolescence. Alex Ireland¹, Adrian Sayers², Kevin Deere², Alan Emond³, Jon Tobias^{1,2}. ¹Manchester Metropolitan University, United Kingdom, ²School of Clinical Sciences, University of Bristol, United Kingdom, ³School of Social & Community Medicine, University of Bristol, United Kingdom

Early life motor milestones (standing, walking, etc.) represent the first exposure of the skeleton to large reaction and muscular forces associated with locomotion. Recent work has shown a strong link between walking onset age and early childhood bone strength. However, it is unknown whether these relationships continue into later life. Therefore data from 2,327 children enrolled in the Avon Longitudinal Study of Children and Adolescents (ALSPAC) was examined. Early life motor ability was measured using Gross Motor Score (GMS) assessed by questionnaire at 18 months, and by the ALSPAC Coordination Test (ACT) conducted in a clinic visit at 7 years. Bone outcomes at 17 years were total hip bone mineral density (BMD) and hip cross-sectional moment of inertia (CSMI) assessed by dual-energy X-ray absorptiometry (DXA) and tibial periosteal circumference (PC), cortical thickness (CT), cortical bone area (CBA), cortical BMD (BMD_C) and CSMI assessed by peripheral quantitative computed tomography (pQCT) at 66% distal-proximal tibia length. When adjusted for sex, maternal social class and age at outcome and exposure GMS and ACT were positively associated with hip BMD [0.086(0.067,0.105) and 0.089(0.07,0.108)], hip CSMI [0.072(0.057,0.087) and 0.074(0.059,0.089)], PC [0.089(0.074,0.104) and 0.083(0.068,0.098)], CT [0.089(0.07,0.108) and 0.061(0.042,0.08)], CBA [0.097(0.081,0.113) and 0.083(0.067,0.099)] and CSMI [0.084(0.069,0.099) and 0.09(0.075,0.105)] (all $P < 0.001$) but not BMD_C ($P > 0.2$). Adjustment for perinatal factors (gestational age and birthweight) did not substantially attenuate regression coefficients. Adjustment for adolescent body size (height, lean mass and fat mass) resulted in 18-75% decrease in coefficients suggesting a mediating pathway. There was evidence of gender interaction for all variables such that associations with motor score were greater in males e.g. total hip BMD and PC regression coefficients for ACT and GMS were twice as large in males. In conclusion, early childhood motor ability is positively associated with skeletal development in late adolescence, most markedly in males. This results from greater periosteal expansion and reduced endosteal expansion, leading to greater cortical area and predicted bone strength. Body size and composition (particularly lean mass) appear to partly mediate these relationships and may reflect differences in physical activity.

Physiological oxygen tension modulates the profiles of soluble growth factors in chondrocytes after co-culture with osteoblasts. Tao Zhang^{*}, Jing Xie. West China School of Stomatology; State Key Laboratory of Oral Disease, China

Objective: Physiological oxygen tension plays a critical role in the homeostatic maintenance and development of endochondral bone. Based on the adjacent location

between uncalcified cartilage and subchondral bone and the microchannels served as message delivery between them, we aim to explore the influence of low oxygen tension on the soluble factor secretion in both chondrocytes and osteoblasts after co-culture. **Material and methods:** Non-contact co-culture was achieved by transwell chamber; Semi-quantitative polymerase chain reaction was used to screen the gene variation of growth factor profile of chondrocytes and osteoblasts including HIF-1 α , IGF-1, TGF- β ₁, FGF-1, FGF-2, EGF, VEGF-A/B, VE-cadherin, BMP-2/-4/-5/-6/-7 and the respective phenotype markers of these two cells. **Results:** Hypoxia regulates the marker genes in both chondrocytes and osteoblasts in the co-culture system. The physiological oxygen tension activates its sensitive transcription factor HIF-1 α and up-regulates angiogenesis-related growth factors including VEGF-A, VEGF-B and VE-cadherin. Additionally, BMP family is also modulated by oxygen tension after co-culture. **Conclusions:** These results not only indicate the importance of crosstalk between chondrocytes and osteoblasts, but also reveal the change of soluble growth factors modulated by physiological oxygen tension in this crosstalk. The changes of these factors can help to increase understanding of the mechanism underlying homeostatic maintenance of endochondral bone.

Raf Kinases regulate growth plate maturation. Garyfallia Papaioannou*¹, Eva Liu², Adalbert Raimann³, Byongsoo Timothy Chae⁴, Marie Demay¹.

¹Massachusetts General Hospital & Harvard Medical School, USA, ²Brigham & Women's Hospital, Massachusetts General Hospital & Harvard Medical School, USA, ³Medical University Vienna & Massachusetts General Hospital, Austria, ⁴Massachusetts General Hospital, USA

During endochondral ossification chondrocytes form an organized structure which, following vascular invasion, is progressively replaced by bone. The growth plate is comprised of three zones, resting, proliferating and hypertrophic chondrocytes which undergo coordinated proliferation, differentiation and apoptosis. MAPKs play a significant role in growth plate maturation. The Raf kinases A-Raf, B-Raf and C-Raf activate MEK1/2 that activates Erk1/2. A- and B-Raf are mainly expressed in proliferative chondrocytes whereas C-Raf is predominantly expressed in hypertrophic chondrocytes. While activation of MEK1/2 by phosphate is required for ERK1/2 phosphorylation and phosphate-induced hypertrophic chondrocyte apoptosis, a role for the Raf kinases in growth plate maturation has not been defined.

Mice with chondrocyte-specific ablation of C-Raf were generated by crossing mice expressing Cre recombinase driven by the Col2 promoter with mice bearing C-Raf alleles floxed at exon 3 (C-Raf^{fl/Col2-Cre+}). These mice were crossed with germline A-Raf knockout mice (A-Raf X^{KO}Y) to create mice with deletion of both A- and C-Raf in chondrocytes. Growth plates were analyzed postnatally.

Chondrocyte-specific C-Raf deletion led to an expansion of the hypertrophic layer, accompanied by decreased p-Erk1/2 and impaired chondrocyte apoptosis. However, in cultured primary chondrocytes, phosphate-induced pERK1/2 was not impaired by C-Raf ablation, suggesting other factors were responsible for the *in vivo* phenotype. Impaired function of VEGF, an inducer of vascular invasion, leads to expansion of the hypertrophic chondrocyte layer in growing mice. While VEGF mRNA was not altered by C-Raf ablation, VEGF protein was reduced in cultured chondrocytes and in the growth plates of C-Raf^{fl/Col2-Cre+} mice. This was accompanied by a decrease in vasculature assessed by CD31 IHC, suggesting that a reduction in metaphyseal angiogenesis underlies the observed phenotype. Mice lacking both A- and C-Raf exhibited a more marked expansion of the hypertrophic zone compared to mice with C-Raf deletion alone.

These data suggest that A-Raf and C-Raf coordinately regulate growth plate maturation. While C-Raf expression in hypertrophic chondrocytes promotes vascular invasion and hypertrophic chondrocyte apoptosis, concomitant ablation of A-Raf, leads to a more significant phenotype, suggesting that A-Raf may play a compensatory role or activate pathways that synergistically regulate growth plate maturation.

MO0420

Runx2 is required for the osteo-anabolic effects of Sost-deficiency. Meghan McGee-Lawrence*¹, Zachary Ryan², Rajiv Kumar², Jennifer Westendorf².

¹Georgia Regents University, USA, ²Mayo Clinic, USA

Sost deficiency is responsible for high bone mass disorders, Sclerosteosis and van Buchem's disease, and sclerostin neutralizing antibodies are in late-stage clinical trials as novel anabolic therapies for osteoporosis. Sclerostin, the Sost gene product, is highly expressed in osteocytes and inhibits multiple signaling pathways, most notably canonical Wnt signaling via Lrp5/6. Runx2 is an essential transcription factor during skeletal development, as Runx2^{-/-} mice lack a mineralized skeleton and die immediately after birth. Runx2^{+/-} mice are viable but develop cleidocranial dysplasia (CCD), characterized by low bone mass and persistent cranial fontanels. The role of Runx2 in the bone phenotype of Sost-deficient mice is not yet known. The goal of the current study was to determine if the high bone mass phenotype caused by Sost deficiency requires Runx2, and in turn, if modifying Wnt signaling through inducing Sost deficiency would correct the CCD phenotype of Runx2^{+/-} mice. A novel Sost deficient mouse model, which develops high bone mass and has increased Wnt signaling, was crossed with Runx2^{+/-} animals. Parietal bones of double mutant Sost^{-/-}:Runx2^{+/-} mice demonstrated increased calvarial thickness as compared to WT or Runx2^{+/-} mice but had thinner calvarial bones than Sost^{-/-} mice. Genetic dominance of Runx2 was apparent in the calvarial fontanel and clavicle phenotype, where Runx2^{+/-} and Sost^{-/-}:Runx2^{+/-} mice presented with comparable skeletal morphology. No exacerbation or rescue of the fontanel or clavicle phenotypes was found in the Sost^{-/-}:Runx2^{+/-} animals. In intramembranous fracture healing studies, double mutant Sost^{-/-}:Runx2^{+/-} mice presented with an intermediate bone volume fraction in healing bone defects as compared to Runx2^{+/-} or Sost^{-/-} mice. Endochondral bone formation phenotypes (long bone mass, trabecular bone remodeling, fontanel and clavicle morphology) were also quantified. Trabecular bone properties, trabecular bone remodeling indices, cortical bone thickness, and cortical bone mineral density generally demonstrated an intermediate phenotype in Sost^{-/-}:Runx2^{+/-} mice between that of Sost^{-/-} and Runx2^{+/-} single mutants. Interestingly, cortical bone periosteal area and cortical bone area were greatest in Sost^{-/-}:Runx2^{+/-} animals as compared to either Sost^{-/-} or Runx2^{+/-} mice. Taken together, these data suggest that the osteo-anabolic effects of Sost deficiency require Runx2.

Trabecular Bone Parameters in the Distal Femur and L5 Spine are Differentially Influenced by Genetics and Dietary Calcium Restriction in Growing Mice. James Fleet*, Perla Reyes Fernandez, Sarah Mace, Rebecca Replogle, Xu Lan. Purdue University, USA

Purpose: Attaining peak bone mass is an important osteoporosis prevention goal that is influenced by diet and genetics. We studied if gene-by-diet (GxD) interactions influence distal femur and L5 spine trabecular bone (Tb) parameters in a genetically diverse population of mice. We also examined whether genetic, diet, or GxD effects are different at the two sites. **Methods:** 51 BXD recombinant inbred mouse lines were fed diets with 0.5% (reference) or 0.25% calcium (Ca) from 4 to 12 wks of age (n=8/diet/line). At termination, the right femur and L5 spine were removed, cleaned, fixed, and Tb was analyzed by high-throughput micro computed tomography (uCT). Means were adjusted for the confounding influence of body size by ANCOVA. The response of uCT parameters to dietary Ca restriction (RCR) was calculated: 0.25% value – line mean for 0.5% value.

Results: BV/TV, Tb.N, and Tb.Th were higher, and Tb.Sp. was lower in spine than femur. Structural model index (SMI) showed a rod-like structure in femur and a plate-like structure in spine. Dietary Ca restriction significantly reduced BV/TV and Tb.Th. at both sites and changed SMI to a more rod-like structure. However, the total loss was significantly greater in spine than femur (for BV/TV, -0.023 and -0.015, respectively). Phenotypic diversity was seen across lines for all parameters and a significant line effect was seen for all femur and spine uCT endpoints. This indicates that genetics influences the development of Tb mass and structure. Consistent with this, narrow sense heritability was high at both sites (e.g. 0.5% Ca; femur BV/TV = 0.52; spine BV/TV = 0.56). For each femur and spine parameter, the RCR was significantly influenced by line indicating the existence of GxD interactions. Basal phenotypes and the RCR were negatively correlated, demonstrating that lines with high Tb mass on the reference diet were more sensitive to the consequences of low Ca diets. Compared to basal phenotypes, the heritability of the RCR was moderate (e.g. femur BV/TV = 0.37; spine BV/TV = 0.22). Finally, there was a significant site x line interaction affecting the RCR of BV/TV suggesting the existence of site-specific genetic effects for the impact of dietary Ca on Tb mass.

Conclusions: Our data demonstrates that a complex interaction exists between dietary Ca intake and genetics to influence development of peak Tb mass during growth. There is also evidence that this interaction is different by bone site.

Reduced Mortality and Subsequent Fracture Risk with Oral Bisphosphonate Treatment in Secondary Fracture Prevention: an Observational 8-Year Follow-Up Study. Tineke van Geel¹, Dana Bliuc², Piet Geusens³, Jacqueline Center⁴, Geert-Jan Dinant⁵, Joop van den Bergh⁶, Alastair McLellan⁷, John A Eisman². ¹Maastricht University, NL, ²Garvan Institute of Medical Research, ³Maastricht University Medical Center, ⁴+61 (02) 9295 8100, ⁵Maastricht University, ⁶VieCuri Medical Centre of Noord-Limburg, ⁷NHS Education for Scotland

Purpose: To analyze the effect of oral bisphosphonate therapy on subsequent fracture and mortality over 8-years of follow-up.

Methods: Between 1999 and 2007, 5011 of 9439 men and women aged ≥ 50 years who had sustained a clinical fracture accepted an invitation to attend the Glasgow Fracture Liaison Service. Mortality and subsequent fracture risk were the pre-defined outcomes. Cox proportional hazard models compared outcomes between patients who were or were not prescribed bisphosphonates.

Results: Of the 9439 patients, 53.1% (n=5011) attended the service and were fully assessed; 22.2% declined assessment, 19.3% were too frail to be assessed and 5.4% were already on treatment. All 5011 patients received calcium and vitamin D and of these, 2534 (50.7%) were prescribed oral bisphosphonates, based on pre-defined fracture history and age-defined bone mineral density cut-offs.

After 8-years of follow-up, absolute subsequent fracture risks for patients who were prescribed bisphosphonates was 13.3% vs 11.8% (p = 0.126) for those on calcium and vitamin D alone. The absolute mortality risks were 15.0% vs. 9.5%, respectively (p < 0.001). These differences related to the treatment selection criteria. Hence, although those prescribed bisphosphonates were more likely to be female (82.9 vs. 72.4%), they were older (73.4 vs. 64.4 years), had lower bone mineral density (T-score: -3.1 vs. -1.5) and had more hip fractures (21.7 vs. 6.2%; p < 0.001).

In the two groups, analysed separately, the predictors of fracture and mortality were age, gender, bone mineral density, fracture location, alcohol, glucocorticoid use and smoking and were similar. After adjustment for these characteristics, patients prescribed bisphosphonates had lower subsequent fracture risk (Hazard Ratio (HR): 0.59; 95%CI: 0.48-0.73) and lower mortality risk (HR: 0.79: 0.64-0.96); the latter not attributable to fewer subsequent fractures.

Conclusions: Amongst patients, fully assessed after a fragility fracture, those with higher fracture risk and prescribed bisphosphonates had worse baseline characteristics. After adjusting for these differences, those prescribed bisphosphonate treatment had a substantially lower hazard for subsequent fragility fracture (0.59) and lower hazard (0.79) for mortality. These long-term community-based data indicate a clear benefit of bisphosphonate therapy for both subsequent fracture and mortality outcomes.

Vosoritide (BMN 111) in children with achondroplasia: Results from a Phase 2, open-label, sequential cohort, dose-escalation study. Melita Irving¹, Carlos Bacino², Xiaofan Cao³, Joel Charrow⁴, Valerie Cormier-Daire⁵, Paul Harmatz⁶, Leonid Katz³, John Phillips⁷, Sagar Vaidya³, Julie Hoover-Fong⁸, Ravi Savarirayan⁹. ¹Guy's & St. Thomas' NHS Foundation Trust, ²Evelina Children's Hospital, ³Baylor College of Medicine, ⁴BioMarin Pharmaceutical Inc., ⁵Ann & Robert H. Lurie Children's Hospital of Chicago, ⁶Institut Imagine, Université Paris Descartes, Hôpital Necker - Enfants Malades, ⁷UCSF Benioff Children's Hospital Oakland, ⁸Vanderbilt University Medical Center, ⁹Johns Hopkins University School of Medicine, ⁹Royal Children's Hospital Victoria, University of Melbourne

Background and objectives. Achondroplasia, the most common form of human dwarfism, is caused by a gain-of-function mutation in the fibroblast growth factor receptor 3 gene (*FGFR3*) and is characterized by abnormal endochondral bone formation. C-type natriuretic peptide (CNP) is a potent stimulator of endochondral bone growth. This phase 2, multi-center, open-label, sequential cohort, dose-escalation study evaluated the safety, tolerability and efficacy of daily subcutaneous injections of vosoritide (BMN 111), a CNP analog, in children with achondroplasia aged 5-14 years.

Design and methods. Subjects were required to complete at least 6 months of pretreatment growth assessment in a natural history study prior to enrollment. 26 children with achondroplasia (12 male, 14 female, mean age 7.8 ± 1.8 years) were assigned to one of three dose cohorts: 2.5 $\mu\text{g}/\text{kg}/\text{day}$ (n = 8), 7.5 $\mu\text{g}/\text{kg}/\text{day}$ (n = 8), and 15.0 $\mu\text{g}/\text{kg}/\text{day}$ (n=10). Subjects remained on a fixed dose for 6 months. Safety was assessed by measures including incidence of adverse events (AEs) and changes in vital signs and clinical laboratory parameters. Efficacy was measured by changes in annualized growth velocity, absolute growth, and body proportions.

Results. Vosoritide was well tolerated across all dose cohorts. The majority of AEs were mild and included injection site reactions, asymptomatic hypotension, and

headache. No serious AEs were reported, and no AEs led to permanent discontinuation of study drug. Mean (SD) baseline annualized growth velocity based on the last 6 month natural history growth measurements was 3.8 ± 1.1 cm/year in the 2.5 $\mu\text{g}/\text{kg}/\text{day}$ dose group, 2.9 ± 1.4 cm/year in the 7.5 $\mu\text{g}/\text{kg}/\text{day}$ dose cohort, and 4.0 ± 2.3 cm/year in the 15.0 $\mu\text{g}/\text{kg}/\text{day}$ dose cohort. Post-treatment mean annualized growth velocity was 3.4 ± 0.9 cm/year in the 2.5 $\mu\text{g}/\text{kg}/\text{day}$ dose cohort, 4.2 ± 1.3 cm/year in the 7.5 $\mu\text{g}/\text{kg}/\text{day}$ dose cohort, and 6.1 ± 1.1 cm/year in the 15.0 $\mu\text{g}/\text{kg}/\text{day}$ dose cohort. A mean increase of 2.0 ± 2.0 cm/year (95% CI 0.6, 3.4; p = 0.0111), which represents a 50% increase from mean baseline annualized growth velocity, was observed in the 15.0 $\mu\text{g}/\text{kg}/\text{day}$ dose cohort. Changes from baseline in body proportionality were not observed after 6 months of treatment.

Conclusions. These data support the further development of vosoritide for the treatment of children with achondroplasia with open growth plates.

The *ACVRI*^{R206H} mutant receptor causes Fibrodysplasia Ossificans Progressiva by gaining responsiveness to Activin A. Aris Economides¹, Sarah Hatsell², Vincent Idone², Dana Alessi Wolken², Lily Huang², Hyon Kim², Lili Wang², Xialing Wen², Kalyan Nannuru², Johanna Jimenez², LiQin Xie², Genevieve Makhoul², Rostislav Chernomorsky², David D'Ambrosio³, Richard Corpin², Christopher Schoenherr², Kieran Feeley⁴, Paul Yu⁵, Harikiran Nistala⁶, George Yancopoulos², Andrew Murphy². ¹Regeneron Pharmaceuticals, Inc., USA, ²Regeneron Pharmaceuticals, Inc., ³R, ⁴Ohio State University College of Medicine, ⁵Brigham & Women's Hospital, ⁶Regeneron Genetics Center

Fibrodysplasia Ossificans Progressiva (FOP) is a rare genetic disorder characterized by episodic exuberant heterotopic ossification (HO), whereby certain skeletal muscles, fascia, ligaments, and tendons are abnormally converted into histologically "normal" bone. The HO process may be preceded by "flare-ups", characterized by painful swelling of connective tissue; however, HO can also occur in the absence of obvious flare-ups. Episodes of HO can be spontaneous or may result from trauma or other insults that trigger inflammation. More importantly, the HO that forms in FOP patients is effectively permanent, as attempts to resect it almost invariably trigger additional episodes of HO. Hence, the cumulative effect is progressive immobility with catastrophic consequences. FOP results from mutations in the intracellular domain of the type I BMP receptor ACVRI (also known as ALK2). The most common mutation alters arginine 206 to histidine (*ACVRI*^{R206H}) that has been thought to drive HO as a result of receptor hyperactivity. In contrast to what has been described in the literature, we unexpectedly found that this mutation rendered ACVRI responsive to Activin A, AB, AC, and B, a set of ligands that normally antagonize BMP signaling mediated through ACVRI, and which normally do not induce bone formation. To test the implications of this finding in vivo, we engineered a genetically accurate mouse model of FOP that carries the *Acvri*^{R206H} mutation. As mice that constitutively express *Acvri*[R206H] die perinatally, we generated a Cre/lox-based conditional-on knock-in model of *ACVRI*^{R206H}. When *Acvri*[R206H] expression was induced, mice developed HO mirroring that observed in FOP, whether spontaneously or in response to trauma. Administration of Activin A (using collagen sponges) also triggered HO in the *Acvri*^{R206H/+} mice but not in wild-type controls; mice treated with vehicle did not develop HO irrespective of their *Acvri* genotype. Importantly, the development of both spontaneous and trauma-induced HO in *Acvri*^{R206H/+} mice could be blocked by a fully human neutralizing antibody specific to Activin A. Our results indicate that *ACVRI*^{R206H} causes FOP by gaining responsiveness to Activin A, a ligand that is normally antagonistic to ACVRI-mediated BMP signaling. Furthermore, Activin A is necessary and sufficient for driving HO in our model of FOP; hence, inhibition of Activin A (e.g. by neutralizing antibodies) presents a new potential therapeutic option for FOP.

The Association of Race Ethnicity and Risk of Atypical Femur Fracture in Women Treated with Oral Bisphosphonate Drugs. Joan Lo¹, Rita Hui², Christopher Grimsrud³, Malini Chandra³, Romain Neugebauer³, Joel Gonzalez³, Amer Budavr³, Gene Lau³, Bruce Ettlinger³. ¹Kaiser Permanente, ²Kaiser Permanente California, ³Kaiser Permanente Northern California

Purpose: Several epidemiologic studies suggest that compared to white women, Asians have a propensity to suffer an atypical femur fracture (AFF) while taking bisphosphonate (BP) drugs. This study examines the relative risk of AFF following BP initiation for Asian compared to white women. **Methods:** Using data from a large northern California healthcare delivery system, we examined diaphyseal femur fractures among women age ≥ 50 years who initiated oral BP therapy during 2002-2007. Demographic and clinical characteristics at baseline, including prior fracture history, diabetes mellitus, rheumatoid arthritis and treatment with glucocorticoids (≥ 1825 mg prednisone equivalent in prior year), aromatase inhibitors and

pharmacologic proton pump inhibitors were examined using health plan and pharmacy databases. Radiographs of diaphyseal fractures were reviewed and classified as AFF or not based on 2013 American Society of Bone and Mineral Research Task Force criteria. The risk of AFF for Asian compared to white women was examined using Cox proportional hazard analyses, adjusting for differences in BP exposure and other potential risk factors. Results: We identified 48,390 women (mean age 69.5 ± 10.0 years) who initiated BP therapy and had at least three years of follow-up. The cohort was diverse, including 65.3% white, 17.1% Asian, 9.5% Hispanic, 4.1% black and 4.0% other/unknown race. During a median follow-up of 7.7 years, 68 women experienced an AFF. The rate of AFF was 18.7 per 100,000 person-years overall, and eight-fold higher among Asian compared to white women (64.2 vs 7.6 per 100,000 person-years, respectively). The median duration of BP use was greater among Asian women (3.8 years) versus whites (2.7 years). In unadjusted analyses, prior fracture, diabetes, rheumatoid arthritis and baseline glucocorticoid, aromatase inhibitor and proton pump inhibitor therapy were not associated with AFF. However, race/ethnicity was strongly associated with risk of AFF, with an age-adjusted relative hazard of 8.5 (95% confidence interval, CI 4.9-14.9) comparing Asian to white women, that was only modestly reduced to 6.6 (CI 3.7-11.5) after adjusting for BP duration and current use. Conclusion: Our study confirms marked racial disparity in AFF risk that should be further examined, particularly the mechanisms accounting for this difference. In the interim, counseling of Asian women about osteoporosis drug continuation should include consideration of their higher AFF risk.

Ten Years of Denosumab Treatment in Postmenopausal Women With Osteoporosis: Results From the FREEDOM Extension Trial. HG Bone^{*1}, ML Brandi², JP Brown³, R Chapurlat⁴, SR Cummings⁵, E Czerwinski⁶, A Fahrleitner-Pammer⁷, DL Kendler⁸, K Lippuner⁹, J-Y Reginster¹⁰, C Roux¹¹, E Vittinghoff¹², NS Daizadeh¹³, A Wang¹³, P Dakin¹³, RB Wagman¹³, S Papapoulos¹⁴. ¹Michigan Bone & Mineral Clinic, ²University of Florence, ³Laval University & CHU de Québec Research Centre, ⁴Hôpital Edouard Herriot, ⁵San Francisco Coordinating Center, CPMC Research Institute, & UCSF, ⁶Krakow Medical Centre, ⁷Medical University Graz, ⁸University of British Columbia, ⁹Bern University Hospital, ¹⁰University of Liège, ¹¹Paris Descartes University, ¹²UCSF, ¹³Amgen Inc., ¹⁴Leiden University Medical Center

Purpose: Osteoporosis is an important chronic disease, requiring prolonged treatment. Long-term efficacy and safety data are therefore of great importance. Denosumab (DMAB) is used in over 80 countries or administrative districts worldwide for the treatment of postmenopausal women with osteoporosis. The effects of DMAB treatment for up to 10 years have been evaluated in the 3-year FREEDOM study and its 7-year extension. Here, we report results through the final year of the extension, representing up to 10 years of continued DMAB treatment.

Methods: During the extension, all subjects were to receive 60 mg DMAB every 6 months and calcium and vitamin D daily. In this analysis, the long-term group received 10 years of DMAB treatment (3 years in FREEDOM and 7 years in the extension), and the cross-over group received 7 years of DMAB treatment (3 years of placebo in FREEDOM and 7 years of DMAB in the extension).

Results: Of the 4,550 subjects who entered the extension, 2,784 (61%) continued to participate at the beginning of year 10. Of these, 2,212 (80%) have completed their final 10-year visit, 120 (4%) discontinued, and 452 (16%) were ongoing at the time of this submission. In the long-term group, further significant increases in BMD occurred with mean cumulative 10-year gains from FREEDOM baseline of 21.6% (lumbar spine) and 9.1% (total hip). The cross-over group had mean cumulative 7-year gains of 16.3% (lumbar spine) and 7.3% (total hip) from the extension baseline (Figure; all $P < 0.0001$ compared with FREEDOM baseline, extension baseline, and previous measurement). Similar and sustained reductions in bone turnover markers were observed in both groups, with the characteristic attenuation of effect at the end of the dosing period. Yearly rates of new vertebral and nonvertebral fractures remained low. Overall incidence rates of adverse events (AEs) and serious AEs were consistent with data reported previously in the extension study.

Conclusions: DMAB treatment for up to 10 years was associated with persistent reduction of bone turnover, continued increases in BMD without therapeutic plateau, and low fracture incidence. The benefit/risk profile for DMAB in an aging population of postmenopausal women remains favorable.

Marrow Adiposity is Associated With Low Bone Turnover and Sclerostin Levels in Peritoneal Dialysis Patients. Fellype Barreto¹, Carolina Moreira^{*2}, Rodrigo de Oliveira³, Luciene dos Reis⁴, Vanda Jorgetti⁴, Aluizio Carvalho⁵, Rosa Moyses⁶. ¹Pontificia Universidade Católica do Paraná; Laboratório P.R.O, Fundação Pro Renal, Brazil, ²Federal University of Parana, Brazil, ³Universidade Federal do Rio Grande do Norte, ⁴Universidade de São Paulo, Brazil, ⁵Universidade Federal de São Paulo, Brazil, ⁶Universidade de São Paulo, Universidade Nove de Julho, Brazil

Background: Marrow adiposity has been implicated in the pathogenesis of bone disorders, such as osteoporosis and bone fragility. Diabetes mellitus (DM) is very prevalent among peritoneal dialysis patients. The aim of this study is to investigate the relationship between marrow adiposity, bone turnover and sclerostin levels in patients with renal osteodystrophy with and without diabetes who undergoing peritoneal dialysis.

Methods: Transiliac bone biopsy specimens from 41 peritoneal dialysis patients (age: 50.3 ± 10.2 yrs, 56 % male and 43% with DM) were analyzed by quantitative histomorphometry. Bone and marrow adipocyte parameters were assessed and correlated to biochemical markers of bone turnover and sclerostin.

Results: Adipocyte area (Ad.Ar), perimeter (Ad.Pm) and percentage of adipocyte volume per marrow volume (Ad.V/Ma.V) correlated positively with age. Diabetic patients had higher marrow adiposity than non diabetic (Ad.V/Ma.V = 50 ± 14 vs 39 ± 12 ; $P=0.009$; Ad.Ar = 0.19 ± 0.06 vs 0.15 ± 0.05 mm²; $P=0.02$). An inverse association between Ad.V/Ma.V and bone specific alkaline phosphatase (BSAP) ($r = -0.32$; $P=0.04$) and direct relationship with sclerostin ($r=0.38$; $P=0.01$) was observed. Patients with Ad.V/TV > 41% (median) presented higher percentage of low turnover bone disease seen by histomorphometry dynamic parameters ($P=0.04$) as well as lower BSAP (39.5 ± 27.3 vs 65.3 ± 28.9 U/L; $P=0.006$) and higher sclerostin levels (2.3 ± 0.97 vs 1.6 ± 0.97 ; $P=0.02$) than patients below the median.

Conclusion: Increased marrow adiposity seems to be associated to high sclerostin and to low bone turnover disease in peritoneal dialysis patients. Further studies are required to understand the role of marrow adiposity to the pathogenesis of renal osteodystrophy.

LB-SA0002

Treatment of Autosomal Dominant Hypocalcemia with the Calcilytic NPS795. Mary Ramnitz¹, Rachel Gafni², Beth Brillante², Lori Guthrie², David Gash³, Jeffrey Gelb³, Eva Krusinska³, Sarah Brennan⁴, Daniela Riccardi⁴, Mohd Ezuan Bin Khayat⁵, Donald Ward⁵, Edward Nemeth⁶, Ralf Rosskamp³, Michael Collins². ¹National Institutes of Health, USA, ²Skeletal Clinical Studies Unit, Craniofacial & Skeletal Diseases Branch (CSDB), National Institute of Dental & Craniofacial Research (NIDCR), National Institutes of Health (NIH), United Kingdom, ³NPS Pharmaceuticals, Inc., United Kingdom, ⁴School of Biosciences, Cardiff University, United Kingdom, ⁵Faculty of Life Sciences, University of Manchester, United Kingdom, ⁶MetisMedica, Canada

Autosomal dominant hypocalcemia type 1 (ADH1) is a rare form of hypoparathyroidism caused by heterozygous activating mutations of the calcium-sensing receptor (CaR) gene. Mutant CaRs are more sensitive to activation by extracellular ionized calcium (Ca), resulting in a shift in the set-point for blood Ca homeostasis to a lower level. Affected individuals are hypocalcemic and have inappropriately low levels of parathyroid hormone (PTH) and renal Ca reabsorption. Conventional therapy with Ca and vitamin D analogs raises blood Ca, but exacerbates hypercalciuria, often causing renal complications. Calcilytic compounds directly inhibit CaRs, and by increasing PTH secretion and renal Ca reabsorption, have the potential to restore eucalcemia.

Five adults with ADH1 (aged 24-55 y; 2 women) due to 4 different CaR gene mutations (A840V, Q245R, E228K, and a novel E228A mutation) were studied. After an overnight fast, subjects received escalating doses of NPS795 by iv infusion (5mg/10min, 15mg/3.5h, and 30 mg/3.5h; 2 received 50mg/3.5h). Calcitriol was discontinued 48h and Ca supplements 9-10h prior to infusion. Pharmacokinetics and pharmacodynamics were assessed via serial sampling. Mixed model repeated measures analysis was conducted to assess percent changes in PTH, fractional excretion of Ca (FECa), and blood Ca. Wild type (wt) CaR and the 4 mutant CaR were stably expressed in HEK 293 cells and intracellular responses (cytoplasmic Ca, ERK and p38^{MAPK} phosphorylation) to changes in extracellular Ca concentration were assessed in the presence or absence of NPS795.

Plasma PTH levels increased, and FECa decreased from baseline in a dose-dependent manner. Blood Ca levels remained stable during NPS795 infusion, despite fasting and no Ca or vitamin D supplementation. NPS795 was generally safe and well tolerated. In HEK cells, all mutant CaRs were half-maximally activated (EC₅₀) at lower concentrations of extracellular Ca compared to wt CaR, and exposure to NPS795 increased the EC₅₀ for all CaR activity readouts.

NPS795 increased plasma PTH levels and decreased FECa in subjects with ADH1 in an apparent dose-dependent manner, while maintaining blood calcium levels during fasting. While the optimal dose and dosing regimen are not yet determined, NPS795 appears to represent a potential treatment for ADH.

Effect of Density on the Creep Response of Human Cortical Bone. Gavriel Feuer^{*}, Mariane Espalitie, Subrata Saha. SUNY Downstate, USA.

The time-dependent mechanical properties of cortical bone, or creep, have been shown to contribute to etiologies of vertebral compression fractures and subsidence of press fit implants. This type of mechanical loading causes diffuse damage that may repair itself through mechanisms other than remodeling and has also been shown to induce woven bone formation. The purpose of this study was to characterize the creep response of diseased and healthy bone tissue in bending without neglecting variations that can arise from differences in density and porosity.

Cortical bone beams were harvested from the tibias of three separate donors (55 y/o male, 86 y/o female, 95 y/o female, N=28). Wet apparent density of the samples were measured. Multi-step creep tests were conducted on each sample for a ten minute duration per test. The holding stress for the first step was 50 MPa and after each step the stress was increased by 10 MPa. This process continued until the 130 MPa stress level was completed or the sample failed. Following mechanical testing the samples were embedded and polished to measure the 2D porosity. Using a multiple linear regression the secondary creep phase, the region in the creep versus time curve with a constant strain-rate (de/dt), was fit to a power model and included variables for density (ρ) and normalized stress (σ/E), the stress normalized to the initial elastic modulus (E).

The equation that resulted from the power fit was $de/dt = 104(\sigma/E)^{3.26}(\rho)^{-3.77}$ (R=0.9159) All estimated coefficients in the power model were highly significant (P<0.001). This model was found to fit better than using normalized stress alone. Moreover, when using normalized stress as opposed to stress the influence of porosity became insignificant.

Damage accumulation in human cortical bone due to creep bending may have role in orthopedic problems by reducing the overall strength of the bone. The steady-state creep rate for human cortical bone was strongly correlated to the applied normalized stress level by power relationship. In addition, the inclusion of wet apparent density significantly improved the model prediction. Using normalized stress as a variable instead of stress eliminated the need to include porosity in the model. This information may be useful for simulating the creep response of various states of cortical bone.

Repeated Scanning of Mouse Hind Limbs Using In Vivo Micro-Computed Tomography Does Not Alter Bone Structure and Muscle Contractile Function in CD-1 Mice. Sandra Sacco^{*}, Caitlin Saint², William Gitting¹, Amanda Longo¹, Jordan Bunda¹, Rene Vandenoorn¹, Phil Salmon³, Wendy Ward⁴. ¹Department of Kinesiology, Faculty of Applied Health Sciences, Brock University; Centre for Bone & Muscle Health, Brock University, ²Department of Health Sciences, Faculty of Applied Health Sciences, Brock University; Centre for Bone & Muscle Health, Brock University, ³Bruker-MicroCT, ⁴Department of Kinesiology, Faculty of Applied Health Sciences, Brock University; Department of Health Sciences, Faculty of Applied Health Sciences, Brock University; Centre for Bone & Muscle Health, Brock University

Background: In vivo micro-computed tomography (μ CT) is a powerful imaging tool for measuring longitudinal changes in three-dimensional bone structure in rodents. New applications in μ CT scanning may include parallel assessments of bone and muscle structures for examining associations between these tissues. While one to nine weeks of repeated exposure to low doses of x-ray radiation from μ CT scanning does not impact trabecular bone structure in mice, its long-term effects on the mouse skeleton when scanned through development and at key stages of the lifespan (representing early, mid and later adulthood) are not known. Moreover, it is unknown whether repetitive scanning of the hind limb affects muscle form and contractile performance. Objective: Determine the structural and functional impact of repetitive μ CT scanning on bone and muscle tissues. Methods: At 2, 4 and 6 months of age, mouse hind limbs were scanned using in vivo μ CT (Skyscan 1176) at 9 μ m isotropic resolution with 1 mmAl filter and at one of three scanning parameters: 1) 50kV, 100mA, 1.0° rotation step, 3300 ms; 2) 50kV, 100mA, 0.8° rotation step, 3300 ms; and 3) 40kV, 300mA, 0.8° rotation step, 3350ms providing radiation doses of 222, 261, and 460 mGy, respectively (MOSFET, Best Medical Canada). Contralateral hind limbs were scanned at 6 months to serve as non-irradiated internal controls to determine whether recurrent radiation exposure alters proximal tibia trabecular bone structure. In vitro contractile performance of representative slow (soleus) and fast (extensor digitorum longus) muscles of the radiated and non-radiated hind limbs were also measured at age 6 months (1200A in vitro System, Aurora Scientific Inc.). Results: Trabecular bone volume fraction, thickness, number and separation at the proximal tibia were similar between radiated and non-radiated mice regardless of level of radiation exposure. No differences (radiated vs. non-radiated) with respect to muscle form (i.e. mass, length, cross-sectional area) or function (i.e. peak isometric twitch, tetanic force) were observed. Conclusion: Radiation exposure from repeated μ CT scanning at early, mid and later adulthood did not alter proximal tibia trabecular bone structure and multiple measures of muscle form and function in the hind limbs of CD-1 mice. These findings can be applied to future studies that investigate lifelong responses of both bone and muscle structures from early life exposure to various intervention strategies.

