DISCLOSURE/CONFLICT OF INTEREST

The Federation of American Societies for Experimental Biology (FASEB) requires that audiences at FASEB-sponsored educational programs be informed of a presenter's (speaker, faculty, author, or contributor) academic and professional affiliations, and the existence of any significant financial interest or other relationship a presenter has with the manufacturer(s) of any commercial product(s) discussed in an educational presentation. This policy allows the listener/attendee to be fully knowledgeable in evaluating the information being presented. The Program will note those speakers who have disclosed relationships, including the nature of the relationship and the associated commercial entity.

All authors of submitted abstracts completed the disclosure statement in the online submission program. Invited speakers who are not required to submit an abstract received a form in the mail that they completed and returned.

Disclosure may include any relationship that may bias one's presentation or which, if known, could give the perception of bias. These situations may include, but are not limited to:

DISCLOSURE KEY

1. stock options or bond holdings in a for-profit corporation or self-directed pension plan
2. research grants
3. employment (full or part-time)
4. ownership or partnership
5. consulting fees or other remuneration
6. non-remunerative positions of influence such as officer, board member, trustee, or public spokesperson
7. receipt of royalties
8. speaker's bureau

For full-time employees of industry or government, the affiliation listed in the *2003 Abstracts* will constitute full disclosure.

Disclosures for invited speakers and abstract presenters are provided at the end of the session listing for invited speakers and directly after the body of an abstract for abstract submissions. If there is no conflict of interest or disclosure listed, this means that the invited speaker and/or abstract presenter indicated no conflicts to disclose.

The disclosure information will correspond to the key above. If disclosures are given, the company name, along with the respective disclosure relationship number will be listed (for example: Company Name, 2, 8.).

PTHrP Haploinsufficiency Reduces Bone Volume in Postnatal PTH Deficient Mice. D. Miao[1], J. Li*[1], Y. Xue*[1], H. Su*[2], A. C. Karaplis[2], D. Goltzman[1]. [1]Department of Medicine, Calcium Research Lab, McGill University, Montreal, PQ, Canada, [2]Medicine, SMBD-Jewish General Hospital, McGill University, Montreal, PQ, Canada.

We previously reported that neonatal mice with targeted disruption of the PTH gene ($PTH^{-/-}$) have decreased trabecular bone volume in long bones due to decreased osteoblast numbers in the primary spongiosa. At 4 months of age, however, $PTH^{-/-}$ mice have increased trabecular bone volume. Haploinsufficient $PTHrP^{+/-}$ mice are normal at birth but at 4 months have decreased trabecular bone volume. To determine whether PTHrP plays any role in maintaining higher bone mass in postnatal $PTH^{-/-}$ mice, we generated mice which are homozygous for the PTH null allele and heterozygous for the PTHrP null allele ($PTH^{-/-}$; $PTHrP^{+/-}$) and compared these to wild type and to $PTH^{-/-}$ mice. At 4 months of age, $PTH^{-/-}$; $PTHrP^{+/-}$ mice displayed similar biochemical alterations as $PTH^{-/-}$ mice, i.e. they had undetectable PTH levels and were hypocalcemic, hyperphosphatemic, had enlarged parathyroid glands and decreased serum 1,25-dihydroxy vitamin D_3 ($1,25(OH)_2D_3$) levels. Trabecular bone volumes of tibiae, femora and vertebrae were increased by 148%, 156% and 159%, respectively, in $PTH^{-/-}$ mice compared to their wild littermates, but were decreased in $PTH^{-/-}$; $PTHrP^{+/-}$ mice by 37%, 36% and 36%, respectively, compared to their wild type littermates, and by 58%, 59% and 60%, respectively, compared to $PTH^{-/-}$ mice. Alkaline phosphatase positive osteoblast numbers and bone formation rates (assessed by double-calcein labeling) were decreased in $PTH^{-/-}$ mice, and even more dramatically decreased in $PTH^{-/-}$; $PTHrP^{+/-}$ mice compared to their wild type littermates. The number and size of TRAP positive osteoclasts were also diminished in $PTH^{-/-}$ mice, and more prominently reduced in $PTH^{-/-}$; $PTHrP^{+/-}$ mice compared to their wild type littermates. This reduction was associated with a decrease in RANKL positive osteoblasts as demonstrated by immunohistochemical staining. Bone levels of PTHrP mRNA as determined by RT-PCR and immunohistochemical levels of PTHrP in osteoblasts were enhanced in $PTH^{-/-}$ mice, but not in $PTH^{-/-}$; $PTHrP^{+/-}$ mice compared to their wild type littermates. These studies show that PTHrP haploinsufficiency can reduce further the decreased bone turnover in PTH deficient animals and that the increased postnatal trabecular bone volume observed in PTH deficient animals is dependent on the action of PTHrP. PTHrP therefore is an important mediator of postnatal bone growth.

Relief of Inhibition by Twist Proteins Determines the Onset of Osteoblast Differentiation. P. Bialek*[1], K. Britt[1], M. Schrock*[1], D. Sosic*[2], K. Yu*[3], D. M. Ornitz*[3], E. N. Olson*[4], G. Karsenty[1]. [1]Moleuclar and Human Genetics, Baylor College of Medicine, Houston, TX, USA, [2]Molecular Biology, U T Southwestern Medical Center, Dallas, TX, USA, [3]Molecular Biology and Pharmacology, Washington University Medical School, St Louis, MO, USA, [4]Molecular Biology, UT Southwestern Medical Center, Dallas, TX, USA.

The transcription factor *Runx2* is necessary and sufficient for osteoblast differentiation. That *Runx2* expression precedes osteoblast differentiation by three to four days suggests that its function may be transiently inhibited. The craniosynostosis of *Twist*+/- patients (Saethre-Chotzen syndrome) and mice led us to investigate whether Twist inhibits Runx2 function. Here we show that, in the developing skull, *Twist* is expressed at higher levels than *Runx2* in *Runx2*-expressing cells before osteoblast differentiation occurs. *Twist* inhibits osteoblast gene expression and Runx2 transactivation function without affecting *Runx2*'s expression. Compound heterozygotes for *Twist* and *Runx2* inactivations have none of the skull abnormalities observed in *Runx2*+/- or *Twist*+/- mice revealing a genetic interaction between *Twist* and *Runx2*. Transgenic mice expressing *Twist* in osteoblast progenitors mimic the *Runx2*-null phenotype despite normal *Runx2* expression. Twenty residues in Twist's C-terminus form a unique antiosteogenic domain, the Twist box, that interacts with Runx2's DNA-binding domain to inhibit its DNA-binding function. These findings reveal that osteoblast differentiation only begins when an inhibition is relieved and provide a molecular explanation for Saethre-Chotzen syndrome. *Twist*'s broad expression during development suggests that this may be a general mechanism to control *Runx*-dependent cell differentiation programs.

GADD34/PP1c Recruited by Smad7 Dephosphorylates TGFβ Type I Receptor. W. Shi[1], C. Sun*[1], B. He*[2], W. Xiong[1], X. Shi[1], D. Yao*[1], X. Cao[1]. [1]Pathology, University of Alabama at Birmingham, Birmingham, AL, USA, [2]Microbiology and Immunology, University of Illinois at Chicago, Chicago, IL, USA.

Transforming growth factor β (TGF-β) superfamily, including bone morphogenetic proteins (BMPs), exerts extensive effects on a broad spectrum of cellular processes such as cell growth, differentiation, mobility and apoptosis, and is therefore crucial for development and maintenance of many different tissues, including bone. The cascade of phosphorylation from receptors to effectors is a well-characterized, pivotal event in TGF-β signaling. Smad7, induced by TGF-β, binds to type I receptor (TβRI) and functions as a receptor kinase antagonist that inhibits TβRI Ser/Thr kinase activity as part of a negative feedback mechanism. However, the possible inhibitory mechanism by dephosphorylation in the TGF-β signaling pathway is not known. Screening a human chondrocyte cDNA library in yeast two-hybrid system with Smad7 as bait, we found that Smad7 interacted with the growth arrest and DNA damage protein, GADD34, a regulatory subunit of the protein phosphatase 1 (PP1) holoenzyme. Immunoprecipitation (IP) experiments demonstrated that Smad7 mediated the formation of a complex with GADD34 and PP1 on TGF-β type I receptor (TβRI). The complex was shown to dephosphorylate TβRI both *in vitro* and *in vivo*. Blockage of Smad7 expression by siRNA inhibited association of the GADD34/PP1c complex with TβRI. Overexpression of either dominant-negative Smad7 or GADD34, absent of their binding domain, inhibited Smad7-mediated dephosphorylation of TβRI. Moreover, SARA, as a Smad anchor for receptor activation, also acts as anchor for PP1c via its PP1c-binding motif. Most importantly, dominant-negative SARA, absent of its PP1c-binding motif, inhibited involvement of PP1c in this proposed complex and dephosphorylation of TβRI, indicating that the availability of PP1c to this complex for TβRI dephosphorylation was controlled by SARA. Furthermore, transcriptional response assay and FACS-DNA profiling analysis demonstrated that Smad7/GADD34/PP1c complex inhibited TGF-β-induced gene transactivation and anti-proliferative effect in Mv1Lu cells, respectively, while PP1 inhibitors rescued the effects of TGF-β. These results indicate that Smad7 acts as an adaptor protein in formation of the PP1 holoenzyme that targets TβRI for dephosphorylation. Thus, we have characterized a novel TβRI dephosphorylation mechanism of the first phosphatase identified in the TGF-β/BMP signaling pathway. Dephosphorylation of TβRI mediated by Smad7 is an effective mechanism for governing negative feedback in TGF-β signaling. This complex could potentially be used as a drug target to modulate TGF-β signaling for bone and cancer diseases.

Evidence that JNK/c-Jun Signaling Promotes Osteoclastogenesis using Transgenic Mice Overexpressing Dominant-Negative c-Jun Selectively in Osteoclasts. F. Ikeda[1], T. Matsubara*[1], K. Hata*[1], T. Tsurukai[2], T. Watanabe*[3], T. Kukita[3], S. V. Reddy[4], K. Yoshioka*[5], R. Nishimura[1], T. Yoneda[1]. [1]Dept Biochem, Osaka Univ Grad Sch Dent, Osaka, Japan, [2]Kaken Phram Co., Inc, Kyoto, Japan, [3]Sec Oral Mol Biol, Facult Dent Kyushu Univ, Fukuoka, Japan, [4]Div Hematol Oncol, Univ Pittsburgh Cancer Inst, Pittsburgh, PA, USA, [5]Cancer Res Inst, Kanazawa Univ, Kanazawa, Japan.

RANKL is a central cytokine that promotes osteoclastogenesis. Upon RANKL binding to RANK, cytoplasmic molecules involving JNK, c-Jun, c-Fos and NF-κB are activated, suggesting that these molecules relay RANKL signaling. This notion is supported by genetic studies which demonstrated that c-Fos and NF-κB knockout mice exhibited osteopetrosis due to impaired osteoclastogenesis. On the other hand, the role of JNK and its substrate c-Jun, which forms the AP-1 complex with c-Fos, still needs to be elucidated. In the present study, we investigated the role of JNK/c-Jun signaling in osteoclast differentiation by generating transgenic mice (DN-c-Jun Tg) carrying DN-c-Jun driven by the TRAP gene promoter. The DN-c-Jun Tg manifested severe phenotype of osteopetrosis including defect of tooth eruption, smaller body size and increased radiodensity in long bones. Histological examination showed that bone marrow cavity was markedly reduced due to reduced trabecular bone resorption and the number of osteoclasts was markedly diminished. To examine whether the osteopetrosis was due to the abnormality of osteoclast development, we determined multinucleated TRAP-positive osteoclast-like cell (OC) formation in spleen cells isolated from DN-c-Jun Tg or wild-type littermate mice. Number of OC formed in spleen cells of DN-c-Jun Tg was significantly reduced compared with that of wild type mice, indicating that the osteopetrosis seen in DN-c-Jun Tg is due to impaired osteoclastogenesis. We then examined the relationship between RANKL and JNK/c-Jun activation in vitro. Soluble RANKL (sRANKL) activated JNK and c-Jun in the BMMø osteoclast progenitor cells and the RAW264 mouse monocytic cells. Consistent with the in vivo results, OC formation in the presence of sRANKL and M-CSF in mouse bone marrow cultures was significantly inhibited by a specific inhibitor of JNK, SP600125. Furthermore, overexpression of dominant-negative (DN)-JNK1 or DN-c-Jun using adenovirus system suppressed OC formation and increased apoptosis. In conclusion, these results collectively suggest that activation of JNK/c-Jun signaling pathway is essential to osteoclastogenesis that regulated by RANKL both *in vivo* and *in vitro*. Thus, our data provide the new insight into the molecular mechanisms by which RANKL regulates the osteoclast differentiation.

The Role of the PERK eIF2alpha Kinase in Regulating Skeletal Growth and Development. D. R. Cavener, A. Frank*, A. Gabai*. Biology, Penn State University, University Park, PA, USA.

The orchestration of skeletal growth is regulated by a complex repertoire of differentiation factors and hormonal signals that control cell proliferation and secretion of the extracellular matrix (ECM). Inasmuch as the ECM comprises the major organic fraction of bone and cartilage, the growth and development of the skeletal system is more dependent upon protein secretion than any other major tissue in the body. Recently, a new eIF2alpha kinase denoted PERK was discovered that is highly expressed in secretory tissues, predominately in bone tissue and the endocrine and exocrine pancreas. We have generated a knockout mutation of the mouse *Perk* gene (Zhang, et al., Mol. Cell. Biol 22:3864-74, 2002); these mice display severe multiple skeletal dysplasias, postnatal growth retardation, and loss of endocrine and exocrine pancreatic functions similar to defects seen in human Wolcott-Rallison syndrome (WRS). The skeletal dysplasias exhibited by *Perk-/-* mice include severe osteopenia, reduced cortical bone, delayed mineralization, and a marked deficiency of ECM in the hypertrophic region of the growth plate. The long bones of *Perk-/-* mice display reduced trabecular bone (24% normal in tibias), reduced BMD (2.3 fold compared to controls, femur) and reduced growth plates. Bone collagen-I in *Perk-/-* mice is reduced approximately 2-fold, whereas intracellular procollagen-I in osteoblasts is increased 8-fold. Ultrastructural analysis of osteoblasts indicated that procollagen-I processing and secretion are impaired in the endoplasmic reticulum. These defects are similar to that seen

in osteogenesis imperfecta associated with mutations in the procollagen gene that result in abnormal procollagen retention in the ER. In addition to the cortical defects, histomorphic analyses of long bone growth plates in *Perk-/-* mice identified an array of defects including a reduction in the height of the hypertrophic and proliferative zones. The reduction in the hypertrophic zone is due to a 28% reduction of the number of cells in the longitudinal axis. In addition, an abrupt transition from the proliferative to the hypertrophic zone in the *Perk-/-* growth plates was seen, as indicated by a deficiency in chondrocytes exhibiting intermediate width-height ratios. *Perk-/-* mice display a 3.1-fold reduction in the apparent volume of ECM in the hypertrophic zone. In *Perk-/-* mice, the parallel ECM tracts are diminished in number and width giving rise to abnormally thin trabeculae. We are examining the cell-autonomous nature of these defects by generating tissue-specific knockout mutations of *Perk* in the skeletal system using the Cre/loxP system.

Fra-2: A Novel Regulator of Bone Remodeling. A. Hoebertz*[1], R. Eferl*[1], F. Karreth*[1], A. F. Schilling[2], M. Priemel[2], M. Amling[2], E. F. Wagner[1]. [1]Research Institute of Molecular Pathology, Vienna, Austria, [2]Hamburg University School of Medicine, Hamburg, Germany.

The three Fos proteins c-Fos, FosB, Fra-1 have been shown to play crucial roles in bone biology, but little is known about Fra-2, the fourth Fos protein. To study its role in bone development and remodeling, we generated both Fra-2 knock-out mice, mice carrying a conditional "floxed" Fra-2 allele, and mice overexpressing Fra-2.

Transgenic mice overexpressing Fra-2 (Fra-2 Tg mice) showed initially no overt phenotype. However, histomorphometrical analysis of 3 month-old Fra-2 Tg mice revealed that these mice had a 2 times increase in bone volume and an increased bone formation rate, whereas numbers of osteoclasts and osteoblasts were unchanged. This indicates that enhanced bone matrix production by osteoblasts leads to the increase in bone mass. *In vitro*, primary Fra-2 Tg calvarial osteoblasts and bone marrow osteoclasts displayed both enhanced differentiation potential.

Fra-2 knock-out (-/-) mice die postnatally between day 1-5, are growth retarded and display severe osteoporosis. Analysis by bone histomorphometry showed that bone volume is reduced by 50% and both number and size of osteoclasts were dramatically increased, whereas the absolute number of osteoblasts was unchanged. However, *in situ* hybridization revealed a dramatic decrease in mature, osteocalcin-expressing osteoblasts in Fra-2 -/- long bones, suggesting that decreased bone formation by osteoblasts is also contributing to the bone loss *in vivo*, in addition to enhanced bone resorption. To study the mechanism leading to the bone loss and "giant" osteoclast appearance, we performed *in vitro* cultures of osteoclasts derived either from Fra-2 -/- fetal liver cells or from Fra-2 deficient bone marrow, and primary calvarial osteoblasts. Primary Fra-2 -/- osteoblasts showed a severe differentiation defect, as assessed by bone nodule formation. Unexpectedly, primary osteoclast cultures showed a defect in differentiation and fusion; the numbers, but also the size, of TRAP-positive osteoclasts were smaller compared to controls. However, this defect could be rescued by addition of TGFbeta to the cultures. Reciprocal co-cultures of Fra-2 -/- osteoclasts and wildtype or Fra-2 -/- osteoblasts could not rescue the osteoclast differentiation defect, indicating that other systemic or paracrine signals must be responsible for the "giant" osteoclasts *in vivo*. This loss-of-function approach supports our data from the Fra-2 transgenic model.

In conclusion, we provide first evidence that Fra-2 plays important roles in both osteoclast and osteoblast differentiation and that loss or overexpression of Fra-2 result in imbalanced bone remodeling leading to severe bone diseases.

The Effects of PTH, Alendronate Alone or in Combination on Bone Mass and Turnover: 12 Month Results of the PATH Trial. D. M. Black[1], K. Ensrud[2], S. Greenspan[3], J. Bilezikian[4], J. McGowan[5], T. Lang[6], P. Garnero[7], C. Rosen[8]. [1]Dept of Epidemiology & Biostatistics, University of California, San Francisco, CA, USA, [2]Dept of Medicine, University of Minnesota, Minneapolis, MN, USA, [3]Dept of Medicine, University of Pittsburgh, Pittsburgh, PA, USA, [4]Dept of Medicine, Columbia University, New York, NY, USA, [5]National Institute of Health, Bethesda, MD, USA, [6]Dept of Radiology, University of California, San Francisco, CA, USA, [7]Synarc, Lyon, France, [8]Maine Ctr for Osteo. Res & Education, St. Josephs Hosp., Bangor, ME, USA.

Parathyroid hormone (PTH) increases bone strength, in part, by stimulating bone formation while antiresorptives work, in part, by reducing bone resorption. Their use together might be expected to lead to synergistic effects in bone by simultaneously increasing formation while reducing resorption. The PaTH study was designed to test the effects of PTH or alendronate (ALN) alone or concurrently administered on bone mass and bone turnover. We randomized 238 PM women (not currently using bisphosphonates) with low hip or spine BMD (T-score <-2.5 or <-2.0 with a risk factor) to a daily regimen of: 100 µg rhPTH (1-84) (NPS); ALN 10 mg (Merck); or PTH and ALN together. The single therapy arms had placebo ALN or PTH. BMD at the spine and hip was assessed by DXA and QCT. Bone turnover markers were measured in fasting blood samples.

Mean 1 year % change in bone mass/marker (p-value vs. PTH alone)

	PTH	PTH + ALN	ALN
DXA Spine BMD	+6.2%	+6.1% (0.8)	+4.6% (0.09)
QCT trabecular spine BMD	+23.8%	+11.3% (0.001)	+7.6% (0.001)
DXA Femoral neck BMD	+0.8%	+1.8% (0.09)	+2.0% (0.05)
QCT fem neck cortical BMD	-2.4%	-0.1% (0.002)	+1.2% (<.001)
QCT fem neck cortical volume	+3.4%	-0.6% (0.03)	+0.9% (0.25)
Formation (P1NP)	+146%	-16% (<.001)	-74% (<.001)
Resorption (serum CTX)	+104%	-14% (<.001)	-73% (<.001)

In the spine, DXA BMD increases were similar for PTH alone and in combination, and somewhat greater (ns) than those for ALN. However, for trabecular spine BMD, there were larger increases with PTH compared to either PTH+ALN or ALN. At the femoral neck, DXA BMD increases were greater for ALN than PTH alone and the combination was similar to ALN. However, cortical volume at the hip increased with PTH alone compared to PTH + ALN (or ALN). Large increases in both formation and resorption were seen with PTH while PTH + ALN resulted in slight decreases in both formation and resorption. In summary, changes in hip BMD suggest an advantage of adding ALN to PTH. However, changes in vertebral trabecular BMD, hip cortical volume and bone markers, suggest that concurrent use of ALN may blunt the anabolic effect of PTH. Our data shows no evidence of a synergism between PTH and ALN when used concurrently. Longer term and larger studies are needed to determine if and how antiresorptives should be optimally combined with PTH.

Novel and Selective Small Molecule Stimulators of Osteoprotegerin Expression Inhibit Bone Resorption. R. J. S. Galvin[1], J. E. Onyia[1], Y. L. Ma[1], D. L. Halladay*[1], R. R. Miles*[1], X. Yang*[1], T. Fuson*[1], R. L. Cain*[1], Q. Q. Zeng*[1], S. Chandrasekhar[1], R. Emkey*[1], Y. Xu*[1], K. Thirunavukkarasu[1], H. U. Bryant[1], T. J. Martin[2]. [1]Gene Regulation, Lilly Research Labs, Indianapolis, IN, USA, [2]St. Vincent's Institute of Medical Research, Fitzroy, Australia.

Treatment with osteoprotegerin (OPG) inhibits osteoclastogenesis and bone resorption in numerous animal models for diseases associated with increased osteoclast formation and activity. Since OPG is produced in bone and acts as a paracrine factor, a high-throughput screen (approximately 387,000 compounds) was conducted to identify small molecule stimulators of OPG expression. The compounds were screened in UMR 106 osteosarcoma cells stably transfected with the human OPG promoter (-5917 to +19) fused with β-galactosidase (βgal)-reporter gene (OPG-βgal). Three structurally unrelated molecules (LY359454, LY119863, and LY42584) were identified which selectively increased OPG transcription (OPG-βgal activity following 24 h of treatment). These compounds did not induce βgal activity in UMR 106 cells harboring the SV40 promoter-βgal. In SaOS cells, these compounds increased OPG mRNA levels within 24h, but the time course for onset of OPG activation was compound dependent. Additionally, these compounds increased OPG protein production and release from SaOS cells (2-5 fold following 48 h of treatment), as determined by ELISA. The benzamide derivative, LY359454, was further analyzed and 4 structurally related molecules (LY481736, LY377332, LY54224, LY368571) were identified as OPG inducers. In this class of compounds, LY481736 was the most potent (EC_{50}=4.6 µM in the OPG-βgal assay and EC_{50} =0.25 µM for OPG protein release from SaOS cells) and was examined in functional assays. *In vitro*, LY481736 inhibited osteoclast formation in $1,25(OH)_2D_3$-treated co-cultures of bone marrow and BALC cells (IC_{50}=0.02 µM). Parathyroid hormone (PTH)- induced bone resorption, in a calvarial organ culture model, was also inhibited in a concentration-dependent manner by LY481736. *In vivo*, LY481736 reduced basal bone resorption and completely blocked resorptive activity (serum calcium, osteoclast number) in rats infused subcutaneously with rhPTH (1-38). Furthermore, LY481736 reduced bone tumor burden (number and size following 3 and 4 weeks of treatment) in a rat mammary carcinoma (13762)- induced-bone metastasis model. Finally, periarticular bone loss was reduced by LY481736 in a rat adjuvant arthritis model. These results provide proof of the concept that low molecular weight compounds can enhance OPG production in a manner that could be therapeutically beneficial for the treatment of bone diseases associated with increased bone resorption.

Increased Plasma Homocysteine Concentrations Are Strongly Associated with Increased Risk of Hip Fracture in Elderly Men and Women: The Framingham Study. R. R. McLean[1], P. F. Jacques*[2], J. Selhub*[2], E. J. Samelson[1], K. E. Broe[1], M. T. Hannan[3], L. A. Cupples*[4], D. P. Kiel[3]. [1]Hebrew Rehab Ctr for Aged, Boston, MA, USA, [2]USDA HNRC, Tufts Univ, Boston, MA, USA, [3]Hebrew Rehab Ctr for Aged & Harv Med Sch Div on Aging, Boston, MA, USA, [4]Biostat Dept, BU Sch of Public Health, Boston, MA, USA.

Increased prevalence of osteoporosis among individuals with homocystinuria suggests high serum homocysteine levels may weaken bone by interfering with collagen cross-linking. Thus, individuals with elevated plasma total homocysteine (tHcy) concentration may be at increased risk of osteoporotic fracture. To our knowledge, no studies have investigated the relation between tHcy level and hip fracture (HFx). We examined the association between tHcy concentration and risk of HFx in men and women in the Framingham Study original cohort. Non-fasting blood samples were drawn from 825 men and 1174 women (mean age 70 yr, range 59-91) between 1979 and 1982 and stored at -20ºC. tHcy (µmol/L) was measured by high-performance liquid chromatography with fluorescence detection in 1997. Incident

HFxs were ascertained from time of blood draw through June 1998. Sex-specific age-adjusted incidence rates of HFx were calculated for quartiles (Q1=low, Q4=high) of tHcy. Cox proportional hazards regression was used to calculate hazard ratios (HR) to estimate relative risk of HFx across quartiles (Q1 referent), adjusting for baseline measures: age (yr), height (in), weight (lbs), smoking (cig/d), alcohol consumption (oz/wk), caffeine intake (>2 cup/d: y/n), high school education (y/n) and current estrogen use (y/n) in women. Mean tHcy was 13.4±9.1 and 12.1±5.3 μmol/L for men and women, respectively. Mean follow-up time was 11.1 yr for men and 12.2 yr for women, with 41 and 146 HFx occurring for each gender, respectively. Age-adjusted incidence rates (1000 person-yrs^{-1}) for HFx from Q1-Q4 were 1.96, 3.24, 4.43 and 8.14 for men and 9.42, 7.01, 9.58 and 16.57 for women.

Range of tHcy and Hazard Ratios for Hip Fracture per Quartile of tHcy

	Men		Women	
Quartile	Range (μmol/L)	HR (95% CI)	Range (μmol/L)	HR (95% CI)
Q1 (low)	5.8-9.8	1.00	4.1-8.9	1.00
Q2	9.8-12.0	1.67 (0.54-5.14)	8.9-11.1	0.78 (0.45-1.33)
Q3	12.1-15.0	2.07 (0.70-6.09)	11.2-13.7	1.07 (0.64-1.78)
Q4 (high)	15.0-219.8	3.84 (1.38-10.7)	13.8-59.3	1.92 (1.18-3.10)

Men and women in the highest quartile had a significantly elevated risk of HFx: almost four-fold in men and nearly double in women. These findings suggest that tHcy concentration, easily modifiable through dietary intervention, is an important risk factor for HFx in older populations. Thus, folic acid fortification of grain products may potentially decrease fracture rates in the U.S.

Overweight Protects Against Vertebral Fracture but Increases Risk for Estrogen-Related Cancers: The PERF Study. Y. Z. Bagger, L. B. Tankó, P. Alexandersen, B. J. Riis, C. Christiansen. Center for Clinical and Basic Research, Ballerup, Denmark.

Vertebral bone loss and related fracture are almost exclusively related to estrogen deficiency accompanying the menopause. Body fat mass is an important resource of endogen estrogens in the elderly and overweight tend to be associated with higher bone mineral density (BMD). However, overweight may also increase the risk for estrogen-related cancers. In the present study, we investigated longitudinal associations between baseline body weight and changes in body weight and the incidence of vertebral fractures or the risk for estrogen related cancers.

We followed a group of 2552 healthy postmenopausal Danish women for 7 years. BMD at the spine, hip or forearm were assessed both at baseline and the follow-up using DEXA. Vertebral fractures at the follow-up visit were assessed on digitalized lateral X-rays of the thoracic and lumbar spine. A more than 20% reduction of the vertebral height was considered as a fracture. Non-vertebral fractures were recorded by questionnaire. Cut-off values for the quartiles of baseline weight were 54.3, 62.6, 69.2 and 82.2 kg. Cut-off values for the quartiles of yearly changes in weight were -0.7, -0.1, 0.3 or 1.1 kg/year. Information on the new incidence of breast cancer, uterine cancer and ovarian cancer was collected at the follow-up.

The mean age at baseline was 62.7 years old (years since menopause 14.5 years). In this population, 38.5% of the women had experienced either a vertebral or a non-vertebral fracture. Age-corrected baseline measures of BMD at the spine, hip or forearm were significantly different between the lowest 75th highest quartile of body weight. When comparing women belonging to the highest quartile of body weight (>75th) who showed the largest changes in body weight (>75th, n=181) with those belonging to the lowest body weight (75th quartile) increased the risk for estrogen related cancer to 2.1 compared to the lowest (< 25th) quartile (OR: 2.1, 95% CI, 0.99-4.53, p=0.05).

These results indicate that body fat mass provides an important long-term protection against vertebral fracture, but may increase the risk for breast and genital cancer, emphasizing the potential benefits and risks of being overweight in the elderly age.

A Missense Mutation in FGFR1 Causes a Novel Syndrome: Craniofacial Dysplasia with Hypophosphatemia (CFDH). K. E. White[1], J. M. Cabral*[2], W. E. Evans*[1], S. Ichikawa*[1], S. I. Davis*[1], M. J. Econs[1]. [1]Medicine, Indiana Univ. School of Medicine, Indianapolis, IN, USA, [2]Endocrinology, Cleveland Clinic Florida, Weston, FL, USA.

Craniofacial dysplasia with hypophosphatemia (CFDH) is a novel renal phosphate wasting disorder with a previously undetermined molecular etiology. Here we report a CFDH kindred distinguished by short limb dwarfism (proband stature=40 in.) and brachydactyly, as well as craniofacial deformities, including craniosynostosis, prominent superorbital ridge, and depressed nasal bridge. X-ray analyses revealed shortened humeri, and insufficiency fractures. The skeletal manisfestations of the disorder cosegregated with hypophosphatemia (1.0 mg/dl) secondary to severe renal phosphate wasting (TmP/GFR=0.9 mg/dl), inappropriately low calcitriol concentrations (10 pg/ml or undetectable), normocalcemia, and elevated alkaline phosphatase concentrations. The kindred displayed male to male transmission, indicating an autosomal dominant mode of inheritance. In light of the fact that mutations in FGF23 result in autosomal dominant hypophosphatemic rickets (ADHR) we tested genomic DNA for mutations in the known FGF receptors (FGFR1-5). Direct DNA sequencing of FGFR1 exons revealed that the proband and his father had heterozygous A1115G substitutions in exon 10. This change resulted in replacement of Tyr 372 with a Cys (Y372C) in the extracellular portion of FGFR1. RFLP analysis demonstrated that the A1115G mutation was not present in 880 control alleles. The Y372C allele was transcribed in a CFDH patient's lymphocytes and the mutation creates a seventh, and unpaired extracellular Cys, which may lead to inappropriate coupling and activation of mutant FGFR1. Y372 is conserved between human and mouse FGFR1/Fgfr1, and resides at the site where homologous mutations in FGFR2 and FGFR3 cause neonatal lethal syndromes. We did not detect mutations in FGFR1-5 for index cases of tumoral calcinosis, hypophosphatemic bone disease (HBD), or several isolated adult-onset hypophosphatemias. In summary, CFDH is caused by a single FGFR1 defect that results both in renal phosphate wasting and in impaired vitamin D regulation. ADHR, tumor induced osteomalacia, and CFDH patients share strikingly similar metabolic bone and biochemical disease profiles, thus we hypothesize that FGF-23 signals through FGFR1 to regulate kidney phosphate reabsorption and $1,25(OH)_2$vitamin D_3 production. We conclude that in addition to its known roles in skull and extremity patterning, FGFR1 has essential functions in long bone development, phosphate homeostasis, and vitamin D metabolism.

Serotonin (5-HT) Influences Bone Mass, Size and Strength, but Is not Involved in Mechanotransduction. S. J. Warden*[1], A. G. Robling[2], M. M. Bliziotes[3], C. H. Turner[1]. [1]Orthopaedic Surgery, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Anatomy and Cell Biology, Indiana University School of Medicine, Indianapolis, IN, USA, [3]Oregon Health and Science University/Portland VAMC, Portland, OR, USA.

There is mounting evidence for the central regulation of bone via neural pathways, with possible involvement of neurotransmitters. One transmitter showing potential in modulating bone is serotonin (5-HT). Osteoblasts and osteocytes contain 5-HT transporters (5-HTT), and functional receptors for 5-HT have been identified on osteoblastic cells within the periosteum. 5-HT potentiates the PTH-induced increase in AP-1 activity in UMR cells and modulates the response of osteoblasts to mechanical stimuli. This study compared 5-HTT knockout mice (5-HTT-/-) to wild-type controls (5-HTT+/+) to investigate the impact of 5-HT on bone mass, size and strength, and investigated whether 5-HT is involved in mechanotransduction. The 5-HTT regulates the duration of 5-HT activity with its deletion allowing prolonged 5-HT transmission. 5-HTT-/- mice had lower bone mass compared to 5-HTT+/+ mice. Whole body and femoral BMC were 12.9% and 13.8% lower by DXA, and femoral and tibial midshaft BMC were 14.8% and 14.7% lower by pQCT. At the distal femur 5-HTT-/- mice had 10.9% lower vBMD and 15.4% lower BMC, and at the proximal tibia BMC was 14.4% lower. 5-HTT-/- mice had smaller bones than 5-HTT+/+ mice with femoral and tibial midshaft cross-sectional area being 14.7% and 16.7% lower, and tibial midshaft cortical area being 9.1% lower. The polar second moment of area in 5-HTT-/- mice was 11.9% and 16.9% lower in the femoral and tibial midshaft. Consistent with the lower bone mass and smaller bones, femurs from 5-HTT-/- mice failed in three-point bending at 12.5% lower force and 16.5% lower energy, whereas tibias failed at 20.7% lower force and 20.9% lower energy. Thus, 5-HTT-/- mice had a consistent skeletal phenotype of lower bone mass, size and strength. One possible mechanism for this phenotype is a reduction in skeletal mechanical responsiveness in 5-HTT-/- mice. However, exposing ulnas of 5-HTT-/- and 5-HTT+/+ mice to an identical mechanical stimulus, no influence of genotype was observed on histomorphometric measures of bone formation. Thus, 5-HT does not appear to play a major role in mechanotransduction. Alternative explanations for the observed skeletal phenotype include a direct effect of 5-HT on skeletal biology or indirect effects like genotype differences in physical activity levels. Overall, the results show that deletion of the 5-HTT in mice generates significant skeletal effects, raising questions regarding the potential skeletal effects of widely-used selective 5-HT reuptake inhibitors.

Osteoblast and Osteoclast Isolated and Cultured *In Vitro* from Wild Type and TIEG Null Mice Show Defects in Differentiation. M. Subramaniam[1], G. Gorny*[2], S. A. Johnsen*[1], K. Rasmussen*[1], M. Oursler[2], T. C. Spelsberg[1]. [1]Biochem & Mol Biol, Mayo Clinic, Rochester, MN, USA, [2]Biology, Univ of Minnesota, Duluth, MN, USA.

TGFβ inducible early gene (TIEG) is a member of the Krüppel-like transcription factor family. We have recently demonstrated that TIEG overexpression enhances TGFβ induced Smad signaling by down-regulating negative feedback through the inhibitory Smad7. In order to understand the role of TIEG in bone development, we generated TIEG knockout mice (-/-). TIEG null mice appeared to be normal with normal breeding. Calvarial osteoblasts (OB) were isolated from 3 day old -/- and +/+ pups, cultured these cells *in vitro*, and performed RT-PCR for alkaline phosphatase, Cbfa-1, osteocalcin and osterix gene expression. The -/- OB cells displayed a reduced expression of important OB differentiation markers. The osteoblast cells were then differentiated *in vitro* with BMP-2 for 18 days. The OB from +/+ calvaria displayed several nodules in culture when stained with Alizarin red, whereas the OB from -/- calvaria showed no nodule formation. These -/- calvarial OB appear to have a defect in mediating the signals to differentiate in culture. To characterize the osteoclasts (OC) from +/+ and -/- mice, we isolated OC precursor cells from bone marrow and characterized the interactions between OC precursors and calvarial OB from both -/- and +/+ mice. Bone marrow containing OC precursors were cultured with calvarial OB or ST2 stromal support cells in presence of vitamin D and dexamethazone to generate OC-like cells. Cultures of -/- OC precursors with either ST2 or +/+ OB cells significantly decreased OC differentiation compared with +/+ marrow cells cultured with either support cell type. These data support that there is a defect in OC precursors in -/- mice. Cultures of +/+ OC precursors were cultured with -/- OB also resulted in significantly lower differentiation. Examination of gene expression by real time PCR of the calvarial OB revealed decreased RANKL and increased OPG expression in the -/- calvarial OB compared with +/+ calvarial OB cells. These data suggest that the decreased ability of -/- calvarial cells to support OC differentiation is due to a

decrease in ratio of RANKL to OPG in these cells. To examine TGFβ responses in OC precursors during differentiation, we cultured spleen cells with RANKL and M-CSF during differentiation with and without TGFβ . In +/+ cultures, there was a TGFβ dose-dependent increase in the number of OC, as expected. Interestingly, the -/- OC cells showed no impact of TGFβ on OC differentiation. These data support that TGFβ stimulation of OC differentiation is mediated by TIEG gene expression. We conclude from these data that TIEG expression is critical for OB and OC differentiation *in vivo*.

Receptor Tyrosine Kinase Orphan Receptor 2 (Ror2) Modulates Wnt Signaling Pathways in Osteoblastic Cells. J. Billiard, R. Moran*, D. Way*, P. Bodine. Women's Health Research Institute, Wyeth, Collegeville, PA, USA.

Ror2 is an orphan receptor tyrosine kinase with no known ligand or association with a signaling pathway. Mutations in the Ror2 gene cause severe skeletal defects in humans and mice. Ror2 contains an extracellular cystein-rich domain that has been shown to mediate Wnt binding to other proteins. Using GeneChip and TaqMan analyses of human conditionally immortalized cell lines in discrete stages of osteoblast differentiation, we show that Ror2 is downregulated during human osteoblast differentiation. We also demonstrate that osteoblastic cells stably overexpressing a Wnt antagonist, secreted frizzled-related protein 1 (SFRP1), have significantly less Ror2 than cells expressing the control vector; whereas SFRP1-null mice have 3.5 times more Ror2 than the wild-types.

We used luciferase reporter assays to test if Ror2 modulates Wnt signaling in osteoblasts. Luciferase expression driven by Wnt-responsive TCF binding elements was stimulated over 20-fold after co-transfection of U2OS human osteosarcoma cells with Wnt3. In contrast, co-transfection with Ror2 dose-dependently inhibited Wnt3-induced activation, while Ror2 alone did not affect promoter activity. When the same reporter was activated by Wnt1, Ror2 potentiated Wnt1 activity. SFRP1 suppressed Wnt3 and Wnt1 activity even in presence of Ror2. Thus, Ror2 has opposing effects on Wnt1 and Wnt3 signaling.

We next asked if Ror2 binds Wnts. COS7 cells were transfected with flag-tagged Ror2 and HA-tagged Wnt1 or 3. Anti-flag agarose precipitated both Ror2 and Wnt1 and 3 as shown by western immunoblotting with anti-flag and anti-HA antibodies. The Ror2-Wnt interactions were specific since no Wnts were precipitated out of the extracts not containing Ror2.

To address participation of the Ror2 functional domains in modulating Wnt signaling, we generated Ror2 lacking the cytoplasmic domain. This construct inhibited Wnt3 activity, but had no effect on Wnt1 activation. Based on these results, we believe that Ror2 inhibits Wnt3 signaling by binding Wnt3 and sequestering it away from the frizzled receptor. On the other hand, potentiation of Wnt1 requires the intracellular domain of Ror2, and may involve activation of the Ror2 tyrosine kinase.

In summary, our studies have identified Ror2 as a new regulator of Wnt signaling with selective activities, antagonizing Wnt3 and enhancing Wnt1 mediated transcription in osteoblasts. The downregulation of Ror2 during osteoblast differentiation and its inverse expression pattern with SFRP1 suggest that Ror2 may regulate osteoblast survival and differentiation.

MINT (Msx2-Interacting Nuclear Target) Promotes Runx2-Dependent Transcription via Runx2 Activation Domain 3 (AD3). O. L. Sierra, A. P. Loewy*, N. Charlton-Kachigian*, S. Cheng, D. A. Towler. Bone & Mineral Diseases, Washington University, St Louis, MO, USA.

Msx2 suppresses expression of the late osteoblast phenotypic marker osteocalcin (OC) by inhibiting the assembly of nuclear protein-DNA complexes on the OCFRE, the rat OC FGF2 responsive element (nucleotides –154 to –113). This FGF2-activated promoter region is recognized by the osteoblast transactivator, Runx2, and by Ku antigen and MINT – components of the osteoblast nuclear matrix. Msx2 selectively inhibits Ku and Runx2 association with the OC promoter. However, the role and regulation of MINT (Msx2-interacting nuclear target) in transcription driven by the OCFRE is poorly characterized. Therefore, we studied the effect of MINT on transcription driven by the OCFRE (OCFRE-LUC) in transient co-transfection studies using CV-1 fibroblasts. In one-hybrid analyses, we identify that the major FGF2 – stimulated trans-activation functions reside in the Runx2 component of the OCFRE DNA-protein complex; no intrinsic transactivation functions reside in the nuclear matrix constituents. By generating and analyzing a series of systematically altered Runx2 variants, we show that FGF2 stimulation is dependent upon Runx2 activation domains AD1 and AD2. By contrast, Runx2 AD3 is not required for basal or FGF2-stimulated activity. We next examined the effect of MINT on OCFRE – dependent transcription. Under basal conditions co-expression of MINT has no effect on OCFRE – dependent transcription. By contrast, MINT stimulates Runx2-dependent transcription 4-fold; upregulation is completely dependent upon activated FGFR2 signaling. Runx2 structure-function analyses reveal that MINT-dependent transcription requires Runx2 AD3; although equivalent to full length Runx2 (1-528) under basal and FGF2-stimulated conditions, Runx2(1-528; Δ 307-376) that lacks AD3 cannot functionally interact with MINT to augment OCFRE-dependent transcription. As expected, Msx2 completely abrogates all transcription directed by the OCFRE. In pull-down analyses, Msx2 physically interacts with both MINT and Runx2; interactions with Runx2 require residues 118-256 (Runt domain) and 312-392 (AD3). Taken together, these data indicate that the nuclear matrix protein MINT regulates Runx2-dependent transcription, triggered by FGFR2 activation. Msx2 inhibits OC transcription via protein-protein interactions with the nuclear matrix complex assembled by the OCFRE. Since MINT is homologous to Drosophilan *spen* -- genetically identified as participating in growth factor signaling and homeoprotein-dependent cell specification -- this nuclear matrix protein may biochemically integrate growth factor signaling with stage-specific osteoblast gene expression.

Transcription-Independent Inhibition of Caspases by C/EBPβ in Osteocytes: An Anti-Apoptotic Signaling Cascade Uniquely Activated by Bisphosphonates. L. I. Plotkin, J. I. Aguirre, S. C. Manolagas, T. Bellido. Endocrinology, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. Arkansas for Med. Sci., Little Rock, AR, USA.

The anti-fracture efficacy of bisphosphonates (BPs) may be due in part to preservation of the osteocyte network resulting from prevention of osteocyte apoptosis. This effect of BPs involves opening of connexin (cx) 43 hemichannels and requires phosphorylation of the extracellular signal regulated kinases (ERKs). However, it does not require gene transcription nor the activation of ERK-dependent transcription factors, and it is abolished by restricting ERKs to the nucleus, suggesting that the nuclear pool of ERKs is not involved. We report that, in contrast to ERK activation by growth factors and sex steroids, which results in nuclear ERK accumulation, exposure of MLO-Y4 osteocytic cells to BPs from 2 to 60 min did not induce nuclear accumulation of ERK2 fused to green fluorescent protein. Moreover, BPs prevented apoptosis in cells expressing an ERK2 mutant with impaired nuclear translocation as effectively as in cells expressing wild type ERK2; whereas they were ineffective in cells expressing an ERK2 mutant that constitutively localizes in the nucleus. Taken together, these findings indicate that cytoplasmic ERK substrates mediate the effect of BPs. Previous results have demonstrated that one of these substrates is C/EBPβ, in which phosphorylation of ^{217}Thr by ERKs creates a functional XGluXAsp sequence through which C/EBPβ, binds to and prevents procaspase activation leading to cell survival – independently from its function as a transcription factor. Consistent with the dispensability of nuclear functions of ERKs for the effect of BPs, we found that cells expressing a transcriptionally inactive C/EBPβ mutant were protected from apoptosis by BPs as effectively as cells expressing wild type C/EBPβ. On the other hand, cells expressing a caspase binding deficient mutant in which ^{217}Thr was replaced by Ala were not protected. Notably, cells expressing a C/EBPβ mutant in which the caspase inhibitory site was mimicked by replacing ^{217}Thr by Glu were resistant to apoptosis, even in the absence of BP treatment. Lastly, and consistent with the requirement of cx43 hemichannel opening for survival, BPs induced C/EBPβ phosphorylation in MLO-Y4 osteocytic cells and in embryonic fibroblasts derived from wild type mice that express cx43, but not in embryonic fibroblasts derived from cx43 deficient mice. We conclude that the cx43/ERK pathway activated by BPs promotes osteocyte survival through a novel, transcription-independent mechanism that involves the creation of a functional caspase inhibitory domain in C/EBPβ.

Osteoblastic and Stromal Cell Activation of the PTH/PTHrP Receptor Alters the Bone Marrow Microenvironment and Increases Osteoblastic Expression of the Notch Ligand Jagged1. L. M. Calvi[1], J. Weber*[1], G. B. Adams*[2], J. Harvey*[1], E. Schipani[2], J. E. Puzas[1], H. M. Kronenberg[2], D. T. Scadden*[2], L. A. Milner*[1]. [1]University of Rochester School of Medicine, Rochester, NY, USA, [2]Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

In the bone marrow, hematopoietic stem cells (HSC) are found in close proximity to osteoblastic cells. We recently showed that mice expressing a constitutively active PTH/PTHrP receptor in osteoblastic cells (col1-caPPR) have an increased frequency of HSC. This effect could be reproduced by treating normal stromal cells with PTH (1-34) or by injecting normal mice with PTH. To understand how activation of the PPR in osteoblastic cells could improve their ability to support hematopoiesis, we studied *in vivo* and *in vitro* models of PTH excess. Col1-caPPR mice have a striking increase in trabecular bone and osteoblastic cells, as we previously reported. Consistent with this *in vivo* finding, there was a substantial increase in alkaline phosphatase positive cells in primary stromal cell cultures from col1-caPPR mice compared to normal littermates. This was in part due to a doubling in osteoprogenitor numbers in transgenic vs normal littermates. *In vitro* treatment of normal primary stromal cells with PTH(1-34) also resulted in an increase in alkaline phosphatase positive cells compared to vehicle treated cells. In addition to the increased number of osteoblastic cells, the metaphyseal areas of the long bones of col1-caPPR mice compared to littermates showed a striking increase in sinusoids and PECAM positive endothelial cells. Therefore, osteoblastic PPR activation significantly alters the cellular composition of the bone marrow microenvironment.

We next explored the involvement of the Notch receptors and their ligands Jagged1 and Delta1 in mediating the PTH induced enhanced osteoblastic support of HSCs, since this cell-cell interaction pathway plays a fundamental role in HSC self-renewal and vascular development . By immunohistochemistry, we observed a dramatic increase in osteoblastic Jagged1 protein levels in long bones from col1-caPPR mice compared to normal littermates, while Delta1 protein level was unchanged. Interestingly, the Notch3 protein, which is thought to be important for vascular smooth muscle and endothelial cell homeostasis and survival, was increased in the endothelial cells along the metaphyseal trabecular bone in the transgenic mice.

In conclusion, activation of the PPR in osteoblastic cells increases protein levels of the Notch ligand Jagged1, and alters dramatically the cellular composition of the bone marrow microenvironment. These changes may play an important role in the PTH induced enhanced osteoblastic support of HSC.

Notch 1 Constitutive Activation Induces a Shift from Osteoblastogenesis to Adipogenesis in Marrow Stromal Cells. E. Gazzerro, M. Sciaudone*, L. Priest*, A. M. Delany, E. Canalis. Department of Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA.

Pluripotential mesenchymal cells from bone marrow stroma can differentiate into osteoblasts, adipocytes, chondrocytes and myoblasts. Glucocorticoids induce differentiation of stromal cells toward the adipocytic pathway at the expense of osteoblastogenesis. Notch receptors are a family of single pass transmembrane proteins activated by their membrane-bound ligands, Delta/Jagged**.** Unstimulated osteoblasts express modest levels of Notch 1 and 2, and their transcripts are increased by cortisol. Activation of the Notch signaling pathway regulates the expression of transcription factors involved in terminal differentiation, and is essential for adipocyte formation. To investigate the effects of Notch 1 constitutive activation on the differentiation of marrow stromal cells, we used a retroviral system to overexpress Notch 1 intracellular domain (NIC) in a murine stromal cell line (ST-2). NIC overexpression was confirmed by Northern blot analysis, and by the increased activity of a HES-5 promoter construct, known to be induced by Notch. Compared to ST-2 cells transduced with vector alone, overespression of NIC abolished the ability of bone morphogenetic protein 2 to stimulate their osteoblastic differentiation. These cells had decreased type I collagen and osteocalcin mRNA and did not form mineralized nodules. Further, ST-2 NIC presented decreased levels of deltafosB and delta2deltafosB, transcription factors that favor osteosblastogenesis at the expense of adipogenesis. In ST-2, cortisol precludes osteoblast differentiation and induces the expression of the adipocytic markers. NIC overexpression enhanced the positive effect of cortisol on adipocytic makers and accelerated the formation of mature fat cells. In conclusion, Notch 1 constitutive activation in marrow stromal cells causes a shift from osteoblastogenesis to adipogenesis, an action similar to that observed with glucocorticoid excess. Notch 1 receptor could play a role in enhancing cortisol effects on marrow stromal cell differentiation.

Cbl-Dependent Ubiquitination of Src Proteins Induced by Constitutive FGFR-2 Activation Results in Src Downregulation and Increased Osteoblast Differentiation. K. Kaabeche*[1], J. Lemonnier*[2], J. Caverzasio[2], P. Marie[1]. [1]Biology and Pathology of Bone, INSERM U349, Paris, France, [2]Division of Bone Diseases, Geneva, Switzerland.

We previously showed that constitutive activation of FGFR-2 induced by the activating S252W mutation in Apert syndrome results in increased expression of osteoblast differentiation genes (ALP, COLIA1). Here we examined the role of Src in osteoblast differentiation induced by the activating FGFR-2 mutation. Western blot analysis in immortalised human Apert (Ap) calvaria osteoblastic cells bearing the activating S252W FGFR-2 mutation revealed decreased expression and phosphorylation of Src proteins (Lyn, Fyn) compared to normal age-matched control (Co) calvaria cells, in basal culture conditions and in the presence of FGF-2 (50 ng/ml). In contrast, Src mRNA levels were similar in Ap and Co cells. Biochemical analysis confirmed that Src kinase activity was 50% lower in Ap cells compared to Co cells. Lysophosphatidic acid (LPA, 20 nM, 48 hrs), a non specific activator of Src, decreased ALP mRNA levels and activity in Ap cells. UK 14,304 (20 µM, 48 hrs), a specific Fyn stimulator, also inhibited ALP activity in Ap cells, whereas COLIA1 mRNA levels were unaffected. Transient transfection of Ap cells with Fyn or Lyn vectors reduced ALP activity without change in COLIA1 mRNA levels, further showing a role for Fyn and Lyn in the increased ALP activity induced by FGFR-2 activation in Ap cells. We hypothesized that Fyn or Lyn down-regulation in FGFR-2 mutant osteoblasts may result from increased ubiquitination via the proteasome. Lactacystin (10 µM, 48 hrs), a specific proteasome inhibitor, restored Fyn expression and ALP activity in Ap cells, indicating that the increased ALP activity induced by the mutation results from increased Fyn ubiquitination and proteasome degradation. The proto-oncogene Cbl has recently emerged as a ubiquitin ligase for Src. We examined wether Cbl may be involved in Fyn ubiquitination in Ap osteoblasts. Immunoprecipitation studies showed that Fyn associated with Cbl was decreased in Ap cells compared to Co cells, indicating that Cbl interacts with Fyn to promote Fyn ubiquitination. These data show that 1) constitutive activation of FGFR-2 leads to downregulation of Fyn and Lyn protein levels and kinase activity in mutant osteoblasts; 2) overexpression of ALP in mutant osteoblasts results in part from downregulation of Fyn induced by FGFR-2 activation and 3) Fyn downregulation results from increased Cbl-dependent Fyn ubiquitination. Thus, Cbl-dependent ubiquitination of Src proteins induced by FGFR-2 activation mediates in part the increased osteoblast differentiation induced by the Apert FGFR-2 mutation in human osteoblasts.

BMP Signaling through the Smad1 Pathway Is Required for Normal Postnatal Bone Formation. D. Chen[1], M. Qiao*[1], B. Story*[1], M. Zhao[1], Y. Jiang[2], J. Zhao[2], J. Feng[3], Y. Xie*[3], S. Huang*[4], A. Roberts*[4], G. Karsenty[5], G. Mundy[1]. [1]University of Texas Health Science Center, San Antonio, TX, USA, [2]University of California, San Francisco, CA, USA, [3]University of Missouri, Kansas City, MO, USA, [4]NIH, Bethesda, MD, USA, [5]Baylor College of Medicine, Houston, TX, USA.

The physiological role of BMP signaling in bone formation in post-natal life remains undefined. Since null mutations of the Smad1 and Smad5 genes cause perinatal lethality, it is not possible to use these mice to investigate this issue. To determine the role of the BMP signaling pathway, and specifically its dependence on Smad1, in postnatal bone formation, we have used 2 genetic murine models: 1) A tissue-specific, Cre-mediated recombination was achieved in mice to specifically disrupt Smad1 expression in osteoblasts; and 2) transgenic mice were produced in which a truncated dominant-negative BMP receptor (dnBMPR) is targeted to osteoblasts by the 2.3 kb type I collagen promoter. We generated mice for a floxed Smad1 allele, in which exon 2 of the Smad1 gene was flanked by loxP sites. Smad1-loxP (Smad1$^{flox/wt}$) mice were bred with Cre transgenic mice in which Cre recombinase is driven by the 2.3 kb type I collagen promoter (Col1a1-Cre). Col1a1-Cre$^{+/-}$;Smad1$^{flox/wt}$ mice were then bred with Smad1$^{flox/flox}$ mice to generate mice with osteoblasts lacking the Smad1 gene (Col1a1-Cre$^{+/-}$;Smad1$^{flox/flox}$ mice or Smad1 conditional knockout [cko] mice). The Smad1 cko mice are viable and survive into adulthood. Trabecular bone volume, osteoblast numbers and bone formation rates in proximal tibiae were reduced 27, 38 and 44%, respectively in Smad1 cko mice compared with control littermates (Col1a1-Cre$^{+/-}$;Smad1$^{flox/wt}$ and Col1a1-Cre$^{-/-}$;Smad1$^{flox/flox}$ mice). 3D micro CT examination showed that in tibiae and femora of Smad1 cko mice, trabecular volume, number, thickness, and connectivity density were decreased and trabecular separation was increased. The formation of mineralized bone nodules in long-term cultures of primary osteoblasts was decreased in Smad1 cko mice. mRNA expression of Smad1 was detected in osteoblasts in trabecular bone by in situ hybridization and protein expression of Smad1 was detected in primary osteoblasts by Western blot in control mice. In Smad1 cko mice, expression of Smad1 mRNA and protein was undetectable in osteoblasts *in vivo* and *in vitro*. In the dnBMPR transgenic mice, there was an identical phenotype to that observed in the Smad1 cko mice, namely blockage of BMP signaling, decreased trabecular bone volume and decreased bone formation rates. These results demonstrate that Smad1 is necessary for normal postnatal bone formation and suggest that BMPs exert their effects on bone formation through the Smad1 signaling pathway.

Subnuclear Targeting Supports Functional Interrelationships between Runx2 and the BMP-2 Regulated Smad 1 Protein. F. Afzal, S. K. Zaidi, A. Javed, A. J. van Wijnen, J. L. Stein*, J. B. Lian, G. S. Stein. Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA.