LB-SA0005

Three-dimensional analysis of chin bone for secondary bone graft with beta-TCP in unilateral cleft patients. Kazuaki Miyagawa^{*}, Sachie Hiroishi, Yutaka Matsushita, Susumu Tanaka, Mikihiko Kogo.

Autogenous bone grafting with chin for the reconstruction of alveolar cleft was more noninvasive than iliac crest. We thereby proactively use chin bone as a donor site for secondary bone graft in those with patients with unilateral alveolar cleft. In general, chin bone is not employed as harvesting area because the amount of bone is small compare to other site such as ilium and is restricted because of surgical risk to damage the dental root or mental nerve. It has also a problem of the contour change in the chin area. To resolve these problems, we use beta-tricalcium phosphate, beta-TCP in mixture with chin bone. Thereby, we can increase the amount of donor bone and enable to apply for some extent of wide cleft case. In the present study, we evaluated the usefulness of the secondary bone grafting by chin bone in the mixture with beta-TCP in the patients with unilateral alveolar cleft, the biomechanical properties of alveolar grafted bone and regenerated bone at harvested site are analyzed using cone-beam computed tomography images. This study comprised 34 non syndromic case of unilateral cleft lip (CLA) and cleft lip palate (CLP) Japanese patients. Eight of these were underwent bone grafting without beta-TCP and the rest of them were operated with beta-TCP at the mean age of 9.5 and 9.6 years old, respectively. Furthermore, beta-TCP group was also classified into two subdivisions

by cleft volume. Three-dimensional built images before and after the surgery of each patient were overlaid by several landmarks on facial bone and newly formed (or regenerated) bone could be extracted by subtraction the images using three-dimensional analysis software (Ratoc, Japan). In the formed bone bridge at alveolar cleft site, BV/TV showed no significant difference among three groups, but in the case of CLA, beta-TCP group showed high mean rate in the comparison with the control (without beta-TCP) group. Tb.th, Tb.N and Tb.sp exhibited no statistically significant. As for the regenerated bone at donor site. BV/TV, Tb.Th, Tb.N, Tb.sp, TBPf and SMI were superior in the beta-TCP group compared to those of control group. These results suggested that alveolar bone graft by chin bone in the mixture with beta-TCP is useful for sufficient bone bridge in some degree of wider unilateral alveolar cleft. Also, especially in the case of cleft lip and alveolus, the trabecular bone quality of grafted and regenerated bone could show favorable results in the presence of beta-TCP.

Early developmental effects of Bisphenol-A (BPA) on bone structure and function are sex dependent. Karl Jepsen¹, Lauren Smith^{*2}, Martha Susiarjo³, Marisa Bartolomei³. ¹University of Michigan, USA, ²The University of Michigan, USA, ³University of Pennsylvania Perelman School of Medicine, USA

BPA is a widely used synthetic compound (e.g., plastics, receipts, can-linings, water supply pipes). BPA, which leaches from products and is found ubiquitously in the environment, is associated with estrogenic disrupting effects and can induce metabolic changes across multiple generations. Sex hormones, both in concentration and in timing, are critical to bone growth and development. Effects on bone via direct exposure have been shown but to our knowledge data of trans-placental effects are lacking. We hypothesized that exposure of a filial (F1) generation to BPA during prenatal development and through weaning would lead to detectable changes in bone morphology and/or function. To test this, female C57BL/6 (B6) mice (F0) were assigned to 1 of 3 diets (control (C), lower dose (LD) BPA (10µg/kg/d), or upper dose (UD) BPA (10mg/kg/d)) two weeks prior to mating and through gestation and lactation. F1 mice were placed on control diets upon weaning. Male and female femurs were analyzed as adults (4-13months of age, n=8-29/group) for bone morphology and composition via nanoCT (8µm voxel size) and mechanical properties via 4-point bending. Student's t-test was used for unadjusted comparisons and general linear model ANOVAs for adjusted comparisons, significance of p<0.05. Each dose-group was compared back to the control, and sexes were analyzed independently. We found no significant difference in body mass (BM) across groups, but body composition was altered in both LD and UD males 5% (p=0.04) and 6% (p=0.03), respectively. After BM adjustment both UD and LD males, but not females, showed 6.5% (p=0.01) and 10% (p<0.01) reduced robustness (total cross sectional area (Tt.Ar)/femur length), respectively, compared to controls. BM adjusted Tt.Ar was significantly decreased in UD and LD (p<0.01 and p=0.04, respectively), while femoral length was similar, indicating that the decreased robustness was due to altered periosteal expansion. Only the males, both UD and LD, showed a reduction in maximum load, 13.5% (p<0.02) and 13.7% (p=0.06), respectively after adjustment for BM. The only altered traits in female F1 mice was decreased cortical area and tissue mineral density, 3.5% (p=0.03) and 1.7% (p<0.01), respectively, for the UD group, after adjusting for BM and robustness. This data indicated that exposure of a F0 pregnant female to BPA leads to more slender and weaker bones in F1 males and only minor effects on F1 females with no change in bone strength.

Bone-specific underdevelopment of trabecular bone microarchitecture in ambulatory children with mild cerebral palsy. Daniel Whitney^{*1}, Harshvardhan Singh¹, Freeman Miller², Keri DiAlessandro², Nancy Lennon², Christopher Modlesky¹. ¹University of Delaware, USA, ²AI duPont Hospital for Children, USA

Nonambulatory children with more severe forms of cerebral palsy (CP) have underdeveloped trabecular bone microarchitecture at the distal femur, their primary fracture site. However, whether ambulatory children with mild CP also have underdeveloped trabecular bone microarchitecture has not been determined. Ten ambulatory children with mild spastic CP and 10 typically developing control children between 5 and 12 years of age participated in this study. Twenty-six axial magnetic resonance images (175 x 175 x 700 µm³) of the distal tibia and the distal femur were collected from the more affected limb in children with CP and the nondominant limb in controls. Measures of trabecular bone microarchitecture [apparent trabecular bone volume to total volume (appBV/TV), trabecular number (appTb.N), trabecular thickness (appTb.Th) and trabecular separation (appTb.Sp)] were estimated using the 20 most central images at each site and custom software (Interactive Data Language, Boulder, CO). Dual-energy X-ray absorptiometry was used to assess bone mineral content (BMC) and areal bone mineral density (aBMD) at the distal tibia and the distal femur. Compared to controls, the distal tibia and the distal femur in ambulatory children with CP had lower appBV/TV by 22% (d = 2.32, p < 0.05) and 13% (d = 1.15, p < 0.05), lower appTb.N by 15% (d = 2.32, p < 0.05) and 10%

(d = 1.66, p < 0.05), and higher appTb.Sp by 32% (d = 2.10, p < 0.05) and 19% (d = 1.5, p < 0.05), respectively. Additionally, compared to controls, children with CP had lower appTb.Th by 8% (d = 1.36, p < 0.05) at the distal tibia, but there was no significant difference between groups at the distal femur. Moreover, the difference in appTb.Sp between children with CP and controls was greater at the distal tibia than at the distal femur (p < 0.05). Compared to controls, children with CP also had lower BMC and aBMD at the distal tibia by 31% (d = 1.25, p < 0.05) and 26% (d = 1.55, p < 0.05) and at the distal femur by 25% (d = 1.12, p < 0.05) and 21% (d = 1.23, p < 0.05), but the degree of the difference was similar (p > 0.25). The findings suggest that, relative to typically developing children, ambulatory children with mild CP have an underdeveloped trabecular bone microarchitecture and lower aBMD and BMC in the distal tibia and the distal femur. However, the degree of compromise in trabecular bone microarchitecture is more pronounced in the distal tibia than the distal femur.

Simulating Tumor Induced Bone Disease using a population dynamic model. Ushashi Dadwal^{*}, Mathilde Granke, Junhwan Jeon, Alyssa Merkel, Peter Cummings, Julie Sterling, Scott Guelcher. Vanderbilt University Medical Center, USA

Bone is a frequent site of metastasis of primary breast, prostate, and lung cancer. Upon establishment of tumor cells in the bone, bone remodeling is disrupted which causes clinical morbidities that lead to a decrease in patient quality of life. There are no clinical therapeutics that target tumor in the bone. Despite years of research, the temporal dynamic interactions between tumor cells and bone cells are still not understood. Integrating information from basic studies examining how each cell type behaves is challenging, and restricts our ability, to combine information into a comprehensive understanding of the complexities of tumor-induced bone disease (TIBD), and limits our ability to predict how potential therapeutics may perform. Recent studies have highlighted the potential of mathematical models of tumor progression, but none have been developed to model TIBD. Additionally, the use of experimental data to predict bone destruction and tumor burden using computational modelling has not been reported. We hypothesize that using a fundamental mathematical model to simulate progression of TIBD would allow us predict responses to novel therapeutics. We report the development and validation of a time dependent mathematical model using ordinary differential equations based on Komarova et al(1), to predict rate of bone resorption and tumor burden. Our model takes into account the cellular interaction between osteoclasts, osteoblasts and tumor cells and predicts bone resorption and tumor progression using experimental data over a four week time course by approximating power law relations. We injected bone tropic MDA GFP 231 cells (triple negative breast cancer cell line), using intratibial injections in athymic mice and sacrificed mice every week to input data to parameterize the computational model. We measured bone and tumor cell populations via histomorphometry and bone quality and loss using radiography and µCT imaging. In conclusion, this model fits experimental data, and describes the key events in the vicious cycle and will allow us to predict the effects of novel drug therapies on tumor burden and bone resorption which may aid in the development of clinical strategies for the treatment of metastatic bone disease.

Validation of Marrow Fat Quantification using HRpQCT: A Pilot Study. Tiffany Butler^{*}, Joshua Johnson, Karen Troy. Worcester Polytechnic Institute, USA

Novel imaging techniques like high resolution peripheral quantitative computed tomography (HRpQCT) accurately quantify bone microarchitecture and volumetric bone mineral density in vivo. Marrow adipose tissue (MAT) has been linked with decreases in bone mineral density negatively regulating bone formation (1, 2). No studies to date have investigated changes in long bone MAT using HRpQCT, which could provide a noninvasive clinical tool to examine changes in marrow adipose tissue.

We set out to determine if MAT could accurately be quantified using HRpQCT. Twenty bovine femurs transversely cut in 5.5-7.5cm pieces were obtained from a local butcher and frozen. Computed tomography (CT) scans were taken (XtremeCT, Scanco, Switzerland) at 246µm isotropic voxel size. Images were analyzed in Mimics v18.0 (Materialise, Belgium). Fat voxels were identified by thresholding the volume located inside the endosteal envelope (Figure 1). Three Hounsfield unit (Hu) ranges that overlapped with typical CT fat values were tested: [-200 to -50, -300 to 50, and -400 to 50]. CT-MAT volume was calculated by multiplying the number of fat voxels by the volume of each voxel. Next, medullary tissue, marrow and fat, was removed and placed in 50 ml tubes filled with 20 ml of water. Tubes were inverted 5 times and centrifuged at 2000 RPM for 5 minutes twice for fat isolation. Fat was removed from the tubes and weighed. Gross MAT volume was calculated by dividing gross MAT mass by fat density (assumed to be 0.9196 g/cm³ (3)). Pearson correlations were used to determine relationships between gross MAT volume and CT-MAT volume (mm³).

Significance was set at $p \leq 0.05$. All statistical analyses were performed in SPSS 17.0 (SPSS Inc, Chicago, Illinois, USA).

No significant correlations were found between gross MAT and CT-MAT volumes within the specified threshold ranges: [-200 to 50 Hu] ($r = .374$, $p = .104$); [-300 to 50 Hu] ($r = .369$, $p = .110$) and [-400 to 50 Hu] ($r = .254$, $p = .280$).

Currently, no studies have investigated MAT quantification using HRpQCT. Although the simple thresholding technique utilized here was not able to accurately delineate MAT, lower resolution CT has been used to measure fat volumes (4,5). Adjusting CT acquisition settings, additional image processing and filtering may be needed to reduce noise and identify fat voxels more reliably and repeatably. Noninvasive *in vivo* quantification of MAT could lead to a better understanding of the role MAT plays in bone health.

Zoledronic Acid: A Novel Treatment for Langerhans Cell Histiocytosis Bone Lesions in Children. Karine Bourdet, Melissa Fisceletti*, Anne-Sophie Carret, Sophie Turpin, Nathalie Alos. University of Montreal, Canada

Background:

Langerhans cell histiocytosis (LCH) is a rare disease characterized by proliferation of Langerhans cells in various organs. In children, bone lesions are frequent in up to 80% of cases, leading to pain and functional disabilities. High doses of zoledronic acid were shown to relieve the bone pain and seemed to stabilize the disease in a few adult patients.

Case report :

A 4-month-old boy diagnosed with systemic LCH, including multifocal bone lesions, was treated with chemotherapy. He presented two bone relapses despite second line treatment. Zoledronic acid was added (3 doses of 0.025 mg/kg at 0, 3 and 6 months). Patient is in remission one year post-treatment.

A 5-year-old boy presented with focal bone lesions and progression after six months of chemotherapy. He received 3 doses of zoledronic acid (0.025 mg/kg initially and 0.05 mg/kg at 3 and 6 months) in combination with chemotherapy.

A 10-year-old girl was diagnosed with multifocal bone LCH, including vertebral fracture. She responded well to a combination of chemotherapy and zoledronic acid.

In all 3 patients, F18-FDG PET/CT was used to follow the treatment response and showed rapid normalization of the metabolic activity after one month. Alternatively to Tc99m-MDP bone scintigraphy, F18-FDG biodistribution is not affected by zoledronic acid.

Low dose bisphosphonates was well tolerated and was able to control bone disease.

Results:

Zoledronic acid showed beneficial effects in 3 children with LCH bone lesions. F18-FDG PET/CT could be useful to monitor response to therapy.

LB-SA0011

Inhibition of epigenetic factor Dnmt3b within articular chondrocytes coordinates cellular metabolic response during the development of osteoarthritis. Jie Shen*¹, Cuicui Wang², Jason Myers³, John Ashton³, Audrey McAlinden², Regis O'Keefe². ¹Washington University in St Louis, USA, ²Washington University in St Louis, ³University of Rochester, USA

Osteoarthritis (OA) is a degenerative joint disease that will affect 67 million people in the US by 2030. Recent genome-wide association screens have implicated a distinct DNA methylation signature in OA patients, indicating DNA methyltransferases (*Dnmt*) may play a role in regulating cartilage homeostasis. We found intense expression of *Dnmt3b* in murine and human articular cartilage. We observed a marked decrease in *Dnmt3b* expression in murine cartilage with aging as well as following meniscal ligament injury (MLI). An IHC array of 14 OA cartilage and 11 healthy cartilage showed that DNMT3b expression was similarly reduced in human OA tissues compared to healthy cartilage.

To define a direct role of *Dnmt3b* in chondrocytes, we treated primary articular chondrocytes with *Dnmt3b* siRNA and found that loss of *Dnmt3b* stimulated cell hypertrophy by reducing TGF β signaling and increasing BMP signaling. To further investigate the role of *Dnmt3b* during OA development, we generated *Dnmt3b* loss-of-function (LOF) mice (*Dnmt3b*^{Age1ER}) and showed that ablation of *Dnmt3b* in articular chondrocytes led to a progressive OA-like pathology in adult mice. Changes in gene expression and methylation profiles were investigated in *Dnmt3b* LOF chondrocytes by integrative analysis of RNA-Seq and Methyl-Seq data. Gene ontology analysis revealed cellular metabolism was primarily affected in LOF cells and 4-aminobutyrate aminotransferase (*Abat*) was further identified as a potential target of *Dnmt3b*. In agreement with elevated *Abat* level, HPLC-MS reviewed an increase of succinate, the product of *Abat*, as well as other downstream TCA metabolites in *Dnmt3b* LOF cells. Mitochondria function was also affected, the basal respiration and ATP production were increased due to accelerated TCA inflow. Notably, inhibition of *Abat* with vigabatrin led to attenuation of hypertrophic gene expression induced in *Dnmt3b* LOF chondrocytes and over-expression of *Abat* stimulated chondrocyte hypertrophy *in vitro*, indicating *Dnmt3b*/*Abat* axis regulates chondrocyte homeostasis. *Dnmt3b* and *Abat* expression were regulated by inflammatory factors in primary murine and human articular chondrocytes. Finally, *Dnmt3b* gain-of-function mice were protected against cartilage breakdown and subchondral bone sclerosis induced by MLI surgery. Therefore, *Dnmt3b*/*Abat* axis is required for appropriate cartilage metabolism during postnatal joint homeostasis and *Dnmt3b*/*Abat* may serve as a novel and important therapeutic target for OA.

Bone marrow adipocytes selectively resist lipolysis in response to fasting and β -adrenergic stimulation. Erica Scheller*¹, William Cawthorn², Brian Learman³, Brent Wu⁴, Lindsay Andersen³, Hoai An Pham³, Shaima Khandaker³, Aaron Burr³, Sebastian Parlee³, Becky Simon³, Hirovuki Mori³, Adam Bree³, Benjamin Schell³, Ormond MacDougald³. ¹University of Michigan, USA, ²University of Edinburgh, ³University of Michigan, USA, ⁴University of Illinois, USA

Marrow adipose tissue (MAT) is a functionally distinct adipose depot with the potential to contribute to both local and systemic metabolism [1]. We recently reported that MAT exists in two forms, regulated and constitutive, with underlying differences in development, regulation, adipocyte size, lipid composition, gene expression and genetic determinants [2] (Figure 1). We herein report that unlike adipocytes within regulated MAT (rMAT) and white adipose tissue (WAT), constitutive MAT (cMAT) adipocytes do not decrease in size after a 48-hour fast in rats. Similarly, cMAT remains unchanged after a 72-hour treatment with β 3-agonist CL316,243 in mice. Ingenuity pathway analysis[®] suggests that global MAT gene expression patterns are consistent with resistance to insulin and β -adrenergic agonists. Functionally, β -adrenergic-stimulated phosphorylation of hormone sensitive lipase (HSL) and perilipin (PLIN) is blunted in distal tibial MAT from rats *in vivo*, though phosphorylation of ERK1/2 is maintained. Expression of *Cav1* is decreased in MAT at the gene and protein level. Mice with knock-out of *Cav1* have decreased CL316-243-stimulated phosphorylation of HSL and PLIN in WAT. However, in mice with transgenic overexpression of *Cav1*, rMAT is depleted in response to CL316,243 but cMAT remains unchanged. When stimulated *ex vivo*, purified rMAT, but not cMAT adipocytes, undergo lipolysis and glycerol release in response to β 3-agonist CL316,243. Impaired cMAT lipolysis is rescued by downstream agonists forskolin, dibutyryl cyclic-AMP, and IBMX. These data define cell-autonomous pathways driving the selective resistance of marrow adipose tissue to lipolysis, contributing to the resistance of cMAT to both fasting and β -adrenergic stimulation.

LB-SA0013**Novel Metabolic Pathways Controlled by Metformin in Diabetic Mouse Bone Marrow.** Yuqi Guo, Xin Li^{*}. NYU

Metformin is the leading drug used to treat diabetic patients, who often experience many symptoms including bone loss. However, both the molecular targets and the biological pathways affected by metformin in bone are poorly understood. We used a metabolomics approach to investigate the biological pathways affected by metformin in bone marrow cells of mice. Metabolite levels were examined in bone marrow samples extracted from metformin-treated healthy and hyperglycemic (diabetic) mice using LC-MS-based metabolomics. A total of 346 unique metabolites were identified, and they are grouped into distinctive clusters that reflected general and diabetes-specific responses to metformin. As evidenced by changes in the TCA and urea cycles, increased catabolism and nitrogen waste that are commonly associated with diabetes were rebalanced upon treatment with metformin. In particular, we found succinate levels which were drastically elevated in diabetic animals are reduced to normal levels by metformin. We demonstrated that succinate stimulated osteoclastogenesis *in vitro*, which was suppressed by metformin. Overall our study revealed the metabolic pathways modulated by metformin in bones and identified a novel molecular target of metformin in osteoclastogenesis. These results have broad implication in our understanding of enhanced osteoclastogenesis with hyperglycemia and its control in mammals.

LB-SA0014**Tibial Geomorphometry Indicate Stronger Bones in *mdx* Mice at 10 and 20 Weeks of Age.** Caitlin Saint^{*}¹, Maral Zibamanzarmofrad², Sandra Sacco², William Gittings², Rene Vandenboom², Wendy Ward², Paul LeBlanc². ¹Canada, ²Brock University

Background: Duchenne muscular dystrophy (DMD) is a recessive x-linked form of muscular dystrophy characterized by muscle weakness, muscle fiber degeneration, and premature death of the individual. An often overlooked phenotype of DMD is fragile bones that occurs in parallel with the advancement of the disease. The *mdx* mouse is a common rodent model of DMD, demonstrating similar muscle fiber degeneration and declines in muscle function. However, due to their efficient muscle regenerative capacity, the *mdx* model demonstrates a slow-progressing phenotype that does not impact lifespan. The trajectory of bone health also differs in the *mdx* model compared to DMD, where *mdx* bone quality has shown to not change or improve with age. Others have hypothesized that repeated degeneration-regeneration of *mdx* muscle may stimulate bone formation early on and this effect is lost after the regenerative capacity of muscle peaks at 16 weeks of age. However, no studies have examined *mdx* bone quality between 7 and 96 weeks of age. Objective: Thus, the purpose of this study was to determine the influence of age on *mdx* bone geomorphometry using micro-computed tomography (μ CT) at 10 and 20 weeks of age compared to wild-type. Methods: Ten 8 week old wild-type (C57BL/10) and *mdx* (C57BL/10ScSn-Dmdmdx/J) male mice were obtained from Jackson's Laboratory (Bar Harbour, Maine, USA). At 10 and 20 weeks of age, tibia were removed and cortical (mid-diaphysis) and trabecular (proximal metaphysis) were scanned using *in vivo* μ CT (Skyscan 1176) with the following parameters: 45 kV, 545 μ A, 0.2° rotation step, 9 μ m resolution, and 0.25 mm Al filter. Results: Cortical cross-sectional area and wall thickness did not differ with age or phenotype. Trabecular bone volume fraction ($p=0.02$) and number ($p=0.01$) were higher in *mdx* but did not differ with age. Trabecular thickness ($p=0.05$) increased with age but did not differ with phenotype. Finally, trabecular spacing increased with age in both phenotypes, more so in wild-type ($p<0.05$). Conclusion: Improved bone quality, as measured by higher trabecular bone volume and number and lower trabecular spacing, occurs in *mdx* tibia at ages 10 and 20 weeks. These findings support the hypothesis that repeated degeneration-regeneration cycles before and shortly after peak regenerative capacity of *mdx* muscle provides an environment that stimulates bone formation. Future work should examine putative osteogenic factors found in the *mdx* model at these ages.

Disclosures: Caitlin Saint, None.

LB-SA0015**LIAISON XL Assay for the Measurement & Monitoring of Active Vitamin D Analogs.** Frank Blocki^{*}¹, Greg Olson¹, John Wall¹, Jeremy Seeman¹, Fabrizio Bonelli¹, J.Ruth Wu-Wong². ¹DiaSorin Incorporated, USA, ²VidaSym

Background: Despite years of vitamin D analogs (for vitamin D receptor agonist, VDRA) research, currently VDRA are indicated mainly for managing secondary hyperparathyroidism in chronic kidney disease, and to a lesser degree are used to treat osteoporosis and psoriasis. The fact that on-the market VDRA are not more widely used for treating osteoporosis is in part due to their narrow therapeutic index, which presents at least two significant, albeit related, challenges. First, the need to frequently monitor serum Ca^{2+} levels to avoid hypercalcemia, which leads secondly, to the need for frequent titration of VDRA dosing. Clearly, emergent VDRA such as VS-105 and VS-110 with a wider therapeutic index will allow expanded utility in

osteoporosis and also into new indications including left ventricular hypertrophy, endothelial-dependent aortic relaxation and fibrosis without the pall of impending hypercalcemia.

Methods: The DiaSorin LIAISON assay was initially designed to specifically detect the complexed form of the nuclear receptor's ligand binding domain (LBD) with 1,25(OH)₂D (calcitriol) for the measurement of serum 1,25(OH)₂D levels, and can be potentially used to measure serum samples of subjects treated with Zemplar, Hecetrol and calcitriol. The assay was further characterized for its broader applicability to measure four novel VDRA with significantly wider therapeutic indices. Real time kinetic (ForteBio *Octer*) binding constants for each LBD-VDRA complex using a specific monoclonal antibody against LBD-1,25(OH)₂D were generated.

Results: 125 normal adults assessed with the DiaSorin LIAISON 1,25(OH)₂D assay had a mean of 49.6 pg/mL (95% CI: 19.9 – 79.3pg/mL). Standard curves constructed from VS-104, VS-105, VS-110 & VS-411 were all linear ($R^2>0.999$ for each) with slopes relative to the 1,25(OH)₂D standard curve of 16%, 69%, 79% and 93%. In the presence of a mean endogenous 1,25(OH)₂D level of 50pg/mL, the assay had sufficient capacity to accurately and precisely detect Zemplar across a linear range of up to 200pg/mL with complete linearity $R^2=0.997$ and a recovery of 93%. Similar results were obtained for VS-105, VS-104, VS-110 & VS-411. Conclusion: The DiaSorin LIAISON assay has potential to provide a convenient and extremely accurate and precise method for the confident clinical management of novel VDRA with a wider therapeutic index as they become cleared for clinical use.

Disclosures: Frank Blocki, DiaSorin Inc

LB-SA0016**Timing of Indomethacin Administration Causes Differential PGE₂ Response in Fluid Shear Stress Stimulated MLO-Y4 Cells.** Cheryl Drucho^{*}¹, Lidan You², Gregory Wohl³. ¹McMaster University, Canada, ²Department of Biomechanical & Industrial Engineering, Institute of Biomaterials & Biomedical Engineering, University of Toronto, Canada, ³Department of Mechanical Engineering, McMaster School of Biomedical Engineering, McMaster University, Canada

Background: Prostaglandins (PGs) are important signaling factors for bone mechanotransduction. Non-steroidal anti-inflammatory drugs (NSAIDs) have been shown to inhibit PG production of bone cells subjected to fluid shear stress *in vitro*. The purpose of this study was to assess the effects of indomethacin and its timing on the PGE₂ response of fluid shear stress stimulated MLO-Y4 cells.

Methods: MLO-Y4 cells were seeded on collagen coated 6-well culture plates 48hrs prior to loading, at 20,000 cells per well to ensure 70–80% confluence at the time of experiment. Plates were placed on an orbital shaker rotating at 200rpm to generate a fluid shear stress of approximately 1.9Pa for 2hrs. The shaker was placed in an incubator at 37°C and 5% CO₂. The media in the control (CON) group contained no NSAID. Media containing indomethacin (1×10^{-5} M) was added 30mins prior to loading in the PRE group and was present during the loading and 30mins after. Media containing indomethacin was added 30mins after loading in the POST group and was present for 3hrs. Plates subjected to shear stress (CON-F, PRE-F, POST-F) were left to sit for 30mins, loaded for 2hrs and then left to sit for 30mins before the media was sampled. Stationary non-loaded plates (CON-S, PRE-S, POST-S) were placed on a shelf in the incubator for 3hrs. Media samples were collected 30mins and 24hrs after loading. Fresh media was added 30mins prior to loading and 30mins, 3.5hrs and 6.5hrs after loading. Medium PGE₂ concentrations were determined by enzyme immunoassay. Groups were compared by 2-way ANOVA.

Results: Fluid shear stress increased the PGE₂ production of MLO-Y4 cells at 30mins in the CON-F and POST-F groups (Figure 1). At 24hrs PGE₂ concentration was similar in the CON-S and CON-F groups. Indomethacin inhibited PGE₂ production in the PRE-S and PRE-F groups at 30mins. At 24hrs, PGE₂ concentration in the PRE group was similar to that of the CON group. Indomethacin administration after loading resulted in lower PGE₂ concentrations in the POST group at 24hrs compared to the CON group.

Discussion: The PGE₂ response of MLO-Y4 cells to fluid shear stress is inhibited by indomethacin administration and varies depending upon its timing. This altered PGE₂ response may affect subsequent downstream events in the mechanotransductive process. Future studies will further examine how NSAIDs affect osteocyte signaling in response to fluid shear stress and how that in turn influences osteoblast activity.

Conditional Deletion of Protein Kinase D1 in Osteoprogenitor Cells Results in Decreased Osteogenesis *in vitro* and Decreased Bone Mineral Density *in vivo*. Wendy Bollag^{*1}, Vivek Choudhary², Qing Zhong³, Kehong Ding³, Jianrui Xu³, Lakiea Bailey³, Maribeth Johnson³, Yun Su³, Meghan McGee-Lawrence³, Xingming Shi³, Carlos Isaacs³. ¹Charlie Norwood VA Medical Center & Georgia Regents University, USA, ²Charlie Norwood VA Medical Center & Georgia Regents University, USA, ³Georgia Regents University, USA

Protein kinase D1 (PKD1), a protein kinase possessing homology to the protein kinase C and calcium/calmodulin-dependent kinase families, has been reported to play a role in a number of cellular functions, including proliferation and differentiation, cell survival, autophagy, Golgi trafficking and migration. A recent report has shown that heterozygous transgenic mice expressing a knocked in dominant-negative PKD1 mutant allele show reduced pubertal bone mass. However, the dominant-negative mutant used in these studies is known to inhibit both PKD1 and PKD2; furthermore, these investigators found the mutant to exert effects in several bone cell types including bone marrow stromal cells, osteoblasts and osteoclasts, making identification of the exact mechanism of the low bone mass difficult. PKD1 has been shown to protect cells against mitochondrially generated reactive oxygen species (ROS) and apoptosis by upregulating antioxidant systems. Our preliminary data indicate that PKD1 is expressed in bone marrow-derived mesenchymal stem cells (BMMSC) and can be activated in response to agents that trigger oxidative stress, such as hydrogen peroxide. Since PKD1 is known to protect against damage induced by oxidative stress, we hypothesized that PKD1 would be essential for the ability of osteoprogenitor cells to form bone, an ROS-generating process, *in vitro* and *in vivo*. Using BMMSCs isolated from floxed PKD1 mice, we found that PKD1 ablation upon adenovirus-mediated expression of Cre recombinase inhibited BMMSC differentiation (by alizarin red staining) in an osteogenic medium *in vitro*. Furthermore, conditional knockout mice in which PKD1 was ablated in osteoprogenitor cells by osterix promoter-driven Cre recombinase were generated. By DXA adult (3-month-old) conditional knockout (cKO) mice exhibited a significantly reduced femoral and tibial bone mineral content and bone mineral density (BMD) *in vivo* in comparison with littermate controls, with a femur BMD for control of 0.0588 ± 0.0022 (mean \pm SD; n=6) and for cKO of 0.0547 ± 0.0033 g/cm² (n=8). Micro-CT analysis showed a significant decrease in bone volume and bone surface in the cKO mice compared to controls. Histomorphometric analyses are in progress to further characterize the bone phenotype of the cKO mouse model. Taken together, our results suggest an important role for PKD1 in bone formation through modulation of stem cell/osteoprogenitor cell function.

Performance evaluation of the first fully automated immunoassay for Sclerostin detection and measurement. Jennifer Woodley^{*}, Frank Blocki, Kim Hilgers, Christa Klatt, Pete Voth, John Wall, Greg Olson, James Wassenberg, Fabrizio Bonelli, DiaSorin, USA

Background

Sclerostin is an emerging biomarker with an important role in the regulation of bone formation and remodeling. Sclerostin levels have also been implicated in chronic diseases such as kidney disease, diabetes and osteoporosis. However, clinical studies to establish the importance of sclerostin as a diagnostic marker have been hampered by conflicting results about the reliability of the currently available manual Sclerostin assays. Automation can improve the performance and reliability of Sclerostin testing as described herein.

Methods

The LIAISON Sclerostin assay utilizes monoclonal capture antibodies coupled to paramagnetic particles followed by polyclonal antibodies in a "sandwich" format with chemiluminescent detection. The assay is performed on the LIAISON family of analyzers to deliver highly sensitive, precise and fully automated quantitation of Sclerostin from 50 uL of human serum and plasma in 65 minutes.

Results

The LIAISON Sclerostin assay demonstrates linearity over its measuring range from 50 to 6000 pg/mL as standardized to a pure preparation of recombinant human Sclerostin. The within-run imprecision coefficients of variation (CV) calculated on 8 serum samples were between 1.0% and 3.9%. Between run imprecision results were between 2.1% and 8.9%. Limit of detection (LoD) and limit of quantitation (LoQ) were 19.7 pg/mL and 39.2 pg/mL respectively. Analytical recovery of patient samples was between 90% and 104%. Though the Sclerostin protein is subject to thermal degradation, patient samples tested with the LIAISON Sclerostin assay continue to produce reliable results after short term ambient storage, repeated freeze thaw cycles, or long term frozen storage.

Conclusions

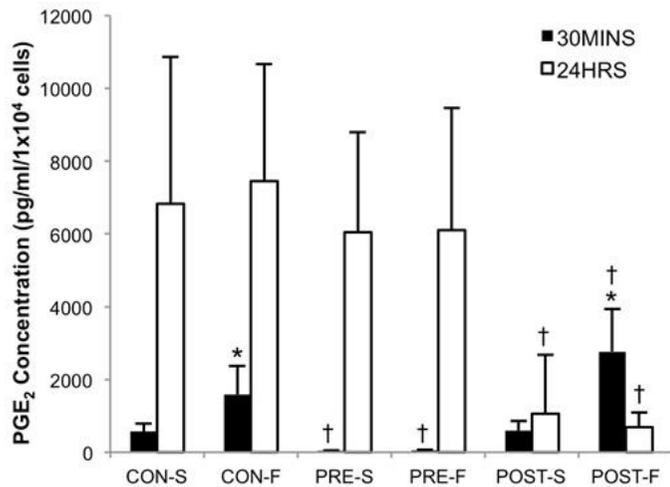

Figure 1. Medium PGE₂ concentration (pg/ml/1x10⁴ cells). Values are mean \pm STD. *Different from static, $p < 0.05$. †Different from CON, $p < 0.05$. S = static; F = flow.

Reversal of *Sost* Deficiency-Induced Sclerosing Bone Gain by Inhibition of Wnt Ligand Secretion. Ina Kramer^{*1}, Sabine Guth-Gundel², Christine Halleux², Shea Carter², Jun Liu³, Jennifer L. Harris³, Michaela Kneissel². ¹Novartis Institutes for Biomedical Research, Switzerland, ²Musculoskeletal Disease Area, Novartis Institutes for BioMedical Research, Switzerland, ³Genomics Institute of the Novartis Research Foundation, Switzerland

Loss-of-function of the bone formation inhibitor sclerostin encoded by the *Sost*/SOST gene results in life-long sclerosing bone growth in mice and humans. Currently, there are no therapeutic treatment options available for patients with rare sclerosing disorders related to *SOST* deficiency, such as sclerosteosis (MIM269500), van Buchem disease (MIM239100) and craniodiaphyseal dysplasia (MIM122860).

Sclerostin has been shown to exert its function as a bone formation inhibitor by blocking canonical Wnt signaling downstream of the Wnt co-receptors low density lipoprotein receptor-related proteins (LRP) 5/6. To test whether the abnormal bone gain in *Sost* deficient mice can be reversed by inhibition of Wnt ligand secretion, we subjected 3-month-old wild-type C57BL/6J and *Sost* deficient female mice to six weeks oral treatment with a novel, potent small-molecule inhibitor of porcupine. Porcupine is an endoplasmic-reticulum-resident acyltransferase that palmitoylates Wnt ligands, a modification required for Wnt secretion.

Porcupine inhibitor treatment decreased femoral and tibial total bone mass and density in a dose-dependent manner in wild-type and *Sost* mutant mice as measured longitudinally by pQCT. Bone gain was similarly suppressed in the cancellous and cortical bone compartment. In contrast, long bone length was not affected by porcupine inhibitor treatment. *Ex vivo* microstructural analyses of the femur and lumbar spine by high-resolution micro-CT confirmed dose-dependent reductions of trabecular bone/tissue volume, cortical bone thickness and total bone mineral density at both skeletal sites. Analysis of serum bone turnover biomarkers osteocalcin and TRACP5b revealed treatment-related combined suppression of osteoblastic bone formation and enhanced osteoclastic bone resorption in line with broad suppression of Wnt signaling activity independent of genotype. Moreover, there was a dose-dependent suppression of circulating sclerostin levels in wild-type mice suggesting feedback-regulation to modulate Wnt pathway activity and maintain skeletal homeostasis. Together, we demonstrate that porcupine function is required for normal bone gain during late-stage skeletal growth in mice. Importantly, porcupine inhibition restores bone growth in *Sost* deficient mice to normal levels present in wild-type mice suggesting that porcupine inhibitors might be a novel treatment strategy for rare sclerosing bone disorders related to *SOST* deficiency.

A Novel Bone Graft with an Osteoinductive Surface: Fortigen has rhBMP-2-like characteristics in vitro. Helen Newman*¹, Larry Shimp². ¹VTS & Progenica Therapeutics, ²Progenica Therapeutics & CaP Biomaterials

In order to enhance bone healing, it is important to engineer grafts with enhanced osteoinductive (OI) features. A commercially available example of a manufactured OI growth factor is Infuse®. It contains recombinant human Bone Morphogenetic Protein-2 (rhBMP-2). The veterinary version is known as Truscent®. rhBMP-2 can cause a dramatic increase in bone formation, but it is not bound to the carrier scaffold, and so is free to migrate away after implantation. This has led to extraskelatal bone growth and other adverse effects including inflammation, swelling and radiculopathy. Although bone allograft naturally contains many growth factor types, including BMP-2, it contains relatively low concentrations of the growth factors, so healing is not as robust as with Infuse/Truscent. This study evaluates a novel approach to solving the problem of provision of effective concentrations of osteoinductive growth factors that will remain in a site. We refer to the most osteoinductive versions as Fortigen™.