The coordinated activity of Runx2 and BMP/TGFbeta-activated Smads is critical for osteoblast differentiation. The Runx2 C-terminus which is essential for its osteogenic function in vivo, contains a 38 amino acid nuclear matrix targeting signal (NMTS) that directs Runx2 to active subnuclear foci to form stable complexes. Furthermore, the subnuclear trafficking of Smads to Runx foci requires interaction with Runx2. However, the precise structural basis for this Runx2-Smad interaction has not been resolved. We have carried out studies to define the sequence required for Smad interaction by generating sequential C terminal deletion mutations of wild type Runx2 protein (aa 1-528) and constructing two internal deletions of the NMTS domain. Functional cooperation between the BMP2 responsive Smad1 and Runx2 wild type and mutant proteins was determined using a luciferase reporter under the control of a promoter with multiple copies of Smad and Runx responsive elements. Our data show 90% reduction of BMP-mediated transcriptional activity of mRunx2 1-432 that retains the NMTS domain, when co-expressed with Smad1 in HeLa cells which lack endogenous Runx expression. However, Smad1-mRunx2 1-432 complexes can still be formed, as determined by co-immunoprecipitation studies. In situ immunofluorescence also revealed that Smad1 was targeted to subnuclear foci in the presence of Runx2 1-432. Further deletion of the C-terminus to 361 amino acids, which lacks the NMTS, results in a complete loss of transcriptional activity when co-expressed with Smad1 and loss of complex formation at subnuclear sites. These data suggest that the Smad functional activity resides largely in the C-terminus and overlaps the NMTS. Internal deletions of the NMTS region of Runx2 abrogate association with subnuclear foci and transcriptional activity is significantly reduced by 2-3 fold. Notably, Smad1 interaction with these Runx2 mutants is retained in the nucleus by in situ and by co-immunoprecipitation studies. These findings indicate that the Smad interacting domain overlaps the NMTS and that the NMTS interaction site is a significant component for the transcription mediated by the Runx2 complex. Thus, in conclusion, these biochemical and in situ nuclear trafficking studies provide conclusive evidence for the temporal-spatial requirement of the NMTS of Runx2 for interaction with Smad for biological activity.

The Transcription Factor STAT-1 Is a Novel Negative Regulator of Bone Mass and Bone Formation. L. Xiao[1], T. Naganawa*[1], E. Abogunde*[1], G. Gronowicz[2], J. D. Coffin[3], M. M. Hurley[1]. [1]Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]Orthopedic, University of Connecticut Health Center, Farmington, CT, USA, [3]Pharmaceutical Sciences, University of Montana, Missoula, MT, USA.

Signal transducers and activators of transcription (STATS) play a central role in the biological responses to a number of cytokines and growth factors. Growth hormone, FGF2, IL-6, MCSF and Interferon γ are important factors that regulate bone cell function that also activate STAT1-dependent DNA binding activity. However, there are no studies on the role of STAT1 in bone formation. To assess the role of STAT1 in bone, we examined wild type Stat1 (+/+) and homozygous Stat1 null (-/-) male mice that are maintained on an inbred 129S6/SvEv background. Body wt and femur length were similar in 13-14 week old Stat1+/+ and Stat1-/- mice. Western blot analysis confirmed the absence of the 92 kDa STAT1 protein in bones from Stat1-/- mice. Bone mineral density (BMD) and bone mineral content (BMC) were determined by DEXA analysis of femoral and vertebral bones from 13-14 week old mice of both genotypes. Femoral BMD was significantly increased by 17% and BMC was increased by 10% in Stat-/- mice when compared with Stat1+/+ mice. Verte-

bral BMC was also significantly increased by 19% in Stat1-/- mice compared with +/+ mice. Micro-computed tomography revealed a marked increase in cortical width of femurs of Stat1-/- mice. As determined by the Structure Model Index, there was significantly more plate like structure of trabecular bone in femoral metaphysis of Stat1-/- mice. There was a 15% increase in trabecular thickness (0.0672±0.00 vs 0.0573+0.00 p<0.05) in Stat1-/- mice but trabecular number was not increased when compared with Stat1+/+ mice. Bone volume/trabecular volume was increased in the Stat1-/- mice compared with bones from Stat1+/+ mice (18.4± 0.025 vs 12.2 ± 0.019). Preliminary histomorphometry of distal femurs showed that osteoblast surface/bone surface (34.5 ± 2.0 vs 19.2 ± 4.2 p< 0.05) and mineralized surface/ bone surface (23.4 ± 1.4 vs 17.5 ± 0.01 p< 0.05) was significantly increased in Stat1-/- compared with Stat1+/+ mice. There were no significant differences in osteoclast number or osteoclast surface/bone surface. In addition calvarial width was significantly increased by 28% in Stat1-/- mice compared with Stat1+/+ mice. These data suggest that STAT1 is a negative regulator of bone mass and bone formation in mice. It is likely that STAT1 is a novel important transcription factor in osteoblast function. Characterization of the role of STAT-1 in bone may have implications for the development of therapeutic targets for treatment of metabolic bone disorders.

Sost **Tissue Expression and Regulation of Wnt Signaling.** M. Shen*[1], D. S. Miao[2], D. Goltzman[2], A. C. Karaplis[1]. [1]Medicine, SMBD-Jewish General Hospital, McGill University, Montreal, PQ, Canada, [2]Medicine, MUHC, McGill University, Montreal, PQ, Canada.

The *SOST* gene encodes a protein that is mutated in patients with sclerosteosis. Loss of function of SOST leads to the formation of massive amounts of normal bone throughout life, implicating suppression of bone formation as its most likely physiological role. Therefore, this protein might become an important tool in the development of therapeutic strategies for osteoporosis.

To further explore SOST function, murine *Sost* cDNA encompassing the entire coding region was cloned from mouse kidney total RNA by PCR. Digoxigenin labeled sense and antisense riboprobes were generated from a 151-bp *Sma*I *Sost* fragment and used for *in situ* hybridization of E-15.5 embryo and 2-month-old adult mouse sections. *Sost* mRNA expression was observed in keratinocytes, kidney tubular epithelial cells, skeletal muscle, growth plate chondrocytes and in bone, where it localized specifically in osteoblasts and osteocytes.

The tissues that express *Sost* are also known sites for *Wnt* gene expression. Wnts are secreted glycoproteins that exert their effects on neighboring cells by binding to the Frizzled (Fz) transmembrane receptor family. Single-pass transmembrane proteins of the LDL receptor-related protein family (LRP5 and -6,) have also been implicated in the reception of the Wnt signal, a key pathway involved in various developmental processes, including osteoblast proliferation and function. Therefore, we next examined whether interplay exists between Sost and Wnt signaling. For these experiments, cultured C3H10T1/2 murine mesenchymal cells were co-transfected with a luciferase reporter gene construct containing Tcf/Lef transcription factor binding site sequences and either Sost expression vector or empty vector alone. Following transfection, the cells were treated with Wnt-3A and luciferase activity was measured. Wnt-3A strongly potentiated Tcf/Lef-mediated luciferase gene transcription (>5-fold) while no activation was observed when the Tcf binding sites were mutated. In the presence of Sost expression, Wnt-mediated transcriptional activation was markedly impaired, thereby identifying Sost as a potent inhibitor of Wnt action.

Based on these observations, it is likely that in the absence of SOST, WNT activity in inducing osteoblast proliferation and function continues unabated, leading to the progressive sclerosing bone dysplasia of sclerosteosis.

High Bone Mineral Density in SOST Knock-out Mice Demonstrates Functional Conservation of Osteocyte Mediated Bone Homeostasis in Mouse and Human. N. Sun*, Y. Gao*, J. Pretorius*, S. Morony, P. J. Kostenuik, S. Simonet, D. L. Lacey, I. Sarosi*, C. Kurahara*, C. Paszty*. Metabolic Disorders, Amgen Inc., Thousand Oaks, CA, USA.

In humans, complete lack of the protein sclerostin due to homozygosity for null mutations in the SOST gene is responsible for causing sclerosteosis, a rare genetic disease characterized by increased bone mineral density (BMD) throughout the skeleton. Sclerostin is a secreted protein and has been previously shown to be expressed in bone by osteocytes, to bind bone morphogenetic proteins (BMPs) and to inhibit osteoblast differentiation/function in cell culture. Based on these genetic and biochemical data a novel bone homeostatic pathway in humans has been proposed in which osteocytes, by secreting sclerostin, negatively modulate osteoblast mediated bone anabolic activity.

To determine the effect of a complete lack of sclerostin in mice we have generated knock-out mice homozygous (-/-) for a deletion of the SOST gene. The -/- mice appear normal compared to controls and are fertile. Qualitative radiographic assessment of 4-month old male and female -/- mice showed normal bone morphology but with a generalized increased radiodensity in all portions of the skeleton (skull, axial skeleton, ribs, pelvis, long bones) as compared to wild-type (+/+) littermates. Peripheral quantitative computed tomography of tibia from -/- mice showed a statistically significant increase in total BMD (38%), trabecular BMD (66%), cortical BMD (22%) and cortical area (56%) as compared to +/+ littermates.

This high bone mineral density phenotype in mice recapitulates the major clinical feature found in humans with sclerosteosis, and demonstrates functional conservation of sclerostin secretion by osteocytes as an important component in the control of bone homeostasis in mouse and human. As such, these sclerostin knock-out mice should serve as a useful tool for gaining a deeper understanding of the basic biology surrounding this novel pathway, as well as it's therapeutic potential in the anabolic treatment of osteoporosis.

Smurf2-Mediated Loss of TGF-β Signaling Stimulates Articular Chondrocyte Maturation. Q. Wu, M. J. Zuscik, J. F. Baden*, E. M. Schwarz, H. Drissi, R. J. O'Keefe, J. E. Puzas, R. N. Rosier. Orthopaedics, University of Rochester, Rochester, NY, USA.

Cartilage within diarthroidal joints is maintained by articular chondrocytes (ACs) which produce matrix and are prevented from undergoing terminal maturation. During osteoarthritis (OA), unknown maturational constraints are lost and ACs recapitulate the differentiation process that occurs during normal endochondral ossification. The aims of this study were to identify these unknown maturational constraints and to define the molecular processes at work during inappropriate stimulation of AC hypertrophy. To address these aims, we developed a cell culture model utilizing 5-azacytidine (Aza) to induce maturation in cultured chick ACs. Aza is known to un-mask expression of silenced genes by replacing cytidine in the DNA, thus blocking the suppressive effect of cytidine methylation on gene transcription. ACs, which do not spontaneously express markers of chondrocyte maturation such as indian hedgehog, type X collagen (colX) or alkaline phosphatase, were induced to express all three of these markers by a 48 hr exposure to 15 μg/ml Aza. Since it is a well established paradigm that TGF-β strongly suppresses chondrocyte maturation, we investigated whether Aza-induction of AC maturation may be due to a loss of TGF-β signaling. We tested this hypothesis i) by comparing Aza effects with those induced by blocking signaling through the TGF-β Smads (2 and 3) using a dominant negative (Δ) approach, ii) by examining the impact of Aza on the expression of Smad2 and 3 and the ubiquitin E3 ligase Smurf2, a protein that targets Smad2 and 3 for degradation, and iii) by measuring the rate of Smad2 and 3 degradation following Aza treatment by using metabolic labeling and ubiquitin immunoprecipitation methods. We found that over-expression of ΔSmad2 or ΔSmad3 mimics Aza by inducing expression of the hypertrophic marker colX. Furthermore, Aza-treated ACs display reduced Smad2 and 3 and increased Smurf2 protein levels. Finally, Aza mimics Smurf2 by ubiquitinating and degrading Smad2 and 3. These results indicate that AC maturation is caused by Smurf2-induced degradation of Smad2 and 3 and raise the possibilty that Smurf2 up-regulation during OA may be an initiator of the disease process. This is supported by immunohistochemical studies which demonstrate that Smurf2 protein expression is significantly increased in human OA cartilage relative to normal cartilage controls. We conclude that AC maturation is induced by Smurf2-dependent loss of TGF-β signaling, suggesting that inhibition of Smurf2 function may represent a novel therapeutic approach for treatment of OA.

Overexpression of the Novel Collagen Triple Helix Repeat Containing Gene (CTHRC1) Indicates a Role in Cartilage and Bone Formation via Regulation of BMP Expression. V. Lindner*[1], P. Pyagay*[1], D. P. Moore*[1], M. L. Mancini*[1], T. N. Wight*[2], L. Liaw*[1]. [1]Center for Molecular Medicine, Maine Medical Center Research Institute, Scarborough, ME, USA, [2]Vascular Biology, The Hope Heart Institute, Seattle, WA, USA.

The purpose of the present study was to understand the function of the novel gene Cthrc1 using both in vitro and in vivo approaches.

Transgenic mice overexpressing Cthrc1 were generated and analyzed using established methods. Routine cell transfection procedures were used to establish CTHRC1 overexpressing and CTHRC1 depleted cell lines.

CTHRC1 is a secreted 26.5kDa protein that is glycosylated and highly conserved from lower chordates to mammals. The sequence contains a short collagen domain which prompted the name 'collagen triple helix repeat containing 1'. Cthrc1 mRNA expression is regulated by TGF-ß family members. Localization of CTHRC1 protein showed remarkable overlap with known sites of bone morphogenetic protein (BMP) expression, such as in the bone matrix and at epithelial-mesenchymal interfaces in the skin and chorioid plexus. In the mouse embryo, CTHRC1 was abundant in the developing heart, proliferating chondrocytes and in the surrounding periosteum. Immunoreactive CTHRC1 was abundant in the bone matrix where it was expressed by osteocytes and osteoblasts. In transgenic mice overexpressing Cthrc1, a striking lack of Alcian blue staining of cartilagenous structures was observed, particularly noticeable in the spinal column indicating a lack of cartilage proteoglycan content and this was confirmed by ultrastructural analysis. The axial skeleton was particularly affected with defects in neural tube closure. Other symptoms included dwarfism, brittle bones, reduction in bone marrow cells and detachment of the epidermis. Downregulation of CTHRC1 in MC3T3-E1 osteoblasts was associated with loss of BMP4 expression in these cells whereas overexpression of CTHRC1 in C3H10T1/2 cells was accompanied with increased BMP4 levels. Furthermore, in co-transfection experiments BMP4 promoter activity was significantly increased in the presence of CTHRC1. Increased levels of BMP4 and the downstream target Msx1, known to be involved in axial development, were also increased in skeletal tissues of Cthrc1 transgenic mice.

In conclusion, we identified Cthrc1 as a novel gene with important functions in cartilage and bone formation, most likely by regulating BMP mediated signaling events.

Role of Reg Growth Factors and Receptor in Osteoarthritis Pathogenesis. A. Moreau[1], D. Wang*[1], S. Jacques*[1], M. Rosec*[1], M. Lacroix*[1], C. Chassaing*[1], J. Martel-Pelletier*[2], J. Fernandes*[3]. [1]Stomatology and Biochemistry, Université de Montréal, Montréal, PQ, Canada, [2]Pharmacology, Université de Montréal, Montréal, PQ, Canada, [3]Surgery and Biomedical Sciences, Université de Montréal, Montréal, PQ, Canada.

The key features of osteoarthritis (OA) are the focal destruction of the articular cartilage and the abnormal growth of the subchondral bone producing outgrowths. Since in humans OA develops and changes very slowly, it is difficult to follow that disease over any length of time. Besides that, the heterogeneity of the disease results in controversy as its aetiology and progression. Thus, study of early events of the degenerative process cannot be made in humans and recourse must be made to animal models. We have recently inactivated the transcription factor Pitx1, which is highly expressed in articular and growth plate chondrocytes during mouse development. Pitx1-null mice displayed poorly developed joints, which are markedly apoptotic. Interestingly, Pitx1+/- mice that are phenotypically normal at birth, exhibit with aging clinical features of OA such as progressive joint stiffness associated with an abnormal fibrillation and calcification of their articular cartilage. Histological analysis of mineralized adult femurs and tibiae revealed also an increased thickening of subchondral, trabecular and cortical bone.
At the molecular level, expression analysis of Pitx1-null and Pitx1+/- mice allowed to identify and characterize a novel molecular cascade involved in OA pathogenesis. Indeed, expression analysis using RNA isolated from articular cartilage of patients with OA and age and gender-matched subjects showed the expression of Pitx1 only in matched controls. Moreover, the lack of Pitx1 in OA articular chondrocytes leads to a marked up regulation of Reg I growth factor and its receptor, which has been confirmed at the protein level by immunohistochemistry assays with human Reg I antibodies on OA articular cartilage. We have also demonstrated *in vitro* that the gain-of-function of Reg receptor enhances by several folds the activation of NF-κB induced by TNF-α or IL-1β suggesting that Reg signaling activity is a key mediator of pro-inflammatory cytokine action in OA pathogenesis. This was further supported by the fact that gain-of-function of Pitx1 abrogates Reg I, Reg II and Reg receptor expression completely, which may explain why pro-inflammatory cytokines cannot activate NF-κB in cells devoid of Reg receptor. Taken together these results revealed the role of new emerging transcription and growth factors involved in OA pathogenesis, which could lead to a more rational approach for the development of better therapeutic compounds to prevent and cure OA.

Soluble VEGF Isoforms Are Essential to Establish Vascularization of Cartilage Elements and Regulate Development and Survival of Growth Plate Chondrocytes. C. Maes*[1], I. Stockmans*[1], K. Moermans*[1], R. Van Looveren*[1], N. Smets*[1], P. Carmeliet*[2], R. Bouillon[1], G. Carmeliet[1]. [1]Laboratory of Experimental Medicine and Endocrinology, Katholieke Universiteit Leuven, Leuven, Belgium, [2]The Center for Transgene Technology and Gene Therapy, V.I.B., Katholieke Universiteit Leuven, Leuven, Belgium.

Vascular endothelial growth factor (VEGF) exists as 3 major isoforms, VEGF120, VEGF164 and VEGF188, which differ in matrix- and receptor-binding. Inhibition of VEGF or expression of only the soluble VEGF120 isoform resulted in impaired bone vascularization associated with reduced trabecular bone volume and an enlargement of the hypertrophic chondrocyte zone of the growth plate.
Here we report that neonatal mice that express exclusively VEGF164 showed no bone abnormalities. However, mice expressing only the matrix-associated isoform VEGF188 (VEGF188/188 mice) showed dwarfism, completely disrupted growth plate development and severe knee joint dysplasia. Developmental analysis of VEGF188/188 mice demonstrated increased and ectopic hypoxia in the epiphyseal cartilage elements, preceding massive apoptosis of immature chondrocytes in the interior of the growth plates. Although metaphyseal angiogenesis was not altered, vascularization surrounding the epiphysis was impaired likely causing the increased hypoxia. Concomitantly, peripheral growth plate chondrocytes showed increased proliferation and decreased differentiation in vivo. In agreement, VEGF188/188 hindlimbs cultured in hypoxic conditions lacked growth inhibition and showed increased apoptosis in the resting chondrocyte zone as compared to WT limbs. Because expression of both VEGF and the isoform-specific VEGF164 receptor neuropilin-1 was detected in immature growth plate chondrocytes, VEGF164 may directly regulate cellular proliferation and survival in hypoxic cartilage. However, abnormal expression of genes of the parathyroid hormone-related peptide (PTHrP) - Indian hedgehog (Ihh) pathway was observed in VEGF188/188 mice suggesting an indirect effect of VEGF. These findings indicate that the insoluble VEGF188 isoform is insufficient to establish an epiphyseal vascular network that meets the oxygen needs of cartilage elements in growing bones, resulting in increased hypoxia. Additionally, our data provide in vivo and in vitro evidence for a previously unknown role for VEGF isoform-specific signalling, regulating chondrocyte development. We conclude that the integrated actions of the three VEGF isoforms are essential to couple metaphyseal and epiphyseal vascularization, chondrocyte development and ossification during endochondral bone formation.

Specific Role of Indian Hedgehog in Bone versus Cartilage *in vivo*. A. Eichbichler*[1], D. W. Soegiarto*[2], C. Carr*[1], T. Kobayashi[3], A. P. McMahon*[4], T. L. Clemens[5], B. Lanske[1]. [1]Oral and Developmental Biology, HSDM and Forsyth Institute, Boston, MA, USA, [2]Munich Biotech AG, Neuried, Germany, [3]Endocrine Unit, MGH, Boston, MA, USA, [4]The Biolabs, Harvard University, Cambridge, MA, USA, [5]Div. of Endocrinology, Univ. of Cincinnati, Cincinnati, OH, USA.

Mice lacking the Indian hedgehog gene (Ihh) survive only until birth and exhibit markedly reduced chondrocyte proliferation, abnormal chondrocyte maturation, and absence of mature osteoblasts. Since Ihh is expressed in chondrocytes as well as in osteoblasts, current animal models do not allow us to distinguish whether Ihh has a direct effect on osteoblasts or whether the effects on bone are indirectly mediated through chondrocytes during endochondral ossification. Furthermore, the postnatal function of Ihh is still unclear. We have generated mice using the *cre*-loxP/*flp*-frt gene technology which will allow us to specifically ablate, *in vivo*, the Ihh gene from several types of cells in the chondrocyte and osteoblast lineage, providing a way to uncover the exact role of Ihh in cartilage versus bone. We have established six independent floxed Ihh mouse lines (derived from J1 and R1 ES cell clones) and mated them to several *cre* transgenic mouse lines. Offspring from matings to the ubiquitously expressed *cre* transgenic animals driven by the phosphoglycerate-kinase I-(PGK-1) promoter resembled the phenotype of the conventional Ihh ko animals and established that we had efficient excision of the floxed Ihh gene by the *cre* recombinase. Breeding to collagen type I- and osteocalcin– *cre* transgenics have been performed as well. These mice selectively lack Ihh function in osteoblasts of varying degrees of maturity, and allow us to define the role of Ihh in osteoblasts independent of chondrocytes. Collagen type I-*cre* and osteocalcin-*cre* conditional Ihh ko animals survive postnatally, have shorter long bones and weigh slightly less. Serum ionized calcium levels do not show any major differences. Histological and μCT evaluation of bone density and microarchitecture are in progress. These novel mouse models should allow us to uncover the specific role of Ihh in cartilage versus bone, and this new information will provide a more secure framework for understanding Ihh regulation of chondrocyte and osteoblast development and activity.

Combination of SOX5, SOX6 and SOX9 Is Sufficient for Chondrogenesis. T. Ikeda*[1], H. Kawaguchi[2], S. Kamekura*[2], I. Kou*[1], K. Hoshi[2], K. Nakamura*[2], S. Ikegawa*[1], U. Chung[2]. [1]Riken SNP Res. Ctr., Tokyo, Japan, [2]Tissue Engineering & Orthopaedic Surgery, Univ. of Tokyo, Tokyo, Japan.

To better understand skeletal development and devise treatment for irreversible cartilage damage requiring cartilage regeneration such as osteoarthritis, it is essential to know both the requisite and sufficient conditions for chondrogenesis at molecular levels. Although recent genetic studies have shown the necessity of SOX5, 6 and 9 for chondrogenesis *in vivo*, it is still unknown whether they are sufficient for chondrogenesis or other factors are also needed. To address this question, we expressed various combinations of SOX5, 6 and 9 in a variety of primary and immortalized cells by adenovirus vectors, and cultured them in serum-free medium without known chondrogenic supplements such as insulin, BMP and TGF-ß. Co-expression of SOX5, 6 and 9 (the SOX trio) started to induce differentiation of human mesenchymal stem cells (hMSC) into chondrocytes within 2 days; they expressed cartilage-specific mRNAs of type II, IX, XI collagens, aggrecan, chondromodulin-1, and matrilin-3 as well as cartilage-specific matrix by histology, to a level comparable to articular cartilage and chondrocytic cell lines within 2 weeks. Expression of SOX9 alone induced chondrogenesis to a much lesser extent, while that of SOX5 and/or 6 completely failed to do so. The SOX trio differentiated embryoid bodies derived from mouse ES cells into chondrocytes. Even cells committed to other lineages could be differentiated into chondrocytes: non-chondrogenic human immortalized cell lines HeLa, HEK293, HuH-7, and primary human dermal fibroblasts. Some non-chondrogenic cells responded to expression of SOX9 alone, but the response was correlated with endogenous expression levels of SOX5 and 6, further supporting the essential role of the SOX trio. Although the best efficiency of differentiation was achieved in 3-dimensional culture on atelocollagen gel, the SOX trio induced substantial chondrocytic differentiation even in monolayer culture, which is usually hostile to chondrogenesis. Contrary to the conventional methods, the SOX trio inhibited marker genes for hypertrophic chondrocytes and osteoblasts such as type I & X collagens, bone sialoprotein, Runx2, and osteopontin. A single application of the SOX trio adenovirus to a cortical bone defect in the mouse tibia produced a substantial cartilage within 1 week, while the LacZ virus failed to do so. These lines of evidence strongly suggest that the SOX trio is not only necessary but also sufficient for chondrogenesis both *in vitro* and *in vivo*. Rapid and potent induction of permanent cartilage from hMSC and dermal fibroblasts by transduction of the SOX trio may innovate cartilage tissue engineering.

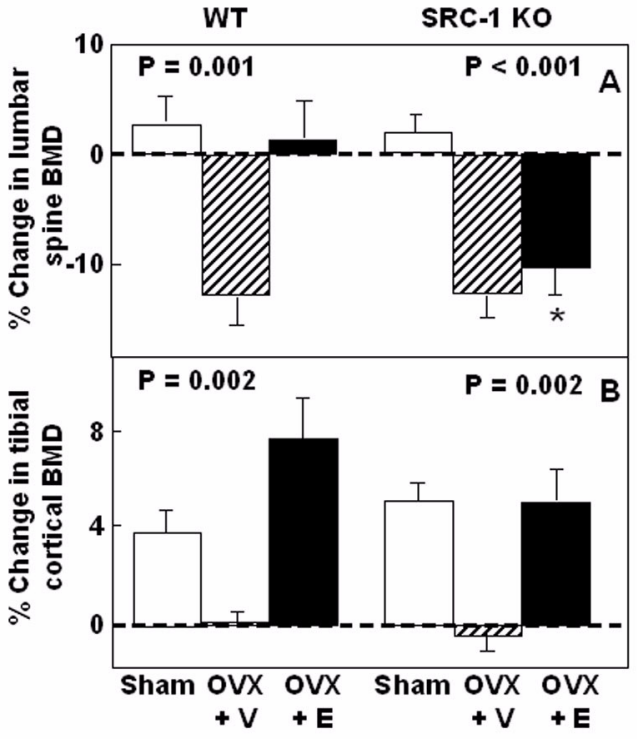
Steroid Receptor Coactivator (SRC)-1 Knockout Mice Have an Impaired Response to Estrogen in Cancellous but not in Cortical Bone. U. I. L. Moedder[1], B. L. Riggs[1], A. E. Kearns[1], A. Sanyal[1], J. D. Sibonga[2], J. Xu*[3], B. W. O'Malley*[4], T. C. Spelsberg[5], S. Khosla[1]. [1]Endocrinology, Mayo Clinic, Rochester, MN, USA, [2]Orthopedic Research, Mayo Clinic, Rochester, MN, USA, [3]Department of Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX, USA, [4]Department of Molecular and Cellular Biology, Baylor College of medicine, Houston, TX, USA, [5]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA.

SRC-1 is an important nuclear receptor coactivator that enhances estrogen (E) action in many tissues, but its role in mediating E effects on bone is unknown. We recently demonstrated that in osteoblastic cells, SRC-1 potentiates the activity of co-expressed ER-α/β or ER-β alone, with little or no potentiation of ER-α. Since cancellous bone contains both ER-α and -β, whereas cortical bone contains predominantly ER-α (JCEM 86:2309, 2001), we tested whether E action on bone would be impaired primarily in cancellous bone in SRC-1 knock out (KO) mice. Initial dose ranging studies in wild type (WT) C57BL/6 mice established an estradiol (E_2) dose of 10 μg/kg/d as the minimal physiologic E dose needed to prevent bone loss. Next, 3 month old WT and SRC-1 KO mice underwent either sham surgery, ovx with vehicle (V), and ovx with a 10 μg/kg/d E_2 pellet for 60 days (n = 9-11 per group). BMD was measured at baseline and the end of the study by DXA and pQCT. While this dose of E completely prevented loss of cancellous bone at the spine in WT mice, it was entirely ineffective in the SRC-1 KO mice (Panel A; P-values are for within strain ANOVAs; *P < 0.02 for comparison with WT, ovx + E group). However, E effects on cortical bone at the tibia were similar in the SRC-1 KO and WT mice (panel B). Bone histomorphometry confirmed the BMD measurements. Consistent with previous studies, we also found by RT-PCR that in mice, cancellous bone (at the vertebrae) contained both ER-α and -β, whereas only ER-α was detectable in cortical bone (at the femur shaft). We thus conclude that SRC-1 deficiency impairs the skeletal response to E in cancellous but not in cortical bone. We hypothesize that this may be due to the relative expression of ER-β versus -α in cancellous and cortical bone and the specific interactions of SRC-1 with these receptor isoforms in bone cells. Moreover, similar to mice, variations in SRC-1 levels or function may also determine the skeletal response to E in cancellous bone in humans.



Disclosures: ***U.I.L. Moedder****, None.*

Recombinant hCG, but not DHT Stimulates Osteoblastic Collagen Synthesis in Older Men with Partial Age-Related Androgen Deficiency. C. Meier[1], P. Y. Liu*[2], L. P. Ly*[2], J. de Winter-Modzelewski*[1], M. Jimenez*[2], D. J. Handelsman*[2], M. J. Seibel[1]. [1]Bone Research Program, ANZAC Research Institute, University Sydney, Concord NSW, Australia, [2]Department of Andrology, ANZAC Research Institute, University Sydney, Concord NSW, Australia.