Both control and investigational particles (synthetic and natural bone grafts) were tested for inductivity using an Alkaline Phosphatase Assay (ALP) (Han et al., 2003). This *in vitro* ALP method is a validated model for assessment of OI. It is based on the ability of inductive agents to transform mesenchymal stem cells into osteoblasts. Controls included positive and negative conditions: a known positive reference lot of rhBMP-2 was used for positive controls; negative controls were graft materials without surface modifications. Cell viability studies were also conducted to determine if the modifications had any adverse impact on cell survival. ALP activity was normalized to cell survival data.

Some versions of surface-modified particles (Fortigen™-S2 and Fortigen™-P) had significantly higher OI when compared to the negative controls (p-values=0.000; n=3). The OI of some of the investigational particles (Fortigen-V2) was similar to the OI of positive control cultures (p-value=0.102 at a non-inferiority margin of 15%; n=3). The data show that these surface modifications can result in substantial increases in standard markers of OI *in vitro*; in some cases comparable to rhBMP-2. Additionally, the modifications did not have an adverse impact on the viability of the cells in culture or their ability to adhere to the particles. These data are very promising. The design has the potential benefit of accelerating bone healing locally without the risk of signaling molecules leaving the site.

Increased bone mass and biomechanical properties in mice deficient for FIAT (Factor Inhibiting ATF4-mediated Transcription). Bahareh Hekmatnejad*¹, Vionnie W.C. Yu², Vice Mandic², Martin Pellicelli¹, Alice Arabian², Rene St-Arnaud³. ¹Dept of Human Genetics, McGill University, ²Shriners Hospitals for Children - Canada, ³Shriners Hospital for Children & McGill University, Canada

We previously reported that FIAT (Factor Inhibiting ATF4-mediated Transcription) interacts with ATF4 to repress its transcriptional activity. Transgenic mice overexpressing FIAT exhibit osteopenia while silencing FIAT in osteoblasts by RNA interference enhanced all ATF4 functions tested. This study reports the first bone phenotype of *Fiat* KO mice at 8- and 16-week of age and the impact of the mutation on the response to functional loading. RT-qPCR and Western blot analysis confirmed efficient *Fiat* gene inactivation with undetectable mRNA or protein levels. *Fiat* mutant mice appeared normal at birth and weight gain was identical between wild type and knock-out animals. Expression of the ATF4 transcriptional target Osteocalcin (*Bglap1*) was significantly increased in *Fiat*-deficient bone. Microcomputed tomography analysis of proximal femur demonstrated an age-dependent increase in trabecular bone volume and thickness in *Fiat* KO mice compared with their wild-type littermates. In addition, cortical bone measurements at the femoral midshaft revealed a significant increase in cortical thickness in older *Fiat* KO mice and consequently a significant increase in stiffness and strength was measured. FIAT protein expression is strongly detected in osteocytes; we thus compared the response to mechanical loading *in vivo* between 16-week-old wild-type and *Fiat*-deficient mice. We measured a difference in baseline BFR of cortical bone between control and *Fiat* KO mice as assessed by calcein double labeling in the unloaded ulna. We observed a robust bone formation response in the loaded bones that was not significantly different between wild-type and *Fiat*-deficient mice. Our results confirm that FIAT is a negative regulator of bone biology contributing to both trabecular and cortical bone homeostasis *in vivo*.

Insulin Receptor Substrate 1 Time-dependently Regulates Bone Formation by Controlling Collagen I Alpha 2 Expression Through miR-342. Hou-De Zhou*¹, Yue Guo², Chen-Yi Tang², Xiao-Fei Man², She-Wen Tan², Hao-Neng Tang², Fang Wang², Jun Tang², Ci-La Zhou². ¹The 2nd Xiangya Hospital of Central South University, China, ²Institute of Endocrinology & Metabolism, the Second Xiangya Hospital of Central South University, China

Insulin promotes bone formation through canonical insulin signal pathway, the repaired insulin signal was found to be correlated to the diabetic osteopathy. Insulin receptor substrate 1 (IRS-1) is an important signal molecule in insulin signal pathway, which was attenuated in many tissues such as bone and adipose tissue of patients with diabetic osteopathy. As adipocytes and osteoblasts are derived from the same progenitor-mesenchymal stem cells (MSC), and bone marrow stem cells (BMSC) are the primitive source for MSC, we supposed that IRS-1 could regulate differentiation of BMSC and function of osteoblast. So we identified an IRS-1 deficiency mice (IRS-1^{smia/smia}) with a spontaneous mutation at position 57 (S57X) which resulting in complete loss of IRS1 protein expression. We found that the bone mineral density and trabecular number were increased in 3-month of IRS-1^{smia/smia} mice, but were decreased in 12-month of IRS-1^{smia/smia} mice. We then compared the differential expressed genes and miRNAs by osteogenesis PCR array and miRNA array respectively in 3-month of wild type and IRS-1^{smia/smia} mice. We identified 72 differential expressed miRNAs and 39 differential expressed osteogenesis related genes. We then predicted all the target genes of differential miRNAs and compared them with the differentially expressed osteogenesis related genes, and found that collagen type I alpha 2 (Col1a2), one of the target genes of miR-342, were up-regulated in IRS-1^{smia/smia} mice, while miR-342 was down-regulated. Transfection of miR-342 inhibits the collagen 1 alpha 2 expression in primary cultured osteoblast, while antagonist for miR-342 increases Col1a2 expression. Further study *in situ* showed that Col1a2 in osteoblast and bone marrow of 3-month old IRS1^{smia/smia} mice were higher than that of wild type mice, but decreased in 12-month old mice. During *in vitro* induction of bone marrow cells (BMCs) into matured osteoblast and osteocytes, Col1a2 expression gradually increased and reached the peak at the 8th day, and then reduced. While miR-342 expression showed an obvious negative relation with the expression of Col1a2. Col1a2 siRNA decreased the ALP activity, while miR-342 inhibitor can increase the ALP activity and Col1a2 expression of BMCs. Thus our researches showed that IRS-1 can time-dependently regulate bone formation by regulating Col1a2 expression through miR-342, and disclosed a new mechanism for insulin signal involved in the bone formation.

Loss of the nutrient sensor Tas1R3 leads to reduced bone resorption. Michael Eaton¹, Jordan Newby², Maggie Plattes³, Hannah Foster³, Brian Dewar³, Eric Wauson⁴, Jon Arthur⁵, Jonathan Lowery*⁵. ¹Department of Biomedical Science, Marian University College of Osteopathic Medicine, ²Department of Biomedical Science, Marian University College of Osteopathic Medicine & Department of Biology, Freed-Hardeman University, ³Department of Biology, Taylor University, ⁴Department of Physiology & Pharmacology, ⁵Department of Biomedical Science

The TAS1R family of heterotrimeric G protein-coupled receptors participates in monitoring energy and nutrient needs. TAS1R3 is a bi-functional protein that either recognizes amino acids such as glycine and L-glutamate or sweet molecules such as sucrose and fructose when dimerized with TAS1R1 or TAS1R2, respectively. Loss of TAS1R3 expression leads to impaired mTORC1 signaling and increased autophagy, indicating that signaling through this receptor is critical for assessing nutrient needs. Recently, it was reported that global deletion of TAS1R3 expression in mice (*Tas1R3* mutant) leads to increased cortical bone mass and trabecular remodeling (Simon et al 2014) but the underlying cellular mechanism leading to this phenotype remains unclear. To address this open question, we quantified bone turnover markers in serum from 20-week-old wild type and *Tas1R3* mutant mice and found that levels of the resorption marker Collagen Type I C-telopeptide (CTX) were reduced on average by >60% in the absence of TAS1R3 expression (wild type: 8.791 ± 0.75 ng/ml, n=3; *Tas1R3* mutant 3.248 ± 1.14 ng/ml, n=4; p<0.02 by unpaired t test). Levels of the bone formation marker Procollagen Type I N-terminal Propeptide (PINP) tend to be higher in *Tas1R3* mutant mice (wild type: 981 ± 407.5 pg/ml, n=3; *Tas1R3* mutant 2009 ± 421.5 pg/ml, n=3) but this finding did not reach statistical significance (p<0.15 by unpaired t test). These preliminary results suggest that high bone mass in *Tas1R3* mutant mice is due to uncoupled bone remodeling with reduced osteoclast function. We examined the skeletal expression profile of *Tas1R3* in order to determine the cellular compartment(s) in which TAS1R3 impacts bone remodeling. Consistent with the observed defect in bone resorption in *Tas1R3* mutant mice, *Tas1R3* mRNA is expressed in primary osteoclasts obtained from wild type mice. However, *Tas1R3* mRNA is also present in marrow-free humeri, primary bone marrow stromal cells,

and several osteoblast-like cell lines, raising the possibility that osteoblast-to-osteoclast communication may be disrupted in *Tas1r3* mutant mice. Collectively, these findings provide the rationale for future experiments examining the cell type-dependent role for TAS1R3 function in nutrient sensing in postnatal bone remodeling and differentiation of osteoclasts and osteoblasts.

Cellular senescence phenotype attributes trigger of bone remodeling to monocyte recruitment. Insun Song*, Yong Jun Choi, Yoon-Sok Chung. Ajou University School of Medicine, South Korea

Aims: To understand the trigger of monocyte recruitment for bone remodeling, we introduced the model of cellular senescence and examined mouse osteocytes and hypertrophic chondrocytes.

Main Methods: To determine whether the cellular senescence phenotype involved in monocyte recruitment, we first performed senescence-associated β -galactosidase (SA- β -gal) assay in osteocytes and hypertrophic chondrocytes. And we introduced immunohistochemistry with anti-F4/80 and tartrate-resistant acid phosphatase (TRAP) assay for detecting monocytes and mature osteoclasts at mouse osteocytes and hypertrophic chondrocytes in femur and tibia of 8-week-old C57b/6 mice.

Key Findings: Generally recruitment of monocytes occurs by chemokines and their receptors during infection and inflammation. However the process of monocyte recruitment for osteoclasts involved in bone remodeling still remained unclear. So, we hypothesize that the cellular senescence phenotype could appear in bone cells and have a role in bone remodeling initiating recruitment of monocytes. Cellular senescence shows some specific characteristics; cell-cycle arrest, positive SA- β -gal, enlarged and flat cell morphology, and senescence-associated secretory phenotype (SASP) including some inflammatory factors and many kinds of cytokines. So we investigated the cellular senescence pattern in osteocytes and hypertrophic chondrocytes associated with bone remodeling and bone formation. Osteocytes and hypertrophic chondrocytes show growth arrest with enlarged and flat cell morphology. We have examined the endogenous SA- β -gal response related recruitment of immune cells for elimination of semi-permanent structures. We found that hypertrophic chondrocytes and some osteocytes show a clear positive SA- β -gal response. Our results also reveal that these locations show positive anti-F4/80 and TRAP in the almost same region.

Significance: Based on the results of positive endogenous SA- β -gal, anti-F4/80 and TRAP response in the same boundary of bone cells, we propose that the cellular senescence phenotype leads to recruitment of monocytes involved in the first step of osteoclast resorption, triggering of bone remodeling.

Disclosures: Insun Song, None.

LB-SA0025

Transgene expression by Dmp1 promoter fragments occurs in various organs. Hiroaki Saito*¹, Hanna Taipaleenmäki², Ahmed Al-Jazzar³, Andreas Gasser¹, Behzad Javaheri³, Cheryl Scudamore³, Teresita Bellido⁴, Andrew A. Pitsillides³, Eric Hesse¹. ¹Heisenberg-Group for Molecular Skeletal Biology, Department of Trauma, Hand & Reconstructive Surgery, University Medical Center Hamburg-Eppendorf, ²Heisenberg-Group for Molecular Skeletal Biology, Department of Trauma, Hand & Reconstructive Surgery, University Medical Center Hamburg-Eppendorf, Germany, ³Comparative Biomedical Sciences, The Royal Veterinary College, ⁴Department of Anatomy & Cell Biology, Indiana University School of Medicine

Osteocytes are key players in regulating bone mass maintenance and thus constitute a major research focus in the field of bone biology. Since analysis of osteocyte function often requires *in vivo* investigations, promoter elements of osteocyte-specific genes i.e. *SOST* or *Dentin-matrix-protein 1* (*Dmp1*) are used to overexpress genes of interest or the Cre-recombinase for conditional deletion studies. While these tools have been very useful, emerging evidence suggests that these promoters may not be osteocyte-specific, which would be critical for subsequent data interpretation. To investigate the selectivity of these proposed osteocyte-specific *in vivo* models, we crossed 8kb-Dmp1-Cre mice (i) with Ai9 tomato reporter mice (Dmp1-Cre⁺;Ai9^{T/wt}), and (ii) with mice, in which the expression of the diphtheria toxin receptor (DTR) is controlled in a Cre-inducible manner (Dmp1-Cre⁺;iDTR^{T/wt}) to ablate Dmp1-positive cells. Furthermore, we explored the effects of diphtheria toxin (DT) in mice harboring the human DTR (hDTR) regulated by a 10kb-Dmp1 promoter fragment (Dmp1-hDTR). Immunohistochemical staining of tibiae harvested from 8-week old Dmp1-Cre⁺;Ai9^{T/wt} mice revealed a strong tomato expression in all osteocytes and osteoblasts covering endocortical and trabecular surfaces. Furthermore, we detected tomato expression in muscle, brain, testis and in vessels in the heart, spleen, lung, and intestine. Consistently, histological analyses of bones seven days after DT administration in Dmp1-Cre⁺;iDTR^{T/wt} and Dmp1-hDTR mice revealed partial, yet significant ablation of not only osteocytes but also osteoblasts and lining cells. In addition, DT injection resulted in liver vacuolation, acute kidney necrosis, splenic atrophy, and disturbance of bone marrow composition in Dmp1-hDTR mice, which is consistent with expression of hDTR mRNA in these tissues. Taken together,

our results indicate that in 8kb-Dmp1-Cre mice as well as in 10kb-Dmp1-hDTR mice, expression of the respective transgene is not restricted to osteocytes, but also takes place in other organs, some of which are known to be functionally involved in the regulation of bone homeostasis. Our findings therefore suggest that despite the great usefulness of these *in vivo* systems, the expression pattern of the gene of interest should be determined carefully and the results need to be interpreted accordingly.

Defined Sets of Transcription Factors Induce the Expression of Functional Sclerostin in Human Dermal Fibroblasts and Its Expression Responds to Parathyroid Hormone, Hypoxia and Prostaglandin E2. Makoto Fujiwara*¹, Wei Wang², Taichi Kitaoka², Takuo Kubota², Yasuji Kitabatake², Noriyuki Namba³, Toshimi Michigami⁴, Keiichi Ozono². ¹Osaka University graduate school of medicine, Japan, ²Department of Pediatrics, Osaka University Graduate School of Medicine, ³Department of Pediatrics, Osaka University Graduate School of Medicine, ⁴Department of Bone & Mineral Research, Osaka Medical Center & Research Institute for Maternal & Child Health, Japan

Background: Sclerostin, encoded by *SOST*, is a secretory protein expressed specifically in osteocytes and suppresses osteogenesis by the inhibition of the WNT signaling. Regulatory mechanism of *SOST* expression remains unclear mainly due to difficulty in using osteocytes *in vitro*. With the aim to establish the method for inducing the *SOST* expression in human fibroblasts as a substitute for osteocytes, we have identified 4 transcription factors, ATF3, KLF4, PAX4 and SP7 and reported at the annual meeting of ASBMR in 2014.

Purpose: In the present study, we aim to elucidate the function of sclerostin and factors which regulate *SOST* expression in this system.

Methods: We introduced ATF3, KLF4, PAX4 and SP7 genes into human dermal fibroblasts (purchased from Lonza) using retrovirus, and analyzed *SOST* expression levels by real time PCR and measured sclerostin concentrations in conditioned medium by ELISA. Functional analysis of induced sclerostin on the WNT/beta-catenin signal was performed using the TOPflash reporter vector. The changes of *SOST* and sclerostin expression by the addition of Parathyroid Hormone (PTH) or prostaglandin E2 (PGE2) and under hypoxia were also analyzed.

Results: Combination of ATF3, KLF4, PAX4 and SP7 induced *SOST* expression 1000 times and sclerostin at concentration 21.2 pmol/L in the conditioned medium in human dermal fibroblasts at 4 weeks after transduction. Functional analysis using TOPflash reporter vector revealed that the induced sclerostin suppressed the WNT10b-induced transcriptional activity. PTH addition significantly suppressed the induced *SOST* (62.3 % compared to vehicle) and sclerostin (addition: 5.7 pmol/L, vehicle: 31.2 pmol/L). Hypoxia culture caused increase of the induced *SOST*, 162 % compared to normoxia. Furthermore, PGE2 enhance the *SOST* expression remarkably, 1630 % compared to vehicle.

Conclusion: Induced sclerostin expression in human dermal fibroblasts achieved by transduction of ATF3, KLF4, PAX4 and SP7 have an activity of suppressing the WNT/ beta-catenin signaling, and its expression was regulated by PTH, hypoxia and PGE2. This method may contribute to elucidation of sclerostin function and drug developments that regulate sclerostin expression in various kinds of bone diseases.

Disclosures: Makoto Fujiwara, None.

LB-SA0027

Bone Turnover Markers in Young Women. Emma Callegari*¹, Alexandra Gorelik², Nicola Reavley¹, Suzanne M. Garland³, Cherie Chiang⁴, John D. Wark⁵. ¹The University of Melbourne, Grattan St, Melbourne, Victoria, Australia, ²Melbourne EpiCentre, Royal Melbourne Hospital, University of Melbourne, Parkville, Victoria, Australia, ³The University of Melbourne, Grattan St, Melbourne, Victoria, Australia; Murdoch Childrens Research Institute, Melbourne, Victoria, Australia; Royal Women's Hospital, Parkville, Melbourne, Victoria, Australia, ⁴Melbourne Health Shared Pathology Services, Royal Melbourne Hospital, Parkville, Melbourne, Victoria, Australia, ⁵The University of Melbourne, Grattan St, Melbourne, Victoria, Australia; Bone & Mineral Medicine, Royal Melbourne Hospital, Parkville, Victoria, Australia

Bone turnover markers (BTMs) may provide insight into bone development and bone health in young women but have been little studied in this demographic and normative data are lacking. The aim of this analysis was to examine the distribution and association of C-terminal telopeptide of type 1 collagen (CTX) and total procollagen type 1 N-propeptide (PINP) with relevant covariates as well as to determine the reference intervals of BTMs in healthy females aged 16-25 years participating in the Safe-D study. Participants were recruited through the social networking site Facebook, completed an extensive, online questionnaire and attended a study site visit. Fasting blood was collected from 255 participants and tested for CTX and PINP using the Roche Elecsys automated analyser. The reference interval was defined as the central 95% of normalized values. After excluding 54 participants

based on medical history, medication use or abnormal pathology (creatinine <45 or >90 $\mu\text{mol/L}$, corrected calcium <2.10 or >2.60 mmol/L , 25-hydroxyvitamin D (25OHD) <25 nmol/L , parathyroid hormone (PTH) >14 pmol/L , thyroid stimulating hormone <0.35 or >4.94 mIU/L , C-reactive protein >10 mg/L), the reference interval was 0.2-1.2 ng/mL for CTX and 15-177 ug/L for P1NP. BTMs were inversely associated with age and years since menarche [for CTX ($r = -0.40$ and $r = -0.41$, respectively) and for P1NP ($r = -0.38$ and $r = -0.44$, respectively); $p < 0.001$ for both variables]. In a multivariate model, CTX and P1NP were significantly lower in subjects who used hormonal contraception (CTX: users 0.5 vs. non-users 0.7 ng/mL , $p < 0.001$; P1NP: users 60 vs. non-users 83 ug/L , $p < 0.001$). CTX and P1NP were not associated with BMI but CTX was negatively associated with body fat percentage ($\beta = -0.005$, 95% CI -0.0093 to -0.0004, $p = 0.035$). CTX and P1NP were associated with PTH ($\beta = 0.027$, 95% CI 0.012 to 0.041, $p < 0.001$ and $\beta = 0.252$, 95% CI 0.056-0.448, $p = 0.012$, respectively). CTX and P1NP were not associated with 25OHD or whole body BMD as continuous variables. In conclusion: age, menarche, PTH and hormonal contraceptive use were all significantly associated with CTX and P1NP concentrations. Body fat percentage was significantly associated with CTX but not P1NP. To our knowledge this is the first study to report BTMs in healthy young women aged 16-25 years; findings will have important application in bone health research and in the generation of age-specific reference intervals in this demographic.

Disclosures: Emma Callegari, None.

LB-SA0028

Bone Microstructure Identifies Women Without Osteoporosis Suffering Fragility Fractures: the prospective OFELY study. Stephanie Boutroy^{1*}, Roger Zebaze², Elisabeth Sornay-Rendu³, Ego Seeman², Roland Chapurlat³. ¹INSERM UMR1033 & Université de Lyon, France, ²Depts. Medicine & Endocrinology, Austin Health, University of Melbourne, & Straxcorp, ³INSERM UMR1033 & Université de Lyon

Introduction: The aim of treatment is to prevent the first, and all subsequent fractures. The bone mineral density (BMD) diagnostic threshold for 'osteoporosis' (T-score ≤ -2.5 SD) lacks sensitivity because more than half of all the fractures in the community, and around 30% of the morbidity and mortality arise in women with osteopenia or normal BMD (1). The challenge is to identify and target therapy to those women with bone fragility among this large low risk group, before they fracture. We hypothesized that women who sustain incident fractures have disrupted microarchitecture which disproportionately compromises bone strength relative to the modest bone lost (because loss of strength is a 7th power function of porosity and a 3rd power function trabecular bone volume (2)).

Methods: To identify these women we monitored 589 women aged 42 to 94 years for a median of 8.1 [0.9] years [interquartile range IQ] in Lyon, France. We measured hip and lumbar spine BMD using Hologic QDR 4500A, microarchitecture of the distal radius using high resolution peripheral quantitative computed tomography, and quantified cortical and trabecular morphology using StrAx1.0 (Straxcorp, Melbourne).

Results: Fractures occurred in 111 women. These women had 0.36 SD lower cortical thickness, 0.38 SD higher porosity, and 0.44 SD fewer trabeculae compared with women without incident fractures (all $p < 0.001$). Porosity predicted fracture independently of hip BMD, hazards ratio [95%CI] = 1.28 [1.03-1.59] per SD increase ($p = 0.027$) and identified 25 (22%) more women sustaining fracture than the BMD T-score of ≤ -2.5 SD.

Only 27% ($n = 30$) of the 111 women who fractured had osteoporosis at baseline; the majority having an incident fracture [$n = 81$ (73%)] had osteopenia [$n = 49$ (44%)] or normal BMD [$n = 32$ (29%)]. In these 81 women, adding a measurement of porosity identified 25 (31%) more women sustaining fractures and identified 16 (20%) more women than using FRAX alone while increasing the false positive rate by 14%.

Conclusion: This is the first prospective study demonstrating that women who sustain fragility fractures can be identified before they fracture by measuring microarchitecture, particularly women with osteopenia or normal BMD who would usually not be investigated further or considered for treatment.

Digital X-ray radiogrammetry in the Study of Osteoporotic Fractures: Comparison to dual energy X-ray absorptiometry and FRAX. Johan Kalvesten^{1*}, Lily Y Lui², Torkel B Brismar³, Steven R Cummings². ¹Linköping University, CMIV & Sectra AB, Sweden, ²San Francisco Coordinating Center, California Pacific Medical Center, San Francisco, CA, USA, ³Karolinska Institutet, Department for Clinical Science, Intervention & Technology, Division of Radiology, Karolinska University Hospital, Sweden

Background: Osteoporosis is often underdiagnosed and undertreated. Bone mineral density (BMD) screening of post-menopausal women has been proposed to overcome this. However, due to cost, workflow and accessibility not all eligible women are evaluated with central dual X-ray absorptiometry (DXA). More accessible and lower cost techniques for identifying individuals who would benefit from anti-

osteoporotic intervention or further evaluation by central DXA, if available, might improve patient care. One such tool that is widely used is the FRAX[®] online tool. Digital X-ray radiogrammetry (DXR) estimates hand BMD from standard hand X-ray images and have shown to predict fractures and osteoporosis. Digital radiology and the internet have opened up the possibility of conducting automated opportunistic screening with DXR in post-fracture care or in combination with mammography. The purpose of the study was to compare the performance of DXR with FRAX and DXA in discriminating major osteoporotic fracture (MOF) (hip, clinical spine, forearm or shoulder), hip fracture and femoral neck osteoporosis.

Methods: The prospective cohort study was conducted on 5,358 women 65 years and older in the Study of Osteoporotic Fractures (SOF) cohort. Hand X-ray images collected at baseline were analyzed and fractures were ascertained during 10 years of follow up. For comparison of the methods area under age adjusted receiver operating characteristic curve (AUC) for MOF and hip fracture and for osteoporotic DXA FN BMD was used.

Results: DXR was similar to FRAX (no BMD) in fracture discrimination performance with an AUC around 0.65 for MOF and 0.70 for hip fractures for both methods, Table 1. As expected fracture discrimination performance by femoral neck DXA BMD was superior to both DXR and to FRAX (no BMD) with AUC of 0.68 for MOF and 0.75 for hip fractures. AUC for selection of patients with femoral neck osteoporosis (femoral neck DXA BMD T-score < -2.5) was higher for DXR-BMD, 0.76 (0.74-0.77), than for FRAX, 0.69 (0.67-0.71), ($p < 0.0001$), Table 1.

Conclusions: DXR-BMD discriminates incident fractures in women to a similar degree as FRAX. DXR-BMD predicts femoral neck osteoporosis to a larger degree than FRAX. In a possible screening scenario DXR shows promise as a selection tool for DXA. Results require confirmation in other studies.

| | AUC MOF fracture ^a 10 years | AUC hip fracture 10 years | AUC DXA FN BMD T-score < -2.5 |
|-------------------------|--|---------------------------|-------------------------------|
| Age alone | 0.59 (0.57, 0.61) | 0.68 (0.65, 0.71) | 0.64 (0.61, 0.65) |
| Age + DXR | 0.65 (0.63, 0.67) | 0.69 (0.66, 0.72) | 0.76 (0.74, 0.77) |
| Age + DXA FN BMD | 0.68 (0.66, 0.70) | 0.75 (0.72, 0.77) | - |
| Age + FRAX (no BMD) | 0.64 (0.61, 0.65) | 0.71 (0.67, 0.73) | 0.69 (0.67, 0.71) |
| Age + DXA FN BMD + FRAX | 0.69 (0.67, 0.70) | 0.76 (0.73, 0.78) | - |

Low Bone Mass Density Is Associated with Tooth Loss in Postmenopausal Women: A Nationwide Representative Study. Jeong Gyu Lee^{*}. Pusan National University Hospital,

Purpose

Both osteoporosis and tooth loss are major health problems that are frequently observed in postmenopausal women in the fast-aging country. A lack of a nationwide, representative study has made the association between low bone mineral density (BMD) and tooth loss still a controversial issue to this day.

Methods

We conducted a cross-sectional study using data from the fifth Korea National Health and Nutrition Examination Survey 2010-2011. A total of 1,938 postmenopausal women (50-75 years) who had undergone BMD measured by dual-energy X-ray absorptiometry were included as study subjects. All participants had dental examination by a dentist and were examined for the number of remaining teeth, dental prosthetics, dental implants, and periodontal diseases. In addition, the participants self-reported their oral health behaviors. Multivariate logistic regression via complex sampling was used to estimate odds ratio (OR) for osteopenia and osteoporosis regarding to eight or more of tooth loss after the adjustment for confound factor including menopausal age.

Results

Age of subjects was 61.3 ± 0.2 years and 529 (27 %) women had osteoporosis and 923 (47.6 %) women had osteopenia. Mean number of tooth loss was 7.1 ± 0.3 in all participants. Compared to the group with normal BMD, the number of tooth loss was significantly higher in the groups with osteopenia and osteoporosis (4.52 ± 0.4 vs. 6.45 ± 0.4 vs. 9.28 ± 0.5 , P value = 0.001). Women with osteoporosis in femur had a higher risk for eight or more of tooth loss [OR, 2.13; 95% confidence interval (CI), 1.70-2.67] compared to the group with normal BMD in femur after the adjustment of confounding factors including age, menopausal age, oral care related behaviors, and chronic diseases. Similarly, the subjects with osteoporosis in spine had a higher risk for eight or more tooth loss (OR, 1.92; 95% CI, 1.53-2.42) in comparison with the group with normal BMD in spine.

Conclusions

We observed a significant relationship between excessive tooth loss and low BMD in postmenopausal women. Our findings suggest persistent dental care and early intervention in prevention for excessive tooth loss in the postmenopausal women with low BMD.

Relation between decreased IL-18BP levels and risk of osteoporosis in post menopausal osteoporotic patients: Role of IL-18BP in preventing bone loss by positively regulating Treg/Th17 balance. Mohd Nizam Mansoori^{1*}, Priyanka Shukla¹, Abdul Malik¹, Kamini Srivastava¹, Manisha Kakai², Karam bir Kumar², Manisha Dixit¹, Jyoti Kureel¹, Sushil Kumar Gupta², Divya Singh¹. ¹CDRI, ²SGPGI

Abstract

IL-18BP is a natural antagonist of IL-18 cytokine whose level is increased in several autoimmune disorders. IL-18 promotes IL-17 production and plays important role in autoimmune diseases like rheumatoid arthritis. However its role in Estrogen deficiency induced bone loss is still unknown. In this study we have investigated the effect of mIL-18BP administration to estrogen-deficient mice on T and B cells, Th17/Treg balance and its impact on skeletal parameters. Adult female Balb/c mice were taken for the study. The groups were: sham, sham+mIL-18BP (0.5mg/kg body weight), Ovx, Ovx + mIL-18BP (0.5mg/kg body weight). Treatment was continued for a period of 4 week with s.c. injection twice weekly. After one month, animals were sacrificed; long bones were collected for static and dynamic histomorphometry. Bone marrow was flushed out for peripheral blood mononuclear cell isolation. mIL-18BP robustly inhibited the proliferation of IL-17 secreting Th17 cells with concomitant increase in CD4+CD25+FoxP3 T regulatory cells. mIL-18BP treatment restored trabecular microarchitecture, preserved cortical bone parameters likely attributable to increased number of bone lining cells and reduced osteoclast activity. mIL-18BP treatment restored the levels of proinflammatory and anti inflammatory cytokine to sham level which were altered due to ovariectomy in Balb/c mice. Importantly, these results were corroborated in female human subjects where IL-18BP levels have been evaluated in post menopausal women and serum level of IL-18BP was correlated with BMD data. Based on T score value volunteers were divided in three groups of normal, osteopenic and osteoporotic. Post menopausal females between the age group (55-65yrs) were included in the study. Blood was withdrawn from them and BMD analysis was done using DXA. Serum level of hIL-18BP was found to be decreased to base line level in Osteoporotic patients. BMD data of these groups showed positive correlation with the serum concentration of hIL-18BP. Conclusively we can say that exogenous mIL-18BP administration provides protection against Estrogen deficiency induced bone loss and has the potential as a therapy for postmenopausal osteoporosis.

Imminent Risk of Fracture after Fracture. Helena Johansson¹, Kristin Siggeirsdottir², Nicholas Harvey³, Anders Odén⁴, Vilmundur Gudnason⁵, Eugene McCloskey⁴, Gunnar Sigurdsson², John Kanis⁴. ¹Centre for Metabolic Bone Diseases, University of Sheffield Medical School, Sweden, ²Icelandic Heart Association, ³MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, ⁴Centre for Metabolic Bone Diseases, University of Sheffield, ⁵Icelandic Heart Association, Kopavogur, University of Iceland

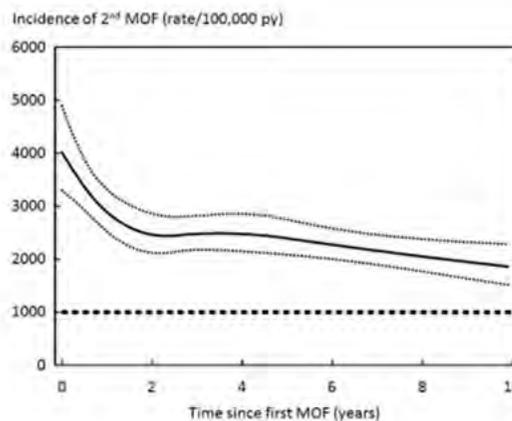

A history of fracture is a strong risk factor for future fractures. The aim of the present study was to determine whether the predictive value of a past major osteoporotic fracture (MOF) for future major fractures changed with time.

The current study was based on a population-based cohort of 18,872 men and women (52% women) born between 1907 and 1935 who attended the Reykjavik Study during the recruitment period in 1967–1991. All fractures from their entry into the study until December 31, 2012 were retrieved and analysed. Where reports contained records of more than one fracture at the same site within 30 days, only the first fracture was included. 5039 patients experienced one or more MOF and could be included in the analysis of a second MOF. An extension of Poisson regression was used to investigate the relationship between the first fracture and the second. All associations were adjusted for age and time since baseline.

During 10 year after the first Following a MOF, 1310 patients experienced a second MOF. The risk of a second MOF after a first increased by 4–5% for each year of age depending on age (95 % CI: 1.02-1.07) and was 25% higher for women than

men (95% CI: 1.09-1.44). The risk of a second MOF was highest immediately after the first fracture and thereafter decreased with time though remained higher than the population risk throughout follow up (Figure). For example, 1 year after the first MOF the risk of a second fracture was 2.9 (95% CI: 2.5-3.3) higher than the population risk. After 10 year this risk ratio was 1.8 (95% CI: 1.5-2.3). The risk of MOF after a first MOF is increased over the whole 10 year follow up but the imminent risk is even higher. If the acute increment in risk in the few years following MOF is amenable to therapeutic, intervention then immediate short-term treatments may provide worthwhile clinical dividends in a very cost-effective manner

Figure Risk of a second major osteoporotic fracture after a first major osteoporotic fracture per 100 000 (95% CI). The knots for the spline function are in 0.5, 2.5 and 5 years of follow up after the first fracture. The dashed line is the risk of first fracture in all patients. The risk of fracture in the figure is for a woman 60 years of age.

Clinically effective PKPD in Post-Menopausal Women after Transdermal hPTH(1-34) Delivery. Bobby Singh^{1*}, Vaeling Miller², ²Corium

Purpose: Forteo[®] [hPTH(1-34)] is approved by FDA for the treatment of osteoporosis as a daily subcutaneous injection. Patient adherence to therapy is poor due to required daily injections. The transdermal delivery of hPTH(1-34) using biodegradable microstructures (MicroCor[®]) is expected to improve adherence by providing a convenient and needle-free alternative to daily injections.

Methods: This Phase 2a study was conducted as a two part study in postmenopausal women aged 50 to 85. Part A was a crossover study, with 18 subjects randomized to either MicroCor PTH 16 mcg, MicroCor PTH 38 mcg or Forteo[®] 20 mcg. The primary objective was to assess the single dose PK of MicroCor PTH compared to Forteo. The secondary objectives were assessment of safety and dose proportionality between the two MicroCor doses. Part B was a 28-day parallel group study, with 21 subjects randomized to either MicroCor PTH 38 mcg or Forteo 20 mcg. The primary objective was to assess the multiple dose PK. The secondary objectives were assessment of safety and changes in concentrations of well characterized bone formation biomarker PINP (procollagen Type 1 N-terminal propeptide) and bone resorption biomarker CTX (collagen type 1 crosslinked C-telopeptide).

Results: All subjects treated with MicroCor PTH completed the trial. Rapid uptake (mean tmax < 10 minutes) and clearance of hPTH(1-34) was observed with the MicroCor PTH. The PK profile of MicroCor PTH was dose proportional across the two doses. Subjects exhibited similar PK profiles at Day 1 compared to Day 28, indicating the absence of drug accumulation. The PINP concentrations increased significantly over baseline and were comparable between MicroCor PTH and Forteo. The CTX concentrations were essentially unchanged compared to baseline for MicroCor PTH and increased above baseline for Forteo starting at day 21. Subjects treated with MicroCor PTH experienced excellent skin tolerability and no systemic adverse events beyond those observed with Forteo. There were no reports of delayed contact sensitization or anti-PTH antibodies.

Conclusions: Rapid and pulsatile PK were demonstrated with MicroCor PTH which is an important factor in stimulating bone formation. This was confirmed by significant and clinically relevant increases in concentrations of PINP. MicroCor PTH showed excellent skin tolerability. Future clinical studies will further establish safety and efficacy of MicroCor PTH transdermal system in osteoporotic patients.

National Observational Study of Subtrochanteric, Femoral Shaft and Hip Fractures in New Alendronate Users 1996 to 2003. Bo Abrahamsen*¹, Daniel Prieto-Alhambra², Pia Eiken³, Richard Eastell⁴. ¹University of Southern Denmark, Denmark, ²Oxford NIHR Musculoskeletal Biomedical Research Unit, Nuffield Department of Orthopaedics, ³Hillerød Hospital, ⁴Academic Unit of Bone Metabolism, The University of Sheffield

Atypical femur fractures (AFF) are a subset of subtrochanteric and shaft fractures of the femur (ST/FS). Only if rate_{ST/FS} increases during treatment can AFFs be added to the net number of fractures; otherwise any increases must have been offset by prevention of a larger number of conventional ST/FS fractures. Even a net increase in rate_{ST/FS} will allow for an overall risk reduction so long as it is offset by hip fractures saved.

Methods: We used Danish national health registers to track hip and ST/FS fracture events until 31/DEC/2013 in 61,990 men and women aged 50 to 94 who began alendronate treatment between 1/JAN/1996 and 31/DEC/2007. We conducted nested case control (c-c) studies for ST/FS (N=1,428) and hip fractures (neck or IT, N=6,784) against matched controls, and assessed history of cumulative use and refill adherence (Medication Possession Ratio, MPR) of alendronate.

Results: Paralleling the FIT study, alendronate users with optimal adherence (MPR > 80%) had a lower risk of hip fracture (OR 0.73, 95%CI 0.68-0.78), and hip fracture risk was lower with 10+ years of use than with <5 years (OR 0.74, 95%CI 0.56-0.97). The risk of ST/FS fracture was not increased in current (OR 0.91, 95%CI 0.79-1.06) or recent (OR 1.00, 95%CI 0.81-1.23) alendronate users compared with past users. Also, the risk was not higher with 10+ dose years (worth ≥10 years of cumulative use) of alendronate (OR 0.70, 95%CI 0.44-1.11) or with optimal adherence (OR 0.88, 95%CI 0.77-1.01). Including switching to other oral bisphosphonates or dmb in the analysis did not change the results. The risk was higher with diabetes, prior fractures and PPI use.

Conclusions: Long term adherent use of alendronate in excess of 10 dose years was associated with a 25% reduced hip fracture risk but no increase in the risk of ST/FS fractures.

| Dose years | Hip fracture (c-c OR, 95%CI) | ST/FS fracture (c-c OR, 95%CI) |
|--------------------------------------|---------------------------------|-----------------------------------|
| <5 | reference | reference |

Striking Response of Tumor-Induced Osteomalacia to the FGFR Inhibitor NVP-BGJ398. Michael Collins*¹, Clemens Bergwitz², Gabriella Aitchison¹, Jenny Blau¹, Alison Boyce¹, Rachel Gafni³, Lori Guthrie¹, Flora Miranda⁴, Eric Slosberg⁵, Diana Graus Porta⁶, Christine Hopmann⁶, Karim Welava⁷, Randi Isaacs⁸, Carole Miller⁷. ¹National Institutes of Health, ²Yale School of Medicine, ³National Institutes of Health, USA, ⁴Novartis Pharmaceuticals, ⁵Novartis Institutes for BioMedical Research, ⁶Saint Agnes Cancer Center, ⁷St. Agnes Cancer Center, ⁸Novartis Institute Biomedical Research

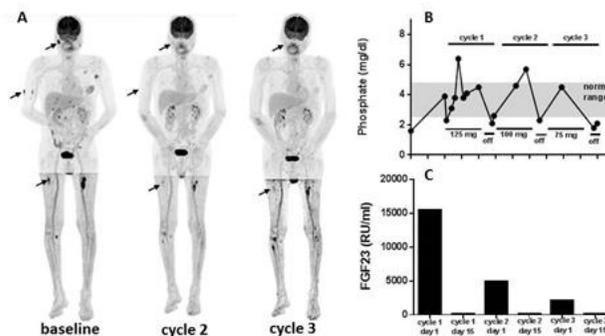

Tumor-induced osteomalacia (TIO) is a paraneoplastic syndrome characterized by bone pain, muscle weakness, and fractures. Symptoms are due to renal phosphate wasting, which results in hypophosphatemia and osteomalacia. TIO is caused by ectopic production of the phosphate- and vitamin D-regulating hormone, FGF23, usually by mixed tissue mesenchymal tumors. Several lines of evidence suggest a role for FGFR signaling in FGF23 regulation and TIO tumorigenesis, especially the recent finding of a fibronectin 1(FN1)/FGFR1 gene fusion in TIO tumors that presumably generates a FN/FGFR chimeric protein with active FGFR signaling. NVP-BGJ398 is a selective pan-FGFR inhibitor that has been shown to have anti-tumor activity in FGFR-driven tumors, and to inhibit the phosphaturic effects of FGF23 in preclinical models. These combined properties suggest a possible role for NVP-BGJ398 in treating TIO.

We identified a FGFR rearrangement in a tumor from a patient with an extremely rare case of widely metastatic TIO, who had previously failed Yttrium-90/Lutetium-177 peptide receptor radionuclide therapy. Based on the FGFR1 rearrangement, the patient enrolled in an IRB-approved phase 2 trial (NVP-BGJ398 Signature Trial; NCT02160041). Through cycles 1, 2, and 3, (1 cycle = 3 weeks on/1 week off drug), doses were 125, 100, and 75mg/day, respectively – adjusted to maintain normal serum phosphate levels.

The major findings are represented in the figure: A) FDG PET scans performed before the 1st, 2nd and 3rd cycles. Treatment resulted in disappearance of pulmonary and hepatic metastases after just one cycle, and progressive shrinkage of multiple

metastatic lesions (arrows). B) serum phosphate increased during treatment and returned to baseline when off, C) plasma FGF23 levels (C-terminal, Immunotopics, San Clemente, CA), which were approximately 100 fold above normal before treatment, decreased to normal on drug and increased when off. Of note, off-drug FGF23 values progressively decreased with each cycle. Treatment was accompanied by hyperuricemia. Side effects included grade 1 stomatitis, hand-foot syndrome, and retinal detachment, which were addressed by dose interruptions and reductions.

The data support: 1) NVP-BGJ398 is tumoricidal to phosphaturic mesenchymal tumors in TIO, and 2) in TIO FGF23 production is FGFR-dependent. While it remains to be proven if these effects will also occur in typical non-malignant TIO, the data support a role for NVP-BGJ398 in the treatment of TIO.

M-CSF is a potential target for Gorham-Stout disease, a disease characterized by lymphatic vessel invasion of bone marrow and massive osteolysis. Lianping Xing*¹, Wensheng Wang, Mengmeng Wang, Li Xing, Sun Wen, Brendan Boyce. University of Rochester, USA

Gorham-Stout disease (GSD) is a rare bone disorder, characterized by proliferation of lymphatic vessels within bone marrow cavities, which is associated with aggressive osteolysis that can lead to complete loss of some bones. The etiology of GSD is poorly understood and there is no effective therapy. The goal of this study is to determine if the GSD osteolytic phenotype occurs because lymphatic endothelial cells (LECs) adversely affect the function of osteoclasts (OCs) or osteoblasts (OBs). We first examined the effect of a mouse LEC line on OC and OB differentiation in cocultures. LECs significantly increased OC formation and bone resorption, but had no clear effect on OBs. We hypothesize that LECs produce factors that promote OC formation and thereby induce osteolysis in GSD. To test this, we examined expression of osteoclastogenic cytokines in LECs by qPCR and found very high levels of M-CSF mRNA compared to other factors (e.g. >1,000, >100 and >60-fold greater than RANKL, TNF, and IL-6, respectively). Conditioned media (CM) from LECs express high levels of M-CSF protein (ng/ml: 2.05 ± 0.02 ng/ml vs 0.018 ± 0.003 in PBS) by ELISA, and LEC CM-mediated OC formation and bone resorption were blocked by a M-CSF neutralizing antibody (OC#/well: 13 ± 1 vs. 218 ± 7 in IgG; pit area/slice: 0 ± 0 vs. 0.61 ± 0.03 mm² in IgG) or by Ki20227, a specific inhibitor of c-fms, the M-CSF receptor, (OC#/well: 0 ± 0 vs. 248 ± 24 in DMSO). To determine if LECs cause the GSD-like phenotype in vivo, we performed intra-tibial injection of LECs in WT mice and examined X-rays of their bones weekly for up to 9 weeks. LECs caused osteolysis of injected tibiae, starting at 2 weeks post-injection. MicroCT analysis confirmed severe bone loss (BV/TV: 1.2 ± 0.5 vs. 30 ± 1% in PBS, N=10 mice/group), and histology showed that LEC-injected tibiae had significantly reduced bone mass, increased OC numbers, and trabecular and cortical bone loss. Furthermore, we detected significantly increased levels of M-CSF in serum and bone marrow plasma of mice that received intra-tibial injection of LECs by ELISA (serum: 1.8 ± 0.3 vs 1.3 ± 0.15 ng/ml in PBS-injected; bone marrow: 59 ± 6 vs 22 ± 4 pg/ml in PBS-injected). Thus, LECs could function as effector cells in GSD to cause bone destruction by producing large amounts of M-CSF. Thus, M-CSF represents a new therapeutic target and perhaps a clinical biomarker for patients suffering from GSD and other lymphatic anomalies that are associated with destruction of bone.

LB-SA0037

***Enterococcus faecalis* attenuates both osteoclastogenesis and osteoblastogenesis.** Ok-Jin Park^{*1}, Jiseon Kim², Jihyun Yang³, Cheol-Heui Yun², Seung Hyun Han². ¹Seoul National University School of Dentistry, South Korea, ²Seoul National University, ³Korea Research Institute of Bioscience & Biotechnology

Enterococcus faecalis is closely associated with refractory apical periodontitis often causing apical bone loss and impaired bone regeneration. Despite the fact that *E. faecalis* could contact osteoblast and osteoclast in periapical lesions, little is known about how the bacteria affect osteoclast and osteoblast. In the present study, we investigated the effect of *E. faecalis* on the differentiation of osteoclast and osteoblast. When mouse bone marrow-derived macrophages (BMMs) were treated with heat-killed *E. faecalis* (HKEF), the osteoclast differentiation was remarkably attenuated. HKEF also prevented a reduction in the phagocytic capacity of BMMs after differentiation into osteoclasts, while it induced the expression of inflammatory cytokines and chemokines. HKEF inhibited the RANKL-induced expression of c-Fos and NFATc1, both of which are crucial transcription factors for osteoclast differentiation. On the other hand, when primary osteoblasts derived from mouse calvaria were stimulated with HKEF, there was a substantial decrease in the osteoblast differentiation. Furthermore, HKEF inhibited Runx2 transcriptional activity and the expression of osteogenic marker genes including osterix, β -catenin, osteocalcin, and type I collagen in the osteoblasts. However, it was intriguing that inflammatory chemokines were increased in the cells treated with HKEF. In conclusion, these results suggest that *E. faecalis* attenuates the differentiation of osteoclast and osteoblast but enhances the production of inflammatory cytokines and chemokines, that might contribute to the attenuated bone regeneration.

Oral PTH (1-34) in the Treatment of Hypoparathyroidism. Sofia Ish-Shalom^{*1}, Yoseph Caraco², Nariman Saba Khazen¹, Michal Gershinsky¹, Auryan Szalat², Hillel Galitzer³, Jonathan C. Y. Tang⁴, Gregory Burshtien⁵, Ariel Rothner⁵, Arthur Raskin⁵, Miriam Blum⁵, William D. Fraser⁴. ¹Endocrine Research Center, Lin Medical Center, Clalit Health Services, Haifa, Israel, ²Hebrew University Medical School - Hadassah Medical Center Jerusalem, Israel, ³Entera Bio, IL, ⁴Bioanalytical Facility, Biomedical Research Centre, Norwich Medical School, Faculty of Medicine & Health Sciences, University of East Anglia, Norwich, United Kingdom NR4 7TJ, ⁵Entera Bio Ltd, Hadassah Ein-Kerem, Jerusalem Bio Park, Jerusalem, Israel

Background: Primary hypoparathyroidism (PHP) is a hormone deficiency for which no oral replacement therapy is currently available. Oral PTH administration may allow for more flexibility in providing an adequate therapeutic dose, for achievement of normocalcemia and normophosphatemia in patients with varied severity of hormone deficiency and response to therapy. We present the results of a Phase 2a clinical study.

Objective: A multi-center, open label study to evaluate the safety, tolerability and pharmacokinetics of an oral formulation of PTH (1-34) for treatment of PHP.

Patients and Methods: Patients with established PHP, at least one year on chronic treatment with calcium supplements and alfacalcidol were enrolled for a treatment period of 16 weeks. The first 3 doses of PTH (1-34) 0.75 mg/dose were administered at the research center; subjects were then asked to continue with self-administration 4 times a day (QID). Follow up visits were performed at the end of week 1, 2, 3, 4, 6, 8, 10, 12 and 16. Serum calcium, phosphorus, albumin, creatinine were evaluated on these visits and medication dose adjustments was performed based on albumin adjusted calcium (ACa) levels.

Results: 19 subjects [16(f), 3(m)], mean age 44.5yr (range 20.3-71) were enrolled. 13 subjects had postsurgical hypoparathyroidism (68.4%), 5 autoimmune (26.3%) and 1 hereditary (5.3%). Mean calcium supplement dose at enrollment was 3,640 mg/day (range 1,000- 10,800) and alfacalcidol was 1.1 mcg/day (range 0-2). Mean ACa at enrollment was 7.92 mg/dL, (range 7.2-8.99), mean serum phosphorus was 5.0 mg/dL (range 3.7-7). The calcium supplement dose was gradually and significantly ($P < 0.01$) decreased from the end of week 3 (Figure 1) while maintaining the ACa at a mean level of 8.15 mg/dL (range 6.97-9.14). Serum phosphorus levels were significantly ($P < 0.01$) reduced after each dose and gradually throughout the study (Figure 2) to 4.3 mg/dL (range 2.9-5.2). The study drug was safe and well tolerated - 17 subjects completed with no related adverse events and high adherence ($> 80\%$, average 95.6%). 1 subject withdrew consent on the first day. Another subject was excluded due to hypercalcemia prior to treatment. **Conclusion:** Oral administration of Entera Bio's PTH (1-34) offers a safe and efficient therapeutic option for the treatment of PHP. Further studies are needed for defining the most appropriate treatment regimens for PHP patients with this medication.

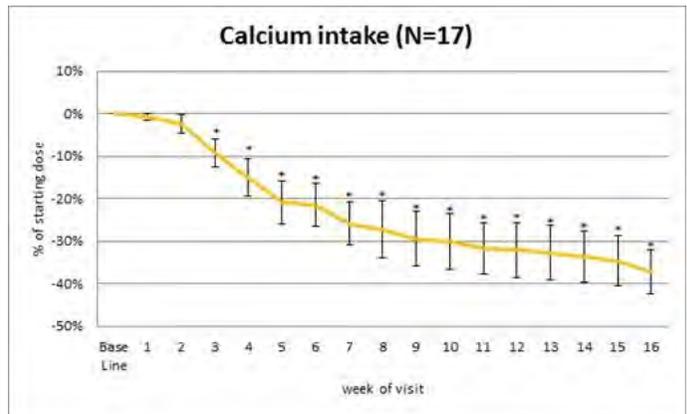

Figure 1: Mean calcium intake as a percent of starting dose at baseline. (* $P < 0.01$)

LB-SU0002

Bone Material Compositional Properties at Actively Bone Forming Trabecular Surfaces are Able to Discriminate Between Chronic Obstructive Pulmonary Disease (COPD) Patients that Sustain Fragility Fractures vs. Those Who Do Not, Irrespective of Glucocorticoid Therapy. Eleftherios Paschalis^{*1}, Sonja Gamsjaeger², David Dempster³, Vanda Jorgetti⁴, Victoria Borba⁵, Klaus Klaushofer², Carolina Moreira⁵. ¹Ludwig Boltzmann Institute for Osteology, Austria, ²Ludwig Boltzmann Institute of Osteology at the Hanusch Hospital of WGKK & AUVA Trauma Centre Meidling, 1st Medical Department, Hanusch Hospital, Vienna, ³Columbia University, ⁴Department of Nephrology, School of Medicine, University of Sao Paulo, SP, ⁵Endocrine Division (SEMPR), Department of Internal Medicine, Clinical Hospital of the Federal University of Parana, Curitiba, PR

Chronic obstructive pulmonary disease (COPD) is associated with low aBMD by DXA and altered microstructure by bone histomorphometry and microcomputed tomography. Nevertheless, not all of COPD patients sustain fragility fractures. In the present study we used Raman microspectroscopic analysis to determine bone compositional properties at actively forming trabecular surfaces (based on double fluorescent labels) in iliac crest biopsies from 19 postmenopausal COPD patients (62.1 ± 7.3 years of age). Additionally, we also analyzed trabecular geometrical centers, representing tissue much older than the forming surfaces. Eight of the patients had sustained fragility fractures, and 13 had received treatment with inhaled glucocorticoids. None of the patients had taken oral glucocorticoids. The monitored parameters were: mineral / matrix ratio (MM), nanoporosity, and relative glycosaminoglycan (GAG), lipid, and pyridinoline contents (PYD). The data were also compared against previously published values in a group of healthy postmenopausal (POSTM), as well as placebo-receiving postmenopausal osteoporosis patients (POSTMOP). At actively forming surfaces, the COPD patients (N=19) had significantly lower MM values compared to POSTM, while the PYD values were significantly higher than POSTM and lower than the POSTMOP groups. The COPD patients had significantly higher nanoporosity compared to either POSTM or POSTMOP, and higher GAG content compared to POSTMOP. Within the COPD

group, there were no significant differences between the glucocorticoid receiving patients and those who did not receive any. COPD patients sustaining fragility fractures had significantly lower nanoporosity and higher MM and PYD values compared to COPD patients without fragility fractures. To the best of our knowledge, this is the first study identifying differences between COPD patients based on fragility fracture incidence. Given that these bone material compositional differences are evident close to the cement line (a major bone interface), they may contribute to the inferior bone toughness and consequent fragility fractures prevalent in these patients.

LB-SU0003

Differential effects of age and BMI on Trabecular Bone Score and Femur geometry. KyongYoung Kim^{*1}, KyoungMin Kim², Sung Hee Choi², Soo Lim², Sang Wan Kim³, Chan Soo Shin⁴, Hak Chul Jang², ¹Seoul National University Bundang Hospital & Seoul National University College of Medicine, ²Borame Hospital & Seoul National University College of Medicine, ³Seoul National University Hospital & Seoul National University College of Medicine

Bone quality is another major component in determining bone strength together with bone mineral density (BMD). Bone geometry, a spatial distribution of bone, is one of parameters of bone quality. The trabecular bone score (TBS) is a geometric parameter of trabecular bone and it represents the quality of trabecular bone. On the other hand, femur geometry reflects cortical bone quality. The aims of this study were to investigate the correlations between age, BMI and structure measures derived from TBS and femur geometry, and to examine the associations between those measures. This was a cross-sectional study and 263 men and 609 women aged over 50 years (mean age, 64.0 years in male and 67.0 years in female) were included. Subjects with any pathological disorders (such as cancer, hyperthyroidism or renal failure) or using medications (such as corticosteroids, heparin, or anticonvulsants) known to alter calcium and bone metabolism or using antiresorptive agents such as raloxifene, bisphosphonate, or hormone replacement therapies were excluded. Study subjects were divided into 3 age groups; 50-59 years, 60-69 years, and 70 years and older. They were also stratified into 2 groups according to their BMI, less than 23.0 kg/m² or higher than 23.0 kg/m². BMDs at lumbar spine and femur neck were measured from dual-energy X-ray absorptiometry (Hologic Discovery A, Hologic Inc., Waltham, MA), and TBS and femur geometry were further analyzed. The TBS was negatively correlated with age, and the associations were greater in women and age group of 50-59 years both in men and women. On the other hands, femur geometric parameters including cortical thickness, cross-sectional area (CSA) showed negative associations with age, and the relationships were quite similar between genders. Moreover, it showed greater associations in age group of 70 years and older both in men and women. In associations between those geometric measures with BMI, TBS provided negative correlation with BMI only in overweight group (BMI > 23.0 kg/m²), whereas cortical thickness showed positive associations both in overweight group and non-overweight group (BMI ≤ 23.0 kg/m²). TBS and cortical thickness showed strong positive correlations both gender, but it was greater in men (R= 0.435 in men and R= 0.296 in women, P< 0.01 respectively). Although TBS and femur geometric parameters were associated strongly, age and BMI provided differential effects on trabecular bone geometry or cortical bone geometry.

Hypophosphatasemia in Duchenne Muscular Dystrophy. Anna Petryk^{*1}, Peter Karachunski², James Hodges², Michael Whyte³. ¹University of Minnesota, USA, ²University of Minnesota, USA, ³Shriners Hospital for Children & Washington University School of Medicine, USA

Background: Duchenne muscular dystrophy (DMD), an X-linked neuromuscular disorder from loss-of-function mutation within the dystrophin gene, features progressive muscle weakness and wasting, loss of ambulation, and cardiorespiratory compromise with death usually in the third decade of life. Glucocorticoid treatment delays progression, but only temporarily, and is associated with significant morbidity, underscoring the need for new therapies. Hypophosphatasia (HPP) is the inborn-error-of-metabolism characterized by deficient activity of the tissue-nonspecific isoenzyme of alkaline phosphatase (TNSALP) causing low serum ALP activity (hypophosphatasemia), often with muscle weakness and a waddling gait sometimes mistaken for DMD. In HPP, strength and ambulation are improved with treatment using investigational, bone-targeted, recombinant, human TNSALP (asfotase alfa).

Objective: Report hypophosphatasemia in DMD.

Methods: A retrospective chart review of 69 DMD patients (all males) treated at the University of Minnesota. All had DMD mutations. Among them, 31 had serum ALP measured at Fairview Diagnostic Laboratories at least once between 2004 and 2015 using the bichromatic rate methodology applied successively with three different instruments (Vitros 5,1 FS, Vitros 5600, and Siemens Vista). Age- and gender-matched normal ranges were provided for interpretation of patient serum ALP activities.

Results: The average patient age (±SD) at most recent serum ALP measurement was 14.6 (±7.1) yr (range 3.5-29.7 yr). Among the 31 patients, 20 (65%) had at least one low ALP level using the age- and sex-specific reference ranges. For these 20 patients, 3, 8, and 9 children had average serum ALP activities 25-50%, 50-75%, and 75-99% of the lower limit of normal, respectively. The mean age at first reported low ALP was 10.6 ± 4.2

(range 4.9-19.9 yr). Among the 11 patients with more than one low serum ALP value, hypophosphatasemia remained present for the duration of follow up (0.2-6.8 yr).

Conclusion: A large proportion of our DMD patients exhibited hypophosphatasemia. It is currently unknown whether low serum ALP activity is of functional significance in DMD, but in HPP patients it can be associated with notable muscle weakness. While glucocorticoid exposure is common in DMD patients, and may have contributed to low serum ALP, our findings should generate further investigation of DMD hypophosphatasemia, especially since osteoporosis and fractures are common in these patients.

Atsttrin, an engineered protein derived from progranulin growth factor, is therapeutic in osteoarthritis. Jianlu WEI^{*1}, Qingyun Tian², Brendon Richbrough², chuanju liu². ¹Hospital for Joint Diseases of NYU, USA, ²HJD of NYU

Progranulin (PGRN) is a multifunctional growth factor which is composed of seven-and-a-half repeats directly binds to TNF- α receptors (TNFR), and inhibits TNF- α activity. Atsttrin, an engineered protein composed of three PGRN fragments, exhibited selective TNFR binding, and potentially prevented inflammation in multiple arthritis mouse models (Tang, et al, Science, 2011). In addition, recent studies demonstrated that local injection of PGRN significantly prevented OA progression (Zhao et al, *Annals of the Rheumatic Diseases*, 2015). These previous data promoted us to determine whether Atsttrin also has therapeutic effects in OA, and the molecular mechanism involved. To determine whether Atsttrin can rescue the role of PGRN in PGRN null mice, we established surgically-induced OA model, destabilization of medial meniscus model in PGRN-deficient mice. Safranin O staining showed Atsttrin remarkably prevented loss of proteoglycan and meniscus ossification. In addition, anterior cruciate ligament transection model in wild type mice was established to determine the preventative effect of Atsttrin. Immunohistochemistry staining showed that the Atsttrin decreased the degradation of cartilage matrix molecules, slowing down OA progression. High power photography of HE staining revealed Atsttrin reduced chondrocyte clustering and inhibited migration of the irregular tide mark. Furthermore, Atsttrin dramatically reduced OA-associated pain, measured by open box behavior test, von frey test and inflammatory mediators in the ipsilateral L3-L5 dorsal root ganglion, indicating Atsttrin is a disease- and symptom-modifying drug. Molecular mechanistic studies revealed that Atsttrin significantly inhibited TNF- α -induced catabolic/inflammatory responses. More importantly, Atsttrin stimulated chondrocyte anabolic metabolism through activating Akt and Erk1/2 signaling pathways. To elucidate the contributions of TNFR1 and TNFR2 pathway to Atsttrin-mediated protection in OA, a comparison of Atsttrin's therapeutic effects in OA with ACLT model of wildtype, TNFR1-/-, TNFR2-/- and TNFR1&2 double knockout mice is ongoing. Collectively, Atsttrin has potential to be a novel chondroprotective drug that inhibits OA development through interacting with TNF- α /TNFR signaling pathways. These findings not only provide novel insights into the role of Atsttrin in cartilage homeostasis and arthritis *in vivo*, but may also lead to the development of novel therapeutic intervention strategies for osteoarthritis.

LB-SU0007

Interactive effects of long term high fat high sucrose diet and estrogen deficiency on endothelial function and bone property in 6-month-old female rats. Xiaoli Dong^{*1}, Chunmei Li², Sisi Cao³, Shun Wan Chan³, Man Sau Wong³. ¹The Hong Kong Polytechnic University, Hong kong, ²Guangdong Pharmaceutical College, ³The Hong Kong Polytechnic University

Osteoporosis (OP) and cardiovascular diseases (CVDs) are two multifactorial and degenerative diseases which might co-exist in postmenopausal women. Estrogen deficiency and high fat high sucrose diet (HFS) intake have been recognized as risk factors for OP and CVDs independently. Understanding the combined actions of these two detrimental factors on bone and cardiovascular system is essential for deriving appropriate strategies for simultaneous treatment of OP and CVDs. The present study is designed to determine the interactive actions of estrogen deficiency and HFS on bone properties and endothelial function and to investigate the underlying mechanisms. Six-month-old Sprague Dawley sham or ovariectomized (OVX) rats were fed either a low-fat-low-sucrose (LFS) or a high-fat-high-sucrose (HFS) diet for 12 weeks. The results showed that OVX did not significantly influence endothelium-dependent relaxation in response to acetylcholine (ACh) or sodium nitroprusside (SNP) in the isolated thoracic aorta from LFS fed rats; HFS significantly decreased vasorelaxation in response to ACh (rat aorta gave ~30% maximum relaxation in HFS fed rats and ~50% in LFS fed rats upon ACh challenge; p<0.05) in rats. OVX significantly weakened bone properties as demonstrated by the

reduction of bone property parameters including Tb.BMD, BV/TV, Tb.N, Conn-Des and the increase in Tb.Sp, BS/BV and SMI at femoral metaphysis (FE) of rats ($p < 0.001$). HFS did not result in significant alterations of bone property parameters in sham rats. However, HFS further downregulated Tb.BMD, BV/TV, Tb.N, Tb.Th and Conn-Des; while upregulated Tb.Sp, BS/BV and SMI in the FE of OVX rats ($p < 0.05$). The level of urinary DPD, a bone resorption marker, was significantly upregulated by the interacting actions of HFS and OVX in rats ($p < 0.05$). Mechanistic studies indicated that PPAR γ expressions in the thoracic aorta were induced by HFS to about 1.4-1.7 fold increase ($p < 0.05$) and in the bone by OVX to 1.1-1.7 fold change ($p < 0.05$). In summary, HFS aggravated OVX-induced bone loss. The synergistic detrimental actions of HFS and OVX on bone properties mainly occurred in cancellous bone and were characterized by a high degree of bone resorption. HFS, but not OVX resulted in endothelial dysfunction in rats. Such alterations were associated with PPAR γ expressions in the thoracic aorta and the bone in response to HFS and/or OVX.

Glucose-loading reduces bone remodelling in women and osteoblast function in vitro. Itamar Levinger¹, Ego Seeman², Glenn McConell³, Mark Rybchyn⁴, Samantha Cassar⁵, Elizabeth Byrnes⁶, Steve Selig⁷, Rebecca Mason⁸, Peter Ebeling⁹, Tara Brennan-Speranza⁴. ¹Institute of Sport, Exercise & Active Living (ISEAL), Victoria University, Australia, ²University of Melbourne & the Department of Endocrinology, Austin Health, Melbourne, Australia, ³Clinical Exercise Science Program, Institute of Sport, Exercise & Active Living (ISEAL), Victoria University, Melbourne, Australia, ⁴Department of Physiology, Bosch Institute for Medical Research, University of Sydney, Australia., ⁵Clinical Exercise Science Program, Institute of Sport, Exercise & Active Living (ISEAL), Victoria University, Melbourne, Australia., ⁶PathWest QEII Medical Centre, Perth, Australia, ⁷School of Exercise & Nutrition Sciences, Deakin University, Melbourne, Australia., ⁸Department of Physiology, Bosch Institute for Medical Research, University of Sydney, Australia, ⁹Department of Medicine, School of Clinical Sciences, Faculty of Medicine, Nursing & Health Sciences, Monash University, Australia

Background: Ageing is associated with a reduction in osteoblast life-span and the volume of bone formed by each basic multicellular unit (BMU). Each time bone is resorbed, less is deposited producing microstructural deterioration. Ageing is also associated with insulin resistance and hyperglycaemia, either of which may cause, or be the result of, a decline in undercarboxylated osteocalcin (ucOC), a protein produced by osteoblasts that increases insulin sensitivity. We examined whether glucose loading reduces bone remodelling and ucOC in vivo and osteoblast function in vitro, and so compromises bone formation.

Methods: We administered an oral glucose tolerance test (OGTT) to 18 pre- and post-menopausal, non-diabetic women at rest and following exercise and measured serum levels of bone remodelling markers (BRMs) and ucOC. We also assessed whether increasing glucose concentrations with or without insulin reduced survival and activity of cultured human osteoblasts.

Results: Glucose-loading at rest and following exercise reduced BRMs in pre- and post-menopausal women and reduced ucOC in postmenopausal women. D-glucose (≥ 10 mmol/L) increased osteoblast apoptosis and reduced cell activity compared with 5 mmol/L. Insulin had a protective effect on these parameters.

Conclusions: Circulating glucose reduces osteoblast viability, at least in culture. Suppression of remodelling may preserve bone mineral density by slowing bone loss, but sacrifice bone's material composition. The failure of exercise to attenuate the suppressive effect of glucose on remodelling markers may be due to a direct detrimental effect of glucose on osteoblast survival and function.

LB-SU0009

Serum citrate is inversely related to bone turnover: findings from a large cross-sectional metabolomic study of adolescents. John Kemp¹, Adrian Sayers², William D. Fraser³, David M. Evans⁴, Jonathan H. Tobias². ¹MRC Centre for Causal Analyses in Translational Epidemiology, Australia, ²School of Clinical Sciences, University of Bristol, Bristol, UK, ³Norwich Medical School, University of East Anglia, Norwich, UK, ⁴MRC Integrative Epidemiology Unit, University of Bristol, Bristol, UK & University of Queensland Diamantina Institute, Translational Research Institute, Queensland, Australia

Aim: Bone mineral density and osteoporosis risk are related to circulating blood metabolites. However, most human studies have only examined a few candidate metabolites at a time. Thus, the relationship between normal serum metabolomic variation and bone development remains largely unstudied. We report findings from a population based study of adolescents in which we investigate the relationships

between blood metabolites [derived by proton nuclear magnetic resonance spectroscopy] and cortical bone parameters [measured by peripheral quantitative computed tomography (pQCT)]. **Methods:** Metabolomic profiles and mid-tibial pQCT scans were available in 1617 subjects (mean age 15.5 years) from the Avon Longitudinal Study of Parents and Children. Pearson correlation was used to quantify the relationships between metabolites (adjusted for age and sex) and pQCT parameters. Metabolites with the strongest relationships were investigated using linear regression, adjusting for potential confounders. **Results:** Citrate showed the largest correlation with cortical bone mineral density [BMDc, ($r = -0.25$, $P = 4 \times 10^{-25}$)]. Sex, Tanner stage, weight and height showed strong inverse relationships with citrate and were included in our model shown here, along with age and time of clinic attendance. Citrate was inversely related to BMDc [$\beta = -0.13$ (-0.16-0.09), coefficient=SD change per SD increase in citrate (95%CI)], and positively associated with periosteal circumference [PC, $\beta = 0.05$ (0.01|0.08)]. Based on a hypothesis that i) lower BMDc reflects greater cortical porosity due to higher bone turnover and ii) higher bone turnover leads to greater periosteal expansion; we investigated if the relationship between citrate, BMDc and PC was explained by increased bone turnover as reflected by serum β -C-telopeptides of type I collagen (CTX). A positive correlation between citrate and CTX was observed ($r = 0.38$, $P = 2 \times 10^{-59}$) and a SD increase in citrate was associated with a 0.21 unit increase in CTX. Adjustment for CTX, attenuated the association between citrate and BMDc [$\beta = -0.03$ (-0.07|0.002)] and PC [$\beta = 0.01$ (-0.02|0.05)] to the null. **Conclusions:** Our results suggest that normal variation in serum citrate levels have unrecognised implications for skeletal metabolism during adolescence, such that higher levels are associated with greater bone resorption with consequent effects on BMDc and periosteal expansion. Further studies are justified to explore the mechanistic basis for these relationships.

Targeted Ablation of Macrophages and Mast Cells Impairs Heterotopic Ossification in a Mouse Model of Fibrodysplasia Ossificans Progressiva. Michael Convente¹, EnJun Yang², Salin Chakkalakal², Devu Zhang², Robert Caron², Daniel Perrien³, Taku Kambayashi², Frederick Kaplan², Eileen Shore². ¹University of Pennsylvania School of Medicine, USA, ²University of Pennsylvania, USA, ³Vanderbilt University, USA

Fibrodysplasia Ossificans Progressiva (FOP), a rare and disabling genetic disease characterized by progressive heterotopic ossification (HO), is caused by gain-of-function mutations (most commonly, R206H) in activin A receptor, ACVR1 (also known as ALK2), a bone morphogenetic protein (BMP) type I receptor, resulting in up-regulation of the BMP signaling pathway. BMP signaling amplifies inflammatory pathways, and work from our lab and others has documented the presence of immune cells at pre-ossesous stages of HO formation. HO in FOP can be triggered by soft tissue injury, however the specific role of the immune system in FOP and development of HO remains poorly understood. To investigate the immunological contribution during HO lesion formation, we examined the cellular and molecular response to tissue injury in a knock-in Acvr1^{R206H|FIE/+} mouse FOP model. Following skeletal muscle injury, lesions form and progress through a series of catabolic and anabolic events that forms bone by 14 days. Strikingly, targeted ablation of macrophages via clodronate-encapsulated liposomes or mast cells via a double-transgenic mast cell-deficient Acvr1^{R206H/+}; c-kit^{W-sh/W-sh} mouse each results in ~50% reduction of HO. Further, our preliminary data support an additive decrease in HO when both macrophages and mast cells are ablated. Examination of lesions at early and intermediate stages from Acvr1^{R206H/+} mice shows increased immune cell invasion and protein expression of the inflammatory cytokines TNF α , IL-1 β , and IL-6, predictive biomarkers for non-genetic trauma-induced HO, suggesting common inflammatory-mediated mechanisms during HO formation. We also show that macrophages and mast cells express multiple type I and type II receptors from the TGF- β /BMP superfamily, including Acvr1/Alk2. BMP signaling, assayed by phosphorylated Smad1/5, is substantially up-regulated in Acvr1^{R206H/+} mast cells and macrophages. Consistent with our *in vivo* data, mRNA expression of the pro-inflammatory cytokines TNF α and IL-6 is significantly elevated in mutant cells. Mast cell degranulation, a functional response to inflammatory stimulation, was also significantly increased in mast cells expressing Alk2^{R206H}. Our study identifies key immune cells vital for HO development, as well as dysregulated inflammatory pathways caused by the FOP ACVR1 R206H mutation, providing novel cellular and molecular targets for prophylactic and therapeutic intervention in genetic and non-genetic forms of HO.

“Raine Syndrome”, Caused By Mutations In *FAM20C*, Is “Congenital Sclerosing Osteomalacia With Cerebral Calcification”. Michael P. Whyte^{*1}, William H. McAlister², Vinieth N. Bijancki³, Shenghui Duan⁴, Steven Mum⁵. ¹Center for Metabolic Bone Disease & Molecular Research, Shriners Hospital for Children; ²Department of Pediatric Radiology, Mallinckrodt Institute of Radiology at St. Louis Children’s Hospital, Washington University School of Medicine; St. Louis, MO, USA, 63110, ³Center for Metabolic Bone Disease & Molecular Research, Shriners Hospital for Children, ⁴Division of Bone & Mineral Diseases, Washington University School of Medicine at St. Louis, ⁵Washington University School of Medicine, USA

In 1985, we briefly reported infant sisters with a unique and lethal disorder designated “congenital sclerosing osteomalacia with cerebral calcification” (CSOCC) (Figure). In 1986, CSOCC entered Mendelian Inheritance in Man as a new autosomal recessive entity designated “osteomalacia, sclerosing, with cerebral calcification” (MIM 259660). However, no further citations followed in MIM. Instead, in 1989 Raine and colleagues, apparently unaware of this MIM entry, described the features of CSOCC in a fetus as a new condition. After several additional case reports, this disorder became known in 1992 as “Raine syndrome”, and was included that same year in MIM as “osteosclerotic bone dysplasia, lethal” (259775). In 2007, the etiology was discovered to be loss-of-function mutations within the gene that encodes “family with sequence similarity 20, member C” (*FAM20C*). This advance then enabled characterization of mild variants of the disorder that were associated with hypophosphatemia. *FAM20C* is conserved among mammals, highly expressed in calcified tissues, and importantly involved in the phosphorylation of proteins that regulate skeletal mineralization. *FAM20C* phosphorylates the caseins and several secreted proteins implicated in biomineralization, including the small integrin-binding ligand, N-linked glycoproteins (SIBLINGs).

Here, we detail the clinical, radiological, biochemical, histopathological, and mutational studies of these two patients. The proposita had undergone dual tetracycline labeling just before her death when assessment of her skeletal histopathology became possible at autopsy. Despite no histopathological evidence of rickets, defective bone mineralization (osteomalacia) was a key finding associated with the severe osteosclerosis. Dental radiographs revealed “ghost teeth” consistent with this pathogenesis. Hypophosphatemia had been documented in the affected sister. Using archival DNA from the proposita, an unaffected sibling, and the mother, we found that compound heterozygosity for a unique missense *FAM20C* defect (Gly365Asp, paternal allele) and a deletion of *FAM20C* (maternal allele) explained the disorder. Thus, “Raine syndrome” is “congenital sclerosing osteomalacia with cerebral calcification”.

BGJ398, a Pan-specific FGFR Inhibitor, Ameliorates Phosphate Wasting and Impaired Wnt Signaling in FGF2 High Molecular Weight Isoform Transgenic Mice. Erxia Du^{*}, Liping Xiao, Marja Hurley, UCONN Health, USA

High molecular weight FGF2 transgenic (HMWTg) mouse that phenocopies the Hyp mouse homolog of human X-linked hypophosphatemic rickets display dwarfism, hypophosphatemia, osteomalacia, reduced bone mineral density (BMD), increased FGF23 in bone and serum. Hyp mice overexpress HMWFGF2 in bone associated with increased FGF23 and phosphate (Pi) wasting in part via abnormal FGF23/FGFR/Klotho signaling. Since abnormal Wnt signaling was reported in Hyp mice we assessed whether Wnt signaling was impaired in kidneys of HMWTg mice and the effect of blocking FGFR signaling using a novel FGFR inhibitor BGJ398 (Novartis).