The relative contributions of androgens and estrogens on bone metabolism are still controversial. Within the setting of two double-blind, placebo-controlled studies, we evaluated the effect of DHT and recombinant human chorionic gonadotropin (rhCG) on bone turnover in healthy, community-dwelling older men with partial androgen deficiency (total testosterone [TT] ≤15 nmol/l twice).In the first study, 35 men (mean age 68.3±6.8 yrs, mean baseline TT 13.9±3.3 nmol/l) were randomized to receive either daily transdermal DHT gel (Andractim, Lab. Besins-Iscovesco; 70 mg; n=17) or placebo for 3 months. In the second study, 40 men (mean age 67.4±5.4 yrs, mean baseline TT 11.4±2.2 nmol/l) were randomized to receive either twice weekly rhCG sc (Ovidrel, Serono; 5000 IU; n=20) or placebo for 3 months. The following parameters were measured in serum before, at monthly intervals and 1 month after treatment: Aminoterminal propeptide of type I procollagen (PINP), osteocalcin (OC), carboxyterminal crosslinked telopeptide of type I collagen (ICTP), free (FT) and total testosterone, estradiol (E2), LH, and FSH. Compared to placebo, treatment with DHT resulted in a significant increase of serum DHT (15-20 nmol/l above baseline), paralleled by a suppression in LH, FSH, TT and FT, but not in E2 levels. Markers of both bone formation (serum PINP and OC) and bone resorption (serum ICTP) remained unchanged throughout the study. In contrast, administration of rhCG induced a significant rise in TT, FT and E2 levels. In these men, a significant rise of PINP levels with a max. increase after 1 month (p=0.02 compared to placebo) was observed, while serum levels of OC and ICTP did not change. The change in PINP (ΔPINP) was independent of baseline FT, TT and E2 levels, but correlated with the change in E2 levels (r=0.59, p=0.02). No significant association was found between ΔPINP and ΔTT (r=0.20, p=0.68) or ΔFT (r=0.40, p=0.14).
We conclude that in healthy older men with age-related androgen deficiency, pharmacological DHT doses suppress TT and FT without altering E2 levels or bone metabolism consistent with enhanced aromatization or direct DHT effects via androgen receptor (AR) to maintain stable bone turnover. In contrast, rhCG stimulates osteoblastic collagen formation proportional to increased blood estradiol without changing bone resorption. We conclude that while estradiol has prominent effects on bone in older men, direct AR-mediated androgen effects cannot be excluded.

Disclosures: ***C. Meier****, None.*

Estrogen Prevents Bone Loss by Direct Targeting of TNF Producing $CD4^+$ Lymphocytes, and $CD4^+$ Dependent Regulation Of $CD8^+$ Activation. G. Toraldo[1], Y. Gao[1], W. Qien[2], K. Dark[2], M. Weitzmann[2], R. Pacifici[2]. [1]Division of Bone and Mineral Diseases, Washington University, St. Louis, St. Louis, MO, USA, [2]Division of Endocrinology, Emory University School of Medicine, Atlanta, GA, USA.

A key mechanism by which ovariectomy (ovx) induces bone loss is by expanding the population of TNF producing T cells via stimulation of T cell activation and proliferation. However, the involved T cell sub-populations remain unknown. FACS analysis of the spleens and bone marrow from sham operated mice demonstrated that ~ 40 % of both $CD4^+$ and $CD8^+$ T cells produce TNF. Ovx induced a ~ 2 fold expansion in both $CD4^+$ and $CD8^+$ T cells, although, no change in the % of TNF producing cells within each group was observed. Thus both $CD4^+$ and $CD8^+$ contribute to the enhanced TNF production of ovx mice. However, as there are ~ twice as many $CD4^+$ as $CD8^+$ T cells, TNF is mostly $CD4^+$ derived. To investigate how estrogen (E) regulates $CD4^+$ and $CD8^+$ populations, T cell deficient nude mice were reconstituted with either $CD4^+$ or $CD8^+$ by means of adoptive transfer of $CD4^+$ or $CD8^+$ cells harvested from intact WT mice, and then ovx or sham operated. Effective engraftment of was verified by FACS at 4 weeks after transplantation. Transplanted nude mice were found to contain 6-8 fold higher numbers of $CD4^+$ or $CD8^+$ T cells compared to non-transplanted nude controls, a number equal to ~ 50 % of that of normal WT mice. In vivo BrdU incorporation studies revealed that ovx induced a ~ 2.5 fold increase in the proliferation of both $CD4^+$ and $CD8^+$ cells in WT mice. Likewise, nude mice reconstituted with $CD4^+$ T cells showed enhanced T cell proliferation in response to ovx. In contrast, ovx failed to activate T cell proliferation in $CD8^+$ reconstituted nude mice, suggesting that activation of $CD8^+$ T cells requires signals generated by $CD4^+$ cells. This hypothesis was confirmed by in vivo bone density measurements by DEXA. We found nude mice to be completely protected against ovx induced bone loss, while WT controls lost ~10 % of their bone density in 4 weeks after ovx. In nude mice reconstituted with $CD4^+$ T cells ovx elicited a ~8 % bone loss ($p<0.05$), while sham operation was followed by a non significant ~2% increase in BMD. In contrast, ovx failed to induce bone loss in nude mice reconstituted with $CD8^+$ T cells as their BMD at 4 weeks after ovx was unchanged from baseline. We conclude that ovx regulates TNF production by $CD4^+$ T cell by directly inducing activation and proliferation of these lymphocytes. In contrast, CD8 activation is a secondary event induced by $CD4^+$ lymphocytes. Although, $CD4^+$ T cells are responsible for the majority of TNF production and ovx induced bone loss, $CD8^+$ cells contribute to this process by producing additional TNF as a result of signaling between $CD4^+$ and $CD8^+$ cells.

Osteopenia and Impaired Fracture Healing in the EP4 Receptor Knockout Mice. M. Li, D. R. Healy*, Y. Li*, H. A. Simmons, D. T. Crawford*, H. Z. Ke, L. C. Pan, T. A. Brown, D. D. Thompson. Cardiovascular and Metabolic Diseases, Pfizer Global Research and Development, Groton, CT, USA.

Prostaglandin E_2 (PGE_2) is a known bone anabolic agent and it binds to 4 receptor subtypes, EP1-EP4. In vitro and animal studies have suggested that the EP4 receptor subtype plays a critical role in PGE_2's bone anabolic effects. However, its role in the maintenance of bone mass and fracture healing is not known. Therefore, the studies reported here were designed to address this issue by characterizing the skeletal phenotype of EP4 receptor knockout (KO) mice and by comparing fracture healing in KO mice with wild type (WT) mice. Male EP4 KO and strain-matched WT mice at 15 to 16 months of age were used in these studies. There were no significant differences in body weights and femoral length between KO and WT mice. Lower bone mass was seen radiographically in both axial and

long bones of KO mice relative to WT mice. Micro-CT images of the distal femurs showed thinner cortices, fewer trabeculae, and deteriorated trabecular network in KO mice. The pQCT analysis showed significant decreases in total mineral content (-27%), trabecular content (-24%) and cortical content (-25%) of the distal femoral metaphyses in KO mice compared with WT controls. Histomorphometric measurements of the distal femoral metaphyses showed that trabecular bone volume, trabecular number, trabecular thickness, mineralizing surface, and bone formation rate were significantly decreased and osteoclast number was significantly increased in KO mice compared with WT mice. These data indicate that knocking out the EP4 receptor results in decreased bone formation and increased bone resorption, leading to loss of cancellous and cortical bone mass. To investigate whether EP4 receptor plays a role in fracture healing, KO and WT mice were subjected to transverse femoral fracture under general anesthesia. The fracture healing was examined by radiography and histomorphometry at 1, 2, 3, and 4 weeks after fracture. Callus formation was significant delayed as evidenced both radiographically and histologically in the fractured femurs of KO mice compared with those of WT mice. Histological measurements of fracture calluses showed significant decreases in total callus area and bony callus area by 31% and 43% at 2 weeks, and by 68% and 77% at 3 weeks, respectively, in KO mice compared with WT mice after fracture. By 4 weeks, complete bony bridging was seen in WT mice but not in KO mice. Our data demonstrate that the absence of EP4 receptor decreases bone mass and impairs fracture healing in mice. This finding suggests that the EP4 receptor is a positive regulator in the maintenance of bone mass and fracture healing.

A Crucial Role for Thiol Antioxidants in Estrogen-Deficiency Bone Loss. J. M. Lean*, J. T. Davies*, K. Fuller, C. J. Jagger*, B. Kirstein*, G. A. Partington*, Z. L. Urry*, T. J. Chambers. Cellular Pathology, St George's Hospital Medical School, London, United Kingdom.

The mechanisms through which estrogen prevents bone loss are uncertain. In several other tissues, the beneficial effects of estrogen on lipids, endothelial cells and neurons are considered to occur through suppression of oxidant stress. Although high levels of reactive oxygen species (ROS) damage cells, lower levels serve as signaling molecules, and the ROS hydrogen peroxide stimulates osteoclastic bone resorption. Thus, estrogen might prevent bone loss by increasing antioxidant defenses in bone. We therefore tested the effects of ovariectomy and estrogen on the antioxidant defenses of rodent bone marrow. We found that glutathione and thioredoxin, the major thiol antioxidants, and glutathione and thioredoxin reductases, the enzymes responsible for maintaining these in a reduced state, fell substantially after ovariectomy. Levels were rapidly normalized by replacement doses of exogenous 17β-estradiol, but not by the inactive stereoisomer 17α-estradiol. To test whether these altered thiol antioxidant levels were causally related to bone loss, we administered N-acetyl cysteine (NAC) or ascorbate, antioxidants that increase tissue glutathione levels, or L-buthionine-(S,R)-sulphoximine (BSO), a specific inhibitor of glutathione synthesis, to mice. NAC and ascorbate abolished ovariectomy-induced bone loss. In contrast, BSO administration provided a phenocopy for estrogen-deficiency: it decreased bone marrow glutathione, increased osteoclast number and caused substantial bone loss.
The osteoclast is a prime candidate as target for antioxidant-mediated regulation, because osteoclastic function is dependent upon NFκB, which is regulated by ROS. We therefore tested the effects of estrogen on the thiol antioxidant system in osteoclasts. We found that 17b-estradiol strongly stimulated glutathione and thioredoxin reductases and glutathione in osteoclast-like cells in vitro.
Expression of cytokines such as IL-1, TNFα and IL-6, that have been shown to be crucial for the bone loss of estrogen-deficiency, is enhanced by ROS-mediated activation of NFκB. We found that NAC prevented activation of NFκB in osteoclasts. BSO did the opposite. Moreover, 17b-estradiol suppressed expression of TNFα and IL-1 in osteoclasts in culture. These observations strongly suggest that estrogen deficiency causes bone loss by lowering thiol antioxidants in osteoclasts, which leads to ROS-enhanced activation of NFκB and the expression of resorptive cytokines in osteoclasts, thereby promoting osteoclastic resorption while simultaneously impairing osteoblastic function.

Spatial Mediation of Intracortical Resorption. K. A. King*, N. A. Rabaia*, Z. Zhang*, S. Srinivasan, T. S. Gross. Orthopaedics, University of Washington, Seattle, WA, USA.

Intracortical resorption induced by disuse is highly focused within specific portions of the cortex, but the mechanism underlying this phenomenon is unknown. Recently, we have found that osteocytes upregulate the extracellular matrix protein osteopontin (OPN) in response to disuse and direct oxygen deprivation. Given the role of OPN in osteoclast chemotaxis, we hypothesized that intracortical resorption is temporally preceded by spatially co-localized elevations in osteocyte OPN expression. We assessed the validity of this hypothesis with a series of experiments ranging from the molecular to tissue levels. First, we used semi-quantitative competitive RT-PCR to assess the time course of OPN mRNA elevations in osteocyte-like MLO-Y4 cells exposed to direct oxygen deprivation for up to 24 hr. Normalized to β-actin expression, OPN mRNA was elevated 40% following 6 hr and 104% by 24 hr of oxygen deprivation compared to control normoxic cells. Next, we used image analysis to assess the spatial distribution of intracortical resorption sites induced by 6 wks of disuse in the midshaft of adult male turkey ulnae (n=3). Two sites of interest were identified, the first demonstrating a minimal number (mean + S.E.) of intracortical resorption events (central caudal cortex; 0.3 + 0.3), while the second site demonstrated profound intracortical resorption (cranial/ventral cortex; 20.3 + 1.8). We then turned to immunohistochemistry and confocal microscopy to assess osteocyte OPN expression in ulnae exposed to either 1 d (n=2) or 7 d (n=3) of disuse. Previously, we have found that approximately 16% of osteocytes stain positive for OPN in intact control bones. In the caudal cortex of bones exposed to disuse, 25.8 + 6.9% of osteocytes stained positive for OPN expression. In contrast, 48.2 + 12.9% of osteocytes demonstrated OPN expression in the cranial/ventral cortex. In summary, osteocytes rapidly upregulated OPN mRNA expression within a few hours of exposure to hypoxia. Within days, disuse induced osteocyte OPN upregulation in a spatially non-homogenous manner. Critically, specific locations of minimal and maximal osteocyte OPN expression observed at 1 and 7 d of disuse (prior to intracortical resorption) corresponded with the locations of minimal and maximal intracortical resorption observed following 6 wk of disuse. We conclude that these data support our initial hypothesis across a time scale ranging from hours to weeks and speculate that osteocyte OPN expression can be used to predict specific locations of intracortical resorption. As a result, it may be possible to identify novel strategies to minimize intracortical resorption, a disproportionate contributor to the degradation of bone strength associated with bone loss pathologies.

Mechanical Loading Induces the Expression of Wnt Pathway Genes and Activation of the Wnt Pathway in Osteoblasts Enhances Loading Responses. J. Robinson[1], M. Chatterjee-Kishore*[2], C. Li*[2], V. Gironda*[1], P. Green*[1], F. Bex[1]. [1]Women's Health Research Institute, Wyeth Research, Collegeville, PA, USA, [2]Genomics Division, Wyeth Research, Cambridge, MA, USA.

Increases in bone mass in response to skeletal loading is an important adaptive response which ensures the integrity of bone under vigorous physical stress. However, the molecular events that translate a mechanical stimulus into a biological response are not clear. Mechanical stress has been shown to induce genes including nitric oxide synthase (eNOS), cycloxygenase-2 (COX2) and prostacyclin synthase (PTGS). Low density lipoprotein receptor related protein (LRP) 5 and the Wnt/B-catenin pathway have recently been shown to play an important role in bone metabolism and have been implicated in the response of bone cells to stress. Therefore we designed experiments to determine whether mechanical loading could regulate Wnt/B-catenin related genes and whether activation of the Wnt/beta-catenin pathway could further modulate the expression of known stress responsive genes. Using a Flexercell strain (FX-3000) instrument, we applied mechanical strain (3,400 microstrain, 2Hz, 7200 cycles/hr) for 5 hrs to MC3T3 cells and analyzed by real time PCR the gene expression of known stress responsive genes as well as Wnt/B-catenin related genes immediately post-load or 24 hr post-load. The application of strain on MC3T3 cells elicited a significant induction of COX-2, eNOS, PTGS, connexin 43, jun, c-fos, cyclin D1, Wnt 10B and secreted frizzled related protein 1 (SFRP1) expression compared to non-loaded controls. We next tested whether activating the Wnt pathway in an osteoblast prior to applying a mechanical load would have a synergistic effect on gene expression following a loading stimulus. In these experiments, MC3T3 cells were treated with a glycogen synthase kinase-3β inhibitor (GSK3i) to increase B-catenin nuclear translocation and thereby activate the canonical Wnt/B-catenin pathway. Immediately following GSK3i administration, the cells were subjected to load (3,400 microstrain, 2Hz, 7200 cycles/hr) for 5 hrs. The GSK3β inhibitor treatment resulted in increases in COX-2 (3X), eNOS (3X), connexin 43 (2X), jun (3X), c-fos (3X), cyclin D1 (2X), Wnt 10B (2X) and SFRP1 (3X) above the load response alone.
In summary, these experiments further support the effects of mechanical load on the expression of genes known to influence osteoblast growth and differentiation and now show that transcriptional activation of Wnt/B-catenin pathway genes may also be involved in a loading response. Additionally, our data suggest that activation of the canonical Wnt/B-catenin pathway in osteoblasts makes cells more responsive to a loading stimulus.

Mechanical Strain Differentially Regulates eNOS and RANKL Expression via ERK1/2 in Primary Bone Stromal Cells. J. Rubin, T. C. Murphy*, L. Zhu*, E. Roy*, M. S. Nanes, X. Fan. Medicine, VAMC & Emory University, Decatur, GA, USA.

Complex interactions between signals controlling both osteoblast and osteoclast functions are ultimately responsible for the adaptive response of the skeleton to its loading environment. We here evaluate the cellular response to mechanical input in terms of 2 signals which affect bone coupling, nitric oxide (NO) and RANKL. NO, released after mechanical stimulation from many cell types, has been implicated in both repression of osteoclast activity and stimulation of osteoblast function. In mature bone, NO is generated from endothelial nitric oxide synthase (eNOS). In contrast, RANKL expression promotes resorption. We have previously shown that straining bone stromal cells diminishes RANKL expression via ERK1/2 activation. Here we found that application of 2% strain (BioFlex, Flexcell) to primary murine stromal cultures increased NO secretion and eNOS expression as measured by real-time PCR. iNOS was unchanged. The effect of strain on eNOS was magnitude-dependent increasing to 161 ± 28% that of control eNOS (see figure). Concurrently, 0.25% strain significantly inhibited RANKL expression with increased repression at 1% strain (44 ± 3% cf with controls). Both responses to strain were blocked when an ERK1/2 inhibitor was present during strain application. To confirm ERK1/2's central role, cells were treated with an adenovirus encoding constitutively active MEK (Ad.caMEK). Ad.caMEK increased basal ERK1/2 activation resulting in increased eNOS expression and NO production by >4-fold and decreased RANKL expression by half. In contrast, inhibition of JNK failed to prevent strain effects. Thus we have shown that strain has a magnitude-specific ability to control two genes in entirely divergent directions. For the coordinate regulation of eNOS and RANKL, the mechanical effect relies on activation of ERK1/2. The divergent gene expression resulting from ERK1/2 activation suggests that the final regulatory result is determined by recruitment of specific co-regulators. In total, in

vitro strain represents a paradigm for understanding how loading the skeleton results in positive bone remodeling.

VEGF-Mediated Angiogenesis Is a Key Event for Exercise-Induced Bone Gain. Z. Yao*[1], M. Lafage-Proust[1], J. Plouët*[2], C. Alexandre[1], L. Vico[1]. [1]Lbto, INSERM E366, Fac Med, St Etienne, France, [2]CNRS UMR 5089, Toulouse, France.

Appropriate physical training is able to increase bone mass and strength. But its mechanism remains unclear. Although increased capillary supply during training-induced muscle hypertrophy is well described, no parallel mechanism was studied in bone. Among vasoactive factors, VEGF has multi-functional activities on wall vessel cells and is an osteoblastic growth factor. We hypothesized that bone vascular and VEGF changes are involved in bone remodelling alteration leading to increased bone mass. Nine-week male Wistar rats underwent treadmill training experiment at 60% of their VO2max. (regimen showed to be osteogenic after 5 weeks, Bourrin et al., JBMR 1995). Exercise-induced BMD changes were assessed longitudinally by Dexa and bone cellular activities and vessel number and area - after India ink/barium sulphate infusion - were analyzed by histomorphometry (n=8/group) in tibial metaphyses. VEGF and Flt1/R1 and KDR/R2 receptor expressions in tibia were evaluated by on line RT-PCR (n=6/group). We tested several running period durations: 14 and 10 days, and 5 weeks. In the latter experience, a VEGF inhibitory antibody (RUN-anti-VEGF) or a placebo (RUN) was administrated IP twice a week. Results obtained in running rats were compared to those of sedentary rats (SED). After a 14d. running period metaphyseal vessel number increased by 20% in RUN vs. SED ($p<0.05$), this increase was associated with an increased bone formation rate ($p<0.001$) and a decreased active resorption surfaces ($p<0.03$), while trabecular bone mass had not changed yet. Mineralizing surfaces positively correlated with vessel number ($r= 0.85$, $p<0.001$) in running rats. A 10-day training period induced an up-regulation of VEGF (153%) and Flt1 (83%, $p<0.01$) in the tibial periosteum and metaphysis while KDR expression increased not significantly. After a 5-week training period, metaphyseal tibial BMD did increase by 9% in RUN rats only vs. SED. Cancellous bone mass increased by 21% in RUN compared to RUN-anti-VEGF and SED groups ($p<0.03$). Anti-VEGF antibody also prevented the increase in vessel number observed in RUN tibial metaphysis (25%, $p<0.02$ vs. SED). In RUN group, bone formation rate resumed at this time while osteoclastic surfaces continued to decline (22%, $p<0.05$) as compared to both SED and RUN-anti-VEGF. We showed that an osteogenic exercise regimen induced an early VEGF expression increase in bone tissue, followed by an increased cancellous vessel network which was associated to bone remodelling uncoupling. These bone and vascular events preceded the exercise-induced increase in bone mass and are fully prevented by a VEGF antagonist.

PTH Replaces Cancellous Bone Lost During 28 Days of Hindlimb Unloading in Skeletally Mature Rats. S. A. Bloomfield[1], M. R. Allen[1], H. Lemmon*[2], H. A. Hogan[2]. [1]Dept of Health & Kinesiology, Texas A&M University, College Station, TX, USA, [2]Dept of Mechanical Engineering, Texas A&M University, College Station, TX, USA.

Skeletally mature rats subjected to 28 days of hindlimb unloading (HU) experience a significant loss of proximal tibia bone mineral density (BMD) and plantar flexor muscle strength. Although muscle strength recovers within 14 days of reambulation, there is no sign of BMD recovery through 28 days. The purpose of this study was to evaluate the effectiveness of daily PTH (1-34; 80µg/kg/day) administration on the recovery of bone parameters following 28 days of HU. Six-month-old male Sprague Dawley rats were divided into 3 groups: 28 day HU (HU; n=4), 28 day HU + 28 day recovery with vehicle (VEH; n=8) and 28 day HU + 28 day recovery with PTH (PTH; n=8). Both recovery groups received daily subcutaneous injections for 28 days during recovery from HU. In vivo peripheral quantitative computed tomography (pQCT; Stratec, Research M) scans of the proximal tibia metaphysis, providing total and cancellous bone mineral density (BMD), were obtained at baseline, after 28 days of HU (R+0), and at recovery days 14 (R+14) and 28 (R+28). In vivo peak isometric torque (ISO) and mass of plantar flexor muscles were obtained at sacrifice. VEH- and PTH-treated groups both had non-significantly higher body mass at R+28 compared to HU (+11 and 14%, respectively). After HU (R+0), there was a significant loss of total and cancellous BMD (-7 and 9%, respectively). At R+14, total and cancellous BMD of VEH-treated animals (544 ± 14 and 223 ± 10 mg/cm^3, respectively) remained similar to R+0 values while PTH-treated animals significantly increased both total and cancellous BMD (635 ± 17 and 257 ± 6 mg/cm^3, respectively) to baseline levels. By R+28, BMD of VEH animals remained at R+0 levels while values had significantly increased over baseline values in PTH-treated animals (+11 and 21% for total and cancellous BMD). Muscle mass was significantly greater in both VEH and PTH groups compared to HU (+37 and 29%, respectively) while ISO was non-significantly higher (+3 and 4%, respectively). A subset of bones (n=2/gp) were analyzed ex vivo using microCT (EVS, Explore RS) at the same location as studied by pQCT. PTH-treated animals had significantly higher cancellous BV/TV (+ 141%), accounted for by higher trabecular thickness (+ 33%) and number (+ 83%), compared to VEH-treated animals; there was no difference between HU and VEH-treated values. These data demonstrate that daily PTH injections significantly enhance the recovery of unloading-induced decrements in bone density, apparently due to significant increases in cancellous bone volume.

Genetic Variations Regulate Bone Loss and Gene Expression Related to Skeletal Unloading. M. Squire[1], L. Donahue[2], C. Rubin[1], S. Judex[1]. [1]Biomedical Engineering, SUNY Stony Brook, Stony Brook, NY, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

The influence of the genome on the skeleton is highlighted not only by variations in bone morphology but also by a differential sensitivity to altered levels of mechanical loading. Using genetically distinct strains of inbred mice, we previously demonstrated that *female* BALB/cByJ (BALB) mice are highly sensitive to their mechanical environment (losing up to 60% of femoral trabecular bone in 3wk) while trabecular and cortical bone of C3H/HeJ (C3H) mice is less responsive. Here, we subjected *male* adult BALB and C3H mice (16wk old, n=10 each) to hindlimb unloading to determine the influence of genetics and gender on the magnitude of bone loss and to investigate whether alterations in bone morphology are paralleled by changes in the expression of candidate genes. After 21 days of unloading, indices of bone morphology in the distal femur were assessed via high-resolution (11 µm) micro computed tomography scanning (µCT). Total RNA was extracted from the proximal tibia (including bone marrow and cartilage, n=4 each) and relative changes in gene expression (normalized to GAPDH) were determined using real-time reverse transcription polymerase chain reaction. In stark contrast to our previous data from female mice, male BALB mice subjected to hindlimb unloading did not lose trabecular bone from the distal femoral metaphysis, yet C3H mice lost 22% ($p<0.03$) of metaphyseal trabecular bone. Additionally, both male BALB and C3H mice lost significant amounts of epiphyseal trabecular bone (23% and 15%, respectively, $p<0.008$), but loss of functional weight bearing did not produce changes in metaphyseal cortical bone of either strain. At the molecular level, hindlimb unloading down-regulated the expression of collagen type I (α1) by 23% ± 13% (mean ± SE) in BALB mice. Expression levels of bone morphogenic protein 2 (BMP-2) and receptor activator of NF-κB ligand (RANKL) were also lower in disuse BALB than in controls (31% ± 18% and 18% ± 12%, respectively). In C3H males, however, collagen I expression levels were not different between disuse and control mice, while BMP-2 and RANKL expression levels were 25% ± 9% and 26% ± 19% higher, respectively, in disuse mice. These data indicate a strong influence of genetics and gender on both the susceptibility of bone to disuse osteoporosis and the specific sites within bone that are most heavily affected. The differential expression of genes involved in bone formation and resorption further demonstrate the strain specificity of bone's response to unloading. The future exploration of the underlying molecular and genetic basis may enable the early identification of individuals most likely to suffer from osteoporosis based on their genotype.

Rest-Insertion Augments Periosteal Bone Formation Rates in Response to Short-Term High-Frequency Loading. J. M. LaMothe*[1], G. M. Peters*[1], T. S. Gross[2], S. Srinivasan[2], R. F. Zernicke[3]. [1]Faculty of Kinesiology, University of Calgary, Calgary, AB, Canada, [2]Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, WA, USA, [3]Faculties of Kinesiology, Medicine, and Engineering, University of Calgary, Calgary, AB, Canada.

High-frequency vibrations can stimulate bone growth, and insertion of short rest periods between consecutive loading cycles may also augment bone formation rates. Thus, we investigated if rest-insertion increased bone growth in response to short-term high-frequency loading in the mature murine skeleton. Right tibiae of skeletally mature (16 wk) female C57BL/6 mice were loaded in cantilever bending at 800 µ (*in vivo* strain gauge calibration; CV = 14%), 30 Hz, 5 d/wk for 3 wk. Mice were randomized into one of two groups: continuous high-frequency (HF) stimulation for 100 s (n = 9), or 1-s pulses of high-frequency stimulation followed by 10 s of rest (rest inserted = RI) for 100 s (n = 9). Upon completion of the 3 wk loading protocol, mice were allowed 4 d of cage ambulation before euthanization. Calcein injections were administered on days 1 and 21; label incorporation was used histomorphometrically to assess (blinded) periosteal bone formation rate (BFR) with bone surface as a referent. Pilot data showed that anaesthesia and immobilization in the loader did not alter indices of bone formation, and that the contralateral limb suitably represented the normal control situation. Non parametric Mann Whitney tests identified differences between groups, and Wilcoxon tests identified differences between left and right limbs ($p < 0.05$). All values were represented as means ± standard deviation. HF stimulation alone significantly increased BFR (0.43 ± 0.20 µm/day) compared to the

contralateral control limb (0.13 ± 0.10 μm/day). Similarly, RI loading significantly ($p < 0.05$) increased BFR (0.76 ± 0.31 μm/day) compared to the contralateral control limb (0.35 ± 0.19 μm/day). BFR in response to RI loading was significantly increased compared to HF loading (77%; $p < 0.05$). Thus, short-term, moderate-magnitude high-frequency loading augmented periosteal bone formation rates in skeletally mature female C57BL/6 mice. Furthermore, high-frequency stimulation was more osteogenic if applied in short pulses with intermittent rest periods, despite a ten-fold decrease in the absolute number of loading cycles. Optimization of osteogenesis in response to exogenous loading may underpin the development of non-pharmacological regiments designed to increase bone strength in individuals with compromised bone structures.