Six-7 week old female HMWTg mice were gavaged with one dose of BGJ398 50mg/kg body weight, or Vehicle. Vector/control mice were treated with Vehicle. DXA analysis was performed at baseline. Compared with Vector mice, there were significant reductions in BMD and BMC in HMWTg (Fig.1). Twenty-four hour urine

was collected after gavage. Mice were euthanized at 24 hours post-treatment to collect serum for biochemistry, and kidneys for gene and protein analysis by q-PCR and immunohistochemistry. Serum Pi was significantly reduced in HMWTg (Fig.2) and was partially rescued by BGJ398. Urine Pi was significantly increased and was normalized by BGJ398.

FGFRs and genes important in Pi homeostasis are shown in Fig.3. FGFR2, FGFR4 and Klotho mRNAs were increased and sodium-phosphate co-transporters Npt2a and Npt2c mRNAs were decreased in HMWTg. BGJ398 partially reduced Klotho and significantly increased Npt2a and Npt2c mRNAs in HMWTg. Cyp24 and Cyp27b1, regulated by mitogen activated protein kinases (MAPK/p-ERK) modulates serum Pi via 1,25(OH)2D3 in kidney. Cyp24 was significantly increased in HMWTg while Cyp27b1 was inappropriately decreased. BGJ398 further increased both Cyp24 and Cyp27b1 mRNA. Immunohistochemistry (Fig.4) shows that increased FGFR1, KLOTHO, p-ERK, and decreased NPT2a in HMWTg were rescued by BGJ398.

Wnt signaling studies (Fig.5) revealed that Wnt inhibitors, Sclerostin Domain Containing 1 (Sostdc1) and Engrailed-1 (En-1) mRNA, were significantly increased in HMWTg and were significantly decreased by BGJ398. Beta-catenin mRNA was increased by BGJ398 in HMWTg. Immunohistochemistry showed increased phosphorylated β -catenin in HMWTg which was decreased by BGJ398 and decreased active β -catenin in HMWTg that was increased by BGJ398.

We conclude that blocking FGFR partially rescued serum Pi by regulating FGFR and Wnt signaling in HMWTg.

LB-SU0013

1-84PTH Amino Terminal Specific Immunoassay Mitigates Sample Instability due to *ex vivo* Processing and Oxidation: A Prevalent Haemodialysis Sample Analysis. Frank Blocki¹, Greg Olson¹, John Wall¹, Angela Podgorski¹, Dawn Vaught¹, Fabrizio Bonelli¹, Gavin Reid², Kevin Martin³. ¹DiaSorin Inc, ²University of Melbourne, ³Saint Louis University

Background: Assay of PTH has been historically problematic due to variable standardization, variable cross reactivity with PTH fragments, and variable correlations with biological parameters. Recent description of endogenous oxidation to PTH peptides further complicates these issues since, aside from lacking biological activity, oxidized PTH is of sufficiently altered structure to significantly impact assay specificity.

Methods: To characterize this issue further, an 'immunocapture LC-MS/MS' assay was developed using stable N15 and C13 isotope labels of both native PTH and 7-84 PTH fragment with each possible permutation of sulfoxide or sulfone at methionine 8 and 18. N15 labels were added to plasma samples just prior to immunocapture (Phases 1 & 2) or coincident with plasma collection (Phase 3) and for C13 internal standards, just prior to LC-MS/MS for all Phases 1-3. Immunoassays with specificity to both native and oxidized PTH were related to LC-MS/MS characterized samples.

Results: Phase 1: Greater than 10% oxidation was detected in 10% and 83% of HD samples collected from site A and B, respectively. Phase 2: Controlled, paired HD plasma samples, collected from site A and processed according to Site A and Site B workflow in parallel, failed to replicate Phase 1; however, overall PTH content of the samples evaluated were significantly lower. Phase 3: HD samples with intact PTH values between 200 and 1400pg/mL, whose workflow mimicked Phase 2, disclosed neither endogenous nor exogenous oxidation.

Conclusion: Extent of sample oxidation exceeding that of N15 standards would indicate in-vivo oxidation. Equivalent percentages of observed oxidation between N15 standards and endogenous PTH indicate oxidation originating with sample collection, environmental exposure / transit and processing. That significant, variable amounts of *ex vivo* oxidation were detected underscores the need for PTH measurement methods that are not impacted by compromised sample integrity due to exposure to widely variable shipping and storage conditions experienced prior to analytical measurement. Only the DiaSorin LIAISON 1-84PTH automated assay returns a measurement of true baseline PTH levels, even from samples of compromised quality, since its N-terminal specificity reports both native and oxidized PTH forms. Since oxidation of PTH peptides was found to vary greatly from sample batch to sample batch, it appears that any PTH oxidation is occurring *ex-vivo*.

Altered Calcium Homeostasis in the Klotho Mutant Mouse Does Not Reflect Changes in Calcium Homeostasis that Occur with Aging. Vaishali Yeldurthy¹, Puneet Dhawan¹, Leila mady¹, Sylvia Christakos². ¹Department of Microbiology, Biochemistry & Molecular Genetics, NJMS, Rutgers University, ²Rutgers - New Jersey Medical School, USA

Klotho is a multifunctional protein which acts as an obligate coreceptor for FGF23 and is involved in calcium and phosphate homeostasis. Klotho mutant mice show a premature aging phenotype characterized by infertility, atherosclerosis, ectopic calcification, osteoporosis and skin atrophy. To understand the mechanisms of the premature aging phenotype we examined genes and transcription factors involved in calcium homeostasis and the activity of VDR coactivators by *in vivo* ChIP. Klotho mutant mice display elevated serum calcium and 1,25(OH)₂D₃, increased expression of intestinal TRPV6 and calbindin-D_{9k} and intestinal calcium hyperabsorption. In aging 20 month (mo.) old mice there is a marked decline in calbindin-D_{9k} and TRPV6 mRNA expression in all segments of the intestine [3 -5 fold; p < 0.05 compared to young (3 mo. old) and adult (6 mo. old) mice]. mRNA expression of renal CYP24A1, which is involved in the metabolic inactivation of 1,25(OH)₂D₃, increased with aging, suggesting that increased catabolism of 1,25(OH)₂D₃ correlates with the decreased capacity with age to absorb calcium and age related bone loss. Since CARM1 [a methyltransferase that methylates histone 3 at arginine 17] is a coactivator of VDR (vitamin D receptor) mediated CYP24A1 transcription, *in vivo* ChIP assays were done examining VDR binding and H3R17 methylation in response to 1,25(OH)₂D₃. *In vivo* ChIP revealed enhanced H3 arginine methylation and enhanced recruitment of VDR at the CYP24A1 VDREs (vitamin D response elements) in aged 20 mo. old mice (3 h after 1,25(OH)₂D₃ treatment; 10ng/g bw) compared to young and 6 mo. old adult mice. Our findings are the first to address mechanisms contributing to enhanced CYP24A1 and thus increased catabolism of 1,25(OH)₂D₃ with age. In contrast, using klotho mutant mice similarly injected with 1,25(OH)₂D₃. ChIP assays revealed a 2 - 4 fold significant decrease in both VDR binding and histone 3 methylation at the regulatory regions of the CYP24A1 gene (klotho mutant mice compared to WT mice or aging mice respectively; p < 0.05), suggesting that prolonged exposure to high levels of 1,25(OH)₂D₃ results in renal desensitization to 1,25(OH)₂D₃. These findings indicate that altered calcium homeostasis in the klotho mutant mouse is in contrast to changes observed in aging and reflects overproduction of 1,25(OH)₂D₃ and 1,25(OH)₂D₃ toxicity rather than effects on intestinal calcium absorption that contribute to bone loss in aging.

Osteoclasts Exhibit Rheotaxis in Response to Fluid Flow: Crawling Against the Tide. Noelle M. Ochotny¹, Brandon H. Kim¹, David W. Holdsworth², S. Jeffrey Dixon¹, Stephen M. Sims¹. ¹Department of Physiology & Pharmacology, Schulich School of Medicine & Dentistry, Bone & Joint Institute, Western University, ²Department of Surgery, Schulich School of Medicine & Dentistry, Bone & Joint Institute, Western University

Cells display a wide range of directed movements in response to environmental cues. One of these is rheotaxis, the orientation and migration of a cell in response to extracellular fluid flow. Positive rheotaxis, the tendency of a cell to move against the flow, was first reported for spermatozoa. When bone experiences mechanical loading, fluid flows through its canalicular network. The ability of fluid shear stress (FSS) to affect osteoclast behaviour is poorly understood. Our goal was to investigate the effects of FSS on osteoclast migration. Osteoclasts were isolated from the long bones of neonatal Wistar rats. Fluid flow was applied to single osteoclasts using glass micropipettes. The micropipettes, filled with the same medium bathing the cells, were positioned by micromanipulation and fluid flow was directed towards the osteoclast. Osteoclast morphology and motility were monitored using time-lapse phase-contrast microscopy. Migrating osteoclasts were identified by i) a polarized morphology, consisting of a lamellipod at the leading edge and a uropod at the rear (trailing edge), and ii) net displacement of the osteoclast's centroid of at least 50 µm toward the micropipette tip over a 40-minute observation period. In most cases, FSS induced prompt polarization, turning, and migration of osteoclasts toward the flow. As a control, micropipettes were positioned in a similar manner but without flow. To quantify the effect of FSS on osteoclast movement, the net displacement of the osteoclast's centroid from the point of origin was measured over a 40-minute period. The majority of osteoclasts exposed to FSS (28 of the 38 cells tested) migrated at least 50 µm against the flow (toward the micropipette tip). The mean rate of migration was 2.0 ± 0.9 µm/min, markedly greater than during chemotaxis induced by M-CSF or TGF-β. In the absence of FSS, 10 of 10 control osteoclasts showed random movement and no significant orientation toward the micropipette tip. Chi-square analysis revealed statistically significant positive rheotaxis in response to fluid shear ($p < 0.01$). Our data reveal for the first time that osteoclasts exhibit robust positive rheotaxis in response to FSS. This heretofore unrecognized behaviour may play a key role in skeletal mechanotransduction *in vivo*, where osteoclasts are known to accumulate at sites of microcracks. Fluid flow from microcracks may serve to recruit osteoclasts to initiate bone remodeling at these sites.

The effects of local and sustained delivery of estrogen conjugated with hydrogel and nanodiamonds on bone formation. Christine Hong^{*1}, Tania Ohebsion¹, Dong Keun Lee², Dean Ho². ¹UCLA School of Dentistry, USA, ²UCLA School of Bioengineering

Estrogen (E2) is a naturally occurring steroid that plays a critical role in bone homeostasis, and it could be utilized as a new anabolic therapy for craniofacial defects. However, E2's clinical application is less appreciated due to its numerous limitations including E2's pleiotropic effects and short half-life. Therefore, new treatment modalities are required to allow E2 to stimulate bone formation via local and sustained release. In order to address this need, we have investigated nanodiamond-estrogen (ND-E2) complexes embedded within gels (G).

NDs are carbon byproducts that have good biocompatibility and chemical stability in solution. Additionally, NDs are excellent drug delivery platforms due to the physical characteristics of the surface of NDs, like their drug retention properties. In preparation of our novel estrogen delivery platform, NDs were loaded with insoluble E2s. The ND-E2 complexes were then delivered via injections into the desired location, where ND-E2 complexes embedded gels formed with the escalating sustained release ability of E2 (Figure 1).

Furthermore, to determine the ND-E2-G drug delivery platform's potential for bone stimulation in the oral cavity within clinical setting, a novel palatal expansion model was established in rats; since following palatal expansion, a strong probability of relapse of the maxilla exists, especially in cleft lip and/or palate (CLP) patients.

A total of 18 female, Sprague Dawley rats underwent 7 days of palatal expansion and were then divided into five groups (Control, E2, E2+ND, E2+G, E2+ND+G) to be injected in the palate. After retaining the expansion for 14 days, expanders were removed and rats were allowed to relapse (Figure 2). Micro-CT analysis demonstrated that the addition of G and ND to E2 (E2+ND+G) significantly reduced relapse ratio by 5.5 fold and increased bone volume and density, compared to all other groups (Figure 3). While the findings of this study are directly useful to craniofacial patients, future applications of local and sustained delivery of estrogen are immeasurable. The long-term goal of this study is to develop this newly established therapeutic model to aid in optimizing the clinical treatment of regenerating craniofacial and bone defects.

Low dose CAPE treatment in a CAIA model of Inflammatory Arthritis. Bonnie Williams¹, Helen Tsangari², Melissa Cantley¹, Victor Marino³, Jiaki Xu⁴, Egon Perilli⁵, A. Kencana Dharmapatri², Tania Crotti^{*6}. ¹Discipline of Anatomy & Pathology, School of Medicine, University of Adelaide, ²Discipline of Anatomy & Pathology, School of Medicine, The University of Adelaide, ³School of Dentistry, University of Adelaide, ⁴School of Pathology & Laboratory Medicine, The University of Western Australia, ⁵Biomedical Engineering Medical Device Research Institute, School of Computer Science, Engineering & Mathematics, Flinders University, ⁶Discipline of Anatomy & Pathology, School of Medicine, University of Adelaide, Australia

Rheumatoid arthritis is a chronic inflammatory disorder resulting in bone and cartilage destruction. Bone loss has been attributed to the relative increase in the number and activity of bone-resorbing osteoclasts and the activation of NF-kappaB: Caffeic acid phenethyl ester (CAPE) is a natural bioactive compound from the propolis of honeybee hives, which inhibits NFkappa B activity (Ang J Cell Physiol 2009) and has anti-inflammatory and immunomodulatory properties. We have shown inhibition of bone resorption with low doses of CAPE (1mg/kg/day) in a wear particle induced calvarial model of osteolysis (Zawawi Cal Tiss Int 2015).

Aims: Given the toxicity concerns with high dose and the effectiveness on bone loss suppression at 1mg/kg, we propose low dose CAPE as a treatment to target inflammation and bone loss in a CAIA model of inflammatory arthritis.

Methods: CAIA model in Balb/c mice (4 groups of 8 mice each: CAIA, CAIA + CAPE, CAPE, Control). CAPE (Sigma) was administered at 1mg/kg/day subcutaneously on day 3, 7 and 10. Local inflammation was assessed by clinical paw scoring. Serum levels of CRP and CTX-1 were measured by ELISA at day 14 to determine systemic inflammation and systemic bone resorption, respectively.

Results: CAIA mice treated with CAPE exhibited significantly greater local inflammation than CAIA mice by day 5 (paw score 5.75 vs 1.75, $p < 0.01$). By day 14, local inflammation reduced in both CAIA and CAPE-treated CAIA mice, with no significant difference between the groups ($p=0.64$); also CRP levels did not significantly differ between the groups ($p=0.89$). At day 14, the CTX-1 levels were higher in the CAIA mice, although not significantly (48.1 vs 28.5 ng/ml, $p=0.16$).

Conclusion: CAIA mice treated with low dose CAPE exhibited earlier onset of inflammation; low dose CAPE did not suppress local inflammation. Systemic inflammation was not evident by day 14 in the CAIA model, with or without CAPE. Systemic bone resorption may be occurring in the CAIA group at day 14.

Treatment with soluble activin type IIB receptor improves fracture healing in a closed tibial fracture model. Tero Puolakkainen^{*1}, Petri Rummukainen¹, Jemina Lehto¹, Olli Ritvos², Ari Hiltunen³, Anna-Maria Säämänen¹, Riku Kiviranta¹. ¹University of Turku, ²University of Helsinki,

Bone fracture healing is a series of complex events, which happen both simultaneously and in succession aiming to restore the initial form and function of the bone. Despite recent advances in the contemporary treatment methods, bone fractures are still a significant burden to the patients due to pain, disability, long periods of immobility and unproductivity. Extensive research has led to the identification of numerous growth factors and their signaling pathways in bone remodeling. Many of these have also emerged as potential therapeutic agents. Activins are pleiotropic growth factors belonging to the TGF-β superfamily. We and others have recently shown that treatment with recombinant fusion proteins of activin receptors greatly increases bone mass in different animal models by trapping activins and other ligands thus inhibiting their signaling pathways. However, their effects on fracture healing are unknown.

12-week old male C57Bl mice were subjected to a standardized, closed tibial fracture induced by three-point-bending. Animals were divided into control and treatment groups and were administered either PBS control or a soluble activin type IIB receptor (Act-RIIB-Fc) intraperitoneally once a week for a duration of two or four weeks. The calluses were then gathered and analyzed.

There were no significant differences in any of the analyzed parameters between the two-week control and treatment groups but the differences between the four-week groups were robust. As expected, Act-RIIB-Fc treatment resulted in 90-130% higher weight gain during each week compared to controls ($p < 0.001$). Microcomputed tomography imaging results revealed a great increase in callus mineralization in the Act-RIIB-Fc treated animals. Bone volume per tissue volume was 60%, trabecular number 55% and bone mineral density 60% higher in the calluses of the Act-RIIB-Fc treated mice ($p < 0.05$ in all). Biomechanical strength of calluses was also significantly improved by Act-RIIB-Fc treatment as callus stiffness increased by 45% and maximum force by 55% ($p < 0.01$) in the three-point-bending test in treated group compared to PBS-injected controls

These results suggest that Act-RIIB-Fc treatment improves fracture healing in the mineralization and remodeling phases but has little effect on the early endochondral stage. Our findings support the previous reports of activin receptors increasing bone mass but also show a novel approach for using Act-RIIB-Fc to enhance fracture healing.

Loss of Multiple Endocrine Neoplasia Type 1 (*Men1*) Gene in Osteocytes Causes Osteoporosis by Increasing Osteoclastogenesis. Peng Liu*¹, Sooyeon Lee², Jeanette Knoll³, Alexander Rauch⁴, Susanne Ostermay³, Mario Zaiss⁵, Nicole Malkusch², Ulf Lerner⁶, Julia Luther⁷, Mona Neven⁷, Martina Rauner⁸, Jean-Pierre David⁷, Philippe Bertolino⁹, Chang Zhang⁹, Jan Tuckermann². ¹University of Ulm, Germany, ²University of Ulm, ³Leibniz Institute for Age Research, Fritz Lipmann Institute (FLI), ⁴University of Southern Denmark, ⁵Swiss Federal Institute of Technology in Lausanne, ⁶University of Gothenburg, ⁷University Medical Center Hamburg-Eppendorf, ⁸TU Dresden, ⁹University of Lyon 1

Multiple endocrine neoplasia type 1 (MEN1) is caused by mutations in the *Men1* gene encoding the protein menin. Many MEN1 patients suffer from osteoporosis, which is primarily attributed to hyperparathyroidism. Recent studies suggested a direct regulatory role of *Men1* in osteoblasts affecting differentiation and apoptosis in aged mice. Our study, however, challenges the role of *Men1* in osteoblasts for bone integrity and demonstrates a critical role of *Men1* in osteocytes.

We demonstrate that elimination of *Men1* in the osteoblast lineage and in osteoblast derived osteocytes using several transgenic osteoblast specific cre expressing mouse strains (*Runx2Cre*, *OsxCre*) caused severe osteoporosis in adolescent and adult mice. Surprisingly, osteoblast differentiation, numbers and bone formation rate were not affected in these mice. Furthermore, the proposed response to BMP2-Smad signaling was not altered in *Men1* ablated primary calvarial osteoblasts.

Instead, we found enhanced osteoclast numbers in mutant mice explaining the bone loss. Strikingly, we found enhanced osteoclastogenesis when osteoclast progenitor cells were cultured with *Men1* deficient osteocytes (Fig. A), but not with osteoblasts. By restricting elimination of *Men1* to late differentiated osteoblasts and osteocytes (*Men1*^{Dmp1Cre} mice), the osteoporosis persisted, demonstrating a major role of *Men1* in osteocytes *in vivo* (Fig. B). We further demonstrated that soluble factors secreted from *Men1* mutant osteocytes could enhance osteoclastogenesis. Cxcl10, a osteoclast-stimulating chemokine, was highly upregulated in primary *Men1* deficient osteocytes and in *Men1*^{Dmp1Cre} mice *in vivo*. Accordingly, neutralizing antibodies decreased the osteoclastogenic potential of *Men1* deficient osteocytes.

Taken together, we discovered here a novel unexpected role of *Men1* in osteocytes to dampen osteoclastogenesis by controlling osteoclastogenic factors and to retain bone integrity. Modulating *Men1* regulated factors in osteocytes might serve as a novel molecular base to develop therapeutical strategies to combat osteoporosis.

(A). Primary cocultures of wild type osteoclast progenitors (bone marrow cells) with control or *Men1* KO primary osteocytes. Cocultures were stained for TRAP activity. Numbers of multinucleated TRAP positive cells were determined (n=3, ** p < 0.01).

(B). Micro CT reconstruction of trabecular bone from femora of 12-week-old female *Men1*^{flax} and *Men1*^{Dmp1Cre} mice (n=4-9, *** p < 0.001).

Lower leg arterial calcification assessed by high-resolution peripheral quantitative computed tomography is associated with bone microstructure abnormalities in women. Julien Paccou*¹, Mark Edwards¹, Janina Patsch², Karen Jameson¹, Kate Ward³, Charlotte Moss¹, Elaine Dennison¹, Cyrus Cooper⁴. ¹MRC Lifecourse Epidemiology Unit, University of Southampton, Southampton General Hospital, Southampton SO16 6YD, UK, ²Department of Biomedical Imaging & Image-Guided Therapy, Medical University of Vienna, Vienna, Austria, ³MRC Human Nutrition Research, Elsie Widdowson Laboratory, 120 Fulbourn Road, Cambridge CB1 9NL, UK, ⁴University of Southampton, United Kingdom

Purpose: Bone and vascular calcification appear to show overlapping pathogenesis. Here we report the relationships of bone geometry, volumetric BMD, and bone microarchitecture with LLAC as assessed by HR-pQCT.

Methods: We utilised the Hertfordshire Cohort Study, where we were able to study associations between measures obtained from HR-pQCT of the distal radius and distal tibia in 341 participants (162 women and 179 men) aged 72.1-81.4 years with or without LLAC; n=28 (17.3%) vs. n=134 (82.7%) in women; n=83 (46.4%) vs. n=96 (53.6%) in men respectively. Statistical analyses were performed separately for women and men. We used linear regression models to investigate the cross-sectional relationships between LLAC, and bone parameters for men and women, controlling for age, height, weight, smoking status, alcohol intake, diabetes, daily calcium intake, daily vitamin D intake, physical activity, social class and current use of bisphosphonates.

Results: The mean (SD) age of participants was 76.4 (2.6) and 76.1 (2.5) years in women and men, respectively. One hundred and eleven of 341 participants (32.6%) had LLAC (score >1) that were visible and quantifiable by HR-pQCT. The prevalence of LLAC was higher in men than in women (46.4% (n=83) vs. 17.3% (n=28), p<0.001). Women with LLAC had substantially lower cortical area (Ct.area) (p=0.004) and thickness (Ct.Th) (p=0.014) at the distal tibia than those without LLAC. Adjustment for confounding factors did not materially affect the relationship described for Ct.area (p=0.016) at the distal tibia but differences in Ct.Th at the distal tibia were attenuated (p=0.083). Regarding trabecular parameters, trabecular volumetric BMD (Tb.vBMD) and trabecular number (Tb.N) were lower in women with LLAC (p=0.019 and p=0.013, respectively) at the distal tibia while trabecular separation (Tb.Sp) was higher (p=0.008). Adjustment for confounding factors did not materially affect the relationship described for Tb.N (p=0.013) and Tb.Sp (p=0.012) but differences in Tb.vBMD at the distal tibia were attenuated (p=0.087). Similar results were found for Tb.vBMD (p=0.004), Tb.N (p=0.027) and Tb.Sp (p=0.016) at the distal radius with a lower trabecular thickness also observed (Tb.Th) (p=0.009) but results were attenuated after adjustment for confounding factors, with only Tb.Th remaining significant (p=0.027). Distal radial or tibial bone parameters analyses in men according to their LLAC status revealed no significant differences except for Tb.N at the distal tibia when adjusted (p=0.035).

Conclusion: LLAC assessed by HR-pQCT was associated with bone microstructure abnormalities of the distal radius and tibia in women.

LB-SU0022

Increased mortality, functional decline and dependency in elderly patients with dementia admitted with Fragility Fracture. Charles Inderjeeth*¹, Noreen Mughal². ¹University of Western Australia, Australia, ²Sir Charles Gairdner Hospital

Background
Patients with cognitive impairment are 2.7 times more likely to sustain a hip fracture when compared with age and sex matched controls without dementia. Patients with dementia continue to be at high risk of worse outcomes including fractures, functional decline, institutionalisation and mortality compared to those without dementia. Elderly patients with hip fracture have a 5 to 8 fold increased risk for all-cause mortality than in age and sex matched control in the first 3 months after a hip fracture. Twenty percent of the patients die in the year following a hip fracture.

Objectives
The primary outcome of the study was to prospectively assess the rate of pre-fracture OP treatment vs OP treatment on discharge from an Orthogeriatric Unit. The secondary outcomes were to evaluate mortality and functional decline.

Results
There were 502 consecutive admissions to the unit. At admission 78% were from home. On discharge only 42% returned to their own home. 30 day mortality was 3 times higher & 90 day 1.5 times higher in patients with a diagnosis of OP with dementia. The 30 and 90 day mortality in those with any fracture was 7% and 27% in those with dementia and 4% and 11% respectively in non-demented patients. This compares to the overall mortality in hip fracture patients of 8% and 22% respectively.

Conclusions
The imperative to treat for OP should be greater in those with dementia to prevent hip fractures and minimise the associated morbidity, mortality, social care burden and health care cost. Hospital admissions of elderly patients should be used as an opportunity for comprehensive assessment and effective management of osteoporosis and comorbidities.

Disclosures: Charles Inderjeeth, None.

Aim: Bone Mineral Density (BMD) is a highly heritable trait used to assess skeletal health in children and risk of osteoporosis later in life. To date >60 loci associated with BMD or bone-related traits measured at different skeletal sites have been identified. We conducted a genome-wide association study (GWAS) meta-analysis of total body (TB)-BMD in children and adults to identify genetic determinants and age specific effects of loci on this trait. **Methods:** We included 24 different study populations comprising ~49,000 individuals with DXA measurements at different age

ranges (0-15 years, n=11,200; 15-45 years, n=9,600; and >45 years, n=28,500) and genetic data imputed to the 1000 Genomes reference panel. Association models were adjusted for sex, age, weight, height and genomic principal components (to control for population stratification). Inverse variance meta-analysis was performed on all the data and within each age strata and comparisons between the two extreme groups leading variants were made. Genome-wide significance (GWS) was set at $P < 5 \times 10^{-8}$. Results: We identified variants associated at GWS level in 45 loci, including both common and less frequent (MAF < 5%) polymorphisms. Of these, 14 loci represent novel associations with variants not clustering within 500kb of previously reported bone loci. Several of the novel signals map in close vicinity of genes with a proven role in bone metabolism such as: *EN1*, *AQPI1*, *RIC8A*, *CSF1*, *SLC8A1-AS1* and *SMAD3*, whereas the other variants, including a missense polymorphism in *NLRP6* are likely to implicate new biology. Loci with previously described skeletal specificity (i.e. *SOX6*, *LIN7C*, *RIN3*, *ABCF2*), age heterogeneity (i.e. *CPED1*, *C17orf53*) and bone compartment specificity (i.e. trabecular volumetric BMD, *FMN2*; or heel ultrasound, *TMEM135*) were all identified by our TB-BMD GWAS meta-analysis. The strongest age specific effects were found for variants in the *RIN3* with GWS effect ($\beta = 0.1$ SD, $P = 1 \times 10^{-8}$) only in children ($P_{\text{het}} = 3 \times 10^{-12}$) and *ESR1* only exerting a GWS effect ($\beta = 0.07$ SD, $P = 9.3 \times 10^{-13}$) in adults ($P_{\text{het}} = 7 \times 10^{-10}$) loci. Conclusion: TB-BMD is a relevant trait for genetic studies of osteoporosis, capable of identifying (novel) variants influencing different bone compartments at different skeletal sites. Applying an age-stratified GWAS approach allowed us to identify loci exerting effects at different stages of the lifespan, helping to unveil further the complex genetic architecture of osteoporosis.

Osteoporotic Fractures in Heart failure; Findings from National Health Insurance Data in Korea. Da Hea Seo¹, Jong-Chan Youn², Jung Wha Hong³, Seok-Min Kang², Yumie Rhee⁴. ¹Department of Internal Medicine, Endocrine Research Institute, Yonsei University College of Medicine, ²Division of Cardiology, Severance Cardiovascular Hospital, Yonsei University College of Medicine, ³Department of Biostatistics, Yonsei University College of Medicine, ⁴Department of Internal Medicine, College of Medicine, Yonsei University, South Korea

Osteoporosis and heart failure are prevalent conditions, particularly among the elderly. Recent findings suggest a role for heart failure in the etiology of osteoporotic fractures, yet the national trends of the incidence and treatment rates of osteoporotic fractures in heart failure patients in Korea is unknown. We investigated osteoporotic fractures in heart failure patients in Korea is unknown. We investigated osteoporotic fractures (spine, hip, humerus, radius and tibia) and their treatment rates with selective estrogen-receptor modulators (SERM) or bisphosphonates in heart failure patients over age 65 during 2009-2013 using the database from the Health Insurance Review and Assessment Service (HIRA), which covers almost 100% of Korean population. Annualized incidence rates for total osteoporotic fractures were 51 per 1000 person-years in heart failure patients (12 hip, 31 spine, 2 humerus, 9 radius and 4 tibia respectively); the annualized incidence rates for total osteoporotic fractures were 27 per 1000 person-years in men and 66 per 1000 person-years, yielding a female to male ratio of 2.41. The annualized incidence rates for osteoporotic fractures were proportional to age until 80 years old when it starts to decline; 8 in 65-70 years, 13 in 70-75 years, 14 in 75-80 years, 10 in 80-85 and 6 in ≥ 85 years. Although higher than general population with osteoporotic fractures, it was estimated that only 24.88% of heart failure patients with osteoporotic fractures are treated with either SERM or bisphosphonate. Our study offers nationwide epidemiological data on osteoporotic fractures in heart failure patients in Korea. Because diagnosis of heart failure predicts a substantial risk of osteoporotic fractures, proper evaluation and treatment for osteoporosis is necessary in heart failure patients.

Retrospective Analysis of Osteoporosis Evaluation and Treatment Following Fragility Fracture of the Hip. Sara Heintzman¹, Mitchell Hughes², Tamara Scerpella². ¹University of Wisconsin Hospitals & Clinics, ²University of Wisconsin School of Medicine & Public Health, USA

Purpose: Current practice guidelines recommend evaluation and treatment of osteoporosis in all patients with a fragility fracture. We assessed compliance following operative treatment of hip fractures at an upper Midwest academic medical center.

Methods: This retrospective cohort study reviewed EMR data for all patients, ≥ 65 years, who had surgical treatment of a hip fracture at a single academic medical center, between 2007 and 2013. Subjects were identified via data query, and excluded for failure to meet fragility fracture criteria. The group was refined to patients with an in-network PCP, ensuring maximal data capture. DXA scans were recorded within 1-yr post-fracture. In addition, detailed demographic and treatment outcomes were recorded for the youngest 20% of patients included.

Results: 607 patients were treated during the index period; 6% (38) did not meet fragility fracture criteria, 20% (122) died within 12 months and 35% (214) did not have an in-network PCP. Of the remaining 39% (233), only 16% (38) had a DXA in the 1-yr post-fracture window. Detailed review included the 122 youngest patients; 84% (102) met fragility fracture criteria; average age was 69 yrs. Of these, pre-fracture treatment

included calcium and/or vitamin D in 36% (37) and anti-resorptive therapy in 20% (20). Patients with an in-network PCP were more likely to have been prescribed pre-fracture treatment medication ($p=0.006$); likelihood did not vary based on urban vs. rural residence ($p=NS$). 18% (18) had a change/addition in osteoporosis treatment medication during hospitalization; this did not vary based on residence or PCP ($p=NS$). Vitamin D level was evaluated during hospitalization for 27% (27); likelihood was greater for non-network PCP and rural patients ($p=0.013$, $p=0.021$, respectively). For 52 in-network PCP patients, detailed review over 1-yr post-fracture revealed: 44% (15) had a vitamin D level evaluated, 23% (12) had a DXA, 15% (8) had a medication changed/added, and 12% (6) had a second fracture.

Conclusion: Established guidelines for evaluation of osteoporosis following fragility fracture were met for only 1/6th of patients in this retrospective cohort study. A similarly low rate of treatment was also noted, both during hospitalization and in a 1-yr follow-up period. The status quo for osteoporotic treatment following fragility hip fracture remains inadequate.

Enhanced Hip Fracture Management: Use of Sfn System to Evaluate a Fractured Neck of Femur Fast Track Pathway – Pilot Study. Nigel Gilchrist^{*1}, Kris Dalzell², Scott Pearson³, Jeremy Hickling⁴, Kit Hoeben⁵, Ma Yi⁶. ¹Department of Orthopaedic Surgery, Canterbury District Health Board, ²Department of Orthopaedic Surgery, Canterbury District Health Board, ³Emergency Department, Canterbury District Health Board, ⁴Department of Anaesthesia, Canterbury District Health Board, ⁵Planning & Funding, Canterbury District Health Board, ⁶Biosatistician, Canterbury District Health Board, United Kingdom

The purpose of this pilot study was to evaluate the change in management of acute hip fracture patients >65yrs (450/yr) from the time they presented at the Emergency Department of Christchurch Hospital, New Zealand to the time that they were discharged from hospital.

Changes to each facet of the pathway, Emergency Department, peri-operative management, operation, rehabilitation and discharge were agreed by the individual teams and integrated. Data was captured electronically and processed using the sfn toolset to produce statically based performance measurements on all activities in all areas of the Fast Track Fractured Neck of Femur Pathway.

The pilot study began in November 2014, is currently ongoing and the data is shown up to the end of April 2015. Pilot study data was then compared with prior data in a group of similar patients in the preceding 3 years. A Wilcoxon Rank Sum Test was used for statistical comparison.

One hundred and sixty one patients were observed during the pilot study compared to 989 patients from the preceding years. The average time in the Emergency Department reduced significantly from 3.46 +1.46 to 2.87 +1.33 hours ($p<0.0001$), average wait for theatre reduced from 1.62 +1.53 to 1.47 +1.42 days ($p=0.044$), the average wait for rehabilitation reduced from 7.13 +4.49 to 4.29 +2.63 days ($p<0.0001$). Length of stay in the acute hospital with direct discharge home went from 10.44 +8.39 to 7.13 +4.4 days ($p=0.003$). The length of stay in the Orthopaedic Rehabilitation Unit reduced from 24.24 +12.41 to 17.46 +6.68 days ($p<0.0001$) and at another rehabilitation facility (more complex medical co-morbidities) 33.71 +14.2 to 30.43 +14.07 days ($p=0.048$). The overall length of stay for patients reduced from 24.40 +15.06 to 20.48 +13.59 days ($p=0.001$). Total readmissions over this period did not differ significantly from the previous 3 years. Total acute admissions to orthopaedics also did not differ in comparison with the previous years.

We have significantly reduced the time in hospital by a factor of 95 hours in each patient and over the period of the pilot study saved 631 bed days with a projected annual bed day saving of 1,495. Further time could be saved by aiming to get the time from the Emergency Department to Theatre down to 20 hours. This pilot study is ongoing, the immediacy of electronic data to evaluate change in clinical management has shown benefit in reduction in day stay and possible cost savings.

Disclosures: Nigel Gilchrist, None.

LB-SU0027

Falls are increased on Recommended Doses of Vitamin D in Elderly Women.. J. Christopher Gallagher¹, Shervin Yousefian^{*2}, Lynnette Smith³. ¹Creighton University Medical Center, USA, ²Creighton University Medical Center, USA, ³University of Nebraska, USA

Introduction: The effect of vitamin D supplementation on falls and physical performance is controversial. Some studies show a decrease in falls on daily vitamin D 800 IU, others show increased falls on a high annual dose. The American Geriatrics Society consensus statement recommends a daily vitamin D intake from all sources of 4,000 IU daily in the elderly. We analyzed the Fall rate and physical performance tests in our vitamin D dose ranging study.

Design: 163 independent living women entered a 1-year double blind randomized dose ranging study of daily vitamin D 400,800,1600,2400,3200,4,000,4800 IU or placebo together with calcium ~580mg/d (total intake ~1200mg). Diet vitamin D was 114 IU. Inclusion criteria: serum 25OHD \leq 20ng/ml; no known disease or drugs affecting calcium or bone metabolism. Fall history was recorded at baseline and at 3-

monthly visits. Standard physical performance tests included Timed up and Go, Timed walk, Chair Rising test, Grip strength and Balance (Biodex). This was a secondary analysis using Intent to treat and statistical analysis used Chi square and ANOVA

Results: Age range 57-87 years, mean age 66.2 years (SD 7.3), mean BMI 30.3 kg/m² (SD 5.9). Compliance, measured every 3 months, was 94% for vitamin D and 91% calcium. 147 completed study. Fallers: 49% women had falls; the rate was higher 60% in women with a fall history in last year compared to 40% with no fall history. Overall there was no effect of the pooled vitamin D dose on falls. However, when grouped into low dose (400, 800 IU); medium dose (1600-3200 IU) or high dose (4000-4800 IU); the faller rate was reduced by 45% on medium doses compared to placebo and low doses and reduced by 56% compared to the high doses ($p=0.003$). In those with previous fall history 100% of the women on high doses 4,000/4800 IU (serum 25OHD range > 45 ng/ml) suffered a fall. The vitamin D dose and falls followed a U shaped curve. There was a non-significant decline in all physical performance tests on vitamin D in all dose groups.

Conclusions: In this clinical trial Vitamin D 400/800IU had no effect on falls compared to placebo. Vitamin D doses 1600,2400,3200 IU showed a significant decrease in falls. High doses of vitamin D 4,000-4800IU were associated with a marked increase in falls. The American Geriatrics Society recommendation of vitamin D 4,000 IU daily for fall prevention especially in those with fall history should be reconsidered since it may lead to more rather than less falls.