The COMT Val158Met Polymorphism Is Highly Associated with Maturation and Musculoskeletal Growth in Early Pubertal Girls. A. L. Eriksson[1], M. Suuriniemi[2], A. Mahonen[3], S. Cheng[2], C. Ohlsson[1]. [1]Centre for Bone Research at the Sahlgrenska Academy (CBS), Department of Internal Medicine, Göteborg University, Göteborg, Sweden, [2]LIKES-Foundation for Sport and Health Sciences and Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland, [3]Department of Medical Biochemistry, University of Kuopio, Kuopio, Finland.

Estrogen plays a vital role in the growth of adolescents. Catechol-O-Methyltransferase (COMT) is a key enzyme in the degradation of estrogens. A functional polymorphism in the COMT gene (val158met) decreases the activity of the enzyme by 60-75%. The aim of the present study was to investigate the influence of the COMT polymorphism on maturation and growth in early pubertal Finnish girls.

246 healthy 10-12 year old girls in Tanner stage 1-3 were genotyped for the COMT val158met polymorphism. They were classified as homozygous for the low activity genotype ($COMT^{LL}$), heterozygous ($COMT^{HL}$) or homozygous for the high activity genotype ($COMT^{HH}$). The relationship between COMT genotype and height, bone phenotype, hormone levels and pubertal development was investigated.

Girls with $COMT^{LL}$ were 5,4 cm taller than girls with $COMT^{HH}$ and 2,4 cm taller than $COMT^{HL}$ (p ANOVA = 0,001). DEXA measurements showed an increase in BMC and bone area in total body, femur neck, total femur, and L2-L4 spine in $COMT^{LL}$ compared to $COMT^{HH}$. $COMT^{HL}$ was an intermediate group. No major effect was seen on aBMD. pQCT measurements of the tibia showed an increased BMC in $COMT^{LL}$. This was due to an increased cross sectional cortical area which in turn was caused by an increased periosteal circumference. No influence was seen on cortical or trabecular vBMD suggesting that the effects were caused by an increased longitudinal and radial growth.

$COMT^{LL}$ had higher levels of free estradiol and serum IGF-1, and they were more likely to be in Tanner stage 2 or 3 than $COMT^{HH}$. Statistical regression models indicated that the effects of COMT genotype on bone parameters were exerted via a regulation of estrogen and/or IGF-1. The COMT genotype also influenced cross sectional muscle area. The effect on cortical bone vanished when the muscle area was included in a linear regression model suggesting that the COMT effect on cortical bone is mediated via increased muscle mass.

In conclusion the COMT polymorphism is highly associated with height, cortical bone mass and pubertal development in early pubertal girls. Most of these effects can be explained by altered estradiol and IGF-1 status. We propose that a low activity COMT phenotype results in increased estradiol levels which in turn increase the activity in the GH/IGF-1 axis, resulting in increased longitudinal and radial bone growth and earlier pubertal development.

Risk Factors for Upper Limb Fracture in Children: A Population Based Case-Control Study. D. Q. Ma, G. Jones. Menzies Research Institute, Hobart, Australia.

Fractures in younger life are very common especially those involving the upper limb. However, the causes of these fractures are poorly understood. The aim of this population based case-control study was to evaluate the association of both bone dependent and independent factors with upper limb fracture risk in children 9-16 years of age. Areal (aBMD) and apparent (BMAD) bone mineral density were measured by dual energy X-ray absorptiometry (DXA). Skeletal age (SA) and metacarpal index (MI) was determined by hand radiograph. Types and patterns of physical activity, risk taking and diet were assessed by interview-administered questionnaires. Coordination was measured using the 8-point movement ABC. A total of 321 fracture cases and 321 randomly selected age- and gender-matched controls were recruited. Fracture sites were as follows: hand: n=91, wrist and forearm: n=190, upper arm: n=40. Conditional logistic regression analysis showed wrist and forearm fracture risk was significantly associated with lumbar spine BMAD (OR: 1.52/SD reduction, 95% CI 1.18-1.96), MI (OR: 1.43/SD reduction, 95% CI 1.12-1.79), television, computer and video viewing (OR: 1.58/category, 95% CI 1.14-2.20), light physical activity (OR: 0.81/unit, 95% CI 0.65-1.00), cola consumption (OR: 1.43/category, 95% CI 1.03-1.97) and walking backwards score (OR: 1.17/unit, 95% CI 1.02-1.34). Hand fracture was significantly associated with the difference between skeletal age and chronological age (OR 1.45/year reduction, 95%CI 1.05-1.96), high-risk sport participation (1.43/sport, 95% CI 1.08-1.88) and total risk taking score (OR: 1.94/unit, 95% CI 1.01- 3.72). Upper arm fracture risk was only significantly associated with high-risk sport participation (OR: 2.73/sport, 95% CI 1.27-5.84) but conclusions may be limited by sample size considerations. Obesity or overweight was not associated with any fracture type. For total fractures, there was a gender discordant effect of sports participation with an increased fracture risk in boys and decreased fracture risk in girls which reached statistical significance for total, contact, non-contact and high-risk sports participation as well as four individual sports (soccer, cricket, surfing and swimming). In conclusion, both bone dependent and independent factors are important determinants of upper limb fracture risk in children. There is heterogeneity of cause for both gender and different fracture sites which will necessitate different approaches to prevention.

A Co-Twin Calcium Intervention Trial in Young Females: Effects Measured by Hip Structural Analysis. J. D. Wark[1], L. M. Paton*[1], T. J. Beck[2], C. Nowson*[3], M. Cameron*[1], S. Kantor*[1], H. A. McKay[4], M. Forwood[5]. [1]Medicine, University of Melbourne, Parkville, Australia, [2]Department of Radiology, Johns Hopkins University School of Medicine, Baltimore, MD, USA, [3]School of Health Sciences, Deakin University, Burwood, Australia, [4]School of Human Kinetics, University of British Columbia, Vancouver, BC, Canada, [5]Anatomy and Developmental Biology, University of Queensland, Brisbane, Australia.

A high dietary calcium intake is widely recommended for children to enhance peak bone mass but the effect of calcium on the biomechanical properties of the proximal femur is not widely reported. We conducted a randomized, placebo-controlled trial of calcium supplementation (1000 - 1200mg daily) in 79 pairs of female twins aged (mean (SD)) 12.2 (2.0) years at baseline, using a powerful co-twin control design. Bone properties were able to be evaluated by Hip Structural Analysis (HSA) of proximal femur densitometry scans in 64 twin pairs (34 monozygotic, 30 dizygotic) up to 18 months intervention. HSA parameters were measured at the narrowest segment of the femoral neck (NN), intertrochanteric (IT) and upper femoral shaft (FS) sites. All data were adjusted for age, height and weight, none of which differed between groups at any time point. After 18 months at the IT and FS sites, there were significant within- pair differences in percent change from baseline comparing calcium – placebo treated twins, respectively: at the IT site, in areal bone mineral density (ABMD) [2.0 %, $p = 0.04$] and the average buckling ratio [-4.2 %, $p = 0.002$], respectively; at the FS site in ABMD [2.7 %, $p = 0.01$], endocortical diameter [-3.1%, $p = 0.02$], average cortical thickness [3.4%, $p = 0.01$] and average bucking ratio [4.7%, $p = 0.009$], respectively. At 6 months there was a difference in NN subperiosteal width and endocortical diameter but this was not maintained. Therefore, observed effects were limited to the IT and FS sites. At the femoral shaft there was inhibition of modelling at both endosteal and periosteal surfaces, resulting in narrowing of the femoral shaft and a thicker cortex. The implications for adult bone health are uncertain since the effects were more evident at the shaft site rather than the more proximal sites where osteoporotic fractures are common. Our findings complement the sparse body of literature that, importantly, investigates the geometric adaptation of growing bone to lifestyle factors. It is possible that calcium given during growth may reduce bone fragility in later life through an increase in cortical thickness.

Adult Bone Structure and Strength are Influenced by Lean Mass, Exercise History, and Estradiol Levels: The 10-year Longitudinal Penn State Young Women's Health Study. M. A. Petit[1], T. J. Beck[2], H. Lin*[1], C. Bentley*[1], T. Lloyd[1]. [1]Dept. of Health Evaluation Sciences, Penn State University, Hershey, PA, USA, [2]Dept. of Radiology, Johns Hopkins University, Baltimore, MD, USA.

We used longitudinal data from the 10-year Penn State Young Women's Health Study to establish determinants of adult bone mass, structure and strength. 112 participants were enrolled in the study at age 12 and measurements made bi-annually for 6 years and annually thereafter. Proximal femur DXA scans (Hologic QDR 2000) were taken from age 17-22y and analyzed using a hip structure analysis program to assess areal BMD (g/cm^2), subperiosteal width, cortical thickness, bone axial strength (cross-sectional area, CSA) and bone bending strength (section modulus) at the femoral neck and femoral shaft regions. Height and weight were measured by standard procedures and body composition taken from DXA total body scans. Other variables were measured at each time point and the average of all data from age 12-22y used including: calcium and total calorie intake from 3-day food records; estradiol and testosterone values converted to log transformed and then standardized scores; sports exercise score by questionnaire; and age at menarche. Backward regression models were used to assess determinants of change in bone variables and absolute bone values at age 21-22y, controlling for height and weight in each model. Models were run both with and without lean mass. Femoral neck section modulus (+3.5%) and width (+1.6%), but not BMD (-0.8%), increased significantly from age 17-22y. At the shaft, all variables increased (+1.0-4.0%, $p < 0.01$) from age 17-22y. After controlling for changes in body weight and height, none of the variables contributed significantly to predicting change. Absolute bone values at age 22y were predicted primarily by lean mass, sports exercise scores, and average estradiol levels (controlling for height and weight). At both the neck ($r^2 = 0.48$, $p < 0.01$) and the shaft ($r^2 = 0.67$, $p < 0.01$), only lean mass predicted section modulus. When lean mass was removed from the model, sports exercise score replaced lean mass as a predictor at both neck ($r^2 = 0.41$, $p < 0.01$) and shaft ($r^2 = 0.61$, $p < 0.01$) sites. For neck cortical thickness, BMD, and CSA, both estradiol and sports exercise history were significant predictors ($r^2 = 0.20$-0.40, $p < 0.01$), and for bone width testosterone (negative) and lean were significant ($r^2 = 0.48$). Results were similar for each geometric variable at the shaft site. These data suggest bone adapts its bending strength primarily to mechanical loading either through lean body mass or adolescent exercise.

Maternal Vitamin D Status During Late Pregnancy and Accrual of Childhood Bone Mineral. M. K. Javaid[1], S. R. Shore*[1], P. Taylor*[2], C. Gale*[1], B. J. Boucher*[3], K. Noonan*[3], K. M. Godfrey*[1], N. K. Arden*[1], C. Cooper[1], &. The Princess Anne Hospital Study Group*[1]. [1]MRC Environmental Epidemiology Unit, University of Southampton, Southampton, United Kingdom, [2]Medical Physics and Bioengineering, Southampton University Hospitals NHS Trust, Southampton, United Kingdom, [3]Metabolic Medicine, Royal London Hospital, London, United Kingdom.

Enhancing peak bone mass is a key component of strategies for the primary prevention of osteoporotic fractures in later life. There is growing evidence that the childhood skeletal growth trajectory is established during early life, and epidemiological studies suggest that the mechanism may involve programming of the vitamin D axis.

We therefore investigated specific maternal and neonatal determinants of childhood bone mass in 211 children (113 boys), who were measured at birth and for whom maternal anthropometry, lifestyle characteristics and serum 25OH vitamin D concentrations (25OHD) during late pregnancy were determined. Now aged nine years, the children have had body composition measured using DXA.

There was a significant positive (r=0.21; p=0.008) association between maternal 25OHD in late pregnancy and the whole body bone mineral content (WBBMC) of the children nine years later. However, there was a threshold in the relationship such that mothers with serum 25OHD concentrations below 14 ng/ml (lowest quartile) had children with significantly (p=0.001) lower WBBMC than those born to mothers more vitamin D replete (Figure). Maternal use of vitamin D supplements and maternal sunshine exposure were significant (p<0.01) determinants of maternal vitamin D status, as well as of childhood WBBMC (p<0.05).

These observations support the hypothesis that a mothers vitamin D status during pregnancy has persisting effects on bone mass accrual rates of her child. The use of vitamin D supplements during pregnancy may increase bone mass accrual during childhood and reduce that child's risk of osteoporotic fracture in later years.

Maternal 25OHD concentration during late pregnancy predicts whole body bone mass of her child nine years later

Effects of Use and Discontinuation of Depot Medroxyprogesterone Acetate Injectable Contraception on Bone Density in Adolescents: Results from a Longitudinal Study. D. Scholes[1], A. Z. LaCroix[1], L. E. Ichikawa*[1], W. E. Barlow*[1], S. M. Ott[2]. [1]Center for Health Studies, Group Health Cooperative, Seattle, WA, USA, [2]Dept. of Medicine, University of Washington, Seattle, WA, USA.

Use of depot medroxyprogesterone acetate injectable contraception (Depo-Provera, DMPA) is associated with decreased bone mineral density (BMD), but bone effects in adolescents have received little study. We report on a prospective evaluation of the effects of DMPA on bone in a cohort of 174 adolescents. Participants, ages 14-18 at baseline, were enrollees of a Washington state HMO and were selected using computerized databases. We recruited 81 participants who were using DMPA (range 1-39 mo. at baseline) and 93 comparison women. Hip, spine and whole body BMD were measured by DEXA every 6 months for up to 36 months. We collected data on DMPA use, bone density, and other variables via questionnaire and exam. At baseline, DMPA users were significantly more likely to be African-American, current smokers, to have been pregnant, and to have lower calcium intake; BMD at baseline did not differ significantly between the exposure groups. Data were available for 157 (90%) participants at 6 mos, 146 (84%) at 12 mos, and 135 (78%) at 24 mos. Relative to comparison women, continuous users of DMPA showed significantly decreased BMD at the hip and spine after 12 months (see table). After 24 months, hip BMD for DMPA users declined by 4.5%. Women who discontinued DMPA had 12-month mean percent increases in BMD which were significantly greater than non-users at the hip and whole body.

Adjusted Mean Percent Change in BMD after 12 months, by DMPA Exposure Status

DMPA status	N	Total hip	Spine	Whole body
Continuous use	44	-2.31*	-1.49**	+0.28
Discontinued	29	+1.61*	+2.73	+3.02*
Non-use (comparison)	73	-0.46	+1.81	+1.02

Adjusting for: baseline BMD, age, ethnicity, gravidity, smoking, physical activity, calcium intak

P-values, relative to non-use: *p<0.005; **p<0.0001

These longitudinal data provide evidence that DMPA use among adolescents is strongly associated with bone density loss. These losses may be largely reversible, as indicated by the significant increases in BMD 12 months post-discontinuation.

Disclosures: ***D. Scholes****, None.*

Regulation of Bone Formation by Wnt Signaling. D. Glass*[1], M. Patel[1], F. Long*[2], M. M. Taketo*[3], A. McMahon*[4], G. Karsenty[1]. [1]Molecular and Human Genetics, Baylor College of Medicine, Houston, TX, USA, [2]Washington University Medical School, St. Louis, MO, USA, [3]Biomedical Genetics, The University of Tokyo, Tokyo, Japan, [4]Molecular and Cellular Biology, Harvard University, Cambridge, MA, USA.

Lrp5 loss-of-function mutations lead to low bone mass with fractures while Lrp5 gain-of-function mutations lead to high bone mass and fracture resistance thus identifying Lrp5 as one of the most important regulators of skeletal physiology discovered to date. Lrp5 is thought to signal in response to Wnt proteins but this has not been demonstrated in vivo. To better understand the nature of the Lrp5 signaling pathway we directly activated the canonical Wnt signaling pathway only in osteoblasts in vivo. These mice, harboring a constitutively active allele of β-catenin, have a high bone mass phenotype that, when crossed onto an Lrp5 null background, completely rescues the low bone mass of Lrp5 deficiency. In a converse experiment, we generated an osteoblast-specific deletion of β-catenin; our preliminary analyses indicate that these mice recapitulate the low bone mass of Lrp5 deficiency. To further demonstrate the role of β-catenin in Lrp5 signaling, we also generated transgenic mice expressing the high bone mass $LRP5^{G171V}$ allele in osteoblasts. If β-catenin is indeed downstream of Lrp5, then selective deletion of β-catenin in the osteoblasts of these high bone mass $LRP5^{G171V}$ mice should rescue their phenotype. To test this we are crossing $LRP5^{G171V}$ transgenics to mice with a conditionally null allele of β-catenin in the presence of an *α(I)1 collagen-cre* transgene. Lastly, we used a candidate gene approach to identify the transcriptional partner for β-catenin in osteoblasts. These gene deletion experiments identified a member of the Lef/Tcf family as the putative DNA binding partner of β-catenin. Our results so far strongly suggest that Lrp5 signals through the canonical Wnt signaling pathway in vivo, thus identifying Wnt proteins as critical regulators of differentiated osteoblast function.

The Osteogenic Activity of β-catenin Requires Interaction with BMP-2 Effectors. G. Mbalaviele, S. Sheikh, S. Cheng, J. Stains, R. Civitelli. Bone and Mineral Diseases, Washington University, St. Louis, MO, USA.

Mutations of critical elements of the *Wnt* pathway (Lef1, LRP-5) affect skeletal development and bone mass acquisition, and β-catenin, a component of *Wnt* signaling controls osteogenic differentiation. We have previously reported that a transcriptionally active N-terminal truncated β-catenin mutant (ΔN151) commits mesenchymal stem cells to the osteogenic pathway, while inhibiting adipogenesis. Retroviral transduction of ΔN151 in the uncommitted, multipotential C3H10T1/2 cells has no effect on osteogenesis, but it synergistically stimulates BMP-2 induction of osteoblast genes and matrix mineralization. We now find that in metatarsal bone rudiments from 17-day mouse fetuses, transduction of ΔN151 by itself enhances mineralization 1.5-fold relative to LacZ transduced metatarsals, an effect similar to that of BMP-2. Thus, β-catenin signaling alone is an insufficient activator of osteoblast differentiation *in vitro*, but it is active *in vivo* probably because it synergizes with endogenously produced activators. To test this hypothesis, we studied β-catenin-BMP-2 interactions in C3H10T1/2 cells using promoter-luciferase constructs. As expected, ΔN151 was able to stimulate Tcf-Lef dependent transactivation (2-fold relative to LacZ transduced cells), but BMP-2 was not. By contrast, SMAD-dependent transactivation was stimulated 7-fold by BMP-2, but not by ΔN151. Consistent with a Tcf/Lef independent interaction, transfection of a constitutively active Tcf3 construct in C3H10T1/2 cells did not reproduce the synergism with BMP-2, and a dominant-negative Tcf3 mutant did not prevent BMP-2 induction of alkaline phosphatase. Using the osteocalcin promoter (-637 to –32) as a reporter of tissue-specific transactivation, we found that ΔN151 was a marginal activator (1.2-fold), but it synergized with BMP-2 (1.8-fold increase over BMP-2 alone). However, this synergism was lost when a –199 to –32 osteocalcin promoter (which contains the Tcf/Lef consensus site) was used, while BMP-2 stimulation was retained. Finally using an anti-SMAD4 antibody, we were able to co-immunoprecipitate β-catenin. In sum-

mary, the osteoinductive action of β-catenin does not require Tcf/Lef transactivation. The synergism between β-catenin and BMP-2 is mediated by non-canonical interactions with components of the BMP-2 signaling system and determine the fate of mesenchymal stem cells, shifting differentiation towards the osteogenic lineage. This novel model of osteoinduction offers a mechanism by which β-catenin, a ubiquitous transcription factor, modulates tissue specific events.

NFAT: A Major C-Fos Target Gene During Osteoclast Formation. D. L. Galson[1], C. Zhao*[2], L. Peng*[3], C. Laplace*[3], M. A. Bachler*[4], H. Amano[5], H. Aburatani*[6], H. Ishikawa*[2], E. F. Wagner*[4], K. Matsuo[2]. [1]Center for Bone Biology, Dept. of Medicine, University of Pittsburgh School of Medicine, Pittsburgh, PA, USA, [2]Dept. of Microbiology and Immunology, Keio University School of Medicine, Tokyo, Japan, [3]Dept. of Medicine, Beth Israel Deaconess Medical Center & Harvard Medical School, Boston, MA, USA, [4]Research Institute of Molecular Pathology (IMP), Vienna, Austria, [5]Showa University School of Dentistry, Tokyo, Japan, [6]Research Center for Advance Science and Technology, The University of Tokyo, Tokyo, Japan.

Mice lacking c-Fos (*Fos*$^{-/-}$ mice) are osteopetrotic and lack osteoclasts. Microarray analysis using osteoclastogenic cultures revealed that along with the decreased expression of known osteoclast marker genes such as *Acp5* (tartrate-resistant acid phosphatase; TRAP), *Calcr* (calcitonin receptor; CTR), *Ctsk* (cathepsin K), *Car2* (carbonic anhydrase 2), and *Mmp9* (matrix metalloproteinase 9), the expression of *Nfatc1* is abolished in *Fos*$^{-/-}$ precursors. The lack of NFATc1 expression was confirmed at the protein level by Western blotting. NFAT binding sites were identified in the osteoclast-specific promoters of TRAP and CTR. These sites were shown by EMSA to bind NFATc1 and both the TRAP and CTR promoters were transactivated by cotransfection into RAW264.7 cells with a constitutively active form of NFAT (ΔNFAT). Site-specific mutation of the NFAT binding sites demonstrated a functional role for these sites in responding to NFAT. Furthermore, activation of endogenous NFAT by the Ca^{2+} ionophore A23187 induced transfected CTR promoter-reporters. This was dependent on the identified NFAT binding sites and was inhibited by CsA. Earlier work has shown that transient transfection of ΔNFAT into RAW264.7 cells induced the expression of the endogenous TRAP and CTR genes in the absence of RANKL. Notably, in this report, introduction of a nuclear form of NFAT into *Fos*$^{-/-}$ precursors by retroviral gene transfer restored transcription of most osteoclast marker genes (including *Acp5*, *Calcr*, *Ctsk*, and endogenous *Nfatc1)* and rescued bone resorptive function. These data indicate that the lack of NFATc1 is a major reason for the differentiation block of *Fos*$^{-/-}$ osteoclast precursors.

Decreased Bone Formation and Osteopenia in Mice Lacking aCGRP. S. Liese*[1], T. Schinke[1], P. Catala-Lehnen[1], M. Priemel[1], J. M. Rueger[1], R. B. Emeson*[2], M. Amling[1]. [1]Dept. of Trauma, Hand, and Reconstructive Surgery, Hamburg University School of Medicine, Hamburg, Germany, [2]Dept. of Pharmacology, Vanderbilt University School of Medicine, Nashville, TN, USA.

Cell-type-specific alternative splicing of the primary transcript of the Calca gene results in the expression of two polypeptides, calcitonin and aCGRP. Whereas the hormone calcitonin is secreted by thyroidal C-cells, the neuropeptide aCGRP is widely distributed in the central and peripheral nervous system. We have recently analysed the bone phenotype of Calca-deficient mice that fail to produce both calcitonin and aCGRP. Surprisingly, these mice display a high-bone-mass phenotype caused by an increased bone formation rate. As these results are not consistent with the classical role of calcitonin as an inhibitor of bone resorption, we speculated that the bone phenotype of the Calca-deficient mice is caused by the absence of aCGRP. To address this question we analysed a aCGRP-deficient mouse model where calcitonin expression is not affected. In contrast to the Calca-deficient mice we found that the bone volume (BV/TV) of the aCGRP-deficient mice is significantly decreased compared to wildtype littermates at the age of 6 months (8.7 ± 1.5 vs. 13.3 ± 1.3 %). This osteopenic phenotype is caused by a reduction in the bone formation rate (86.5 ± 4.5 vs. 111.5 ± 11 µm3/µm2/year) whereas bone cell numbers are not affected. Serum levels of calcitonin are not elevated in the aCGRP-deficient mice demonstrating that aCGRP is a physiologic activator of bone formation. Taken together these data suggest that aCGRP is one important player in the regulation of bone formation by the sympathetic nervous system. Most importantly however, they demonstrate that the high-bone-mass phenotype of the Calca-deficient mice is indeed caused by the absence of calcitonin thereby confirming its physiologic function as a negative regulator of bone formation.

BMPR1A and BMPR1B Have Overlapping Functions and Are Required for Chondrogenesis in vivo. B. S. Yoon*[1], Y. Mishina*[2], R. R. Behringer*[2], K. M. Lyons[1]. [1]Molecular, Cell, and Development Biology, University of California Los Angeles, Los Angeles, CA, USA, [2]Department of Molecular Genetics, University of Texas, M. D. Anderson Cancer Center, Houston, TX, USA.

Bone Morphogenetic Proteins (BMPs) are members of the Transforming Growth Factorβ (TGFβ) superfamily, that signal through complexes of type I and type II receptors. There are three type I receptors that transduce BMP signals: BMPR1A, BMPR1B, and ActRI. The sequence similarity of BMPR1A and BMPR1B, and their coexpression during skeletal development raise the possibility of functional redundancy. However, other studies suggest that they have distinct functions in chondrogenesis.

In order to examine the roles of BMPR1A and BMPR1B in skeletal development, we generated mice null for BMPR1B and conditionally null for BMPR1A in cartilage (*Bmpr1b*$^{-/-}$*; Bmpr1a*$^{fx/fx}$; *Col2Cre*). *Bmpr1b*$^{-/-}$ mice are viable and have a mild skeletal phenotype. *Bmpr1a*$^{fx/fx}$; *Col2Cre* mice die postnatally and have general chondrodysplasia. This phenotype is exacerbated by the loss of one allele of *Bmpr1b*. In addition, *Bmpr1b*$^{+/-}$*; Bmpr1a*$^{fx/fx}$*; Col2Cre* mice have expanded hypertrophic zones in apendicular skeletal elements, demonstrating a role of BMPs for the terminal differentiation of chondrocytes *in vivo*. In contrast to these relatively mild phenotypes, double mutants exhibit profound defects in chondrogenesis. In these mice, mesenchymal cells condense but do not differentiate into chondrocytes. This is demonstrated by severely diminished production of Collagen II, Link Protein and Aggrecan. These results show that BMPR1A and BMPR1B are functionally redundant in skeletal development, that BMP signaling is required for chondrocyte differentiation *in vivo*, and that these two receptors are primarily responsible for mediating BMP signaling throughout chondrogenesis. We also show that BMP signaling is required at various stages throughout chondrogenesis, first in the differentiation of condensing mesenchymal cells to chondrocytes and later in the terminal differentiation of chondrocytes to hypertrophy.

Selective Deficiency of Runx2-II Isoform Causes Limited Skeletal Abnormalities Involving Terminal Events in Bone Development. Z. Xiao, L. G. Simpson*, L. D. Quarles. Medicine, Duke University, Durham, NC, USA.

Runx2 (also known as *Cbfa*1) is a complex gene in which two promoters transcribe two major isoforms, designated *Runx2*-II and *Runx*2-I, that differ in their respective 5' untranslated regions and N -termini. *Runx*2-I and -II are presumed to have distinct functions, based on the predominant expression of the Type II isoform in bone and the Type I isoform in non-osseous tissues. Previous *Runx*2 null mouse models produced by targeted disruption of the common *Runt* domain results in the deletion of both isoforms. Double homozygous *Runx*2-I and -II -deficient mice exhibit a global loss of mineralized bone due to the absence of osteoblasts, whereas the double heterozygous *Runx*2-I and -II-deficient mice display skeletal abnormalities that are limited to defects in the skull and distal clavicles. While these studies indicate the importance of *Runx*2 gene products in skeletal development, they do not establish the separate functions of the *Runx*2-I and -II isoforms. In current study, we created mice selectively deficient for the "bone-related" *Runx*2-II gene product by deleting a 2.6 kb region of the *Runx*2 gene containing the P1 promoter, the 5'UTR region, and exon 1 which encodes the N –terminus of *Runx*2-II. Male and female heterozygous *Runx*2-II$^{+/-}$-deficient mice were crossed to create F2 wild-type (*Runx*2-II$^{+/+}$), heterozygous (*Runx*2-II$^{+/-}$), and homozygous (*Runx*2-II $^{-/-}$) -deficient mice. We found that *Runx*2-II$^{+/-}$ mice were fertile, viable and without gross abnormalities of skeletal development. Indeed, heterozygous *Runx*2-II$^{+/-}$ mice were indistinguishable from wild-type mice in their gross appearance,

body weight, and length at birth and had no abnormalities of the skull or clavicles. In contrast, homozygous *Runx* 2-II $^{-/-}$ mice exhibited a high perinatal mortality and a partial arrest of mineralized bone formation that was limited to specific skeletal locations. *Runx*2-II$^{-/-}$ mice were smaller than their littermates, with shortened tails and extremities. Examination of alizarin red/alcian blue stained whole skeletal mounts revealed that the homozygous *Runx*2-II$^{-/-}$ deficient mice had absent formation of the phalangeal bones, distal ribs, caudal spine, hyoid bone, dysplastic distal clavicles, and occipital regions of the skull, but otherwise exhibited complete formation of cervical and lumbar spine, proximal ribs, long-bones, and other regions of the skull, suggesting a site specific arrest of bone formation. These findings support separate functions of *Runx*2-I and -II isoforms. *Runx*2-II appears to be more important in regulating terminal events in bone development, whereas the *Runx*2-I isoform is sufficient to form regions of the skeleton that develop earlier during embryogenesis.

Response of Markers of Bone Turnover and Bone Density to Teriparatide in Postmenopausal Women Previously Treated with an Antiresorptive Drug. B. Ettinger[1], J. San Martin[2], G. G. Crans*[2], I. Pavo*[2]. [1]Division of Research, Kaiser Permanente Medical Care Program, Oakland, CA, USA, [2]Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN, USA.

To determine whether prior treatment with long-term antiresorptive therapy affects the response to teriparatide [rhPTH(1-34),TPTD], we are conducting an 18-month trial in postmenopausal women who started TPTD 20 µg s.c. once-daily immediately after stopping antiresorptive therapy. Six-month results were presented at the ASBMR 2002 meeting. Patients had used either alendronate (ALN, n=33) 10mg/d or raloxifene (RLX, n=26) 60mg/d for ≥18 months prior to entering the trial. Bone mineral density (BMD) T-scores were <-2.5 prior to start of antiresorptive therapy and ≤-2.0 at initiation of TPTD. At baseline, subjects were similar in age, BMD, and duration of antiresorptive therapy (28 months), but markers of bone turnover were significantly lower in the ALN than the RLX group.

Bone markers exhibited rapid significant increases from baseline in both groups during TPTD treatment. After 12 months of TPTD treatment, the RLX-pretreated group increased BMD in the spine and total hip, whereas the ALN-pretreated group increased BMD only at the spine. Despite evidence of significant TPTD-induced stimulation of bone formation in the ALN-pretreatment group, the increase in BMD was less than that observed in RLX-pretreated patients. The discrepancy between bone marker and BMD responses after long-term ALN-pretreatment may be the result of both marked suppression of bone turnover and increase of matrix mineralization at the time these women began TPTD. Stimulation of bone remodeling by TPTD may have removed highly mineralized bone from some surfaces while depositing new, not yet fully mineralized, bone at other surfaces. In addition, low bone turnover may have caused a delayed anabolic response. Preliminary 18-month data suggest that both groups continue to increase in bone density, but cumulative changes appear considerably less in the ALN-pretreated group.

		Duration of teriparatide treatment			
	Previous therapy	1 month	3 months	6 months	12 months
Bone markers		Median absolute change from baseline			
PINP	ALN	22.5*	44.3*	93.4*	118.0*
	RLX	48.5*†	81.1*	142.7*	139.9*
NTX	ALN	1.5*	4.2*	9.0*	7.2*
	RLX	2.9*	6.5*	14.3*	8.6*
BMD		Mean percentage change from baseline			
Lumbar spine	ALN		0.6	0.5†	2.5*†
	RLX		2.1*†	5.2*†	7.7*†
Total hip	ALN		-0.3	-1.8*†	-1.0†
	RLX		0.4	0.5†	1.5*†

Change from baseline within (*P<0.05) and between (†P<0.05) groups

The Neutralization of FGF-23 Ameliorates Hypophosphatemia and Rickets in *Hyp* Mice. Y. Aono*[1], T. Shimada*[2], Y. Yamazaki*[2], R. Hino*[2], Y. Takeuchi[3], T. Fujita[3], S. Fukumoto[4], N. Nagano[1], M. Wada[1], T. Yamashita[2]. [1]Pharmaceutical Development Labs., KIRIN Brewery CO.,LTD., Takasaki, Japan, [2]Pharmaceutical Research Labs., KIRIN Brewery CO.,LTD., Takasaki, Japan, [3]Dept. of Medicine, Univ. of Tokyo school of Medicine, Tokyo, Japan, [4]Dept. of Laboratory Medicine, Univ. of Tokyo Hospital, Tokyo, Japan.

FGF-23 is the latest member of the FGF family and plays a pathogenic role in the development of tumor-induced osteomalacia and autosomal dominant hypophosphatemic rickets/osteomalacia. X-linked hypophosphatemia (XLH) is the most common form of vitamin D-resistant hypophosphatemia characterized by renal phosphate wasting, inappropriately low 1,25-dihydroxyvitamin D (1,25D) levels and rachitic bone lesions. Recent studies have shown that serum FGF-23 levels were elevated in most patients with XLH. Furthermore, based on an ELISA, we showed about 10-fold increase of serum FGF-23 level in *Hyp* mice, a murine homologue of XLH, as compared to normal littermates. These lines of evidence strongly suggest that increased FGF-23 also plays a pathogenic role in XLH. To investigate the therapeutic potential to neutralize excess FGF-23, we examined effects of anti-FGF-23 neutralizing antibodies on phosphate and skeletal abnormalities in *Hyp* mice. Two monoclonal antibodies with neutralizing activity against FGF-23, which recognize different sites of FGF-23, were mixed and used as a neutralizing antibody preparation (NAb). *Hyp* mice and normal littermates were subcutaneously injected with NAb or the isotype-matched control antibody (CAb). A single injection of NAb caused dose-dependent elevations of serum phosphate and 1,25D levels in *Hyp* mice. These findings were supported by evident accumulation of renal type IIa sodium phosphate co-transporter protein in renal brush border membrane fractions and significant elevation of renal 1α-hydroxylase mRNA level. Furthermore, 4-week treatment of *Hyp* mice with 5-time subcutaneous injections of NAb led to the amelioration of rachitic bone lesions and the stimulation of bone elongation (see table). These findings demonstrate that neutralization of elevated FGF-23 can ameliorate hypophosphatemia and rickets in *Hyp* mice and has potential to become a novel therapeutic approach for XLH and other FGF-23-related diseases.

Table: Effects of 4-week Treatment of NAb on Skeletal Parameters of Hyp Mice (Mean ± SEM)

	Normal-CAb	*Hyp*-CAb	*Hyp*- NAb (2 mg/kg)	*Hyp*- NAb (8 mg/kg)

Lifestyle, Clinical Factors & Long-Term Risk for Hip Fracture in Women & Men: 50 Years of Follow-Up from the Framingham Study. E. J. Samelson[1], L. A. Cupples*[2], M. T. Hannan[1], K. E. Broe[1], D. T. Felson*[3], D. P. Kiel[1]. [1]Hebrew Rehab Ctr for Aged, Boston, MA, USA, [2]BU Sch Pub H, Boston, MA, USA, [3]BU Sch Med, Boston, MA, USA.

Studies that have identified risk factors for hip fracture (HFx), including low weight, weight loss, tall height, smoking, and alcohol, have examined factors associated with relatively short-term risk of HFx in elderly persons, age >65 years. It is not known whether these factors, measured in young and middle age (30-65 years) can predict risk of HFx over the long-term. Our goal was to identify lifestyle and clinical factors in young to middle age women and men that predict long-term risk of HFx.

Participants included 2461 women and 1937 men who enrolled in the Framingham Study in 1948 and attended a 10-y follow-up visit in 1958 (mean age 48, range 32-65). Every 2 y, cohort members receive physical exams and complete questionnaires. Subjects without previous HFx were followed for 50 y for first occurrence of HFx, last contact, death, or closing date (6/98). Baseline characteristics (weight, height, BMI, smoking, alcohol, physical activity, grip strength, and heart rate) were averaged over measurements taken at 5 visits (10 y) from 1948-58. Weight change was calculated as 1958 - 1948 weight. Cox regression was used to calculate hazard ratios (HR) and 95% confidence intervals (CI) for risk of HFx associated with each factor, adjusted for age, weight, height, smoking, alcohol, and menopause (women).

During 50 y of follow-up, 371 HFx occurred (295 women, 76 men). In women, lower weight and greater height during young to middle age were associated with slightly increased long-term risk of HFx (Table). In men, only smoking was associated with long-term HFx risk. No other characteristics examined during young to middle age (BMI, 10-y weight change, alcohol, physical activity, grip strength, and heart rate) affected long-term risk of HFx.

Height and weight, easily measured in clinical settings, in young to middle age women predict subsequent hip fracture risk in old age. Men who smoke during young to middle age incur increased risk of hip fracture in the long-term. Factors identified previously as important short-term predictors of hip fracture, such as weight loss and alcohol consumption, were modestly or un-related to long-term incidence over 50 years, suggesting these factors play a more significant role in short- rather than long-term risk of hip fracture.

HR (95% CI) for Long-Term Risk of HFx (through 1998)

Baseline Characteristics (1948-58)	Women	Men
Height (2 inch increase)	1.13 (1.02-1.25)	1.04 (0.85-1.27)
Weight (10 lb decrease)	1.07 (1.01-1.14)	0.99 (0.88-1.11)
10-Y Weight Change (10 lb decrease)	1.04 (0.98-1.10)	1.13 (0.90-1.43)
Smoking (10 cigs/day increase)	1.07 (0.92-1.26)	1.29 (1.08-1.55)
Alcohol (2 oz/wk increase)	1.04 (0.98-1.10)	1.01 (0.95-1.06)

IL-7 Induces Bone Loss in Estrogen Deficient Mice by a Mechanism involving Activation and Expansion of TNF Producing T Lymphocytes. R. Sheperd*[1], Y. Gao[1], W. Qien[1], K. Dark[2], M. Weitzmann[2], R. Pacifici[3]. [1]Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA, [2]Division of Endocrinology, Emory University School of Medicine, Atlanta, GA, USA, [3]Division of Endocrinology and Metabolism, Emory University School of Medicine, Atlanta, GA, USA.

Ovariectomy (ovx) leads to bone loss through an expansion of the pool of TNF producing T cells but the responsible mechanism remains poorly defined. It is now known that IL-7 is elevated in ovx mice, and that neutralization of IL-7 in vivo, prevents ovx induced bone loss (J. Clin. Invest. 2002). As IL-7 regulates T cell activation and proliferation, we have investigated if IL-7 plays a central role in the expansion of T cells critical for ovx induced bone loss. Twelve week old female C57BL6/J mice were ovx or sham operated and treated with the neutralizing IL-7 antibody M-25, or with isotype matched irrelevant antibody (1 mg IP 3 times/week) for 4 weeks. We then performed in vivo BrdU incorporation studies and FACS quantification of the T cell activation markers CD25+ and CD69+ to assess T cell proliferation and activation. Our data revealed that ovx increases T cell activation, proliferation by ~2.5 fold. As a result ovx also increased by ~3 fold the total number of T cells in the bone marrow and spleen and consequently by 3 fold the total number of TNF producing T cells. IL-7 neutralization in vivo completely prevented the ovx-induced increase in T cell number, activation, proliferation, and TNF production, while treatment with irrelevant antibody did not. Since it has been reported that enhanced macrophage antigen presenting cell activity (APC), drives the increased T cell proliferation and the resulting bone loss associated with ovx (ASBMR 2002), we investigated if IL-7 regulates macrophage APC activity. We found that ovx resulted in a 2 fold increase in macrophage APC activity, which was completely reversed by treatment with anti IL-7 antibody, but not with irrelevant antibody. As ovx upregulates macrophage APC activity by increasing production of IFNγ, we investigated if ovx upregulates IFNγ through a IL-7 dependent mechanism. Our data show that in vivo IL-7 neutralization completely prevented the ovx induced increase in IFNγ. In summary, IL-7 is central for the upregulation of IFNγ induced macrophage APC activity and the resulting increase in T cell activation, proliferation and TNF production which follow ovx. Thus, IL-7 is a newly recogmized key "upstream" target through which estrogen regulates immune functions critical for bone homeostasis. Together the data demonstrate that IL-7 plays an essential role in the mechanism by which estrogen deficiency induces bone loss.

Reduction of Type II Collagen Degradation in Postmenopausal Women with Osteoporosis by Alendronate Once-Weekly and Risedronate. P. Garnero[1], M. Valimaki*[2], D. Hosking[3], A. Daifotis[4], C. Peverly*[4], L. Zaru*[4], A. Santora[4]. [1]Synarc SAS, Lyon, France, [2]Helsinki University Central Hospital, Helsinki, Finland, [3]Nottingham City Hospital, Nottingham, United Kingdom, [4]Merck Research Labs, Rahway, NJ, USA.

Urinary type II collagen C-telopeptide breakdown products (CTX-II), reflecting cartilage type II collagen degradation is a potential marker for osteoarthritis (OA) disease activity. Antiresorptive agents such as bisphosphonates may decrease the cartilage destruction associated with OA by reducing subchondral bone turnover and/or by a direct effect on cartilage metabolism. Reduction in urinary CTX-II levels has been previously demonstrated with alendronate use in postmenopausal women (Lehmann et al, Ann Rheum Dis 2002). We report urinary CTX-II results in a head-to-head trial designed to compare the efficacy of alendronate and risedronate for the treatment of osteoporosis. This randomized, double-blind, multicenter, multinational study enrolled 558 postmenopausal women, 60-90 years old (mean, 69), with osteoporosis defined by low BMD T-score (either lumbar spine or total hip/femoral neck ≤ -2.5, or ≤ -2.0 at both sites). Patients were randomized into three treatment groups: alendronate 70 mg† once weekly using standard am dosing (ALN); risedronate 5 mg daily dosed 2 hours after a meal and at least 2 hr before the next (RIS); or matching placebo (PBO) for each. Creatinine (Cr) corrected CTX-II (ng/mmol Cr) (Cartilaps) was measured at baseline, Month 3, and Month 6 in a randomly selected subset of study patients. Per-protocol analysis of urinary CTX-II/Cr was similar for both time points; Month 6 results are shown in the table.

Percent Change in Urinary CTX-II/Cr from Baseline at Month 6

Alendronate N=61		Risedronate N=59		Placebo N=61	
Mean	95% CI	Mean	95% CI	Mean	95% CI
-36.92***	(-43.37, -29.74)	-14.17***	(-23.10, -4.20)	-5.74**	(-15.38, 4.99)

Within-group test of mean percent change: ** not significant; ***p ≤ 0.001
Between treatment difference: ALN vs RIS and ALN vs PBO p ≤ 0.001; RIS vs PBO not significant

In this study, alendronate treatment resulted in twice the reduction of urinary CTX-II compared to risedronate (between-group difference p≤ 0.001). Decreases in both the alendronate and risedronate groups were significant from baseline but only the alendronate group was significantly different from placebo (p≤ 0.001). We conclude that treatment with alendronate, at the currently approved dose for osteoporosis, significantly reduces a biochemical marker of cartilage destruction, suggesting a possible role as a disease-modifier in the management of osteoarthritis.

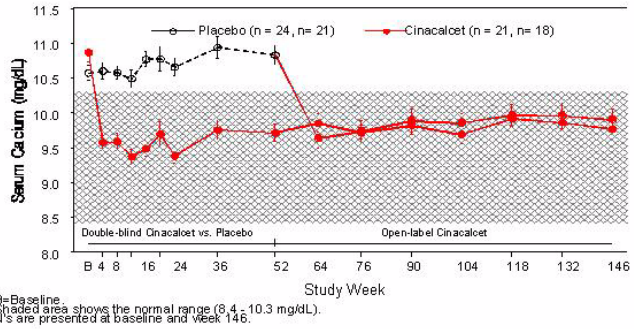
Long-Term Control of Primary Hyperparathyroidism with Cinacalcet HCl (AMG 073). M. Peacock[1], S. Scumpia*[2], M. A. Bolognese*[3], M. A. Borofsky*[4], D. M. Guo*[5], L. C. McCary*[5], L. E. Schwanauer*[5], D. M. Shoback[6]. [1]Indiana Univ Sch of Med, Indianapolis, IN, USA, [2]Ctr for Clin Res, Austin, TX, USA, [3]Bethesda Health Res, Bethesda, MD, USA, [4]Clin Res Ctr of Reading, LLP, West Reading, PA, USA, [5]Amgen Inc., Thousand Oaks, CA, USA, [6]Univ of California, San Francisco, Dept of Veterans Affairs Med Ctr, San Francisco, CA, USA.

Cinacalcet HCl is a calcimimetic that specifically binds and modulates the calcium-sensing receptor on the parathyroid gland to increase its sensitivity to calcium, resulting in decreases in intact parathyroid hormone (iPTH) and serum calcium in patients with primary hyperparathyroidism (HPT). This prospective study evaluated the long-term effects of cinacalcet HCl in patients with primary HPT. Patients were initially randomized into a 1-yr double-blind, placebo-controlled dose-titration study (maximum dose 50 mg bid). At the end of 1 yr, patients were able to enroll in an extension study in which all patients received cinacalcet HCl (no placebo). The effects of cinacalcet HCl on serum calcium, iPTH levels, and bone mineral density (BMD) were examined over a 3 yr period.
Forty-five patients completed 1 yr of double-blind therapy and enrolled in the extension study. The mean (SE) baseline serum calcium was 10.8 (0.1) mg/dL and iPTH was 110 (7) pg/mL. Reductions in serum calcium were observed immediately following initiation of cinacalcet HCl treatment (mean [SE] serum calcium presented in the figure) in the initial double-blind study and in placebo patients who switched to cinacalcet HCl after 1 yr. Thirty-nine patients remained on study for 3 yrs, and 87% of those patients had a serum calcium within the normal range. Mean pre-dose iPTH was reduced by 7% from baseline after 3 yrs. BMD was unchanged from baseline. The majority of patients (~60%) remained on 30 mg bid. Therapy appeared safe and well tolerated in this study with no serious adverse events considered related to cinacalcet HCl.



B=Baseline
Shaded area shows the normal range (8.4 - 10.3 mg/dL).
N's are presented at baseline and week 146.

Primary HPT is frequently asymptomatic, but complications including bone loss, gastrointestinal distress, kidney stones, muscle weakness, and neurobehavioral disorders may exist. In this study in patients with primary HPT, cinacalcet HCl administration was safe and effective, normalizing serum calcium levels and maintaining this effect for 3 yrs. Cinacalcet HCl offers potential as a novel therapy for the treatment of hypercalcemia in patients with primary HPT.

Treatment of c-Fos Over-expressing Osteoclast Precursors with Cytokines Induces Osteoclast Formation and Abrogates Bisphosphonate-induced Osteoclast Apoptosis. T. Yamashita[1], L. Xing[1], K. Matsuo[2], K. Matsuo[2], E. F. Wagner[3], B. F. Boyce[1]. [1]Path, Univ Rochester, Rochester, NY, USA, [2]NILS, Aichi-ken, Japan, [3]Res. Inst. Molec. Path., Vienna, Austria.

Expression of NF-κB and c-Fos is required for osteoclast (ocl) formation during development and is upregulated by cytokines, such as TNF and IL-1, at sites of inflammation. NF-κB in turn can upregulate expression of IL-1, TNF and IL-6 in ocls. Thus, in inflammatory bone diseases, cytokines could initiate self-perpetuating up-regulatory cycles involving c-Fos and NF-κB in ocls to maintain bone resorption along with or independent of RANKL. To explore this possibility, we used retroviral gene transfer to infect M-CSF-dependent splenocytes from NF-κB p50 and p52 double knockout (dKO) or wild-type (wt) mice with c-Fos or a GFP control vector and treated the cells with IL-1 or TNF. Numerous multinucleated ocls (50-100/96 well) formed in c-Fos-expressing dKO cultures treated with TNF or IL-1, but not in GFP-infected controls, indicating that c-Fos can substitute for NF-κB to mediate cytokine-induced ocl formation. No ocls formed in wt or dKO cultures infected with c-Fos or GFP retroviral supernatants alone. Expression of Fos family members, c-jun, fra-1 and fra-2, but not c-Fos or Fosb was higher in dKO than wt types splenocytes, suggesting that NF-κB may regulate c-jun, fra-1 and fra-2 expression. To examine if c-Fos expression is upregulated in ocls in inflammatory arthritis, we stained bone sections from TNF transgenic mice with a c-Fos antibody. c-Fos was strongly expressed in ocls eroding bone in the joints of arthritic mice, but not in ocls in the adjacent normal metaphysis nor in the metaphyses of wt mice. We found a similar staining pattern for IL-6 in ocls in the transgenic mice, suggesting that TNF expression in the inflamed joints induces increased ocl expression of c-Fos and IL-6. Previous studies suggest that bisphosphonates have limited efficacy in preventing inflammation-mediated bone loss which we hypothesize is due to cytokine-mediated increased c-Fos expression in ocls rendering them more resistant to bisphosphonates. To test this, we treated c-Fos- or GFP-expressing wt ocls with Zoledronate and found that the c-Fos-expressing ocls survived at 10^{-7} M, while the GFP-

expressing ocls died at this concentration. Furthermore, alendronate-treated TNF-transgenic mice had significantly more apoptotic ocls in their metaphyses vs PBS controls but not in their inflamed knee joints. Our findings indicate that when c-Fos expression is upregulated in ocls cytokines can induce ocl formation directly. They also support our hypothesis that cytokines may induce c-Fos expression in ocls and that c-Fos protects them from bisphosphonate-induced death.

The NFAT Family of Transcription Factors May Be Key Regulators of the RANKL Gene in T Cells. A. R. Pettit*[1], C. Manning*[1], S. R. Goldring[1], T. Libermann*[1], S. L. Peng*[2], E. M. Gravallese*[1]. [1]Harvard Medical School, Beth Israel Deaconess Medical Center, Boston, MA, USA, [2]School of Medicine, Washington University, St. Louis, MO, USA.

Receptor activator of NF-kB ligand (RANKL) is an essential factor for osteoclast differentiation, and plays a major role in physiologic bone remodeling and in pathologic bone loss in conditions such as inflammatory arthritis and cancer. There is limited understanding of the pathways regulating transcription of the human RANKL gene. Therefore, we have performed analyses to identify transcription factors responsible for RANKL gene regulation in T cells, an important source of RANKL in several diseases associated with bone loss. Jurkat T cells, a human T lymphoma cell line, constitutively express low RANKL mRNA levels and are a useful cell system for investigating RANKL gene regulation. In these cells, RANKL mRNA was induced by stimulation with phorbol 12-myristate 13-acetate and ionomycin (P/I) or by plate-bound anti-CD3/CD28. We cloned a 1902 base pair fragment of the RANKL putative promoter, which contains a nuclear factor of activated T cells (NFAT) and an NFAT/activator protein (AP)-1 consensus element, into a luciferase reporter vector (pXP2-R1902). pXP2-R1902 luciferase activity was assessed in transient transfections of resting and activated Jurkat T cells. Inhibition of the activiation of NFATs activation was achieved by blockade with cyclosporine A (CsA), which inhibits calcineurin activation and subsequently NFAT nuclear translocation. In Jurkat T cells transfected with pXP2-R1902 we observed up to a 40-fold increase in luciferase activity above basic vector. An additional 6- to 8-fold induction of luciferase activity was seen when transfected Jurkat cells were stimulated with P/I, correlating with our mRNA observations. P/I induction of RANKL mRNA and pXP2-R1902 luciferase activity were inhibited by CsA blockade, implicating NFAT transcription factors as regulators of RANKL mRNA induction. We also examined regulation of RANKL mRNA expression by GeneChip analysis in P/I stimulated murine CD4+ T cells isolated from wild type (WT) or NFATc1 and c2 double-deficient (-/-) mice. GeneChip analysis demonstrated that RANKL mRNA expression in stimulated NFATc1-/-/c2-/- CD4+ T cells was 3.5-fold less than expression in stimulated WT CD4+ T cells. Similarly, induction of RANKL protein expression, as assessed by flow cytometry, was impaired in NFATc2-/- CD4+ T cells activated with anti-CD3/CD28 compared with activated WT CD4+ T cells. These data support the hypothesis that the NFAT family of transcription factors may be important transcriptional regulators of the RANKL gene in T cells and may provide novel therapeutic targets for inhibiting RANKL expression.

Unequivocal Demonstration of Estrogen Signaling Through the Androgen Receptor in Osteoblasts and Osteoclasts. J. Chen[1], S. Kousteni[1], L. Han[1], H. Peng*[1], L. K. McCauley[2], S. C. Manolagas[1]. [1]Div Endo/Metab, Center for Osteoporosis and Metabolic Bone Diseases, CA Veterans Healthcare System, Univ of Arkansas for Med Sciences, Little Rock, AR, USA, [2]School of Dentistry, Univ of Michigan, Ann Arbor, MI, USA.

Estrogens or androgens control the survival of osteoblasts and osteoclasts in a non—sex-specific manner. And 4-estren-3α,17β-diol (estren), a synthetic ligand of the estrogen (ERα or ERβ) or androgen receptor (AR) which reproduces the nongenotropic effects of sex steroids without affecting classical transcription, reverses gonadectomy-induced bone loss in both females and males. To search for a molecular explanation of the non-sex-specific nature of these phenomena we employed osteoblasts and osteoclasts from double estrogen receptor knockout (DERKO) mice, kindly provided by P. Chambon, and investigated whether estrogen may signal kinase-mediated control of bone cell survival via the AR. We report that estradiol (E2), dihydrotestosterone (DHT), or the estren stimulated ERK phosphorylation and osteoclast apoptosis and attenuated osteoblast apoptosis in DERKO cells, with identical potencies, over a concentration range of 10-11 to 10-7 M. The effects of E2 or DHT, or estren could be blocked by either the ER antagonist ICI 182,780 or the AR antagonist flutamide. Silencing the AR in DERKO osteoblasts using the small interfering RNA technique (siRNA), but not the non-essential cytoskeletal protein lamin A/C- used as a negative control, abrogated the anti-apoptotic effect of all three compounds. Conversely, the anti-apoptotic effect of all three compounds was restored upon rescuing the AR by introducing a human AR cDNA into DERKO cells in which the endogenous (murine) AR was silenced. The effects of E2, DHT or estren in AR-silenced DERKO cells could be also restored by transfecting an expression construct encoding for the ligand binding domain (LBD) of the human ERα fused to membrane localization sequence. However, transfecting the human ERα LBD fused to a nuclear localization sequence did not rescue the effect of the compounds. Transfection of a Src kinase dead dominant negative mutant into the DERKO cells abrogated the anti-apoptotic effect of either E2 or DHT, as did the transfection of a Src mutant missing the SH3 domain which is required for the physical association of Src to the AR. In contrast, a Src mutant missing the SH2 domain which is required for the association of Src to the ER was ineffective. These results demonstrate unequivocally that the effects of estrogen in the DERKO cells are indeed mediated by the nongenotropic actions of the AR involving activation of cytoplasmic kinases.

Osteoclastogenic Activity of NFAT Family Requires a Partnership with c-Jun/c-Fos. F. Ikeda[1], T. Matsubara*[1], T. Watanabe*[2], T. Kukita[2], K. Yoshioka*[3], S. V. Reddy[4], S. Tanaka[5], J. Inoue*[6], R. Nishumura[1], T. Yoneda[1]. [1]Dept Biochem, Osaka Univ Grad Sch Dent, Osaka, Japan, [2]Sec Oral Mol Biol, Facult Dent Kyushu Univ, Fukuoka, Japan, [3]Cancer Res Inst, Kanazawa Univ, Kanazawa, Japan, [4]Div Hematol Oncol, Univ Pittsburgh Cancer Inst, Pittsburgh, PA, USA, [5]Dept Orthop Surg, Univ of Tokyo, Tokyo, Japan, [6]Inst Med Sci, Univ of Tokyo, Tokyo, Japan.

RANKL signaling plays a central role in the regulation of osteoclast differentiation and function. Recently, NFAT2, one of the family members of the transcription factor of nuclear factor of activated T cell (NFAT), is found to be a target of RANKL and regulate osteoclast differentiation. However, involvement of other NFAT family members is unknown. More importantly, molecular events by which RANKL activates NFAT and NFAT controls osteoclastogenesis are unclear. Determination of the expression of NFAT families in osteoclast lineages by western analysis showed that osteoclasts and RAW264 murine monocytic cells expressed not only NFAT2 but also NFAT1. Soluble RANKL (sRANKL) promoted the nuclear translocation of NFAT1 and stimulated the transcriptional activity of NFAT. Moreover, TRAF6 overexpression dramatically enhanced NFAT transcriptional activity. These results suggest that NFAT activation by RANKL is mediated through TRAF6. Overexpression of either NFAT1 or NFAT2 in RAW264 cells using adenovirus system induced TRAP-positive multinucleated osteoclast-like cell formation and stimulated TRAP gene promoter activity. On the other hand, a specific NFAT inhibitor VIVIT peptide markedly suppressed sRANKL induced-osteoclastogenesis. These results indicate that NFAT is a stimulator of osteoclastogenesis. However, the stimulatory effects of NFAT1 or NFAT2 on osteoclast formation were substantially less than sRANKL, suggesting that an involvement of additional molecules associated with RANKL signaling is required for NFAT1 or NFAT2 to optimally function. In support of this notion, co-overexpression of c-Jun and c-Fos, which were activated by sRANKL, with NFAT1 or NFAT2 enhanced osteoclastogenesis. In contrast, overexpression of dominant-negative c-Jun or c-Fos abolished the NFAT-promoted osteoclastogenesis and TRAP promoter activity. Finally, analyses using a reporter construct driven by sequential deletion mutants of the TRAP gene promoter identified a putative NFAT/AP-1 binding element critical to TRAP promoter activation. In conclusion, our results suggest that both NFAT1 and NFAT2 are important transcription factors that mediate RANKL-induced osteoclastogenesis and that an establishment of a partnership with c-Jun/c-Fos complex optimizes osteoclastogenic activity of NFAT.