Epigenetic priming confers direct cell trans-differentiation in a transgene-free state. YOUNG DAN CHO^{*}, Han-Sol Bae, Bong-Soo Kim, Kyung-Mi Woo, Jeong-Hwa Baek, Hyun-Mo Ryoo. Seoul National University, South Korea

The bone marrow of healthy individuals is primarily composed of osteoblasts and hematopoietic cells, while that of osteoporosis patients has a larger portion of adipocytes. There is evidence that the epigenetic landscape can strongly influence cell differentiation. We have shown that it is possible to direct the trans-differentiation of adipocytes to osteoblasts, both in vitro and in vivo, by modifying the epigenetic landscape with a DNA methyltransferase inhibitor (DNMTi), 5'-aza-dC, followed by Wnt3a treatment to signal osteogenesis. Gene expression profiles of marker genes (Runx2 and Pparg) of osteoblasts and adipocytes were correlated with epigenetic modifications to their promoter regions. Treating 3T3-L1 adipocytes with 5'-aza-dC induced demethylation in the hypermethylated CpG regions of bone marker genes; subsequent Wnt3a treatment drove the cells to osteogenic differentiation. When 15-month old mice with predominantly adipose marrow, a mouse model for osteoporosis, were treated with both 5'-aza-dC and Wnt3a, histological and micro CT analysis suggested that the fatty tissue decrease and bone volume increased. Together, our results indicate that epigenetic modification permits direct programming of adipocytes into osteoblasts in a mouse model of osteoporosis, suggesting that this approach could be useful in bone tissue-engineering applications.

LB-SU0029

High cardiovascular risk in older men with low sclerostin levels – prospective STRAMBO study. Pawel Szulc^{*1}, Lorenz Hofbauer², Roland Chapurlat³. ¹INSERM UMR 1033, University of Lyon, Hopital E. Herriot, Pavillon F, France, ²Division of Endocrinology, Diabetes, & Bone Diseases, Dresden University Medical Center, ³INSERM UMR 1033, University of Lyon, Hospices Civils de Lyon, France

Data on the association between serum sclerostin levels and cardiovascular risk are scarce, discordant and limited to patients with chronic renal diseases. Our aim was to prospectively assess the association between baseline serum sclerostin levels and risk of incident major cardiovascular event in a cohort of 780 home-dwelling men aged 60 and over. Serum sclerostin levels were measured by ELISA (Biomedica). Incident major cardiovascular event was defined as acute coronary syndrome (myocardial infarction, acute coronary insufficiency with or without ST-T elevation confirmed by angiography), stroke or sudden death. During the median follow-up of 7.8 years, 83 men sustained major cardiovascular events. For the statistical analyses, we used Cox model adjusted for age, weight, professional physical activity, current smoking, comorbidities, abdominal aortic calcification, glomerular filtration rate as well as serum levels of osteoprotegerin, DKK1, FGF23 and parathyroid hormone.

Lower sclerostin levels were associated with higher risk of incident major cardiovascular event (HR= 1.30 per SD decrease, 95%CI: 1.04-1.62, $p<0.05$). The risk of cardiovascular event increased across decreasing sclerostin quintiles ($p<0.05$) and was higher (HR= 3.19, 95%CI: 1.42-7.18, $p=0.005$) in the lowest quintile (<47 pmol/L) vs. the upper quintile (>97 pmol/L). Hypertensive men with low sclerostin (<47 pmol/L) had high cardiovascular risk (HR= 6.92, 95%CI: 2.10-22.8, $p<0.005$) compared to normotensive men with high sclerostin (>97 pmol/L). Men with low sclerostin (<47 pmol/L) and high DKK1 levels (>15 pmol/L, median) had higher

cardiovascular risk (HR= 5.08, 95%CI: 1.54-16.8, p<0.01) compared to men with high sclerostin (>97 pmol/L) and low DKK1 (<15 pmol/L).

In conclusion, our data suggest that low serum sclerostin levels are an independent indicator of cardiovascular risk in older home-dwelling men.

Differential changes in bone geometry and microarchitecture in extreme duration type 1 compared to younger type 1's and controls. Ernesto Maddaloni*, Hillary Keenan. Joslin Diabetes Center, USA

Aim. To evaluate the age related changes in bone geometry in a unique population of aging subjects with extreme duration (>50 years) of type 1 diabetes (T1D), the Joslin 50-Year Medalist cohort, and compare to young T1D subjects and controls.

Methods. High-resolution peripheral quantitative computed tomography (HR-pQCT) was used to assess bone geometry, volumetric bone mineral density (vBMD) and microarchitecture of the ultradistal radius and tibia in fourteen subjects with >50 years T1D duration (50% males, mean \pm SD age: 65.7 \pm 8.4yrs; T1D duration 56.3 \pm 6.9yrs, body mass index 26.1 \pm 4.1kg/m²; HbA1c 7.0 \pm 0.8%). Results were compared to values from published data collected from the same system in a cohort of younger T1D subjects (YT1D) (age 45.6 \pm 11.7yrs), and (for the ultradistal radius only, due to data availability) in a population of age and gender matched controls.

Results. Despite the older age, equal trabecular (Tb) vBMD at the radius (166.8 \pm 38.6 vs 158.1 \pm 43.0mgHA/cm³, p=0.43) and increased Tb vBMD at the tibia (192.3 \pm 29.4 vs 172.7 \pm 45.7, p=0.03) in the Medalists vs YT1D were found. No differences were found in Tb vBMD vs control group (p=0.59). Cortical (Ct) vBMD was lower in the Medalist when compared to YT1D at both radius (817.7 \pm 70.2 vs 883.1 \pm 58.3, p=0.006) and tibia (732.6 \pm 109.8 vs 864.1 \pm 58.6, p<0.001). Medalists also showed a decreased Ct vBMD at the radius when compared to controls (862.4 \pm 6.9, p=0.04). In addition, study of the bone microarchitecture showed decreased tibia Ct thickness (th), but increased Tbth amongst Medalists vs YT1D (0.89 \pm 0.38 vs 1.24 \pm 0.29mm, p=0.004; 0.08 \pm 0.02 vs 0.072 \pm 0.014, p=0.04, respectively). The study of bone geometry showed a smaller periosteal perimeter at the radius in the Medalists vs YT1D (75.0 \pm 8.5 vs 81.7 \pm 14.4mm, p=0.01), suggesting decreased periosteal bone apposition.

Conclusions. The association of T1D with increased risk of fragility fractures has been documented. Due to the mean age and the over 50 years of T1D duration, the Joslin Medalist cohort provides a unique opportunity to study the effects of the long exposure to diabetes on bone health, and the interaction of hyperglycemia and aging. In stark contrast to previous reports in people without diabetes, here we show a significant age-related decline in Ct, but not in Tb vBMD. This protection from decline in Tb vBMD may possibly explain the low prevalence of fragility fractures we previously described in the Medalist cohort.

Disclosures: Ernesto Maddaloni, None.

LB-SU0031

MSC therapy for hypophosphatasia. Luke Mortensen*. University of Georgia, USA

Hypophosphatasia (HPP) is a debilitating genetic disease of impaired alkaline phosphatase that limits bone mineralization throughout the skeletal system. Severe infantile cases develop during the first year of life, and often quickly lead to death. Patients that survive exhibit a number of clinical problems, including craniofacial complications like craniosynostosis and tooth loss. Currently there are no approved treatments, and those under investigation have limited craniofacial improvement. We therefore study one potential therapeutic route, administration of mesenchymal stem cells (MSCs), in a mouse model of HPP with a goal of improving mortality and craniofacial mineralization. Several clinical case studies have used MSC or stromal cell administration along with bone marrow transplant under myeloablative conditions, which resulted in improvement of bone mineralization characteristics. This may be due to the presence of alkaline phosphatase-rich stromal cells in the bone, but it remains unclear if MSCs are involved in the observed therapeutic response. Therefore, this work aims to evaluate MSC therapy without myeloablation or bone marrow transplantation for HPP. We hypothesize that MSCs alone will enhance survival in HPP, and that long term cell survival is required for therapy. Our preliminary efforts have isolated and validated an MSC population with inducible apoptosis (CAGCre-ERTM::floxed-DTA) that allow direct evaluation of the need for MSC survival after transplantation in a murine HPP model. Results indicate that cre-induced recombination allows the ablation of cells in vitro, and that cells retain expression of alkaline phosphatase after culture expansion. We determined that intravenously administered MSCs labelled with membrane home to the calvarial bone marrow of mice at a high frequency using our 2-photon imaging strategy and are cleared after apoptosis induction. Ongoing efforts to evaluate the effect of MSC transplantation on HPP therapeutic outcome are ongoing, and future directions will determine the need for long term cell survival in HPP, and develop strategies to enhance cell therapy.

DOES AUTOSOMAL DOMINANT OSTEOPETROSIS TYPE 2 (ADO2) HAVE A CENTRAL NERVOUS SYSTEM PHENOTYPE?. Mattia Capulli*¹, Antonio Maurizi², Juliana Cortes², Laura Di Rito², Nadia Rucci², Anna Teti². ¹University of L'Aquila, Italy, ²University of L'Aquila, Italy

ADO2 is a rare genetic disease characterized by high bone density and bone fragility. So far only heterozygous clcn7 gene mutations are reported to trigger the disease. We recently generated an ADO2 mouse model, knocking-in the clcn7 mutation causing the G213R amino acidic substitution in the CIC7 protein. The bone phenotype of our heterozygous mice phenocopied the human disease, while no obvious alterations of the Central Nervous System (CNS) were observed by conventional histological analysis, in agreement with the paucity of information on CNS involvement in human ADO2. However, to our surprise, during the animal handling, we observed ADO2 mice to be more susceptible to strong sounds and uneasy compared to their WT littermates, suggesting a possible unrecognized behavioral phenotype induced by the clcn7 mutation. Consistently, behavioral tests showed that adult (3 month-old) ADO2 mice displayed 46% (p=0.02) lesser time spent in the lit compartment in the dark and light transition test, 48% (p<0.0001) lesser time spent in the center of arena in the open field test, 42% (p=0.04) lesser time spent in the open arm in the elevated plus maze test, and 40% (p=0.01) more time spent immobile in the forced swimming test, demonstrating greater anxiety and depression compared to WT littermates. Conversely, memory and motor abilities were unremarkable. Intriguingly, analyses of 1 year-old ADO2 mice evidenced a worsening of anxiety and depression related parameters (mean worsening 33%), suggesting a progressive degeneration of the brain function, a condition often observed in storage diseases. In agreement with this hypothesis, in-depth histological analyses showed a prominent increase of β -amyloid accumulation in ADO2 brains (+2.1fold; p=0.002). This phenomenon could be due to abnormal protein storage and consequent cellular degeneration, since immunofluorescence sub-cellular localization analysis showed accumulation of mutant CIC7 protein in the Golgi apparatus, which appeared abnormally enlarged. Consequently, lysosomal levels of mutant CIC7 and subsequent acidification were impaired. Finally, real-time RT-PCR analysis of brain mRNAs showed 30% lower expression of the neuron detoxifying enzyme, glyoxalase 1 (p=0.03), in ADO2 mice compared to WT littermates. These results warn about the need to better evaluate the CNS involvement in human ADO2 and could explain some neurological complications in patients, helping the clinician in managing this complex disease.

Novel Variant of G α -alpha Associated with Albright's Hereditary Osteodystrophy, Osteolysis, and Syndrome of Inappropriate ADH Secretion. Kelly Wentworth*¹, Edward Hsiao², Murat Bastepe³, Yan Zhu³. ¹University of California- San Francisco, ²Endocrine Unit, Massachusetts General Hospital & Harvard Medical School, USA

G-protein coupled receptors (GPCRs) mediate a wide spectrum of biological activities. The GNAS complex locus encodes the stimulatory α -subunit of the guanine nucleotide binding protein (G α), which stimulates production of the second messenger cyclic AMP (cAMP). Several conditions are associated with loss-of-function GNAS mutations, including Albright's Hereditary Osteodystrophy (AHO) and pseudohypoparathyroidism. Patients with AHO often exhibit short stature, brachydactyly, and subcutaneous ossification. Here, we present the case of a child with some clinical features of AHO as well as osteolysis and neonatal SIADH, in whom we have discovered a novel GNAS mutation causing loss of G α activity.

Our patient is an 11-yo female who was referred to our clinic for frequent fractures and osteolysis. At birth, her right femoral diaphysis was fractured, and a bone survey demonstrated diffuse hypomineralization. She sustained a second right femoral fracture at 14 months and subsequent bone surveys showed osteolysis of the distal phalanges of her hands, feet, and metacarpals/metatarsals with progressive bowing of her femurs, tibiae and fibulae. She was started on bisphosphonate therapy at age 4 to prevent further fractures, but subsequently developed fractures in her right fibula and wrists while on therapy. In addition to her skeletal abnormalities, she was diagnosed with SIADH at birth (Na⁺ =116 mEq/L) which has been managed with fluid restriction. Physical exam at age 11 showed normal craniofacial features, bowing of both legs and normal metacarpals but shortened distal phalanges, small café-au-lait spots on her flank, and labial hyperplasia. The patient did not have short stature or show any evidence of subcutaneous ossification. Exome sequencing revealed a heterozygous c.163A>G (p.T55A) mutation in G α s, which was not detected in her parents' DNA samples. Transfection of G α s-null mouse embryonic fibroblasts with cDNA encoding this mutant showed a 64% reduction in isoproterenol-induced cAMP production compared to wild-type G α s (normalized to forskolin-stimulated cAMP levels). In summary, our patient harbors a novel, de novo missense mutation in the p-loop of the G α GTPase domain, leading to decreased agonist-stimulated cAMP formation. The G α s loss-of-function could account for her presentation with some clinical features of AHO, such as shortened distal phalanges. However, the underlying cause of the osteolysis and neonatal SIADH remains unclear.

Factors Predicting Functional Status, Muscle and Bone Parameters in Long-Term Survivors of Acute Lymphoblastic Leukemia (ALL). Louis-Nicolas Veilleux*¹, Frank Rauch², Daniel Curnier³, Maja Krajinovic⁴, Caroline Laverdière⁴, Daniel Sinnett⁴, Nathalie Alos⁴. ¹McGill University/Shriners Hospital for Children-Canada, Canada, ²McGill University-Shriners Hospital for Children, ³Department of Kinesiology, University of Montreal, ⁴Sainte-Justine University Hospital Center, Canada

Context: Overall cure rates for childhood acute lymphoblastic leukemia (ALL) have improved allowing the cure of over 85% of patients. At least 70% of survivors of childhood ALL cancers have substantial morbidities as a result of their disease and/or their treatment. The goal of this study was to determine the factors susceptible to predict musculoskeletal health status in ALL long term survivors. Patients: 190 long-term ALL survivors were part of this study (52% were females; mean age at recruitment [SD]: 22.7 years [6.6]; mean age at diagnosis [SD]: 5.6 years [4.2]; 57% of patients were classified as high risk at diagnosis; average treatment duration [SD]: 26 months [4.7]). Main outcomes. Functional status was assessed with the 6 minutes' walk test (6MWT). Muscle function was measured using mechanography whereas radius and tibia bones status were assessed using pQCT. Stepwise linear regression was used to identify predictors of muscle and bone parameters. Parameters included in the model were age at diagnosis, risk group (high or standard), effective cumulative dose and radiotherapy (Y/N). Results. Results of the 6MWT showed that the distance walked by the survivors was on average 13% lower than what was expected compared to age and sex-specific reference data. The regression analysis showed that the 'risk group' was negatively related to the performance at the 6MWT ($p=0.003$). For muscle function, none of the predictors entered in the regression model was related to muscle parameters. The 'risk group' was a negative predictor of trabecular BMD ($p=0.02$) at the 4% site and of total BMC ($p=0.04$), cortical CSA ($p=0.04$) and cortical BMD ($p<0.001$) at the 14% site. At this site, the 'age at diagnosis' was positively related to total BMC ($p=0.007$), cortical CSA ($p=0.01$) and cortical thickness ($p=0.02$). At the radius, 'age at diagnosis' was found to be positively related to total BMC ($p=0.04$) at the 4% site and to total CSA ($p=0.03$) at the 65% site. Moreover, 'risk group' was found to be a negative predictor of trabecular BMD at the 4% ($p=0.007$) and cortical BMD at the 65% site ($p=0.001$). Conclusion: 'Risk group' was found to be a negative predictor of bone health whereas 'age at diagnosis' was shown to be a positive predictor of bone health. This was observed at both the radius and tibia bones and for both, trabecular and cortical bone. These two parameters should be taken into account in the long term follow-up of bone health in ALL survivors.

Blocking the senescence-associated secretory phenotype (SASP) reduces osteoclastogenesis and prevents age-related bone loss. Ming Xu*, Megan Weivoda, Christine Hachfeld, Merry Jo Oursler, James Kirkland, Mayo Clinic, USA

Age related bone loss occurs in men and women; however the mechanisms for this remain unclear. Senescent cells accumulate in several tissues with age and secrete pro-inflammatory cytokines, defined as the senescence-associated secretory phenotype (SASP). We hypothesized that the SASP increases osteoclastogenesis and contributes to age-related bone loss. Human pre-adipocytes isolated from subcutaneous fat were sham treated or irradiated with 10 Gy to induce senescence. Conditioned media (CM) was collected from control and senescent cultures. Because the JAK signaling pathway has been implicated in senescence, cells were treated with a vehicle or a JAK inhibitor (JAKi) prior to CM collection. Senescence was confirmed by γ H2X staining. Mouse bone marrow was cultured in 50% control or senescent CM, or in the presence of M-CSF overnight. Non-adherent cells were cultured in osteoclast differentiation media and assessed for differentiation. A cytokine array was used to identify senescence induced factors. To assess in vivo responses to JAKi, 22 month male mice were treated with JAKi for 8 weeks. Femurs and vertebrae were assessed by mCT. Bone marrow was assessed for osteoclast and osteoblast progenitor numbers as well as osteoclast differentiation. Irradiated human pre-adipocytes stained positively for senescence markers and CM had increases in numerous inflammatory factors including IL-6, MCP1, and GM-CSF, which were reduced by JAKi treatment. While overnight culture of bone marrow in control CM yielded only minor osteoclast differentiation at day 4, culture in senescent CM yielded osteoclast numbers comparable to bone marrow treated overnight in M-CSF. JAKi treatment of senescent cells prevented senescent cell CM induced osteoclast formation. JAKi did not block M-CSF induced osteoclast differentiation. JAKi treated mice exhibited significantly improved BV/TV in the vertebrae and femur. Vertebral and femur Tb.Th was significantly increased in JAKi treated mice. Tb.N, Tb.Sp, and SMI were not significantly altered. There was no significant difference in total bone marrow colony formation units (CFU) or osteoblast CFU. In contrast, monocyte and granulocyte CFU were significantly reduced in bone marrow isolated from JAKi treated mice. Consistent with this, osteoclast differentiation was significantly reduced in bone marrow derived from JAKi treated mice. Our findings suggest a novel mechanism and therapeutic target for bone loss in aged population.

Targeting CKIP-1 within osteoblast: A potential anabolic strategy for bone formation reduction during aging? Jin Liu*¹, Zongkang Zhang², Jie Li², Baosheng Guo³, Baoting Zhang², Aiping Lu³, Ge Zhang³. ¹Hong Kong Baptist University, Hong Kong, ²School of Chinese Medicine, The Chinese University of Hong Kong, ³Institute for Advancing Translational Medicine in Bone & Joint Diseases, Hong Kong Baptist University

Introduction: The pathophysiological mechanism for the reduction in bone formation during aging is still underexplored. Casein kinase-2 interacting protein-1 (CKIP-1) is an important ubiquitination-related molecule specifically targeting the linker region between the WW domains of Smurf1, thereby augmenting its affinity for and promoting Smad1/5 ubiquitylation (Lu *et al.*, Nat Cell Biol, 2008). In our preliminary study on bone specimens from both aged individuals with fracture and aged ovariectomized (OVX) rat model, we found that aberrantly increased CKIP-1 within osteoblasts was closely associated with suppressed BMP signaling and reduced bone formation during aging. Thus, we hypothesize that CKIP-1 within osteoblasts may participate in the pathological regulation on the bone formation reduction during aging.

Methods: Study 1: We examined the effect of genetic depletion of CKIP-1 gene within osteoblast on bone formation during aging using our established osteoblast-specific *Ckip-1* conditional knockout (CKO) mouse model. Study 2: We evaluated the effect of pharmacological silencing CKIP-1 within osteoblast using CKIP-1 siRNA encapsulated in our recently developed osteoblast-targeting delivery system (CH6-LNPs, Liang *et al.*, Nat Med, 2015) on bone formation in aged rats.

Results: Study 1: The aged CKO mice showed higher BV/TV and improved trabecular micro-architecture than their littermate controls (Fig 1a). The mineral apposition rate (MAR) was also higher in aged CKO mice than that in littermate controls (Fig 1b). In addition, more cells co-expressing ALP and pSmad1/5 were found at the bone sections from aged CKO mice when compared to their littermate controls (Fig 1c). Study 2: The level of CKIP-1 mRNA within osteoblast (ALP+ cells) was remarkably downregulated in the rats received eight consecutive intravenous injection of CKIP-1 siRNA-CH6-LNPs (siRNA group) (Fig 2b). Consequently, the intrasosseous protein levels of CKIP-1 and pSmad1/5 were both elevated in these rats (Fig 2c). In addition, the rats in siRNA group showed improved trabecular micro-architecture at proximal tibiae as well as larger width between xylenol and calcein labeling when compared to the rats in the other groups (Fig 2d&e).

Conclusion: CKIP-1 within osteoblast plays an important role in the pathological regulation on the aging-induced bone formation reduction. Targeting CKIP-1 within osteoblast may be a potential anabolic strategy for the bone formation reduction during aging.

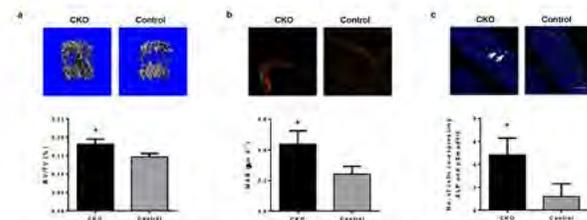

Figure 1 The bone phenotype of the osteoblast-specific *Ckip-1* knockout (CKO) mice. (a) Micro-CT analysis of the trabecular micro-architecture at 5th lumbar vertebra (L5) from the 18-month-old CKO mice and age-matched littermate controls. (b) Dynamic histomorphometric analysis of the trabecular micro-architecture at L5 from the 18-month-old CKO mice and littermate controls. SEN6, a desumoylase, protects osteochondroprogenitors and chondrocytes from senescence and apoptosis. Jianshuang Li¹, Di Lu¹, Kevin Weaver¹, Huadie Liu¹, Hong Dou², Edward Yeh², Bart Williams¹, Tao Yang^{*3}.
¹Van Andel Research Institute, ²MD Anderson Cancer Center, ³Van Andel Research Institute, USA

Sumoylation is a post-translational modification that conjugates small ubiquitin-like modifiers (SUMOs) to the target proteins and alters their functions. In contrast, desumoylation process that is catalyzed by desumoylases removes SUMO modifications from the target proteins. The dynamic balance between sumoylation and desumoylation plays crucial roles in tissue development and homeostasis, and its dysregulation is associated with human disease and aging. A recent GWAS study revealed that a SNP in the upstream sequence of the gene encoding the desumoylase *SEN6* (Sentrin/sumo1 specific peptidase 6), is highly associated with osteoarthritis, providing a tantalizing clue about sumoylation in cartilage development and homeostasis. However, the role of sumoylation/desumoylation in the context of skeletal system is not clear. We have generated mice with osteochondroprogenitor (OCP)-specific *Senp6* deletion using *Prx1-Cre* as well as *Dermo1-Cre*. These mice show distinctively smaller skeletal elements with increased chondrocyte apoptosis and senescence. Moreover, the total level of sumoylated proteins, DNA damage responses, p53 signaling, and expression of genes associated with inflammation are also significantly elevated in *Senp6*-deficient chondrocytes or OCPs. These data suggests that SEN6-mediated desumoylation pathways are pivotal for OCP maintenance and chondrocyte homeostasis, likely through protecting cells from stress-induced apoptosis and senescence during skeletal development. This study will also shed light on the role of sumoylation /desumoylation in osteoarthritis pathogenesis.

Unmasking tumor-induced osteomalacia with bisphosphonate therapy in metastatic prostate cancer, and its management. Tiffany Kim^{*1}, Kelly Wentworth², Jennifer Park-Sigal³, Anne Schafer⁴, Daniel Bikle⁴, Dolores Shoback⁴. ¹University of California, San Francisco, ²University of California, San Francisco, ³San Francisco General Hospital, ⁴San Francisco VA Medical Center, USA

Tumor-induced osteomalacia (TIO) causes profound hypophosphatemia due to renal phosphate wasting and inappropriately normal serum 1,25-dihydroxyvitamin D (1,25 OHD) levels, resulting from excessive fibroblast growth factor 23 (FGF23) production. While mesenchymal tumors typically cause TIO, castration-resistant prostate cancer (CRPC) is also implicated. We describe the course of a 68-year-old man with CRPC and his response to medical therapy. The patient initially had

normal serum phosphate and calcium levels but developed refractory hypophosphatemia while receiving monthly zoledronic acid (ZA) infusions to stabilize bony metastases. ZA had to be intermittently held, due to severe hypophosphatemia and hypocalcemia, from which he was mildly symptomatic with myalgias. Oral phosphate and calcium supplements were started. Initial lab results were notable for hypophosphatemia, hypocalcemia, inappropriately normal 1,25 OHD, secondary hyperparathyroidism, and elevated serum prostate specific antigen (PSA), alkaline phosphatase (AP), C-terminal telopeptide (CTX) and C-terminal FGF23 levels (see Table). PET CT demonstrated diffuse axial sclerotic uptake consistent with osteoblastic metastases. Over the next 2 years, he received daily doses of up to 2 mcg calcitriol, 4 g phosphorus, and 2.4 g elemental calcium. Serum calcium, PTH and CTX levels improved, but there were no changes in serum phosphate or 1,25 OHD levels, and serum PSA, AP and FGF23 levels increased (see Table). Despite therapy, he sustained right radial shaft and left wrist fractures after mechanical falls. TIO in metastatic CRPC is associated with aggressive disease in prior reports. TIO can be unmasked with anti-resorptive therapy or can occur spontaneously. It has been speculated that TIO in the setting of metastatic CRPC is due to FGF23 expression by the prostate cancer, and FGF23 may play a role in progression of this complication. Exogenous FGF23 promotes prostate cancer proliferation *in vitro* and may be produced as a paracrine factor by the tumor or osteocytes adjacent to metastatic deposits (Feng et al, *Oncotarget*, 2015). TIO is difficult to treat with supplements alone. Both cinacalcet, which can decrease FGF23's phosphaturic effects, and FGF23 neutralizing antibodies have therapeutic potential in TIO. This case highlights the importance of recognizing TIO as a potential complication of metastatic CRPC, which may be unmasked with anti-resorptive therapy.

Table

| Laboratory Value | Prior to Treatment* | With Treatment | Normal Range |
|---------------------------|---------------------|----------------|----------------|
| Phosphorus | 1.8 | 1.7 | 2.4-4.5 mg/dL |
| Calcium | 7.4 | 9.1 | 8.5-10.5 mg/dL |
| 25 hydroxyvitamin D | 45 | 43.7 | 20-50 ng/mL |
| 1,25 dihydroxyvitamin D | 38 | 22 | 18-72 pg/mL |
| Parathyroid hormone | 334 | 97.3 | 15-88 pg/mL |
| Alkaline phosphatase | 180 | 914 | 40-125 U/L |
| Prostate specific antigen | 142 | 318 | 0-4 mcg/L |
| C-terminal telopeptide | 1092 | 423 | 87-345 pg/mL |
| C-terminal FGF23 | 398 | 572 | < 181 RU/mL |

Optineurin Negatively Regulates Osteoclast Differentiation by Modulating NFκB and Interferon signalling, Implications for Paget's Disease of Bone. Rami Obaid¹, Sachin Wani¹, Asim Azfer¹, Ruth Jones², Philip Cohen², Stuart Ralston¹, Omar Albagha^{*3}. ¹University of Edinburgh, ²University of Dundee, ³University of Edinburgh, United Kingdom

Paget's disease of bone (PDB) is a common skeletal disorder characterised by osteoclast activation which provokes increased but disorganised bone turnover. Genetic factors play an important role in PDB and we have previously shown that susceptibility to PDB is mediated by a common variant (rs1561570) at the *OPTN* locus (Albagha et al, *Nat Genet* 2010) which is associated with reduced levels of mRNA expression although the mechanism by which this causes PDB is unclear. Optineurin is a ubiquitously expressed cytoplasmic protein with multiple cellular functions but its role in bone metabolism is yet unknown. The aim of this study was to investigate the role of OPTN in bone metabolism both *in vitro* by knockdown and over-expression experiments and *in vivo* by analysis of mice with a loss of function mutation (D477N) in OPTN. We found that expression of optineurin increased considerably during osteoclast differentiation from bone marrow cultures. Knockdown of optineurin by shRNA in bone marrow derived macrophages (BMDM) significantly increased osteoclast numbers and size, upon stimulation with M-CSF and RANKL, when compared with a non-targeting shRNA control. Over expression of Optn in Raw 264 cells resulted in a substantial reduction in the number and size of multinucleated TRAP+ cells formed upon stimulation with RANKL. Reduced expression of *OPTN* in BMDM was associated with enhanced RANKL-induced NFκB activation indicating that OPTN acts as a negative regulator of osteoclast differentiation *in vitro* by modulating NFκB signalling. Mice with a loss of function mutation in Optn have osteoclast over-activity and high bone turnover as determined by bone histomorphometric analysis. BMDM derived from mutant mice generated more and larger osteoclasts when compared to wild type cells, consistent with the knockdown data. Furthermore, osteoclasts derived from OPTN mutant mice had increased levels of NFκB activation, reduced levels of interferon beta expression and increased expression of c-fos in response to RANKL, compared with wild type. These data indicate that optineurin acts as a powerful negative regulator of osteoclast differentiation *in vitro* and *in vivo*. Our studies identify OPTN as a novel regulator of bone resorption and are consistent with a model whereby genetically determined reductions in OPTN expression predispose to PDB by modulating RANKL-induced NFκB activation and interferon beta-signaling in a cell lineage specific manner.

Mechanical consequences of in vivo advanced glycation end-products in aging human bone: comparison of 3-point bending, cyclic reference point indentation, and impact reference point indentation. Simon Tang*, Adam Abraham, Aditya Yadavalli, Avinesh Agarwalla, Jenny Liu. Washington University in St Louis, USA

Advanced glycation end-products (AGEs) accumulate in bone with aging and disease, and are implicated in decreasing bone toughness in diabetics. Reference Point Indentation (RPI) allows the minimally invasive measurement of the mechanical behavior of bone tissue in vivo. Both cyclic and impact RPI, enhance the prediction of bone strength and discriminate between patient cohorts when coupled with DeXA, yet data relating RPI to tissue composition and 3-point bending remain scarce in human bone. Thus this study examines the relationship of bone tissue composition with 3-point bending, cyclic RPI (Biodent), and impact RPI (Osteoprobe) in aging human bone.

Aging female cadaveric limbs were tested (n = 28, Ages: 57-97). Cyclic and impact RPI was performed with soft tissues intact. Cyclic RPI (BioDent 1000) was performed 35 mm above the mid-diaphysis at 5 mm intervals at 15 locations (10 N at 2 Hz x 20). Indentation distance increase is calculated (IDI [μm]; indentation depth change from the 1st and 20th cycle). Impact RPI (Osteoprobe RUO) was performed 5 mm away from the cyclic RPI sites (40 N impact force, 4000 Hz x 1), and Bone Material Strength index (BMSi; 100 x avg PMMA IDI / bone impact IDI) is calculated.

The tibial cortical bone were then sectioned into 50 x 4 x 4 mm planks and tested in 3-point bending to failure (Instron 5866) to determine material properties (40 mm span; 10 N preload; 1 mm/min displacement rate). The RPI-measured cortical bones were scanned using MicroCT (VivaCT 40) to determine the volumetric tissue mineral density (TMD; 30 μm^3 voxel-resolution; 70 keV, 114 mA, 150 ms). Bone from the RPI-sites region were assayed for AGEs.

Cyclic RPI (2 Hz) and impact RPI (4000 Hz) probes bone in dynamic ways that differs from quasi-static 3-point bending. Cyclic RPI ($p = 0.006$, $r = -0.39$) and impact RPI ($p = 0.002$, $r = 0.43$) are more robust than 3-point bending modulus ($p = 0.736$) in predicting TMD variations. Similarly, AGEs were increasingly correlated with cyclic RPI ($p = 0.026$, $r = 0.28$) and impact RPI ($p = 0.001$, $r = -0.61$) but not 3-point bending toughness ($p = 0.126$). As a viscoelastic material, bone protein changes such as AGEs may be most prominent in its time-dependent responses to load. Since fractures are high-frequency, high-energy events, the ability to assess bone in this manner may provide further insight as to how bone may behave under these events.

LB-MO0005

Not only stiffness, but also yield strength of human trabecular bone is best predicted by bone volume fraction and fabric anisotropy. Sarah Musy¹, Ghislain Maquer*², Jarunan Panyasantisuk³, Philippe Zysset⁴. ¹Institute of Nursing Science, University of Basel / Nursing & Midwifery Research Unit, Inselspital Bern University Hospital, ²Institute for Surgical Technology & Biomechanics, University of Bern, Switzerland, ³Institute for Surgical Technology & Biomechanics, University of Bern, ⁴University of Bern, Switzerland

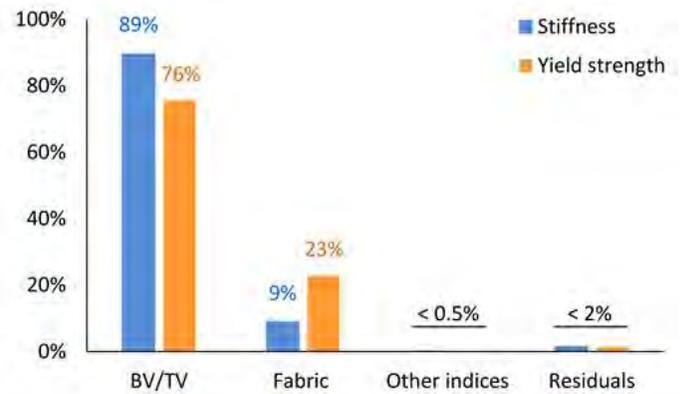

Numerous morphological indices capture the degradation of the trabecular structure characterising osteoporosis. A few even correlate to some extent with the mechanical properties of cancellous bone. Yet, against common belief, bone volume fraction (BV/TV) and fabric anisotropy were shown to determine up to 98% of trabecular bone stiffness variance, a predictive power that no other variables could substantially improve⁽¹⁾. This result remains to be confirmed for yield strength.

The morphology of 126 micro-computed tomography (μCT) scans of trabecular bone cubes extracted from three proximal femora (female, 62-75 years old) was evaluated via 25 indices including standard, individual trabeculae segmentation and textural parameters. Variance inflation factors were computed to evaluate their inter-dependence. Stiffness and yield properties of the samples were determined from independent loadcases performed respectively with linear and non-linear micro finite element analyses (μFEA). Finally, multi-linear regression models for the predictions of either stiffness or yield strength were built upon the independent morphometric indices, which contributions to the predictions were evaluated via ANOVA.

In line with our findings regarding stiffness⁽¹⁾, BV/TV was also the best predictor of yield strength. Accounting for fabric anisotropy had, however, more influence on the yield estimations (stiffness: $r_{\text{iso}}^2 = 0.895$, $r_{\text{aniso}}^2 = 0.985$ vs. yield: $r_{\text{iso}}^2 = 0.755$, $r_{\text{aniso}}^2 = 0.984$). The other independent factors (SMI, Tb.Th.SD, Tb.Sp.SD, pTb.Th, rTb.Th, pTb.S, rTb.l, RR.Junc.D and TBS surrogate) added very little to the models (stiffness & yield: $r_{\text{global}}^2 = 0.986$). Besides, BV/TV and fabric anisotropy explained 76% and 25% of the yield predictions of a global model, the other independent indices less than 1%. Comparatively, fabric anisotropy only described 10% of the variance in stiffness.

Two conclusions can be drawn from this study. First, just as stiffness, trabecular yield strength is best predicted by BV/TV and fabric anisotropy. The lack of influence of the other morphological variables strongly infers that the bone structure remains optimal for load bearing despite bone loss. Second, although stiffness and yield strength are highly correlated, the assessment of trabecular bone anisotropy is even more crucial to ensure accurate simulation of the post-elastic behaviour of whole bones using FEA.

Sequential treatments with alendronate, parathyroid hormone (1-34) and raloxifene alter cortical bone matrix composition and quality in ovariectomized rats by Raman spectroscopy. Xiaomei Yao*¹, Amanuel Berhe², Xinyan Bai², Lucy Wang², Ying Liu², Amber Stern³, Wei Yao⁴, Mark Johnson², Yong Wang², Nancy Lane⁴. ¹University of Missouri-Kansas City, USA, ²University of Missouri-Kansas city, ³Engineering Systems Inc., ⁴University of California Davis Medical Center, USA

Anti-resorptive and anabolic agents are used individually or sequentially in individual patients for the prevention and treatment of osteoporosis. This study evaluated the effect of several of these treatment regimens on cortical bone matrix properties in ovariectomized (OVX) rats using Raman spectroscopy.