Vav3 Regulates Osteoclast Function by Controlling Cytoskeleton Reorganization Downstream of M-CSF and αvβ3 Signaling. R. Faccio[1], K. Fujikawa*[1], A. Zallone[2], S. L. Teitelbaum[1], W. Swat*[1], F. P. Ross[1]. [1]Pathology, Washington University, St Louis, MO, USA, [2]Department of Human Anatomy, Bari, Italy.

Vavs are Guanosine Exchange Factors (GEFs), which mediate the conversion from the inactive GDP- to the active GTP-form of Rho, Rac and Cdc42, known regulators of the actin cytoskeleton. Osteoclasts (OCs) are highly motile cells, which attach to the bone matrix, undergo polarization and resorb bone. These events require several changes in the OC cytoskeleton, and previous studies using overexpression of Rho or the specific inhibitor, C3 exoenzyme, have shown that actin ring assembly is controlled by this GTPase. To overcome the potential problems of Rho, Rac or Cdc42 overexpression, we generated mice lacking Vav1-3, animals in which one or more of the small GTPases may not be activated. We found that Vav3 is the predominant form of Vavs in osteoclasts, more highly expressed than in other hematopoietic cells, and that, compared to WT mice, Vav3 -/- long bones show a marked increase in trabecular bone volume (>2.7 fold, $p<0.001$). While osteoclast differentiation is not affected by lack of Vav3, either in vitro or in vivo, confocal analysis of Vav3-/- OCs reveals that these cells are less spread, with numerous but incomplete actin rings. Podosomes are replaced by irregular actin clusters, and microtubules are completely disorganized. Thus, Vav3-/- OCs fail to polarize when plated onto bone and resorb poorly, explaining the increased trabecular volume in vivo. Both the resorptive and spreading phenotypes are rescued by retroviral transfection of Vav3, but not Vav1, indicating specificity within this family. Since Rho, Rac and Cdc42 have been reported to control cell polarization and spreading, we analyzed the activation of these small GTPases in OCs treated with M-CSF. While cells lacking Vav3 continue to generate GTP-Rho in response to the cytokine, they fail to activate either Cdc42 or Rac. Finally, the same null OCs also exhibit defective αvβ3 signaling in response to cell adhesion, namely failure to phosphorylate either c-Src or ERKs when plated on osteopontin. Thus Vav3, while not regulating OC differentiation, appears to play a key role in controlling cytoskeletal reorganization, cell adhesion-mediated signaling and bone resorption. The fact that Vav3 regulates cytokine-stimulated activation of Cdc42 and Rac, events that correlate with osteoclastic bone resorption, suggests a new role for these GTPases in osteoclast function and M-CSF signaling. Taken together our data suggest that Vav3 is a possible new therapeutic target for osteoporosis.

Control of Multi-Nucleated Osteoclast Formation by RAIN, a Novel RANK-Associated Inhibitor that Regulates Actin Polymerization. A. T. Poblenz*, B. G. Darnay. Bioimmunotherapy, University of Texas M.D. Anderson Cancer Center, Houston, TX, USA.

Formation of multi-nucleated osteoclasts is a central process in bone homeostasis, which is governed by receptor activator of NF-κB (RANK) and its ligand, RANKL. The process of osteoclastogenesis involves at least four basic events: (1) proliferation and migration of precursor cells, (2) early signaling events of differentiation including activation of transcription factors, (3) homotypic cell-cell recognition and membrane fusion in conjunction with the structural reorganization of the multi-nucleated cell, and (4) activation of the multi-nucleated osteoclast to resorb bone. The proteins affecting osteoclast differentiation and activation have been well characterized; however, considerably little is known how triggering RANK causes the fusion and formation of the multi-nucleated osteoclast. We have identified a novel RANK-interacting protein termed RAIN (RANK-Associated Inhibitor), which prevents multi-nucleated osteoclast formation without affecting early RANKL signaling. In contrast, cells lacking RAIN develop a rapid and increased number of osteoclasts after RANKL stimulation. Furthermore, RANKL induces the expression of RAIN at a time when cellular fusion is observed. Consistent with the biological properties of RAIN, *in vitro* studies with recombinant RAIN indicated its ability to co-sediment with G-actin and its ability to prevent the polymerization of actin. On close inspection of the amino acid sequence of RAIN, we observed an actin-binding motif in RAIN when aligned with cofilin and twinfilin, two proteins that cause actin depolymerization. Based upon the potential actin-binding domain in RAIN, a series of point mutations in RAIN (K90/91A, K174/R176A/A180T, and R194A) were constructed, and RAW264.7 cells stably expressing these mutants were generated. Unlike the overexpression of wild-type RAIN in RAW264.7 cells, all RAIN mutants differentiated into TRAP-positive, multi-nucleated osteoclasts and resorbed bone upon RANKL treatment. To our knowledge, this is the first report of a molecule linking RANK to the cellular machinery controlling the formation of the multi-nucleated osteoclast. RAIN's ability to regulate formation of polymerized actin filaments indicates a strong prerequisite for actin turnover in the formation of the multi-nucleated osteoclast.

Transient versus Sustained Activation and Nuclear Accumulation of ERKs Underlie the Anti- Versus the Pro-Apoptotic Effects of Estrogens on Osteoblasts/Osteocytes and Osteoclasts, Respectively. J. Chen, L. I. Plotkin, J. I. Aguirre, L. Han, H. Peng*, S. Kousteni, T. Bellido, S. C. Manolagas. Div Endo/Metab, Center for Osteoporosis and Metabolic Bone Diseases, CA Veterans Healthcare System, Univ of Arkansas for Med Sciences, Little Rock, AR, USA.

Sex steroids exert anti- apoptotic effects on osteoblasts/osteocytes and pro -apoptotic effects on osteoclasts. In spite of such divergent outcomes in both cases the effect of sex steroids requires activation of the extracellular signal regulated kinases (ERKs). To explain the mechanistic basis of this divergence, we searched for potential differences in the kinetics of activation and/or in the subcellular localization of the activated ERKs in response to 17β-estradiol (E2) in the two cell types. To this end, we used the osteocytic MLO-Y4 cell line and osteoclasts generated from murine bone marrow progenitors by treatment with MC-SF and soluble RANKL. In MLO-Y4 cells, E2 produced a rapid and transient phosphorylation of ERKs beginning at 2 min, reaching a peak at 5 minutes and returning to base line by 30 min. In osteoclasts on the other hand, E2 induced ERK phosphorylation within 2 min but the magnitude of this effect increased progressively thereafter until at least 24 h. We then shortened the duration of ERK activation in osteoclasts by pre-treatment for 30 min with 1 mg/ml cholera toxin (CT) which ADP-ribosylates and activates the αs subunit of G proteins leading to activation of the adenyl cyclase/cAMP/PKA pathway, which in turn suppresses ERK phosphorylation. ERK phosphorylation in response to E2 in CT-treated osteoclasts was indeed converted from sustained to transient, with a rapid zenith reached by 2 min, followed by a return to base line by 30 min and remaining low thereafter until at least 24 h. Strikingly, in CT treated-osteoclasts the pro-apoptotic effect of E2 was abrogated. Next we converted transient to prolonged ERK activation in osteocytes by a) inhibiting CRM/exportin1-mediated export of ERKs from the nucleus with leptomycin B, and b) overexpressing a GFP-ERK2 mutant that resides permanently in the nucleus. In either case, instead of preventing, E2 stimulated apoptosis; and, this effect was blocked by the ERK inhibitor PD98059. Overexpression of a wild type GFP-ERK2 or a GFP-ERK2 mutant with impaired translocation into the nucleus did not affect the anti-apoptotic properties of E2. We conclude that the kinetics of ERK phosphorylation and the length of time that phospho-ERKs are retained in the nucleus determines specific downstream patterns of phosphorylation of target transcription factors or other substrates, and thereby defines the pro- versus anti-apoptotic effects of sex steroids on bone and perhaps other cell types.

ER-α Negatively Regulates TGF-β Signaling by Blocking Smad4 Binding to DNA. Y. Wu[1], L. Wu[1], W. E. Gathings*[2], X. Cao[1]. [1]University of Alabama at Birmingham, Birmingham, AL, USA, [2]University of Alabama at Huntsville, Huntsville, AL, USA.

Estrogen is recognized to be essential for bone formation and maintenance since estrogen deficiency can lead to postmenopausal osteoporosis. TGF-β is one of the most abundant cytokines embedded in the bone matrix. It regulates both osteoblast and osteoclast cell proliferation and differentiation as either an autocrine or paracrine factor. Estrogen also enhances TGF-β secretion by osteoblasts and osteocytes. Here we show that ER-α interacts with Smad4 as a transcription cofactor that mediates a direct crosstalk between the estrogen and TGF-β pathways in osteoblasts. Immunoprecipitation assays demonstrated that ER-α co-precipitates with Smad4 in the 2T3 osteoblast cell line. To examine the potential function of this interaction, a TGF-β-responsive luciferase reporter plasmid (pLuc-3Tp) was transfected into 2T3 cells with overexpression of ER-α and treated with TGF-β. The results indicate that ER-α inhibits TGF-β-mediated transcriptional activity from 13 fold to 4 fold. Similar results were obtained when a reporter construct bearing Smad-binding elements (SBE) were used. We also examined endogenous TGF-β downstream gene transcription in 2T3 cells using semi-quantitative RT-PCR. We found that estrogen inhibits TGF-β-induced transcription of these genes (e.g., PAI-1 and Smad7). Mapping of the interaction domains indicates that the N-terminal Mad homologous domain 1 (MH1) and linker region of Smad4 are essential for its interaction with ER-α. Since MH1 is the Smad4 DNA binding domain, these results suggest that interaction of ER-α with Smad4 interferes with Smad4 DNA binding activity. We, therefore, performed Chromatin Immunoprecipitation to examine the effects of ER-α on binding of Samd4 to DNA *in vivo*. TGF-β induced Smad4 binding to the Smad binding elements of the PAI-1 promoter, and co-treatment with estrogen abolished the binding. These results were confirmed with DNA precipitation assays. Smad4 protein co-precipitated with a DNA fragment containing Smad binding elements, and TGF-β enhanced the precipitation. Co-treatment with both estrogen and TGF-β inhibited the formation of the Smad4/SBE complex. In summary, we found that ER-α directly interacts with Smad4. The interaction inhibits TGF-β-induced binding of Smad4 to DNA. Consistent with these observations, estrogen also inhibits TGF-β-induced endogenous gene transcription. Our data suggest that the interaction between ER-α and Smad4 acts as a cross-talk mechanism between estrogen and TGF-β signaling pathways. This cross-talk mechanism may help to further elucidate the roles of TGF-β and estrogen in bone development and remodeling as well as in the pathogenesis of osteoporosis.

Steroid Receptor Coactivator-1 (SRC-1) Contributes to the Maintenance of Bone Volume by Sex Hormones in Both Males and Females. T. Yamada[1], H. Kawano[1], K. Sekine*[2], S. Kato[2], H. Kawaguchi[1]. [1]Orthopaedic Surgery, Univ. of Tokyo, Tokyo, Japan, [2]IMCB, Univ. of Tokyo, Tokyo, Japan.

Although coactivators are known to modulate nuclear receptor activities intracellularly, their physiological roles in skeletal tissues remain unknown. Steroid receptor coactivator-1 (SRC-1) is the first identified coactivator that interacts with steroid receptors and enhances their transcriptional activities. In this study we initially created floxed SRC-1 mice in which the SRC-1 gene locus was flanked by loxP sites, and succeeded in generating SRC-1 deficient mice (SRC-1KO) by mating them with CMV-Cre transgenic mice. SRC-1KO developed normally without abnormalities of major organs except for moderate atrophy of testis in males. In long bones and vertebrae, however, bone densitometry and 3D-μCT analyses revealed significant decreases of trabecular and cortex bone volumes in SRC-1KO as compared to wild-type (WT) littermates at 24 weeks of age in both males and females. Histomorphometric analysis at the proximal tibiae showed that bone volume (BV/TV) of SRC-1KO was about 20% lower than that of WT. Parameters for both bone formation (Ob.S/BS & MAR) and resorption (Oc.N/B.Pm & ES/BS) were higher in SRC-1KO males and females than in WT littermates, indicating a high turnover of osteopenia. Although SRC-1KO showed higher levels of serum and urinary bone metabolic markers (ALP, osteocalcin, deoxypyridinoline), the serum levels of testosterone in males (+30%) and estradiol (E_2) in females (+40%) were also elevated as compared to those of WT littermates. To examine the involvement of SRC-1 in the actions of sex hormones and glucocorticoid on bone, we performed hormone administration experiments. After gonadectomies at 16 weeks of age, bone volumes of WT and SRC-1KO were decreased during the next 8 weeks to the same levels in both sexes. When slow releasing pellets of dihydrotestosterone and E_2 were subcutaneously implanted to gonadectomized males and females, respectively, bone volumes of WT showed full restoration to the sham WT levels; however, in SRC-1KO the restorations were limited to approximately one half, suggesting that osteopenia by SRC-1 deficiency may be due to a partial insensitivity to sex hormones in both sexes. Contrarily, when a slow releasing pellet of prednisolone was implanted, bone volume decrease was similar in WT and SRC-1KO during the following 8 weeks. We conclude that SRC-1 deficiency cannot be compensated by other cofactors in the anabolic actions of sex hormones on bone, although it is not essential in the catabolic action of glucocorticoid. SRC-1 might be involved in the pathophysiology of sex hormone-deficient osteoporosis and therapeutic effects of hormone replacement therapies in humans.

A Deficiency in 1,25-Dihydroxyvitamin D3 Production or Action Is Associated with Parathyroid Hormone Resistance at the Level of Osteoblast-induced Osteoclast Formation. N. K. Shevde, J. A. Reading*, J. M. Prahl*, J. W. Pike, H. F. DeLuca. Biochemistry, University of Wisconsin-Madison, Madison, WI, USA.

Vitamin D and PTH are the two major regulators of mineral homeostasis acting in concert on overlapping tissue targets to regulate serum calcium and phosphorus levels. Early studies support an important physiological interplay between vitamin D3 and PTH. This interplay is highlighted in vitamin D3 deficiency that results in PTH resistance. The mechanism of this resistance remains unknown. To explore this problem, we evaluated the effects of PTH on osteoblast-induced osteoclast (OC) formation in the absence of functional 1,25(OH)2D3 that occurs in 25-hydroxyvitamin D3-1alpha-hydroxylase (1-OHase) null or in vitamin D receptor (VDR) null mice. Bone marrow cells from wildtype (WT) and

VDR null mice were isolated and cultured (106 cells/ml) in the presence of 1,25(OH)2D3 (10-8 M) or PTH (10-7 M). OC formation was assessed after 8 to 10 days by quantitating the total number of multinucleated, TRAP+ cells. Marrow-derived monocytes (105 cells/ml) were also isolated and cultured in the presence of both RANKL and M-CSF to assess the effects of the VDR null phenotype on OC precursor number (OCP). OC were induced by 1,25(OH)2D3 in cultures derived from WT marrow but not from VDR null marrow, as expected. Interestingly, PTH had little effect on VDR null marrow cultures while strongly stimulating OC formation in WT marrow cultures. OCP number was comparable in monocytes derived from both animal sources. These results indicate that the inability of VDR null mice to process 1,25(OH)2D3 signaling impairs the ability of PTH to induce osteoblast-mediated OC formation. We next tested the ability of 1,25(OH)2D3, PTH or the combination to induce OC formation from marrow cells derived from WT and 1-OHase null mice. OC were formed in equal numbers in response to either 1,25(OH)2D3 or the combination of the two hormones from both cell sources. PTH alone, however, induced OC formation only in marrow cells derived from WT mice; no OC were formed from cells derived from 1-OHase null mice. These experiments indicate that a deficiency in either the production or action of 1,25(OH)2D3 reduces the ability of PTH to promote OC formation. This resistance does not appear to be the result of changes in PTH receptor mRNA expression, but may be related to elevated OPG mRNA levels observed in the 1,25(OH)2D3 deficient state. These findings suggest that vitamin D-deficiency may limit the ability of PTH to modulate osteoclast formation, bone resorption and remodeling.

1a,25(OH)2D3 Mediated Rapid Responses in Osteoblasts and Ligand Binding to Caveolae Enriched Membrane Fractions Are Abrogated in VDR Knock-Out Mice but not Wild Type. L. P. Zanello, J. A. Huntakangas*, C. X. Olivera*, J. E. Bishop, A. W. Norman. Biochemistry, University of California-Riverside, Riverside, CA, USA.

The steroid hormone 1a,25(OH)2D3 (1,25D) is known to mediate both genomic responses (hrs-day) via interaction with the classical nuclear vitamin D receptor (VDR) and rapid (sec-min) responses (RR) via interaction with a membrane associated putative steroid receptor VDRmem. A challenging project has been to biochemically identify the VDRmem and to define the RR signal transduction pathway(s) to which it is linked. Here we report comparative studies performed in wild type (WT) and VDR knock-out (KO) mice to assess functional RR (opening of chloride channels and changes in whole cell capacitance) in calvarial osteoblasts and ligand binding [[3H]1,25D] studies to a lipid raft/caveolae enriched membrane fraction (CMF) of intestine (I), kidney (K) and lung (L). We conducted whole-cell patch-clamp measurements in a total of 27 KO and 55 WT primary cultured osteoblasts obtained from 15 and 9 genotyped animals (5 KO couples and 5 WT) respectively. WT osteoblasts expressed Cl- currents that were significantly potentiated by 1,25D, 5nM (n=12 of 12 cells) at depolarizing potentials within the first 1-5 min. However, equivalent Cl- currents in KO osteoblasts were not modified by 0.5-50nM of1,25D. We also found that 1,25D, 0.5-50nM, promoted a significant transient increase in whole cell capacitance value (DCap=2.33 + 1.1pF, n=8 of 12 cells), which is a measure of the cell secretory activity in WT osteoblasts, but not in KO cells (DCap 0.58+0.09, n=8 cells). Using sequential PercollTM and OptiPrepTM gradient ultracentrifugations we prepared a CMF as a source of the VDRmem. Saturable in vitro binding of [3H]-1,25D was detected in CMF of I, K and L (Kd 1.4±0.6 nM and Bmax ≈ 28±10 fmol/mg protein, n=2). VDR knockout (KO) mice displayed a remarkably reduced saturable binding of [3H]-1,25D in both the nuclear fraction (NF) and CMF in all 3 tissues compared with WT mice; for I, K, and L, respectively, WT and KO results were for NF (100% vs. 14±10%, p<0.05 and 100% vs. 28±4%, p<0.05 and 100% vs. 15±18%, p<0.05) and for CMF (100% vs. 50±11%, p=0.05 and 100% vs. 44±39% p=0.15 and 100% vs. 15±5%, p<0.05). Binding of [3H]-1,25D in NF of all WT tissue vs. KO tissue was reduced 100% vs. 19±11%, p<0.001 and in CMF 100% vs. 36±25%, p<0.001.). In western blot analysis expression of classical VDR in chick CMF from I and K was clearly detectable, but was lower in L CMF. These data suggest that a nuclear VDR or slightly altered form may be the VDRmem present in the CMF and that its presence is essential for RR in osteoblasts.

Identification of Calcium Independent Actions of the Vitamin D Endocrine System in Mice with Targeted Disruption of the 1α-Hydroxylase and VDR Genes. D. Panda, D. Miao, I. Bolivar*, J. Li*, G. N. Hendy, D. Goltzman. Department of Medicine, Calcium Research Lab, McGill University, Montreal, PQ, Canada.

Normalization of serum calcium by a "rescue diet" has been reported to reverse abnormalities in mice homozygous for targeted disruption of the VDR gene ($VDR^{-/-}$). To assess whether similar reversal can also occur in mice deficient in the major ligand for the VDR, $1,25(OH)_2D$, we compared parameters of skeletal and calcium homeostasis in $VDR^{-/-}$ mice with the same parameters in mice homozygous for targeted disruption of the 1α- hydroxylase gene ($1\alpha OHase^{-/-}$). Mice were fed either a "high calcium intake diet" (1.5% calcium in the drinking water plus 1% in the diet) or a "rescue diet" (2% calcium plus 20% lactose in the diet) for 3 months after weaning. Both mouse models exhibited hypocalcemia, rickets or osteomalacia and secondary hyperparathyroidism on the high calcium intake. On the rescue diet, serum calcium levels were normalized in both models (11.6mg±0.9 /dl in $1\alpha(OH)ase^{-/-}$ and 12.6mg/dl in $VDR^{-/-}$) and mineralization of bone was normalized. PTH levels decreased 8.4 fold (1430±184 pg/ml to170±19 pg/ml) in the $1\alpha OHase^{-/-}$ mice and 14.4 fold (720±95 pg/ml to 50.0±0.5 pg/ml) in the $VDR^{-/-}$ mice. On the rescue diet, parathyroid gland size normalized in $VDR^{-/-}$ mice, but remained enlarged in $1\alpha(OH)ase^{-/-}$ animals. In addition the cartilaginous growth plate was normalized in $VDR^{-/-}$ mice but remained enlarged and distorted in $1\alpha(OH)ase^{-/-}$ animals. At 4 months of age the increased trabecular bone volume and increased osteoblast numbers observed in both $1\alpha(OH)ase^{-/-}$ and $VDR^{-/-}$ mice on the high calcium intake were decreased below wild type levels in animals fed a rescue diet. These studies confirm that $1,25(OH)_2D$ deficiency and VDR deficiency do not produce identical phenotypes and that parathyroid gland size and the cartilaginous growth plate cartilage abnormalities are normalized by correcting hypocalcemia in VDR deficient but not in $1,25(OH)_2D$ deficient animals. In addition, the reduction of trabecular bone volume below normal in both models, when serum calcium is normal and PTH is measurable, suggests a role for the $1,25(OH)_2D$/VDR system in bone anabolism.

Association of an IGF-I Gene Promoter Polymorphism and Hip Bone Geometry and Its Influence on the Risk of Hip Fracture: The Rotterdam Study. F. Rivadeneira[1], J. Janssen*[2], T. J. Beck[3], J. Houwing*[1], A. Hofman*[1], H. Pols[2], C. M. Van Duijn*[1], A. Uitterlinden[2]. [1]Epidemiology & Biostatistics, Erasmus MC, Rotterdam, Netherlands, [2]Internal Medicine, Erasmus MC, Rotterdam, Netherlands, [3]Radiology, The Johns Hopkins University School of Medicine, Baltimore, MD, USA.

Previously, we genotyped 7012 individuals for a CA-repeat polymorphism in the promoter region of the IGF-I gene and found it associated to bone mineral density (BMD) and frailty fracture with gender specific patterns. We now examined if the association between IGF-I genotypes and hip fracture is related to differences in hip bone geometry (HBG). Structural geometry of the femoral neck (FN) was estimated indirectly from standard DEXA outputs in 2372 men and 3134 women. The computational method assumes the FN as a uniform right circular cylinder and provides estimates of FN properties including *neck width* (*W*), *cross-sectional area* (*CSA*), *cortical thickness* (*T*), and indexes of bone stability and strength such as the *buckling ratio* (*BR*) and *section modulus* (*Z*), respectively. Mean HBG parameters adjusted for age, height and weight were compared among fracture cases vs. non-cases and IGF-I promoter genotypes using ANCOVA. Hip fracture cases in both genders show (highly significant) fracture-predisposing patterns of HBG in all outcomes except for *W* (Table 1). Overall, non-carriers of the *192-bp* allele have patterns of HBG that predispose them to fracture as compared to homozygotes for the allele. In males (Table 2) there is a significant allele dose effect over *W* and *Z*, while in females (Table 3) with *T* and *BR*. These findings suggest that this promoter polymorphism or another polymorphism in linkage disequilibrium influences the distribution patterns of bone mass in a gender specific manner: in males, with a greater influence on size and bone strength, and in females, more on the process of cortical thinning with bone instability. HBG contributes to explain partially the mechanism by which IGF-I genotype differences relate to hip fracture risk in the elderly.

Predicting Long Term Hip Fracture Risk with Bone Mineral Density and Hip Structure in Post-Menopausal Women: The Study of Osteoporotic Fractures (SOF). T. A. Hillier[1], T. J. Beck[2], T. Oreskovic*[2], J. H. Rizzo*[1], K. L. Pedula*[1], D. Black[3], K. L. Stone[3], J. A. Cauley[4], D. C. Bauer[3], B. C. Taylor*[5], S. R. Cummings[3]. [1]Center for Health Research, Portland, OR, USA, [2]Johns Hopkins, Baltimore, MD, USA, [3]UCSF, San Francisco, CA, USA, [4]U Pittsburgh, Pittsburgh, PA, USA, [5]U MN, Minneapolis, MN, USA.

Although BMD is a strong predictor of hip fracture, the majority of fractures occur in older women that do not have osteoporosis by BMD criteria (Wainwright SA ASBMR 2001). The current study seeks to determine if we can improve the prediction of hip fracture in older women with measures of bone geometry and structure.

We applied our hip structural analysis program (Beck TJ et al, JBMR 16(6), 2001) to hip scans obtained in 7646 women participating in SOF who had BMD measured by DXA (Hologic 1000) in 1989-90. Participants were contacted every four months to ascertain falls and fractures, and more than 98% of these follow-up contacts were completed. Hip fractures were adjudicated from radiology reports. We used Cox-proportional hazards model (PH), with stepwise selection, to identify the subset of non-collinear geometry variables that best predict fracture. These variables: cross-sectional area (CSA), subperiosteal width (W), buckling ratio (BR) and neck shaft angle (NSA), were used in subsequent PH models to estimate hazards ratios (HR), per unit SD, for each geometry variable individually, and as a combined group with and without BMD.

Over an average of 10.4 years of follow-up, there were 642 incident hip fractures. After multivariate (MV) adjustment for covariates previously demonstrated to be significant in predicting fracture, the hazard of hip fracture was significant ($p<0.001$) in each model for femoral neck BMD (HR 2.0 per 1 SD decrease), CSA (HR 1.8 per 1 SD decrease), W (HR 1.2), BR (1.6), and NSA (HR 1.2). A MV model of combined geometry variables (CSA, W, BR, NSA) either with or without BMD did not improve the % variance explained (<6% for all models); BMD was the strongest predictor. In a subset of 908 women who reported no falls during the SOF study, the explained variance increased to 8% with the combined geometry variables, and the HR markedly increased for BR (HR 3.7); BMD was not a significant predictor.

We conclude that hip structure variables derived from HSA are strong individual predictors of fracture, but did not significantly improve the overall prediction of hip fracture above BMD alone. However, there are certain subgroups where HSA may be particularly useful in predicting fracture. Future research should continue to focus not only on understanding important structural differences among persons that fracture, but also on finding ways to improve our current ability to predict only a minority of fractures with BMD.

Cumulative Risks of Fracture in Patients Using Oral Glucocorticoids. T. P. van Staa[1], P. Geusens[2], H. Pols[3], C. de Laet[3], H. G. M. Leufkens*[4], C. Cooper[5]. [1]Procter&Gamble Pharmaceuticals, Egham, United Kingdom, [2]University Hospital, Maastricht, Netherlands, [3]Erasmus Medical Center, Rotterdam, Netherlands, [4]Utrecht University, Utrecht, Netherlands, [5]Medical Research Council, Southampton, United Kingdom.

The aim of this study was to estimate 5-year risks of fractures in patients using oral glucocorticoids (GC).

The study population consisted of 191,752 patients aged ≥40 years prescribed an oral GC (in the UK General Practice Research Database). The period of follow-up was divided into time-periods of current (i.e. duration of individual prescription plus 3 months) and no exposure, with patients moving between these exposures. Using Cox proportional hazards models, a risk score, indicating the association to risk, was initially estimated from daily and cumulative GC dose of each exposure period, body mass index (BMI), and disease and drug history. Then, the 5-year risk of fracture (Cox survival function) was estimated for each sum of scores.

The risk scores for osteoporotic (O) and hip (H) fracture are summarised in the table (GC daily dose in mg/day [DD], cumulative dose in grams [CD]; GC scores for a person aged 65 years).