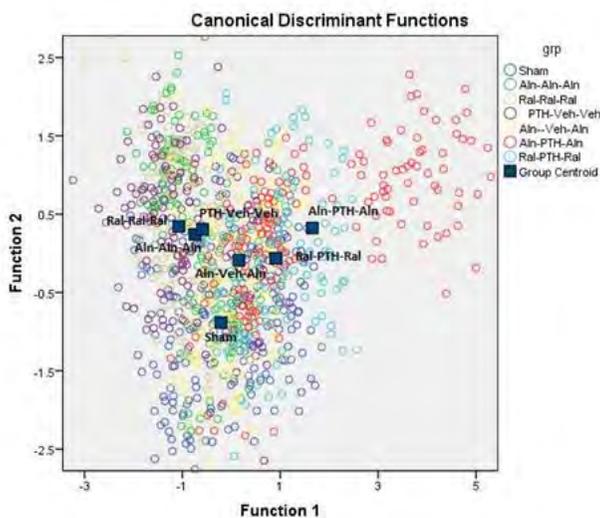

Four-month old female Sprague Dawley rats were either sham operated or OVX, left untreated for two months to develop osteopenia, and then treated with vehicle (Veh), hPTH (1-34) (PTH), alendronate (Aln), or raloxifene (Ral) continuously or sequentially for three, 3-month treatment intervals. Groups included Sham, OVX, Aln-Aln-Aln, Ral-Ral-Ral, PTH-Veh-Veh, Aln-Veh-Aln, Aln-PTH-Aln, and Ral-PTH-Ral (n=5-7/group). A LabRam HR 800 Raman spectrometer with a He-Ne laser (632.8 nm) was used to obtain spectra (700 to 1800 cm^{-1}) from the mid-tibial cortical bone and associated osteocyte perilacunar regions. PO-/amide-I and CO₃/amide-I ratios, mineral crystallinity, and collagen crosslinking were calculated and compared by ANOVA. Principal component analysis (PCA) and discriminant analysis (DA) were used to analyze all spectral data between treatment groups (SPSS v23). The Scree Plot and Analysis of Total Variance Explained functions identified the components that accounted for a threshold of >90% of the total variance in the PCA analysis from the perilacunar (1-4 μm around the lacunae) and the bone matrix (16-20 μm from any lacunae) regions in each of the groups.

Group analyses of the PO-/amide-I and CO₃/amide-I ratios, collagen crosslinking and mineral crystallinity were not different between all groups. 90% of the bone matrix variance was explained by 9 components, while perilacunar matrix included 10 components. PCA/DA analysis indicated that perilacunar and bone matrix regions in OVX were both significantly different from Sham ($p < .001$). Interestingly, single drug treatments clustered separately from the combination treatment groups in both perilacunar and bone matrix regions and were different from the Sham group ($p < .001$).

This study illustrates the power of PCA/DA to identify subtle changes in bone material properties from Raman analysis that are not readily apparent with simple comparison of standard metrics. All therapies restored bone matrix composition in rats with prolonged estrogen deficiency to Sham values. Further analysis is needed to determine which components explain the improvements also observed in bone strength by these sequential therapies.

Neonatal 25(OH)D3 Concentrations at Birth from Archived Dried Blood Spots and Future Risk of Fractures in Childhood - the D-tect study. Mina Händel^{1*}, Peder Frderiksen², Cyrus Cooper³, Berith Lilienthal Heitmann⁴, Bo Abrahamsen⁵. ¹Institute of Clinical Research, OPEN, University of Southern Denmark, Dk, ²Research Unit for Dietary Studies, The Parker Institute & the Institute of Preventive Medicine, ³Medical Research Council Lifecourse Epidemiology Unit, University of Southampton, ⁴Research Unit for Dietary Studies, The Parker Institute & the Institute of Preventive Medicine, Bispebjerg & Frederiksberg Hospital, ⁵Institute of Clinical Research, Odense Patient Data Explorative Network, University of Southern Denmark

Purpose: To examine 25(OH)D3 levels in dried neonatal blood samples (DBS) collected at birth as a predictor of the risk of fractures in childhood.

Methods: Case-cohort study using information on fracture incidence from the Danish National Patient Registry and capillary DBS from the Biological Specimen Bank for Neonatal Screening at *Statens Serum Institut*. Stored blood spots were used to measure neonatal 25(OH)D3 by a highly sensitive liquid chromatography tandem mass spectroscopy coupled with multiple reactant monitoring. A random subcohort of 3,600 individuals born between 1981 and 2002 was selected for analysis. The subcohort was augmented with a random sample of 1,200 fracture cases occurring between ages 6-13 years. The statistical analyses was based on deciles for 25(OH)D3, using Cox regression with Self-Prentice weights. The covariance of the regression coefficients was estimated using the Lin-Ying estimator.

Results: In the entire sample, the distribution of 25(OH)D3 was skewed. The mean (SD) for all subjects was 27.4 (18.7) nmol/L (median, 23.6; IQR, 13.3, 36.8), when corrected for the haematocrit fraction in capillary blood. As expected, 25(OH)D3 showed statistically significant monthly variation ($\chi^2_{11} = 582.36$, $p < 0.001$). The analysis showed that 25(OH)D3 concentrations at birth were not significantly associated with the risk of fractures during childhood. Figure 1 shows the exposure-risk relationship when the 25(OH)D3 concentrations were categorized according to the deciles in the subcohort. Conclusion: While previous studies suggest an association between antenatal maternal vitamin D status and childhood bone mass, our data provide the unique insight that perinatal vitamin D status does not seem to contribute to subsequent fracture risk in childhood. The two sets of findings suggest that intrauterine vitamin D exposure may be the more critical determinant of later offspring skeletal health.

Figure 1. Hazard Ratio (HR) of fractures in offspring at age 6-13 years to the concentration of 25(OH)D3, by the deciles of the distribution of 25(OH)D3 in the subcohort. The HRs are adjusted for season of birth (Nov-Jan, Feb-Apr, May-July, Aug-Oct). Vertical lines indicate 95% confidence intervals (CI). Children in the 70th to 80th percentile of the distribution were chosen as the reference value for the categorical analyses. The HRs are plotted at the median level of 25(OH)D3 within each decile category.

Activation of IKK β in Postnatal Articular Chondrocytes Leads to Catabolism of the Articular Cartilage Matrix. Sarah Catheline^{*}, Martin Chang, Jennifer Jonason. University of Rochester, USA

Osteoarthritis (OA) is a degenerative joint disease that causes degradation and eventual loss of cartilage within the synovial joints. Traumatic injury is known to be an important risk factor for development of OA likely due to the inflammatory environment within the injured joint. Pro-inflammatory cytokines are thought to negatively impact articular chondrocyte function and cartilage metabolism by suppressing production of factors anabolic to, and promoting production of factors catabolic to, the cartilage extracellular matrix (ECM). NF- κ B, a transcriptional regulator of the inflammatory response, has been implicated in regulation of collagenase (i.e., *Mmp13*) and aggrecanase (i.e., *Adamts5*) gene expression, key molecules responsible for the breakdown of the cartilage ECM. The role of NF- κ B in the development and progression of OA, however, is poorly characterized. Here we show evidence of canonical NF- κ B activation in tissues of the knee joint following meniscal/ligamentous injury (MLI) in the mouse. Specifically, we show decreased expression of I κ B α and increased expression of p65/RELA. We, therefore, hypothesize that constitutive activation of the canonical NF- κ B pathway in postnatal articular chondrocytes will be sufficient to drive the onset of an OA-like phenotype. To test this hypothesis, we used a chondrocyte-specific inducible Cre in combination with the *ROSA-Ikk2ca* allele to generate mice that overexpress a constitutively active form of IKK β in chondrocytes. Specifically, *Acan-Cre^{fl}-ER^{T2}*; *ROSA-Ikk2ca^{fl}* and *Acan-Cre^{fl}-ER^{T2}*; *ROSA-Ikk2ca^{fl}* mice were generated and administered tamoxifen at 2 months of age to induce Cre-mediated recombination in postnatal chondrocytes. At 3 months of age, histological analyses of the mutant mice reveal a marked decrease in proteoglycan content of the articular cartilage ECM relative to littermate Cre-negative control mice (Figure 1). Additionally, we detected a decrease in both ACAN and COL2A1, two of the predominant molecules present in the cartilage ECM, in the articular cartilage of the mutant mice by immunohistochemistry. Increased TUNEL staining within the articular cartilage is also observed in these mice. Our results suggest that activation of the canonical NF- κ B pathway can drive both cartilage ECM remodeling as well as chondrocyte apoptosis that, over time, is likely to lead to OA.

Absence of Adiponectin Enhances Exercise Training-Induced Improvements on Bone Structure in Mice. Sandra Sacco^{*1}, Abby Maybee¹, Ian Ritchie², Tara MacDonald², David Wright², David Dyck², Wendy Ward¹. ¹Faculty of Applied Health Sciences & Center for Bone & Muscle Health, Brock University, ²Department of Human Health & Nutritional Sciences, University of Guelph

Background: High-impact exercise such as running improves bone mass and bone structure and stimulates the production of adiponectin. However, human and animal data indicate that adiponectin is associated with negative effects to BMD. Objective: Determine whether the absence of adiponectin potentiates the positive effect of a chronic treadmill running protocol on BMD, bone structure and bone strength. Methods: 12-week-old wild type (WT) and adiponectin knockout (ADKO) mice (n=10 mice per group) received either a progressive treadmill running or a sedentary protocol for 8 weeks. Exercised mice ran 5 days per week for 8 weeks beginning at a speed of 20 m/min for 45 min for the first 3 weeks, with the incline increasing from 5% after week 1 to 15% after week 3. For the remaining 5 weeks, the 15% incline was held constant and the speed increased to 25 m/min by week 5. For the last 3 weeks, exercise duration increased to 60 min and during the last two weeks of training, 30-sec sprints at 32 m/min were performed in 10 min intervals. Tibias and lumbar vertebra (LV3) were scanned *ex vivo* using microcomputed tomography (Skyscan 1176) to measure structural properties of trabecular and cortical bone. BMD of tibias and LV3 were measured using dual energy x-ray absorptiometry (pDEXA[®] SABRETM). Biomechanical strength at the tibia midpoint was determined using a materials testing system (Instron Series IX Automated Materials Tester-Version 8.15.00). Results: WT mice that were exercise trained had higher (p<0.01) bone volume fraction of LV3 compared to sedentary WT mice. In addition, both WT and ADKO mice that were exercise trained had higher (p<0.01) trabecular thickness of LV3 compared to their respective sedentary control group. There was a greater (p<0.05) response to exercise training on bone structure in ADKO mice than in WT mice at both the proximal tibia (i.e. trabecular thickness) and tibia midpoint (i.e. cross-sectional area, cortical thickness). The effect of exercise training on BMD and bone mineral content at the tibia midpoint was dependent on genotype whereby ADKO mice that were exercised trained had higher (p<0.05) BMD and BMC compared to their sedentary counterparts. No other effects of genotype, exercise training or their interaction on bone structure, BMD or biomechanical strength were observed. Conclusion: The absence of adiponectin enhances some improvements to bone structure and BMD, particularly at the tibia, in response to exercise training.

Intermittent administration of parathyroid hormone facilitates osteogenesis by different mechanisms in cancellous and cortical bone. Kenji Ogura^{*1}, Tadahiro Iimura², Toshinori Ishizuwa³, Keiji Moriyama⁴, Akira Yamaguchi⁵. ¹Departments of Oral Pathology & Maxillofacial Orthognathics, Tokyo Medical & Dental University, ²Division of Bio-Imaging, Proteo-Science Center, Ehime University, ³Pharmaceuticals Research Center, Asahi Kasei Pharma Corporation, ⁴Department of Maxillofacial Orthognathics, Tokyo Medical & Dental University, ⁵Department of Oral Pathology, Tokyo Medical & Dental University, Oral Health Science center, Tokyo Dental College

Intermittent administration of parathyroid hormone (PTH) induces anabolic action on the bones. To understand the mechanism underlying the early phase of PTH-induced anabolic action, we investigated the expression profiles of osterix and sclerostin after intermittent administration of PTH using immunohistochemistry in adult rats. In the metaphyseal region, daily PTH administration (30 µg/kg) greatly increased the number of osterix-positive cells in the bone marrow, which had been reported as the osteolineage cells of the adult mouse bone marrow, on day 1, but the

cells gradually decreased on days 3 and 5. The number of osterix-positive osteoblasts on the cancellous bone surface showed no significant difference from control group on day 1, but it significantly increased on days 3 and 5 after daily PTH injections. PTH injections induced no significant changes in the number of sclerostin-positive osteocytes in the cancellous bone. In the cortical bone, intermittent administration of PTH induced no changes in the number of osterix-positive osteoblasts on the bone surface, but it significantly reduced the number of sclerostin-positive osteocytes on days 1, 3 and 5 after PTH injection. The effect of PTH on the reduction of sclerostin-positive osteocytes was more prominent at the endosteal region than periosteal region in the cortical bone. The serum sclerostin level was downregulated and the osteocalcin level was upregulated on day 5 after intermittent administration of PTH. Intermittent PTH injections increased osteoblast surface, osteoid thickness, and osteoid surface in cancellous bone, but not in cortical bone. This study provides the first evidence that intermittent PTH administration exerts anabolic action on bone formation through different mechanisms in cancellous and cortical bone during the early phase of PTH-induced anabolic action on osteogenesis. In cancellous bone, the increase in the osterix-positive osteoprogenitors and the subsequent increase in osterix-positive osteoblasts on the bone surface may be a more important function of PTH than the downregulation of sclerostin-positive osteocytes. Conversely, in cortical bone, a dramatic decrease in the number of sclerostin-positive osteocytes may play a critical role in the anabolic action induced by intermittent PTH administration.

The Elevation of Renal Renin Production Does Not Necessarily Correlate with Blood Pressure in Vitamin D Receptor Gene Knockout Mice Fed Hypocalcemia Rescue Diet. Naoko Tsugawa^{*1}, Miku Wada², Kisato Kanao², Maya Kamao², Kimie Nakagawa², Toshio Okano². ¹Osaka Shoin Women's University, Japan, ²Kobe Pharmaceutical University, Japan

Introduction: 1,25-Dihydroxyvitamin D₃ is thought to play an important role in controlling cardiovascular functions. In both epidemiological and animal studies, vitamin D deficiency has been reported to induce hypertension. It has been reported that *vitamin D receptor (VDR)* and *CYP27B1* gene knockout mice are hypertensive and both express the elevation of renin production in the kidney in both knockout mice. On the other hand, it has been reported that the increased dietary calcium intake correct the low serum ionized calcium concentration and result in a significant amelioration of the prevailing hypertension in the adult spontaneously hypertensive rat. In present study, we examined the correlation of blood pressure and renal renin production or other blood pressure regulated gene expression in *VDR* knockout mice (*VDR-KO*) fed hypocalcemia rescue diet. Methods: After weaning, wild-type (WT) and *VDR-KO* littermates were fed a normal diet (N-Ca) or a hypocalcemia rescue diet (2% calcium, 1.25% phosphorus, and 20% lactose; H-Ca) for 7 weeks. Blood pressure (BP) was measured using a noninvasive computerized tail-cuff system. The mRNA levels of renal renin and epithelial Na⁺ channel (ENaC) were measured by real-time PCR. Serum renin concentration was measured by ELISA. Results: BP of *VDR-KO* fed N-Ca was significantly higher than that of WT fed same diet. On the other hand, no significant difference in BP was observed between *VDR-KO* and WT fed H-Ca diet. Expression of renal renin mRNA of *VDR-KO* was higher than that of WT in both feeding of N-Ca and H-Ca. Also serum renin concentration of *VDR-KO* was higher than that of WT in both feeding of N-Ca and H-Ca. However, serum renin concentration of *VDR-KO* fed H-Ca was slightly lower than that of *VDR-KO* fed N-Ca diet. Although expression of renal ENaC mRNA of *VDR-KO* was significantly higher than that of WT in both feeding of N-Ca and H-Ca diet, the level of ENaC expression in *VDR-KO* fed H-Ca was lower than that in *VDR-KO* fed N-Ca diet. Conclusion: These results suggest that the elevation of renal renin production led to high gene expression of renal ENaC and elevation of BP in *VDR-KO* fed N-Ca. However, the elevation of renal renin production does not necessarily correlate with BP in *VDR-KO* fed H-Ca diet. There is a possibility that this non-correlation was caused by the suppression of renal ENaC expression via improvement of hypocalcemia.

Endothelin 1 Signaling is Required for SOST and IGF1 Secretion in Response to Mechanical Load. Everett Smith¹, Michael Johnson^{*2}, Luisa Meyer², Caitlyn Collins², Karen Hansen², Heidi Ploeg², Robert Blank³. ¹University of Wisconsin, USA, ²University of Wisconsin, USA, ³Medical College of Milwaukee, USA

Previously we demonstrated that addition of exogenous big endothelin to *ex vivo* cultured bovine bone or application of -2000 µe elicits similar biochemical and physical responses, change in apparent elastic modulus (E_{app}), mineral apposition rate and secretion of PGE₂. We hypothesized that endothelin (ET1) signaling was required for physical and biochemical responses of bone to mechanical load. To test this hypothesis, we conducted a 2x2 factorial trial of daily mechanical loading (-3000 µe, 120 cycles daily) and 10 mM BQ-123, an endothelin receptor A antagonist. Forty-eight human, trabecular bone cores (5 mm h x 10 mm d) were obtained from 2 male donors undergoing hip replacement. Donor cores and E_{app} were blocked to blocked

to equivalency. The cores were maintained in bioreactors for 25 days post initiation of treatment. There were four groups: control (CC), control+BQ-123 (CB), load+control (LC) and load+BQ-123 (LB). Each specimen was tested quasi-statically with a maximal compression of ~4000 μe on days 0 and 25 of the study to measure E_{app} . Culture medium from each sample was analyzed for secretion of IGF1, SOST and ET1 on days 0, 8, 11, 18, and 25. Biochemical data over time were analyzed by Wilcoxon test, followed by paired analysis by Kruskal-Wallis. There were significant differences in IGF1, SOST and ET1 secretion over time and between the LC and LB groups with the LB group having increased secretion of SOST and ET1 and decreased secretion of IGF1. The percent change in apparent elastic modulus over the duration of the experiment was not significantly different between groups; however, the LC group tended to be higher than the other groups. The increase in ET1 secretion in the CB and LB groups indicates the presence of a feedback loop. The decrease in SOST secretion in the LC group is similar to the change in SOST seen *in vivo* in response to mechanical load. Blockade of ET1 signaling prevents the decrease in SOST secretion in response to mechanical load. The increase in IGF1 secretion in response to mechanical load and the decrease in secretion seen when ET1 signaling is blocked suggest that ET1 signaling interacts with pathways that respond to mechanical load. This is the first study to show that autocrine ET1 signaling is required for response to mechanical load in human trabecular bone cores and that ET1 signaling is required for transduction of mechanical into biochemical signals during the anabolic response of bone to mechanical load.

Periostin prevents cortical bone loss by increasing OPG levels in response to continuous PTH in mice. Nicolas Bonnet^{*1}, Serge Ferrari². ¹University Geneva Hospital (HUG), Switzerland, ²Division of Bone Diseases, Geneva University Hospital & Faculty of Medicine, Switzerland

Periostin is a matricellular protein expressed in late osteoblasts/osteocytes in response to iPTH. It mediates inhibition of Sost and skeletal bone formation response to iPTH. Interestingly, gene profiling in bones exposed to continuous PTH (cPTH, primary hyperparathyroidism in humans, and mini-pump in rats) have also identified a prominent increase of periostin (Postn) expression. Since cPTH activates osteoclast and induces bone resorption particularly at the endocortical surfaces, we investigated the influence of osteoblastic periostin on osteoclastogenesis and the cortical bone response to cPTH *in vivo* and *in vitro*.

For bone mass and structure evaluations we performed PIXIMUS and microCT after 3 weeks of continuous PTH given by mini-pump (40 $\mu\text{g}/\text{kg}/\text{d}$). To evaluate the role of osteoblastic periostin on osteoclast, we performed co-culture of Postn^{+/+} primary osteoclasts with Postn^{-/-} or Postn^{+/+} primary osteoblasts extracted from long bones of adult mice. We treated cells with recombinant periostin (rPostn, 4 $\mu\text{g}/\text{ml}$, every 2 days for 6 days) or saline (Vehicle, Veh) both containing vitamin D (10^{-6}M). We had 3 wells per group repeated twice. We evaluated the number and activity of osteoclast by TRAP staining and pit resorption assay kit which measure the intensity of fluorescence released from the coated plate into the medium.

In Postn^{-/-}, cPTH decreased femoral BMD (69 ± 1 vs 64 ± 1 mg/cm^2 respectively in Veh, $p < 0.01$), cortical bone volume (-6.2% vs Veh, $p = 0.11$) and increased apparent cortical porosity (+126% vs Veh, $p < 0.05$). No significant changes were observed in Postn^{+/+} in response to cPTH.

In vitro, osteoclast number and activity from Postn^{-/-} was not significantly different than Postn^{+/+}. However co-culture of Postn^{+/+} osteoclasts with Postn^{+/+} or Postn^{-/-} osteoblasts indicate a higher number and activity of osteoclasts in the absence of osteoblast periostin expression (+62% and +50% vs Postn^{+/+}, both $p < 0.01$). Adding rPostn, decreased the number of osteoclasts (-65% vs Veh, $p < 0.001$), as well as their activity (-5.5% vs Veh, $p < 0.001$), in both Postn^{+/+} and Postn^{-/-} osteoblast co-culture. Moreover rPostn increased OPG/RANKL levels in osteoblast conditioned medium by 152% vs Veh ($p = 0.09$). These results highlight the role of periostin not only in bone formation but also in bone resorption. They suggest that PTH-stimulated periostin expression prevents PTH-induced osteoclastogenesis and cortical bone loss by increasing OPG/RANKL levels.

Alpha-1 antitrypsin (AAT) Gene Delivery by Recombinant Adeno Associated Virus Vector for the Treatment of Osteoporosis. Mohammad Akbar^{*1}, Yuanqing Lu², Ahmed Elshikha², Rubina Ahamed², Mark Brantly², Shannon Holliday², Jay Cao³, Sihong Song². ¹USA, ²University of Florida, ³US Department of Agriculture

Purpose: Osteoporosis, a global public health problem, is characterized by reduced bone mass and poor bone microarchitecture. Although the etiology and pathogenesis of osteoporosis are complex and multifactorial, inflammation is involved in the disease development. Therefore, anti-inflammatory strategy holds great potential for the treatment of this disease. Alpha-1 antitrypsin (AAT) is a multifunctional protein with anti-inflammatory properties. We showed that AAT gene therapy had therapeutic effect in inflammation related disease models including type-1 diabetes

and rheumatoid arthritis. Importantly, we showed that AAT protein therapy reduced bone loss in ovariectomized (OVX) osteoporosis mice. In addition, AAT protein therapy is expensive and requires continuous treatment. Therefore, AAT gene therapy may provide a great advantage for osteoporosis treatment. In this study, we investigated the therapeutic potential of AAT on preventing bone loss in an OVX mouse model using recombinant adeno associated virus (rAAV) as a vector of gene delivery approach. Method: To test the protective effect of AAT on osteoclastogenesis, we generated osteoclast from mouse bone marrow monocyte cells and treated with clinical grade AAT. We also generated recombinant adeno associated virus vector expressing AAT (rAAV8-CB-AAT) as AAT gene delivery vector. In animal study, Ovariectomized mice were i.p. injected with either rAAV8-CB-AAT (1×10^{11} particles/mouse), or phosphate buffer saline (PBS). We used age-matched and sham operated animals as a normal control. Eight weeks after the rAAV-CB-AAT administration, all animals were sacrificed and subjected to μCT scanning for the evaluation of vertebral bone microarchitecture.

Results: *In vitro* studies showed that AAT significantly inhibited osteoclast formation by inhibiting TNF- α production and cell surface Receptor Activator Nuclear Factor κB (RANK) expression. *In vivo* results showed that rAAV-CB-AAT administration significantly increased bone volume density, trabecular number, trabecular thickness and connectivity density, and decreased structural model index (SMI) compared to PBS injection in OVX mice. These results demonstrate that AAT gene delivery by rAAV vector mitigates ovariectomy-induced bone loss in mouse model.

Conclusion: Since rAAV vector has been proven to be safe in humans, AAT gene delivery by rAAV-CB-AAT vector could be a new strategy for the treatment of osteoporosis.

The Oral Commensal Flora, a Dynamic Regulator of Alveolar Bone Remodeling. Chad Novince^{*1}, Keith Kirkwood², Caroline Westwater², Carolyn Whittow². ¹Medical University of South Carolina - College of Dental Medicine, USA, ²Medical University of South Carolina, USA

Recent novel findings published by the applicants, indicate the commensal flora stimulation of the host immune system has catabolic effects in the adult skeleton. Despite recognition that the commensal flora plays a significant role in directing T-cell mediated immunity, the impact of the normal flora on osteoimmunology and coupled osteoclast-osteoblast mediated bone remodeling is currently unclear. The purpose of this study was to define the impact of the commensal flora on physiologic bone remodeling processes in the adult skeleton. Specific-pathogen-free (SPF) vs germ-free (GF) mice were used to elucidate the commensal flora's immunomodulatory effects on marrow CD4⁺/CD8⁺ T-cell hematopoiesis, osteoblastogenesis and osteoclastogenesis. SPF & GF mice were sacrificed, femurs & tibias were harvested, and bone marrow was flushed for assays. Marrow CD4⁺/CD8⁺ T-cell subsets were analyzed via flow cytometry, and marrow gene expression was studied via qRT-PCR. Bone marrow stromal cells (BMSCs) were isolated to assess osteoblast expansion, differentiation & mineralization in culture. Magnetic cell sorting was employed to enrich for defined osteoclast progenitors (dOCs); 3 distinct dOC populations (CD11b^{hi}, dOC^{low}, dOC^{neg}) were plated & treated with control (M-CSF) or Tx media (M-CSF & RANKL) to evaluate osteoclast differentiation. SPF mice had increased marrow T_H17 cells, CD4⁺IL17⁺ cells, and TNF α mRNA levels. GF mice had higher marrow IGF-1 mRNA levels. *In vitro*, GF BMSCs had increased cell expansion over time. RunX2 & col2 mRNA were upregulated in GF BMSC cultures. Mineralization via von Kossa was increased in GF BMSC cultures. *In vitro* dOC TRAP stain studies demonstrated that SPF vs GF CD11b^{hi} and dOC^{low} cultures had increased OC size and nuclei # per OC, while SPF dOC^{neg} cultures inversely had decreased OC size and nuclei # per OC. Gene expression studies paralleled the OC differentiation findings elucidated in the TRAP stain cultures; NFATC1 & RANK mRNA were increased in SPF vs GF CD11b^{hi} and dOC^{low} populations, but inversely decreased in the SPF dOC^{neg} population. DC-STAMP mRNA was decreased in the SPF vs GF dOC^{neg} population, suggesting altered osteoclast fusion. This research defining the commensal flora immunomodulatory effects on skeletal homeostasis is highly relevant in advancing the understanding of physiological osteoimmunological processes, having implications for the prevention of skeletal deterioration in both health & disease.

Intravital Analysis of Neovascularization in Nanofiber-mediated Cranial Bone Defect Repair. Xinping Zhang^{*1}, Xiaochuan Yang², Tao Wang², Honjun Wang³. ¹University of Rochester Medical Center, USA, ²University of Rochester, USA, ³Stevens Institute of Technology

Neovascularization plays a key role in bone tissue engineering. Understanding spatiotemporal regulation of blood vessel formation and regression during bone tissue

engineering represents a critical step toward devising successful strategies aimed at enhancing revascularization and promoting bone tissue repair and reconstruction. Utilizing a chronic cranial defect repair model combined with multiphoton laser scanning microscopy (MPLSM) and live microCT analyses, the goal of our current study is to establish the spatiotemporal regulation of neovasculature during nanofiber-assisted cranial bone defect repair. To this end, nanofibrous matrices were prepared from polycaprolactone (PCL), collagen type I, and hydroxyapatite nanoparticles (nHA) via electrospinning, stacked layer-by-layer to form a 3D tissue construct to repair a 2mm critical defect in cranial bone. To facilitate vascular ingrowth, large pores (~200micron in diameter) were introduced into the constructs using a micro-needle. Compared to acellular fibrous scaffolds which only induced limited mineralization at the site of repair, MicroCT analyses demonstrated that bone marrow stromal cells (BMSCs)-seeded constructs induced progressive mineralization at the defect site over a period of 8 weeks. Quantitative histomorphometric analyses demonstrated a 51% increase of bone formation in BMSC-seeded constructs as compared to the controls (n=4). MPLSM-based analyses of the vasculature showed vigorous small vessel angiogenesis within defect at week 5 post-surgery in BMSC-treated group as compared to the controls. While quantitative analyses demonstrated a similar vascular volume between the two groups, a two-fold increase of total vessel length was recorded in defects treated with BMSCs as compared to the controls (p<0.05). Remarkably, vessels less than 10micron in diameter demonstrated a 3-fold increase over the controls (p<0.05), suggesting that small vessel angiogenesis is associated with BMSC-enhanced new bone formation. Further longitudinal analyses of the regions with or without defect closure demonstrated that regression of the vessels was often seen in regions with osseointegration and defect closure, whereas persistent large-diameter vessels were often associated with non-unions and fibrotic tissue. Taken together, our studies strongly suggest that small vessel angiogenesis is critical for BMSC-mediated repair and engineering functional microvascular networks that support regeneration is essential.

Wdfy3 Interacts with TRAF6 and Modulates RANKL-Induced Osteoclastogenesis. Dennis Wu*¹, Ran Gu², Ritu Sarin², Regina Zavodovskaya³, Chia-Pei Chen⁴, Konstantinos S. Zarbalis⁵, Iannis E. Adamopoulos⁶. ¹University of California, Davis, Us, ²Division of Rheumatology, Allergy & Clinical Immunology, University of California at Davis, ³Department of Anatomy, Physiology & Cell Biology, University of California at Davis, ⁴Department of Statistics, University of California at Davis, ⁵Department of Pathology & Laboratory Medicine, University of California at Davis, Institute for Pediatric Regenerative Medicine, Shriners Hospitals for Children, Northern California, ⁶Division of Rheumatology, Allergy & Clinical Immunology, University of California at Davis, Institute for Pediatric Regenerative Medicine, Shriners Hospitals for Children, Northern California

Autophagy and phagocytosis are conserved cellular functions involved in the protein degradation process in immunity. Recently, autophagy-related proteins were shown to regulate osteoclast mediated bone resorption, a critical process in autoimmune diseases such as rheumatoid arthritis. Wdfy3 is a master regulator in selective autophagy for clearing ubiquitinated protein aggregates. In this study, we generated a series Wdfy3 transgenic mice (*Wdfy3^{lacZ}*, and *Wdfy3^{loxP}*) to investigate the function of Wdfy3 in osteoclast development and function. Wdfy3 expression in *Wdfy3^{lacZ}* neonatal mice was analyzed by histology and X-gal staining. Bone marrow-derived macrophages from wild type, *Wdfy3^{lacZ}*, and Wdfy3 conditional knockout (*Wdfy3-cKO*) mice (*Wdfy3^{loxP/loxP}-LysM-Cre⁺*) were differentiated into osteoclasts with macrophage colony-stimulating factor (M-CSF), and receptor activator of NF-κB ligand (RANKL). Wdfy3 expression on osteoclast-like cells was analyzed by X-gal staining and immunohistochemistry. RANKL-induced NF-κB signaling was analyzed by western blot. Osteoclast-related genes *Ctsk*, *Acp5*, *Mmp9* were measured by qPCR. Osteoclasts were characterized by tartrate-resistant acid phosphatase staining and filamentous actin ring formation assay. Osteoclast function was evaluated by dentin resorption assay. Our data showed that Wdfy3 is up regulated in osteoclast in *in vitro* cultures and highly expressed at the growth plate of neonatal mice. Osteoclasts derived from *Wdfy3-cKO*, showed increased osteoclast differentiation and function as evidenced by higher number and enlarged size TRAP⁺ multinucleated cells. Western blot analysis also revealed up-regulation of TRAF6 and an increase in RANKL-induced NF-κB signaling. Consistent with these observations Wdfy3 conditional knockout mice also showed an increase in osteoclast-related genes *Ctsk*, *Acp5*, *Mmp9* and an increase of dentine resorption in *in vitro* assays. Importantly, no difference was observed in autophagic flux in Wdfy3 deficient bone marrow-derived macrophages and control cells at basal level or under starvation. Taken together, our data highlight a novel role for Wdfy3 osteoclast development and function, which can be exploited for the treatment of musculoskeletal diseases.

TBS change with different spine scan modes on Lunar Prodigy. Weiwen Chen*¹, Anthony Slattery², Jacqueline Center³, Nicholas Pocock³. ¹Garvan Institute, Australia, ²Department of Nuclear Medicine, St Vincent's Hospital, ³Garvan Institute of Medical Research, Australia

Trabecular bone score (TBS) is a measure of grey scale homogeneity which correlates with trabecular microarchitecture and is an independent predictor of fracture risk. TBS is being increasingly used in the assessment of patients at risk of osteoporosis and has recently been incorporated into the FRAX algorithms. Currently, TBS software can be used in Hologic and GE Lunar densitometers. GE Lunar machines acquire spine scans using one of three acquisition modes depending on tissue thickness (thin, standard and thick). As per our Department protocol, 20 patients (mean BMI: 30.8, range 26.2 to 34.1) returning for progress BMD evaluation, who had experienced a significant change in weight, were measured using a Lunar Prodigy (software 14.10) on the manufacturer recommended scanning mode as well as the mode which was recommended and used in the baseline scan. This provided 20 paired spine scans in standard mode and thick mode acquired on the same day with no repositioning. TBS was derived from all paired spine scans. There was no significant difference in lumbar spine BMD between the two scanning modes. There was however significant higher TBS values from the spine scans acquired in thick mode compared to the TBS derived from spine acquisition in standard mode (Mean difference: 20 %, SD ± 9.8). The acquisition parameters of the two modes were reviewed. There is no difference in pixel size (0.6 x1.05mm), X-ray tube current (3.0 mA) or voltage (76 kV) between the Lunar Prodigy standard and thick modes. There is however a significant difference in spine image acquisition times, 28 seconds in standard mode versus 56 seconds in thick mode, which would result in a lower signal-to-noise ratio (SNR) in the standard mode and consequently reduced image quality. Reduced image quality in the standard mode compared to the thick mode would theoretically lead to greater inhomogeneity of the image and consequently lower TBS.

In conclusion these preliminary data suggest that TBS values acquired in the GE-Lunar Prodigy are dependent on the scanning mode used. Further evaluation is required to confirm the cause and develop appropriate protocols.

Excessive Bone Loss in Older Men: Effects on Trabecular and Cortical Bone Microarchitecture. Jane Cauley*¹, Andrew Burghardt², Stephanie Harrison³, Peggy Mannen Cawthon³, Andrew Yu⁴, Ann Schwartz³, Elizabeth Barrett Connor⁵, Marcia Stefanick⁶, Sharmila Majumdar⁷, Eric Orwoll⁸. ¹University of Pittsburgh Graduate School of Public Health, USA, ²Department of Radiology & Biomedical Imaging, University of California, San Francisco, ³California Pacific Medical Centre, ⁴Department of Radiology & Biomedical Imaging, University of California, San Francisco, ⁵University of California, San Diego, ⁶School of Medicine, Stanford University, ⁷Department of Radiology & Biomedical Imaging, University of California, San Francisco, ⁸Oregon Health & Science University

Accelerated bone loss has been linked to an increased risk of fracture that was independent of baseline bone mineral density (BMD) perhaps by increasing cortical porosity or decreasing structural or material properties of bone. To test this hypothesis, we used high resolution peripheral quantitative computed tomography (HRpQCT) scans to measure bone microarchitecture in the distal radius and tibia (SCANCO, Inc., Germany). All men who are active in the Osteoporotic Fractures in Men Study (MrOS) are being invited to return for a fourth clinical visit, approximately 14 years since enrolling into MrOS. We defined excessive areal bone loss (EBL) from Visit 3 to Visit 4 (7.1 years) as >10% loss at either the total hip or femoral neck. We used linear regression models to calculate least square mean HRpQCT parameters in men with and without EBL. We adjusted for age, race, clinic, height and weight. To date, 850 men have returned for their visit; of these 84 (10%) have experienced EBL. Their mean percent change in total hip BMD was -14% compared to -2.5% in men without EBL. Compared to men without EBL, men who experienced EBL were older (86.3 vs 83.7 years), had a lower body mass index (25 vs 27 kg/m²) and were more likely to report at least 1 impairment in their instrumental activities of daily living (47% vs 26%). 36% of men with EBL lost >10% body weight since visit 3 compared to 10% of men without EBL (p < 0.0001). As shown (Table), men who experienced EBL had significantly lower trabecular bone volume fraction (BV/TV), fewer trabeculae and greater trabecular separation than men without EBL. Cortical thickness was also significantly lower in men with EBL. However, we found no difference in cortical porosity at either the radius or tibia. Of interest, the mean cortical pore diameter at the radius and cortical pore volume at bone sites were lower among men with EBL. Additional adjustment for weight change had little impact on our results.

In summary, our preliminary data show men with EBL have differences in trabecular microarchitecture and lower cortical thickness than men without EBL. In addition, the changes in cortical bone thickness may reflect endocortical bone loss or trabecularization of cortical bone and not cortical porosity at this time point. Together, these differences in both trabecular and cortical bone architecture may contribute to the increased fracture risk observed with accelerated bone loss.

Keywords: HRpQCT, excessive bone loss, men, oldest old, trabecular microarchitecture, cortical porosity

TABLE: COMPARISON OF BONE MICROARCHITECTURE AMONG MEN WITH AND WITHOUT WITH EXCESSIVE BONE LOSS

| | DISTAL RADIUS (Base + Weight, Height) | DISTAL TIBIA (Base + Weight, Height) |

Prevalence and best skeletal areas to diagnose osteoporosis in women in Buenos Aires (Argentina). Carlos Mautalen¹, Silvina Mastaglia^{*2}. ¹Centro de Osteopatías Médicas, Argentina, ²INIGEM, UBA-CONICET

The aim of the study was to report values for osteoporosis (OP) prevalence in Buenos Aires, measuring the bone mineral density (BMD) at three different skeletal sites. From November 2012 to July 2014 a free measurement of the BMD for osteoporosis detection was offered in newspapers for women over 50 y.o. After signing an informed consent, 5448 Caucasian women living in Buenos Aires and surrounding districts were studied. BMD of the lumbar spine L1-L4 (LS), femoral neck (FN) and total hip (TH) was measured (Lunar Prodigy, software Version 12.3). Osteoporosis was defined as a T-Score \leq -2.5.

General prevalence of OP: 1021 women out of 5448 measured (18.7%), had OP at the lumbar spine or femoral neck. Adjusting the age of the sample to that of the general population a moderate increment of the prevalence (+0.5%) was observed. The figure shows the OP prevalence on each area and its combination per decades of age. Up to 70 y.o a low prevalence was observed if only the femoral neck is used. On the contrary the high prevalence up to the 70 y.o at the lumbar spine tended to level off over that age.

The OP prevalence at lumbar spine or femoral neck was similar to the results of the recent NHANES report (1). The total hip only adds a small (0.8 %) and not significant increment. Burden of OP: 346,500 of a total population of 1,853,000 women over 50 y.o in the area had OP, at lumbar spine or femoral neck, while only 163,500 had OP at the upper femur (femoral neck or total hip). Thus, 53% of the women would have been underdiagnosed.

Conclusions: The OP prevalence on the most populated urban area of Argentina has been assessed. The results are similar to those reported on Caucasian population of US and Canada. Since measurement of only the BMD of femoral neck overlooks the diagnosis on half of the women, it is suggested that future studies should include the measurement of the lumbar spine in combination with femoral neck for a more accurate estimation.

Prevalence of OP per decades at lumbar spine (LS), femoral neck (FN) and at LS or FN in this study

LB-MO0023

Higher femoral shaft density and thickness as measured using Hip Structural Analysis are risk factors for atypical femur fractures. Andy Kin On Wong^{*1}, Shawn Davison², Jonathan Adachi³, Jacques Brown⁴, Robert Josse⁵, Aliya Khan³, Angela MW Cheung⁶. ¹University Health Network, Canada, ²University of Victoria, ³McMaster University, ⁴Centre Hospitalier de l'Université de Laval, ⁵St. Michael's Hospital, ⁶University Health Network, Canada

Atypical femur fractures (AFF) have been associated with long-term use of antiresorptive therapy. However, in individuals with osteopenia or osteoporosis, it is difficult to know when to stop therapy. Objectives: To determine bone characteristics at the femoral shaft (FS) that can discriminate between those with and without AFFs. Methods: We conducted a cross-sectional analysis combining those with AFFs with individuals from the placebo arm of the Vitamin K Supplementation in Postmenopausal Women with Osteopenia Trial (ECKO) and the Canadian Multicentre Osteoporosis Study (CaMos). X-rays confirmed the diagnosis of AFFs based on ASBMR diagnostic criteria. Hip Structural Analysis (HSA) was completed on total hip dual-energy X-ray absorptiometry (DXA) scans in the three cohorts. Femoral neck bone mineral density (BMD) T-score classified individuals as normal, osteopenic or osteoporotic. Age, body mass index (BMI), prior history of fragility fractures (FFx), parental history of hip fractures (PHFx), use of glucocorticoids (GC), and duration of antiresorptive therapy use were obtained. Data analysis: Histograms of age-adjusted HSA parameters illustrated potential diagnostic thresholds. Fixed effects models determined differences in age-adjusted HSA parameters among osteopenic, osteoporotic and AFF groups, adjusting for covariates: BMI, FFX, PHFx, use of GCs, and duration antiresorptives use. Two standard deviations above the osteopenic distribution was used as a diagnostic threshold for each HSA parameter, which was binarized using these thresholds and examined for associations with AFFs in binary logistic regression models, adjusting for the same covariates. Results: 634 individuals were included in final analyses among which the AFF group was older and used antiresorptives for longer (Table 1). There was a clear separation of distributions for age-adjusted FS BMD, cortical thickness and cross-sectional area across classifications (Figures 1a & b). Fixed effects models showed significant differences between AFF and each of osteopenia and osteoporosis groups for these same variables even after accounting for covariates. Correspondingly, odds for an AFF were two to four-folds higher when FS variables exceeded the given thresholds (Table 2). Conclusions: Femoral shaft density and thickness characteristics may be used to identify individuals with osteopenia or osteoporosis who may be at risk for an AFF, and who may therefore be candidates for a drug holiday.

Risk of Hip Fracture in Common Medical Conditions – Meta-Analyses Identify Patients who Warrant Treatment. Steven Cummings¹, Richard Eastell². ¹San Francisco Coordinating Center, USA, ²Sheffield General Hospital, United Kingdom

Background: Many medical conditions have been listed as increasing fracture risk but the magnitudes of those risks have not been quantified. Patients who have some medical diagnoses might have such a high risk of hip fracture that they warrant initiation of osteoporosis, especially in older people. However, the risk of hip fracture with most medical conditions has not been quantified.

Method: We conducted systematic reviews followed by meta-analyses for medical conditions that guidelines list as risk factors for fracture. We took the yardstick of glucocorticoid therapy effects; high-dose glucocorticoids (prednisone >7.5 mg/day) are associated with a 2.2-fold risk of hip fracture, to indicate that a higher risk would be considered to raise concern and perhaps warrant pharmacologic treatment to reduce risk, even without BMD testing.

Results: The Figure shows that the pooled hazard ratio of hip fracture with the broken lines indicating the threshold of 2.2 and above the horizontal broken line, those diseases associated with high risk. The risks ranged from a high of a 4.7-fold increased risk with end stage renal disease (ESRD) down to a 1.1-fold risk of hip fracture for Type 2 Diabetes. Any history of stroke was associated with a 1.7-fold increased risk, however studies found that the risk is about 3.6-fold greater during the 1st 6 months after the stroke.

Conclusions: Patients with ESRD, Parkinson's Disease, HIV infection, recent stroke, Type 1 diabetes, and heart failure have a high risk of hip fracture that warrants treatment to reduce that risk, especially in older women or men. This would extend treatment to numerous patients who are not currently considered for treatment to prevent fractures. On the other hand, patients with COPD, stroke, ischemic heart disease, chronic kidney disease, or Type 2 diabetes have a lesser increase in risk and should be evaluated like any other patient without the disease with FRAX and measurement of BMD to assess fracture risk and make decisions about treatment.

National Fracture Risk Screening Finds Majority at High Risk Not Tested or Treated. Kathleen Cody*¹, David Karpf². ¹American Bone Health, USA, ²Stanford University School of Medicine, Division of Endocrinology, Gerontology & Metabolism

OBJECTIVES: To assess the prevalence of DXA screening and osteoporosis treatment in older adults identified as being at high risk of osteoporotic fracture in a community-based setting.

METHODS: We trained and dispatched 90 local peer educators to 9 independent living facilities, 1 short term rehabilitation center and 2 hospitals in six states to screen adults over age 45 for fracture risk using the validated FORE Fracture Risk Calculator™ (FORE FRC). Peer educators queried subjects about twelve clinical risk factors and entered results into the web-based tool. The resulting risk was displayed on a colored graph and explained onsite by the peer educator using companion worksheets “Steps to Take to Reduce Fracture Risk.” A copy of the graphic display was also emailed to participants with email addresses. The 10-year risk of any one of four major osteoporotic fractures was categorized as low (<10%) moderate (10-20%) or high (>20%). Approximately 10 minutes was required for acquisition and discussion of results.

RESULTS:

Table 1: Most of the individuals (69.4%) were over age 65 years. Proportions at moderate or high risk increased with age. 100% of the 314 individuals ≥ age 65 were at moderate to high risk, and 213 of 314 individuals (67.8%) in this age group were at high risk of osteoporotic fracture.

Table 2: Of the 314 adults age 65 and older who were screened, 56.1% reported not having a bone density test, a covered benefit under Medicare.

Table 3: Of the 237 adults at high risk of fracture, only 11.4% were being treated with an FDA-approved osteoporosis medication.

CONCLUSIONS: Fracture risk aligns closely with age. The proportion of the population with high fracture risk was substantial after age 65 (68%), yet less than half (44%) reported having had a bone density test (which is covered under Medicare), and of all the individuals found to be at high risk of fracture, only 11% were being treated. We are not doing a good job of diagnosing or treating osteoporosis to reduce risk of fractures in these older populations. The individuals screened in participating facilities were largely Caucasian and future outreach should attempt to find facilities serving more ethnically diverse adults. Not only did the outreach screening identify residents at risk for fractures, it also served to educate the facility staff who work with them.

Simultaneous LC-MS/MS measurement of 24,25-dihydroxyvitamin D and 25-hydroxyvitamin D providing a new perspective in the assessment of vitamin D status. Jonathan Tang*¹, Holly Nicholls², John Dutton³, Isabelle Picc³, Christopher Washbourne³, Lanja Saleh⁴, D Nowak⁵, Graeme Close⁶, Helen Macdonald⁷, Sarah Jackson⁸, Julie Greeves⁹, William Fraser³.

¹University of East Anglia, Norwich, UK, ²United Kingdom, ³University of East Anglia, ⁴University of East Anglia, ⁵University Hospital of Zurich, ⁶University Hospital of Zurich, ⁷Liverpool John Moore University, ⁸University of Aberdeen, ⁹HQ Army Recruiting & Training Division, ⁹HQ Army Recruiting & Training Division

Background: 24,25-dihydroxyvitamin D (24,25-d(OH)D) is converted from 25-hydroxyvitamin D (25(OH)D) by 24-hydroxylase. Recent studies suggest the production of 1,25-dihydroxyvitamin D (1,25-d(OH)D) from 25(OH)D is driven by the catabolism of 24,25-d(OH)D. Genetic mutations resulting in loss-of-function of the CYP24A1 gene are associated with hypercalcaemic conditions. We developed a new liquid chromatography tandem mass spectrometry (LC-MS/MS) assay to measure simultaneously 24,25-d(OH)D and 25(OH)D to investigate vitamin D status and metabolism. **Objective:** We describe a LC-MS/MS method used to determine: 1) reference interval of serum 24,25-d(OH)D in healthy individuals; 2) the ratios of serum 25(OH)D to 24,25-d(OH)D and of 1,25-d(OH)D to 24,25-d(OH)D in normals and 3) change in ratios in response to vitamin D supplements. **Method:** Prior to LC-MS/MS analysis 100µL of sample was extracted using [³H]_d-24,25-dihydroxyvitamin D₃ as internal standard, the method involved a derivatisation step to enhance ionisation efficiency. The reference interval of serum 24,25-d(OH)D was determined in samples obtained from 386 healthy unsupplemented individuals, age 17-32 y, mean serum [25(OH)D] 72 nmol/L (range 50-119 nmol/L), 24,25-d(OH)D, 25(OH)D and 1,25-d(OH)D were also measured in serum from three double-blinded randomized controlled studies where participants were given either 400/1000/5000 IU or placebo daily for a minimum of 3 months or a single dose 100,000 IU of vitamin D₃. **Results:** The LC-MS/MS method was able to fully resolve 24,25-d(OH)D₃/D₂ from 25(OH)D₃/D₂. The intra-assay and inter-assay CVs for all analytes were <11% across the analytical range. The reference interval for 24,25-d(OH)D₃ (mean, median, 95% CIs) was 6.5 nmol/L (6.0, 4.6-7.9). In supplement studies, mean (±SD, %CV) ratio of serum 25(OH)D:24,25-d(OH)D in baseline groups were 17.4 (±0.4, 2.6%), mean ratio of serum 1,25d(OH)D (pmol/L):24,25-d(OH)D (nmol/L) was 40.3 (±5.6, 13.9%). Participants who received vitamin D showed a significant increase in serum concentrations of 25(OH)D ($p<0.001$) and 24,25-d(OH)D ($p<0.001$), but showed no significant change in the ratio ($p>0.1$). However, a greater increase in serum 1,25-d(OH)D was observed in individuals with the highest 25(OH)D:24,25-d(OH)D ratio but this resulted in lower 1,25-d(OH)D:24,25-d(OH)D ratios. **Conclusion:** We found remarkable consistency in the ratio of serum 25(OH)D:24,25-d(OH)D. Increasing vitamin D₃ supplementation results in an increase in both metabolites but relative differences in production of 1,25-d(OH)D. The clinical utility of simultaneous measurement of metabolites not only will provide a new assessment tool for indicating loss-of-function mutations of CYP24A1, but can also provide data that may start to explain the lack of “optimal” response to increasing supplementation with vitamin D.

Absence of Complement Component 3 Protects Trabecular Structure and Stiffness of Femora in a Murine Model of Postmenopausal Osteoporosis. Danielle MacKay*¹, Thomas Kean², Kristina Bernardi³, Heather Haerberle⁴, Catherine Ambrose⁵, Feng Lin⁶, James Dennis². ¹Baylor College of Medicine, United States, ²Baylor College of Medicine, ³Seattle Children's, ⁴University of Texas, ⁵University of Texas Health Science Center, ⁶Cleveland Clinic Foundation

The growing field of osteoimmunology seeks to unravel the complex interdependence of the skeletal and immune systems. Notably, we and others have demonstrated that differentiation of osteoblasts and osteoclasts, the two cell types responsible for bone homeostasis, is partially regulated by the complement cascade. It is hypothesized that a deficiency of complement component 3 (C3), a central factor in the three main complement pathways, will reduce bone loss that results from estrogen deprivation in a model of postmenopausal osteoporosis. Wild type and C3^{-/-} mice on a C57BL/6 background were obtained from The Jackson Laboratory and bred and housed in accordance with the guidelines of the ACUC of Benaroya Research Institute. Only mice born on site were used in this study. At 6 weeks of age, ovariectomy or sham surgeries were performed under isoflurane anesthesia. At 12 weeks of age, animals were euthanized, and their uteri and hindlimbs were harvested. Uterine mass validated successful ovariectomies. Hindlimbs were fixed before being processed for microCT, histomorphometry, and/or mechanical testing. MicroCT scans were performed on a Scanco vivaCT 40 desktop scanner with a threshold of 300. Data are presented as a percentage and standard deviation and were normalized by dividing each individual value from ovariectomized mice by the mean value for sham-operated mice. Significance was calculated by unpaired Student's t-test. Micro-computed tomography revealed a 15% increase in the relative trabecular bone volume fraction of ovariectomized C3^{-/-} mice over that of their WT counterparts, an 8% increase in relative trabecular number, and an 11% decrease in relative trabecular separation in

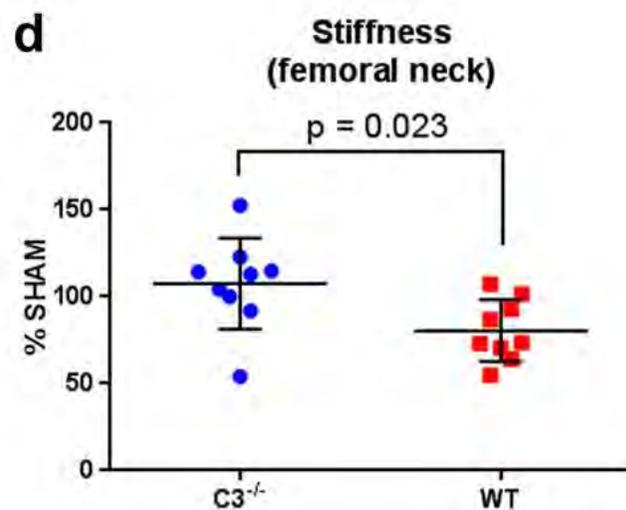

distal femora (a-c). In mechanical testing, the protective effects of the C3 deficiency manifest as a maintenance, compared to a reduction (20% decrease), of stiffness at the femoral neck in estrogen deprivation (d). Using a murine model of postmenopausal osteoporosis, our results demonstrate that the absence of C3 protects against femoral bone loss. In addition to its contribution to our understanding of the role of complement in bone remodeling, this study points to the complement cascade as a potential new target for osteoporosis therapy.

b

c

d

For all graphs, data are presented as % sham, with each data point representing the value for each ovariectomized C3^{-/-} mouse (blue circles) and each ovariectomized wild type mouse (red squares). Horizontal lines indicate the mean ± SD. MicroCT assessment of (a) trabecular bone volume fraction, (b) trabecular number, and (c) trabecular separation of the distal femur are shown. Mechanical testing determined the stiffness at the femoral neck (d).

The Effects of Vitamin D and Sarcopenia on Bone Mineral Density in Korean women. Bom Taek Kim*¹, Myat Kyi La Thein², Sanghoon Lee², Sungwon Yang², Dukjoo Lee². ¹AJOU University School of Medicine, Kr, ²Ajou University School Of Medicine

A osteoporotic fracture has become a global health issue that causes tremendous impact on mortality as well as heavy socioeconomic burden. Previous studies suggested that vitamin D may prevent fractures by improving muscle mass as well as via increasing bone density directly. The purpose of the study is to determine that the influence of vitamin D on bone mineral density depends on its effects on muscle mass.

We analyzed the data from Korean National Health and Nutritional Survey IV in 2009. Women older than age 20 were included for the analyses. Bone mineral density and muscle mass were measured by DXA. Serum vitamin D concentration was tested.

Vitamin D and muscle mass affected BMD at proximal femur, but not at lumbar spine. Vitamin D deficiency and sarcopenia increased odd ratio for osteoporosis before and after adjusted for multiple variables. The effects of vitamin D deficiency on BMD still remained significant after adjustment for sarcopenia, which was vice versa.

Though vitamin D deficiency and sarcopenia shared common effects on BMD, they have their own effects on BMD independent from each other.

Mice Expressing a Hypersensitive Form of the Glucocorticoid Receptor in Osteocytes Have High Cancellous Bone Mass and Reduced Cortical Thickness. Marilina Piemontese*, Jinhu Xiong, Yuko Fujiwara, Priscilla Baltz, Stuart Berryhill, Charles O'Brien. University of Arkansas for Medical Sciences, USA

Exogenous glucocorticoids act directly on cells of the osteoblast lineage to decrease cancellous bone formation and to increase bone resorption at the endocortical surface. However whether osteoblasts, osteocytes, or both mediate these actions of glucocorticoids is unknown. The goal of this study was to determine whether glucocorticoid action specifically on osteocytes is sufficient to mediate some of the negative impact of glucocorticoids on the skeleton. To do this we generated transgenic mice in which a hypersensitive mutant (M610L) of the glucocorticoid receptor (GR) is expressed specifically in osteocytes using the Dmp1 promoter. The GR_{M610L} mutant is activated in the presence of 5-10 fold lower glucocorticoid concentrations than the wild-type receptor. Therefore, osteocyte-specific expression of this mutant should increase the sensitivity of osteocytes, but not other cell types, to endogenous glucocorticoids. Quantitative RT-PCR analysis of mRNA isolated from transgenic mice confirmed bone specific expression of the DMPI-GR_{M610L} transgene. The dose-response curves of two known glucocorticoid target genes, GILZ and FKBP5, to dexamethasone were shifted to the left in osteocyte-enriched cortical bone cultures from transgenic mice compared to littermate controls confirming glucocorticoid hypersensitivity. MicroCT analysis revealed that cancellous bone in the femur and 4th lumbar vertebra was higher in transgenic mice compared to control littermates. These differences were observed in both sexes at 2 and 4 months of age. In contrast, cortical thickness measured at the midshaft of the femur was significantly lower in transgenic mice compared to wild-type mice at both ages and in both sexes. Consistent with reduced cortical bone thickness, transgenic mice displayed reduced bone strength, as measured by 3 point bending in the femur of 2 month old mice. These results demonstrate that activation of the glucocorticoid receptor specifically in osteocytes has positive effects on cancellous bone but negative effects on cortical bone and overall bone strength. Thus the negative impact of exogenous glucocorticoids on cortical bone may be mediated in part by actions on osteocytes where as their effects on cancellous bone may be independent of such actions.

Romozumab (Sclerostin Antibody) Increases Wall Thickness in Remodeling Units in Cynomolgus Monkeys After 28 Weeks. Qing-Tian Niu, Rogely Boyce, Michael Ominsky*, Amgen Inc., USA

Romozumab (Romo), a sclerostin antibody, is a bone-forming agent under clinical investigation for the treatment of osteoporosis. Previous animal studies established Romo's ability to activate modeling-based formation, while its effects on remodeling-based bone formation were less clear. We examined the effects of Romo on bone remodeling using a kinetic reconstruction analysis of the formative site in lumbar vertebra from cynomolgus monkeys (cynos).

Male cynos (10-12 yr) were treated with either vehicle (Veh, n=8) or 30 mg/kg Romo (n=9) SC every 2 weeks for 28 weeks. Sequential fluorochrome labeling was performed from week 1 to 28, including tetracycline (Tet; weeks 4 and 10) and calcein (weeks 26 and 27.5). Kinetic reconstruction was performed (Steiniche et al., Bone 1992) on Villanueva-stained undecalcified sections of L3 vertebral bodies. Remodeling formative sites defined by an underlying scalloped cement line were sampled with a line grid and paired measurements of wall thickness (W.Th) and osteoid thickness (O.Th) were made. Final W.Th was measured in completed packets that contained

any label to provide an average effect across the treatment duration; those that contained Tet labels were separately evaluated to capture the early treatment effect. Final W.Th was also projected for packets near completion to reflect the treatment effect after 28 weeks.

After 28 weeks of Romo, BV/TV was increased from 28% in Vehicle to 46%, and active bone modeling sites were infrequently observed. Projected final W.Th for completing remodeling packets was significantly increased with Romo by 52% (57 vs 37µm in Veh). Similar W.Th values were found for completed packets reflecting the average treatment effect over 28 weeks (60 vs 33µm). In the Romo group, final W.Th in packets active from week 4-10 (containing both Tet labels) was 44% larger than projected final W.Th (82 vs 57µm), suggesting that the effects of treatment on W.Th were greatest early in the treatment period. Romo reduced eroded surfaces (ES/BS) by 64% (5.0 vs 1.8% in Vehicle), consistent with a reduction in remodeling space.

Together these results provide evidence of a positive effect of Romo on remodeling formative site in cyno vertebra. Greater W.Th and reduced remodeling space would contribute to the increases in bone mass during the period of active modeling-based formation as well as following self-regulation of bone formation with continued Romo administration.

Effects of Ibuprofen Supplementation and Resistance Training on Bone and Marrow Properties in Postmenopausal Women. Whitney Duff*¹, Philip D. Chilibeck², Darren G. Candow³, Julianne J. Rooke², Riley S. Mason², Regina Taylor-Gjevre², Bindu Nair², Michael Szafron², Adam D.G. Baxter-Jones², Gordon A. Zello², Anthony M. Kehrig², Saija A. Kontalainen². ¹University of Saskatchewan, Canada, ²University of Saskatchewan, Canada, ³University of Regina, Canada

Fractures of the wrist in postmenopausal women are associated with low bone strength and bone adaptation has been linked to changes in marrow composition. Ibuprofen supplementation (400 mg) after resistance training sessions (3d/week, 9 months) has been shown to enhance hip areal bone mineral density in young women. The purpose of this study was to examine the effects of ibuprofen supplementation (400 mg) after resistance training sessions (3d/week, 9 months) on bone and marrow properties in postmenopausal women. Participants (n = 60, 64.8 ± 4.4y) were randomly assigned (double blind) to supervised resistance training or stretching (placebo-exercise), and ibuprofen or placebo (i.e. 4 groups) for 9 months. Baseline and post-intervention measurements included distal and shaft scans of the forearm and lower leg using pQCT (Stratec XCT2000). Outcomes for the radius and tibia at distal sites included: cross-sectional area, content, and density for total and trabecular bone as well as estimated strength in compression. Outcomes for shaft sites included: total area, and area, content, and density for cortical bone and marrow; estimated bone strength in torsion; and muscle area. Data was analyzed with SPSS using 3-factor ANOVA controlling for multiple comparisons (Bonferroni). Alpha level was 5% with custom hypothesis test for post-hoc analyses. There was an omnibus group effect. Resistance training combined with ibuprofen decreased distal radius total content (-1.6%) versus an increase for resistance training with placebo (0.6%) (p = 0.03). Stretching with ibuprofen increased distal radius total content (0.5%) (p = 0.05) versus a decrease for stretching with placebo (-1.35%). Resistance training with ibuprofen decreased radial shaft marrow content (-20.5%) versus an increase for resistance training with placebo (48.3%) (p = 0.01), with a trend for a decrease versus an increase in marrow density (-15.6%; 50.7%) (p = 0.06). Stretching with ibuprofen increased radial shaft marrow content (21.5%) and density (25.0%) versus a decrease for stretching with placebo (-42.9%; -36.4%) (p < 0.05). There were no interventional effects on remaining pQCT outcomes. Resistance training (without ibuprofen) or ibuprofen (without resistance training) increased bone content at the distal radius and marrow content at the radius shaft while combined interventions appeared to interfere with each other.

Bisphosphonates and "Zebra lines": Relation to Fracture Risk and the Duration of Treatment in Osteogenesis Imperfecta. Jay Shapiro*, Evelise Brizola. Kennedy Krieger Institute, Johns Hopkins, USA

After 20 years of experience with pamidronate treatment in Osteogenesis Imperfecta (OI), uncertainty exists with regarding both the efficacy of extended treatment in fracture prevention and the recommended duration of treatment. Pamidronate treatment will initially decrease fracture rate but studies indicate that after 2-3 years the incidence of fractures tends to plateau. Bachrach and Ward (2009) suggested that in younger patients with OI, perhaps in a lower dose, bisphosphonate (BP) therapy should be continued until growth is fully or nearly complete. This recommendation is related to persistent risk factors and specifically to the risk of fracture at "BP-free zone" in the distal femur occurring with growth. BP induces "zebra lines" in the distal femur metaphysis. Harcke et al. (2012) proposed that zebra lines in patients with cerebral palsy, calcified zones of alternating high and low bone density, create a stress riser effect which could increase the risk of distal femur

fractures. We present a case illustrating the putative relation of zebra lines to femur fracture in OI. Case report: This 11 year old girl has type I OI, blue sclerae and multiple fractures. She completed 11 cycles of pamidronate treatment. Radiography of the right knee at age 8 year showed 5 residual zebra lines with a distal femur fracture just above the zone of zebra lines (Figure 1). Discussion: The risk of distal femur fracture in a “BP-free zone” is one leading argument for continuing BP treatment to the cessation of growth in children and adolescents with OI. This case illustrates the stress riser concept as contrasted with the “BP-free zone” postulate as a mechanism for distal femur fractures in BP- treated OI patients. Studies with *oimloim* model of OI indicate a delay of chondrocyte maturation to chondro-osseous lamellae following BP therapy. Antiresorptive BPs alter osteoclast activity at the growth plate leading to depressed bone remodeling and the formation of zebra lines with the stress riser risk for fracture. Conclusion: The case presented demonstrates a zone of increased fracture risk as previous reported in cerebral palsy cases. We propose this effect as more critical to injury than is the concept of a BP-free zone occurring with growth following cessation of initial treatment. Critical assessment of the relationship of zebra lines to the duration of BP treatment and the occurrence of distal femur fracture in OI is required.

Melorheostosis (MEL) is the rare sporadic dysostosis featuring acquired areas of hyperostosis and osteosclerosis, often following a sclerotome, in one or more bones. Rarely, MEL becomes malignant. The etiology is unknown, but post-zygotic mosaicism is a favored hypothesis.

We studied a boy with MEL in his right ileum and femur (Figure A) with overlying scleroderma-like skin changes (Figure B) – an association some believe reflects a more widely distributed melorheostotic process. Additionally, he had a large epidermal nevus on his back (Figure C) - a dermatosis not associated with MEL but recently reported to harbor mosaic HRAS, NRAS, or KRAS mutations.

To explore for mosaicism underlying MEL in our patient, we performed whole exome sequencing (WES) of DNA from biopsies of both dermatoses, two areas of normal skin, and peripheral leukocytes. WES was conducted to ~100x average read depth (coverage) at every exon base position. Somatic variant calling, with four variant callers using all 20 possible pairwise combinations of the five separate DNA samples, was applied to identify any mutation(s) present in some but not all specimens. MEL bone was not investigated.

As expected for non-cancerous tissues, his overall mutation burden was exceptionally low. Only one high-confidence somatic variant emerged from the analyses – a heterozygous *KRAS* Q61H mutation (a well-established activating mutation) present in both skin lesions, but absent in his normal skin and blood. Interestingly, he and several other family members carried a heterozygous, in-frame, 24-base-pair deletion in the *LEMD3* gene. *LEMD3* mutation causes autosomal dominant Buschke-Ollendorff syndrome (BOS) and osteopoikilosis (OPK) featuring symmetrically distributed punctate osteosclerotic lesions where MEL is sometimes also present in an affected individual. This *LEMD3* deletion was detected in all four skin samples and blood at variant allele frequencies consistent with germline heterozygosity. However, he and other family members with the *LEMD3* mutation did not have the typical clinical or radiographic features of BOS or OPK, and *LEMD3* mutation does not underlie sporadic MEL. We also found in all five DNA samples two potentially interesting heterozygous germline mutations: a stop gain in *AMPD1*, and a frameshift in *MS4A12*.

In conclusion, the *KRAS* mutation in the scleroderma-like tissue overlying MEL of our patient implicates somatic mosaicism involving this oncogene in the etiology of MEL.

Sclerostin Antibody Treatment Stimulates Bone Formation Without Increasing Bone Resorption to Normalize Bone Mass in Down Syndrome. Diarra Williams*¹, Sean Parham¹, Eric Schryver¹, Nisreen Akel¹, Jami Schmidt¹, Jessica Webber¹, Frances Swain¹, Dana Gaddy¹, Larry Suva². ¹Dept Orthopaedic Surgery UAMS, ²University of Arkansas for Medical Sciences, USA

A significant increase in the life expectancy of individuals with Down syndrome (DS) has been observed in recent decades. As such, skeletal complications such as osteopenia and bone fragility, previously not recognized in this population, have begun to appear. We have shown that this bone phenotype is associated with low bone turnover and decreased osteoblast activity, and not to the development of osteoporosis *per se*. Anti-resorptive agents, such as bisphosphonates, are frequently used to treat the low bone mass in people with DS, but the therapy is not directly treating the cause of the low bone mass and may in fact be contraindicated. New treatments which increase bone mass throughout the DS skeleton would therefore be highly beneficial. Sclerostin antibody (Scl-Ab) is a potential candidate anabolic therapy that functions by stimulating osteoblastic bone formation via the canonical Wnt signaling pathway, although the role of this pathway in the setting of low bone turnover is less clear. To determine the effect of Scl-Ab on the DS skeleton, 8 week old male Ts65Dn DS mice, trisomic for a portion of Mmu16 (analogous to Hsa21) that we have previously shown to also have low bone turnover, were treated with 3 weekly I.V. injections of 100 mg/kg Scl-Ab. Scl-Ab had significant anabolic effects by DXA and microCT in both age-matched controls (WT) as well as Ts65Dn mice, and led to increased trabecular and cortical bone formation at multiple skeletal sites. Importantly, Scl-Ab treatment led to the normalization of Ts65Dn BMD to WT levels in the whole body, distal femur and proximal tibia. Histologically, the striking anabolic activity was explained by significantly increased bone formation in Scl-Ab-treated mice, with no measurable differences in any measured *in vivo* osteoclast parameters. In *ex vivo* bone marrow cultures, Scl-Ab was able to significantly increase the recruitment of AP+ progenitors into the osteoblast lineage, resulting in increased AP+ colonies and osteoblastogenesis. In whole marrow or bone marrow macrophage (BMM) osteoclastogenic cultures, Scl-Ab did not change the differentiation of progenitors into osteoclasts. In conclusion, Scl-Ab was able to stimulate bone formation in a murine model of DS in the absence of increased osteoclastogenesis and bone resorption, and represents a potential new therapy to improve bone mass and reduce the fracture risk inherent in people with DS.

Calcified Cartilage Islands in Mouse Bones. Victoria Ip¹, Zach Toth², Sarah McBride³. ¹Cornell University, ²Saint Louis University, ³Saint Louis University, USA

Bone's micro-scale structure differs greatly between humans and rodents, which can significantly affect strengthening mechanisms and limit findings' applicability to humans. Murine bones' lack of osteonal structure is a well-known example. Less obvious is an intracortical band of woven bone. The band's size and structure, which is indistinct using brightfield imaging, has prompted assumptions that it is unremodeled endochondral bone from early postnatal growth. Indeed, recent rat studies confirmed calcified cartilage islands within the band. To our knowledge, the same has not been shown in mice nor have the disorganized bone's origins been definitively proven. We hypothesize that, similar to rats, mouse long bones have cartilage islands within disorganized woven bone that is not evident on standard microCT (uCT), and this tissue is formed early in growth.

Twelve to 14 wk old male (n=4) and female (n=1) control mice generated for a previous study were used. Doxycycline (DOX) was administered via drinking water *in utero* to 3 weeks old. DOX, a fluorescent tetracycline, is typically used to repress Cre expression but also incorporates into actively mineralizing tissues. After euthanasia, both femora were harvested, fixed overnight, and scanned with uCT (cone beam, 12um resolution). Right femora midpoint paraffin sections were stained with alcian blue and picrosirius red to highlight cartilage and bone, respectively. Then polarized and brightfield imaging were used to quantify woven bone and cartilage islands. Left femora midpoint plastic sections were fluorescently imaged to quantify DOX labeled bone. To verify DOX labeling positive (DOX until 8 wks old, n=4) and negative (no DOX, n=4) controls were processed similarly (Fig 1). Paired t-tests compared the cartilage island locations (woven vs lamellar) and DOX labeled bone to woven bone area.

All samples had cartilage islands, although the number and percent area varied greatly (16 ± 8 islands, $0.1 \pm 0.3\%$). Remarkably, cartilage islands resided exclusively in the woven bone band (Fig 2). DOX labeling and woven bone patterns matched well and encompassed an almost identical cross sectional area. However, neither feature could be identified on uCT scans examined visually or by thresholding methods (Fig 3). In conclusion, young adult mice, like rats, have intracortical woven bone unremodeled from early growth. This tissue contains calcified cartilage islands which are indistinguishable from bone using typical uCT.

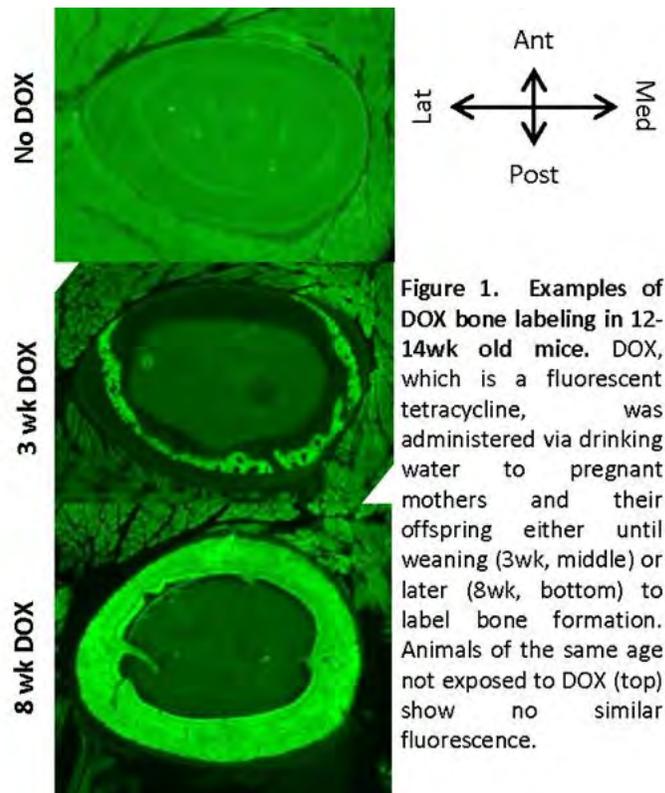

Figure 1. Examples of DOX bone labeling in 12-14wk old mice. DOX, which is a fluorescent tetracycline, was administered via drinking water to pregnant mothers and their offspring either until weaning (3wk, middle) or later (8wk, bottom) to label bone formation. Animals of the same age not exposed to DOX (top) show no similar fluorescence.

Figure 1

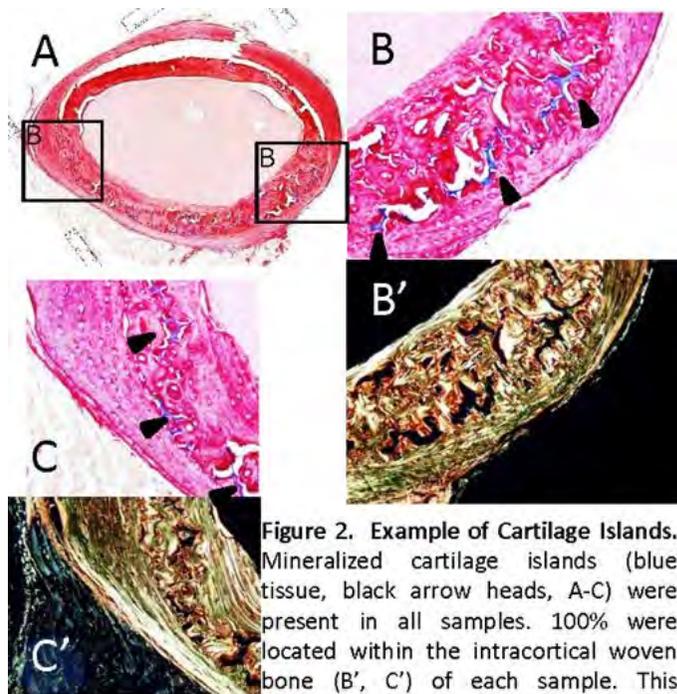

Figure 2. Example of Cartilage Islands. Mineralized cartilage islands (blue tissue, black arrow heads, A-C) were present in all samples. 100% were located within the intracortical woven bone (B', C') of each sample. This remained true even for animals as old as 30wks (data not shown).

Kindlin-2 Controls TGF- β signaling and Sox9 Expression to Regulate Chondrogenesis. Guozhi Xiao^{*1}, Chuanyue Wu², Yumei Lai³, Ke Zhu³, Huiling Cao², Di Chen³. ¹Rush University Medical Center, USA, ²South University of Science & Technology of China, ³Rush University

The signals that control skeletogenesis are incompletely understood. Here we show that deleting Kindlin-2 in Prx1-expressing mesenchymal progenitors in mice causes neonatal lethality, chondrodysplasia, and loss of the skull vault. Kindlin-2 ablation reduces chondrocyte density by decreasing cell proliferation and increasing apoptosis, and disrupts column formation, thus impairing the formation of the primary ossification center and causing severe limb shortening. Remarkably, Kindlin-2 localizes to not only focal adhesions, but also to the nuclei of chondrocytes. Loss of Kindlin-2 reduces, while overexpression of Kindlin-2 increases, Sox9 expression. Furthermore, overexpression of Sox9 restores the defects in chondrogenic differentiation induced by Kindlin-2 deletion in vitro. Additionally, Kindlin-2 ablation inhibits TGF- β 1-induced Smad2 phosphorylation and chondrocyte differentiation. Finally, deleting Kindlin-2 in chondrocytes directly impairs chondrocyte functions, resulting in progressive dwarfism and kyphosis in mice. These studies uncover a previously unrecognized function for Kindlin-2 and a mechanism for regulation of the chondrocyte differentiation program and chondrogenesis.