DD	CD	O	H		O -6	H -6
< 2.5	≤ 1	0	0	Age (10 years)	4	8
	> 1	3	1	Fall history	8	8
2.5-4.9	≤ 1	5	4	Prior fracture	6	5
	> 1	3	4	BMI < 20	3	6
5-7.4	≤ 1	2	5	RA	2	4
	> 1	5	5	IBD	1	2
7.5-14.9	≤ 1	6	9			
	> 1	7	10			
15-29.9	≤ 1	4	9			
	> 1	9	11			
≥ 30	≤ 1	2	2			
	1-5	6	4			
	> 5	12	12			

The 5-year risk of osteoporotic fracture for patients with scores of 30, 40, 50, and 60 was 7.2, 18.5, 42.7, and 78.1%, respectively. Hip fracture scores of 60, 70, 80, and 90 corresponded to 5-year hip fracture risks of 1.7, 4.6, 11.8, and 28.6%, respectively. The 5-year risk of osteoporotic fracture for a 65-year female with RA, low BMI, and fracture and fall history using 7.5 mg GC (total score of 52) was 49.4% (male with similar history 31.2%). Hip fracture risk was 18.6% (male 10.8%). A 80-year old female with COPD and low BMI who used 2.5 mg for 2 years had a 5-year risk of osteoporotic fracture of 12.8% (male 7.2%). Hip fracture risk was 5.1% (male 2.8%). Pulse dosing (defined as short-term use with DD ≥ 30 mg) was associated with only a small increased risk of osteoporotic fracture in first-time users (relative rate 1.20; 95% CI 0.98-1.46) and in patients with pulse dosing at least 3 months after end of prior GC use (1.21; 1.04-1.42).

In conclusion, this risk score allows for assessing an individual's risk of fracture.

A Meta-analysis of Body Mass Index (BMI) as a Predictor of Fracture Risk. C. E. D. De Laet, H. Johansson*, O. Johnell, J. Kanis, E. V. McCloskey, D. Mellstrom*, L. J. Melton, A. Oden*, P. Delmas, P. Garnero, A. Oglesby, J. Eisman, H. Pols, J. Reeve, A. Silman, A. Tenenhouse. Dept of Public Health, Erasmus MC, Rotterdam, Rotterdam, Netherlands.

Today, body mass index (BMI) is a well-documented risk factor for future fracture. The aim of this study was to quantify this effect and to explore the relationship of fracture risk (all osteoporotic fractures and hip fracture) with age, gender and bone mineral density (BMD) from an international perspective using world-wide data. We studied 45,000 men and women from nine prospective population-based cohorts comprising Rotterdam, EVOS/EPOS, CaMos, Rochester, Sheffield, Dubbo, EPIDOS, and two cohorts from Gothenburg with a total follow-up of almost 190,000 person years. The effect of BMI, BMD and age on osteoporotic fracture risk and on hip fracture risk was examined using a Poisson model in each cohort separately. The results of the different studies were then merged using weighted coefficients. Without information on BMD, low BMI was associated with a significantly increased risk of all osteoporotic fractures, controlled for age. But, this risk increase was not linearly distributed across BMI values as shown in the table. At the extremes the risk ratios increased at a steeper rate than around the median. In the common range of BMI (around 26 kg/m²) the risk only modestly increased with decreasing BMI. Also for hip fracture risk, BMI was a significant risk factor, especially at the extremes of the BMI spectrum. We observed no significant differences in risk ratio between men and women. These risk ratios by BMI were markedly reduced when adjusted for BMD suggesting that BMD is an important intermediary.

Risk ratio in men and women combined controlled for age (BMI=25 as reference)

	Osteoporotic fracture		Hip fracture	
BMI	Without BMD	With BMD	Without BMD	With BMD
15	1.95	1.18	4.18	1.64
20	1.30	1.04	1.96	1.32
25	**reference**	**reference**	**reference**	**reference**
30	0.90	0.98	0.83	1.08
35	0.75	0.93	0.76	1.32
40	0.59	0.92	0.52	1.19

We conclude that low BMI confers a risk of fracture of substantial importance that is independent of age and sex. The significance of BMI as a risk factor varies according to the level of BMI. Its validation on an international basis permits the use of this risk factor in case finding strategies. These data also show that there is no conflict between advice for weight control with reasonable target values (such as for the prevention of diabetes or CVD) and the prevention of osteoporotic fractures.

Increased Fracture Risk among Breast Cancer Survivors -Results from the Women's Health Initiative. Z. Chen[1], M. Maricic[1], T. L. Bassford*[1], C. Ritenbaugh*[2], A. M. Lopez*[1], M. S. Leboff[3], M. Gass*[4], D. H. Barad*[5]. [1]University of Arizona, Tucson, AZ, USA, [2]Kaiser Center for Health Research, Portland, OR, USA, [3]Brigham and Women's Hospital, Boston, MA, USA, [4]University of Cincinnati, Cincinnati, OH, USA, [5]Albert Einstein College of Medicine, Bronx, NY, USA.

Breast cancer survivors have an increased risk of low bone density, however, except for vertebral fractures assessed by a radiographic method, the risk of other fractures among breast cancer survivors has not been previously reported. We hypothesized that postmenopausal women with a history of breast cancer have a higher risk for fractures compared to women of the same age who have not had cancer. The study population was a prospective multiethnic cohort of postmenopausal women from the Women's Health Initiative Observational Study (WHI-OS). Among them, participants who replied affirmatively to the question " Did you ever have breast cancer?" at baseline were considered to be breast cancer survivors (n = 5,298). The reference group included WHI-OS women who had not had any type of cancer at baseline (n = 80,848). The average follow-up was 5.1 years. Information on fractures was self-reported from a yearly updated medical questionnaire. The confirmation rate of all self-reported fractures was approximately 70% based on results from a subset of WHI participants. Self-reported hip fractures were further confirmed by reviewing medical records. At baseline, breast cancer survivors were older (65.0 vs. 63.4 years), more years past menopause (17.6 vs. 15.9 years), and heavier (72.4 vs. 71.5 kg) than the women in the reference group. Results from Cox regression models indicated that breast cancer survivors had more than 28% increased risk for all types of fractures except hip fractures after adjusted for age, years since menopause, weight, ethnicity and geographic region of enrollment into the study (Table 1). In conclusion, compared to women without any cancer history, breast cancer survivors are at an increased risk for fractures, other than hip fractures. Our results suggest that prevention is needed to reduce fracture risk in the growing population of breast cancer survivors.

Table 1. Adjusted Results from the Cox Proportional Hazard Models

Fracture Outcomes	Breast Cancer Survivors (N = 5298)	None Cancer Reference Group (N = 80848)	Hazard Ratio	95% CI		p value
	% Fractures	% Fractures		Lower	Upper	
Hip	0.6%	0.6%	0.912	0.621	1.339	0.766
Clinical spine	1.4%	1.0%	1.287	1.001	1.655	0.049
Lower arm / wrist	3.2%	2.3%	1.323	1.119	1.564	0.001
All other	9.7%	7.6%	1.317	1.119	1.447	0.000
Total	13.6%	10.5%	1.305	1.205	1.414	0.000

A Novel Association Between a Frizzled Related Protein Amino Acid Variant and Vertebral Fracture Risk in Older Women. J. M. Zmuda[1], W. C. Hsueh*[2], L. Lui[2], K. L. Stone[2], J. A. Cauley[1], T. A. Hillier[3], S. Germer*[4], R. Higuchi*[4], D. R. Greene*[4], J. Li*[4], J. D. Allard*[5], T. Nikolcheva*[5], J. Mangaccat*[4], N. Umblas*[4], G. Peltz*[5], S. R. Cummings[2]. [1]University of Pittsburgh, Pittsburgh, PA, USA, [2]University of California, San Francisco, CA, USA, [3]Kaiser Permanente Center for Health Research, Portland, OR, USA, [4]Roche Molecular Systems, Alameda, CA, USA, [5]Roche Palo Alto, Palo Alto, CA, USA.

Frizzled related protein (FRZB; aka secreted frizzled related protein 3) is a soluble antagonist of Wnt, a secreted growth factor involved in tissue differentiation including skeletal formation. Recently, FRZB has been implicated in the determination of bone mineral density (BMD) in inbred mice (G. Peltz et al. manuscript in preparation). In addition, transfection of FRZB into mesenchymal stem cells can obviate the Wnt-induced formation of osteoblasts instead of adipocytes in-vitro. In the present study, we tested polymorphisms within FRZB and found that a C→G polymorphism which creates an Arg324Gly amino acid substitution is associated with vertebral fracture among women aged 65 years and older in the Study of Osteoporotic Fractures.

Incident hip fractures over an average of 10.8 years of follow-up were validated by review of X-ray films. Incident vertebral fractures were defined by morphometry using lateral spine radiography at baseline and an average of 3.7 years later. Women with an incident hip fracture (n=275), vertebral fracture (n=262) or low (T score <-2.5) total hip BMD (n=276) were compared to 278 control women without a history of fracture and a total hip BMD above the top 20% percentile of the BMD distribution (Z score >1.28). The Arg324Gly polymorphism was genotyped using allele specific, kinetic polymerase chain reaction (Germer, et al., Genome Res 10:258-266, 2000). Logistic regression was used to estimate the odds ratios (OR) and 95% confidence intervals (CI) associated with at least one 324Gly minor allele. The minor allele frequency was 0.10 among controls. There was no significant association between the Arg324Gly polymorphism and either low hip BMD or hip fracture risk. In contrast, women with at least one 324Gly allele had 51% lower age-adjusted risk of vertebral fracture (95% CI: 0.30, 0.82) compared to women with the Arg324Arg genotype. Additional adjustments for body mass index, use of hormone therapy, and lumbar spine BMD did not alter the relationship between the Arg324Gly polymorphism and vertebral fracture risk (OR: 0.39; 95% CI: 0.17, 0.88). We conclude that the Arg324Gly amino acid polymorphism in FRZB, or a closely linked allelic variant, may contribute to the genetic susceptibility to vertebral fracture among older women.

Gain-of-Function Mutation of FGFR2IIIc: A Mouse Model of Crouzon Syndrome. R. M. Locklin*[1], V. P. Eswarakumar*[2], A. Harmelin*[3], G. M. Morriss-Kay*[1], P. Lonai*[2]. [1]Human Anatomy and Genetics, University of Oxford, Oxford, United Kingdom, [2]Molecular Genetics, Weizmann Institute of Science, Rehovot, Israel, [3]Veterinary Services, Weizmann Institute of Science, Rehovot, Israel.

Crouzon syndrome, the most common craniosynostosis syndrome, is associated with dominant mutations of fibroblast growth factor receptor 2 (FGFR2). Most are in exon IIIc, encoding part of the external ligand-binding domain, and cause receptor dimerization leading to ligand-independent activation.

FGFR2 is alternately spliced, having IIIb or IIIc forms with unique binding specificity and expression patterns. IIIc is expressed in pre-osteogenic cartilage rudiments and binds epithelial FGFs. To investigate the role of FGFR2IIIc in craniosynostosis, we generated a gain of function mouse mutant. The homozygous mutation was perinatal lethal, with pronounced brachycephaly, cleft palate, multiple skeletal synostoses and disorders of other organs. The heterozygote was viable and fertile, exhibiting craniosynostosis, a domed skull vault, ocular proptosis and a milder brachycephaly. No limb defects were apparent. The heterozygous mutant is therefore a good model for the human disorder.

For detailed examination, skeletal preparations of heterozygotes were stained with alizarin red. Coronal sutures were found to be completely fused and lambdoid sutures partially fused. Sagittal sutures, which do not close in the mouse, remained partially separable but contained wormian bones. Parietal bones were larger, and frontal bones, smaller, than wild types, while the skull base was shortened and thickened.

Effects on the proliferation-differentiation balance in developing craniofacial bones was investigated using bromodeoxyuridine (BrdU) immunohistochemistry to label proliferating cells. The proportion of BrdU-labelled nuclei at embryonic day 14 (E14), E16 and postnatal day 1 (P1) was quantitated using an image analysis system. At E14 proliferation at the coronal suture was increased in heterozygotes compared to wild types, while by P1 this appeared to be reversed. Thus the mutation could result in an early increase in proliferation followed by an early switch to differentiation, leading to premature fusion of the suture. In contrast, at the basioccipital-basisphenoid synchondrosis, the heterozygotes exhibited a highly significant decrease in proliferating chondrocytes at E14, as well as an increase in the thickness of the periosteum. This may explain the shortened and thickened skull base.

FGFR2IIIc is important in bone formation but exerts different effects on endochondral and intramembranous ossification. The FGFR2IIIc gain-of-function mutant provides a valuable model of Crouzon syndrome.

Ubiquitous Overexpression of *Phex* Does Not Fully Rescue the *Hyp* Mouse Phenotype. R. G. Erben[1], D. Mayer*[1], K. Weber*[1], T. Johnson*[1], K. Jonsson[2], H. Jüppner[2], B. Lanske[3]. [1]Institute of Animal Physiology, University of Munich, Munich, Germany, [2]Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA, [3]Harvard School of Dental Medicine, The Forsyth Institute, Boston, MA, USA.

Mutations of Phex, a phosphate regulating gene with homologies to endopeptidases on the X chromosome, are responsible for X-linked hypophosphatemia (XLH) in humans, and its mouse homologue, Hyp. Recently, it has been shown that targeted overexpression of Phex in osteoblasts is not sufficient to rescue the Hyp phenotype. Therefore, the aim of this study was to examine whether ubiquitous overexpression of Phex in transgenic mice would fully rescue the Hyp phenotype. To test this hypothesis, we generated two mouse lines overexpressing the human Phex gene under the control of a human β-actin promoter. With the exception of brain, RT-PCR analyses showed expression of the transgene in Phex transgenic (Phex-tg) mice in all tissues examined. Subsequently, we crossed female heterozygous Hyp mice with male heterozygous Phex-tg mice to produce wildtype (WT), Phex-tg,

Hyp, and Hyp/Phex-tg offspring. Twelve-week-old male mice were used for all studies. Compared with their WT littermates, Phex-tg mice had normal bone mineral density (BMD) as measured by peripheral quantitative computed tomography, normal bone histology, and normal serum and urinary phosphate. Hyp mice demonstrated the known phenotype characterized by reduced body weight, hypophosphatemia, hyperphosphaturia, and rickets. Hyp/Phex-tg mice had normal body weight relative to WT controls, and showed a dramatic, albeit not complete, improvement in femoral BMD. Total BMD of the femoral shaft increased from 384 ± 28 in Hyp to 541 ± 27 in Hyp/Phex-tg mice, and total BMD of the femoral metaphysis from 315 ± 38 in Hyp to 407 ± 25 mg/cm³ in Hyp/Phex-tg mice (means ± SD). In WT littermates, the BMD of the femoral shaft and the femoral metaphysis was 596 ± 32 and 455 ± 56 mg/cm³, respectively. Compared with Hyp mice, bone histomorphometry in Hyp/Phex-tg mice revealed pronounced improvements in structural bone parameters, a normal growth plate, and a dramatic reduction in osteoid volume, although some disturbances in bone mineralization remained. Surprisingly, however, Hyp and Hyp/Phex-tg mice had comparable reductions in tubular reabsorption of phosphate, and were hypophosphatemic relative to WT controls. All results were similar for both Phex-tg mouse lines. Thus, our data further strengthen the notion that the pathophysiological mechanisms behind renal phosphate wasting and the bone mineralization defect in XLH may involve different factors.

High-Throughput Analysis of Bone Phenotypes in Gene Knockout Mice to Identify Novel Osteoporosis Drug Targets. R. Brommage[1], Z. Z. Shi*[2], G. Liu*[1], D. R. Powell*[1]. [1]Endocrinology, Lexicon Genetics, The Woodlands, TX, USA, [2]Target Validation, Lexicon Genetics, The Woodlands, TX, USA.

Screening gene function *in vivo* is a powerful approach to discover novel drug targets in the human genome (Zambrowicz and Sands, Nature Review Drug Discovery 2:38-51; 2003). Using both gene-trapping and homologous recombination technologies, 926 knockout (KO) mouse lines have been generated, involving genotyping ~255,000 mice. Mice are F2 crosses from C57BL/6J and 129 SvEv parental strains. Of these 926 KO lines, 229 (25%) are embryonic/neonatal lethal or have reduced viability. All 697 viable lines have been analyzed by PIXImus DEXA at ~14 weeks of age, when peak BMD has been attained. Using a Scanco μCT40, trabecular bone parameters in the fifth lumbar vertebrae (LV5) have been analyzed in 279 lines and midfemur cortical thickness (CT) in 243 lines. DEXA analyses are performed on both male and female mice, but only males are analyzed by μCT. For the vast majority of lines, 4 KO and 2 wild-type control mice are analyzed for each gender. For DEXA screening, volumetric BMD in KOs is compared to both littermate (LM, n = 668 lines) and historical (HC, n = 697 lines) wild-type controls. Volumetric BMD in KOs averages 99.7% of LM values with a standard deviation (SD) of 2.9% and 99.8% of HC values with a SD of 4.4%. LV5 trabecular bone volume (TBV) in KOs averages 20.3% with a SD of 4.2%. Femoral CT averages 253 μm with a SD of 15 μm. Lines with high bone mass resulting from geometrically large bones are of low interest for drug development. These high throughput screens successfully identified two genes known to be important in bone metabolism. LRP5 KOs have low bone mass (vBMD = 89% of LM and 91% of HC, CT = 226 μm) and *klotho* KOs have high vBMD (119% of LM and 133% of HC) and high TBV (43%) but low CT (165 μm). KO of the amino-bisphosphonate target farnesyl diphosphate synthase is embryonic lethal. Using these high throughput procedures, a recently identified gene (LG881) coding for an enzyme has been observed to influence bone mass. TBV in female KO mice is elevated by 52% in LV5 (22.2% ± 1.5%, n = 14 vs 14.6% ± 1.1%, n = 13; $P < 0.001$) and 144% in the distal femur metaphysis (7.8% ± 1.4%, n = 14 vs 3.2% ± 0.7%, n = 13; $P = 0.01$). At both sites, increased trabecular number is more dramatic than changes in trabecular thickness. No nonskeletal phenotypes have been identified. The high bone mass phenotype resulting from genetic ablation of this enzyme provides a novel target for the development of drugs to treat osteoporosis.

The Bone Morphogenetic Protein 2 Gene Contributes to Bone Density and Osteoporotic Fractures. U. Styrkarsdottir[1], J. Cazier*[1], O. Rolfsson*[1], H. Larsen*[1], E. Bjarnadottir*[1], V. D. Johannsdottir*[1], M. S. Sigurdardottir*[1], K. Jonasson*[1], M. L. Frigge*[1], A. Kong*[1], J. R. Gulcher*[1], G. Sigurdsson[2], K. Stefansson*[1]. [1]deCode Genetics, Reykjavik, Iceland, [2]National University Hospital, Reykjavik, Iceland.

The purpose of this study was to map a locus for osteoporosis and isolate the corresponding gene.

A genome wide scan was performed in extended Icelandic osteoporotic families with a framework scan of 1000 microsatellite markers. We used multipoint, affected-only allele-sharing methods to assess the evidence for linkage, obtained using the program Allegro and the Decode Genetic map. An initial set of 207 pedigrees was assembled containing 1334 study individuals. Linkage analysis was performed by defining an osteoporotic phenotype and considering only those meeting criteria as affected. Phenotypes aimed at mapping genes specific to skeletal sites (hip and spine), and mapping genes causing generalized osteoporosis (moderate and severe). Age-sex-and-weight corrected BMD at the hip or spine, below a certain cut-off (lowest 16th for hip, spine, or moderate phenotype and lowest 10th for the severe phenotype) was used as the basic phenotype, adding osteoporotic fractures and bisphosphonate users as affected. Strongest linkage was identified to chromosome 20p12 in all four phenotypes, and after adding more markers to the region, thereby increasing the information content to over 95%, resulted in LOD scores of 2.87, 4.56, 3.75 and 4.96 (P value 8.8×10^{-7}), for spine, hip, moderate and severe phenotypes, respectively.

The 9 cM region defined within the drop of one in LOD score corresponds to a 2.2 MB segment containing 6 known genes (*BMP2*, *CHGB*, *LOC51605, C20orf154*, *C20orf155*, and *C20orf42*), the *BMP2* gene being a strong candidate. However, expression analysis showed that four of the genes in the region are expressed in bone marrow or in an osteoblast cell line (*BMP2, C20orf42, C20orf154, and CHGB*). A very dense set of polymorphic markers distributed across the 1-LOD drop, 30 microsatellites and 99 SNPs, were used for identifying the osteoporosis gene by association analysis and LD analysis. A case-control association analysis in 800 affected (severe phenotype) and 800 randomly collected controls identified haplotypes spanning the *BMP2* gene associated with osteoporosis. *BMP2* is associated with many definitions of an osteoporotic phenotype, including osteoporotic fractures as well as low bone mineral density (BMD), both before and after menopause, and in men. Thus, *BMP2* gene variation appears to be a major risk factor for osteoporosis and osteoporotic fractures in Iceland.

Analysis of *GCMB* Gene Allelic Variants in Isolated Hypoparathyroidism. C. Ding[1], Z. Deng*[1], M. A. Levine[2]. [1]Pediatrics, Johns Hopkins University, Baltimore, MD, USA, [2]Pediatrics, Cleveland Clinic Foundation, Cleveland, OH, USA.

Mutations of the genes encoding PTH and the calcium sensing receptor are associated with isolated hypoparathyroidism (IH), but many cases remain unexplained thus implicating other genes in the molecular pathogenesis. One candidate is the *GCMB* gene located at chromosome 6p23-24, which encodes a human ortholog of the *Drosophila glial cells missing (gcm)* gene, especially as this protein is expressed predominately, if not exclusively, in parathyroid cells and is critical for development of the parathyroid glands. We previously reported homozygous intragenic deletion of the *GCMB* gene as the basis for autosomal recessive IH in one kindred (Ding *et al*, J Clin Invest 2001). To investigate the prevalence of *GCMB* mutations we isolated genomic DNA from 25 patients with sporadic or familial IH from 16 families, and analyzed the 5 exons, intron-exon boundaries, and the promoter of the *GCMB* gene by direct sequencing of PCR products. We identified variant nucleotide changes in 10 patients, including heterozygous promoter mutations (-74 G to T and -149 G to A), neutral mutations (codons 154 AAG to AAA; 203 GGT to AGT) and missense mutations (G203S, I227V, Y282D, and N315D). Among the 8 patients with missense mutations, 6 are heterozygous and 2 are compound heterozygotes. Linkage analysis of *GCMB* mutations in one extended kindred excluded both the Y282D and N315D variants as causative of IH, however neither variant was present as a common polymorphism in a screen of genomic DNA from 50 unrelated subjects. To examine the transactivating potential of the *GCMB* variants, we used site-directed mutagenesis to insert the missense mutations into an epitope-tagged wild type human GCMB cDNA. Wild type or mutant GCMB cDNA's were transiently expressed in HEK293T cells with a luciferase reporter plasmid carrying six tandemly arranged GCM binding sites (6x gbs luc). RT-PCR and immunoblot showed that variant forms of GCMB with amino acid substitutions were expressed at levels similar to that of wild type GCMB. GCMB variants with I227V or Y282D were as effective as wild type GCMB in stimulating luciferase activity (50 to 150-fold stimulation). By contrast, the G203S and N315D variants stimulated luciferase activity at levels that were 40% and 50% lower than wild type GCMB, respectively. Co-transfection of HEK293T cells with equal amounts of wild type and variant GCMB did not show dominant inhibitor activity. Our results suggest that *GCMB* gene mutations are an unusual cause of IH. On the other hand, our study indicates that there are many allelic variants for GCMB, some of which appear to have reduced transactivating potential. The prevalence, and significance, of these allelic variants remains to be determined.

Disclosures: ***M.A. Levine****, None.*

1084

Deletion of *Mepe* in *Hyp* Mice Fails to Correct Hypophosphatemia but Partially Rescues Abnormal Mineralization *Ex Vivo*. S. Liu[1], T. A. Brown*[2], Z. Xiao[1], R. Guo*[1], L. D. Quarles[1]. [1]Medicine, Duke University, Durham, NC, USA, [2]Department of Cardiovascular and Metabolic Diseases, Pfizer Global Research and Development, Groton, CT, USA.

X-linked Hypophosphatemia (XLH) is characterized by hypophosphatemia, impaired mineralization and aberrant $1,25(OH)_2D_3$ regulation. Inactivating mutations of PHEX is the cause of XLH. PHEX deficiency leads to the accumulation of a phosphaturic factor, called phosphatonin. The matrix extracellular phosphoglycoprotein *Mepe* (also called *Of45*) is increased in the *Hyp* mouse homologue of XLH and is a candidate for phosphatonin. To gain further insights into the biological relevance of MEPE in the pathogenesis of the XLH, we transferred *Mepe*-deficient mice onto the *Hyp* mouse background. *Hyp* mice had hypophosphatemia (5.5±0.5 mg/dl), lower serum calcium (7.1±0.1 mg/dl), increased serum PTH (44 ± 6 pg/ml), and inappropriately normal $1,25(OH)_2D_3$ levels (213±40.5 pM) compared to wild-type controls (9.1±0.6 mg/dl, 7.7±0.1mg/dl, 33±9 pg/ml and 217 ±37 pM). *Mepe*$^{-/-}$mice had normal serum phosphorus (9.9±0.6 mg/dl), calcium (7.7±0.1 mg/dl) and $1,25(OH)_2D_3$ (262 ±43 pM), and unexpectedly reduced serum PTH levels (17±3 pg/ml). Transfer of *Mepe* deficiency onto the *Hyp* mouse background failed to correct the hypophosphatemia (5.3±0.3 mg/dl), and resulted in serum calcium (7.4±0.1mg/dl), PTH (34.0 ±9.2 pg/ml) and $1,25(OH)_2D_3$ (221±11 pM) levels in the *Mepe* $^{-/-}$*/Hyp* mice indistinguishable from values in *Hyp* mice. Femoral BMD (g/cm^2) was significantly lower in *Hyp* mice (0.048±0.002) compared to wild-type controls (0.065 ±0.009). BMD in *Mepe*$^{-/-}$mice (0.062±0.001) was not increased and *Mepe*$^{-/-}$*/Hyp* mice retained low BMD values (0.043±0.002). In contrast, serum osteocalcin (pg/ml) and urinary Dpd/creatinine were significantly greater in *Hyp* (249±30 and 92 ±25) compared to respective values in wild-type controls (175±13 pg/ml and 13.5 ±3.9) and *Mepe*$^{-/-}$mice (200±18 and 20±4). *Mepe*$^{-/-}$*/Hyp* mice had further increases in osteocalcin (348±29) but not Ddp/Cr (59±15) levels. Bone marrow stromal cultures (BMSCs) derived from *Hyp* mice displayed impaired mineraliza-

tion compared to wild-type and *Mepe*$^{-/-}$ mice, whereas BMSCs from *Mepe*$^{-/-}$*/Hyp* mice had increased mineralization indistinguishable from wild-type controls. These results demonstrate that M*epe* is not mediating the hypophosphatemia in *Hyp* mice, and that persistent hypophosphatemia in M*epe*$^{-/-}$*/Hyp* may mask the effects of *Mepe* deficiency to improve bone mineralization, since rescue of abnormal mineralization occurred in *Hyp* and *Mepe*-deficient BMSCs. These results demonstrate that *Mepe* is not phosphatonin, but may be involved in the pathogenesis of defective mineralization in *Hyp* mice.

Evidence for a Physiological Role of FGF-23 in the Regulation of Renal Phosphate Reabsorption and Plasma Calcitriol in Healthy Humans. S. L. Ferrari, J. P. Bonjour, R. Rizzoli. Department of Geriatrics and Internal Medicine, Division of Bone Diseases, Geneva, Switzerland.

FGF-23 appears to be responsible for tumor-induced osteomalacia (TIO) and is also implicated in autosomal-dominant hypophosphatemic rickets (ADHR), two disorders characterized by hypophosphatemia, renal phosphate (Pi) wasting and inappropriately low plasma calcitriol. Pi homeostasis is regulated by tubular Pi reabsorption and calcitriol production, two regulators which respond to dietary Pi intake independently of PTH. To investigate whether FGF-23 contributes to the physiological regulation of Pi homeostasis in humans, we measured the renal handling of Pi, calciotropic hormones and serum FGF-23 in 29 healthy male volunteers (mean age ±sem, 24.3 ±0.5 yrs) submitted to a dietary modification trial for two weeks. After 2 days on their regular diet, subjects were advised to a low Pi diet, including a Pi binder (Al and Mg hydroxide, 1g before each meal) for 5 d. During this period, dietary calcium (Ca) was also restricted in order to minimize concomitant changes in PTH. This was followed by 2 d. of regular diet and 5 d. of high Pi diet including a supplement of 1000 mg Pi/d. Measurements were performed on the last day of each diet period after an overnight fast. Serum FGF-23 was measured by ELISA recognizing the COOH-terminus (aa 180-251) of the molecule (Immunotopics Inc. (San Clemente, CA), with a lower limit of detection of 3 RU/ml and an inter-assay CV of 5 to 7.3%.
On regular, low and high Pi diet, 24 hr. urinary (U) Pi excretion was 1.99 ±0.07, 1.03 ± 0.08 and 3.68 ±0.16 (mmole/mmoleCreat/d, p<0.0001), respectively, and plasma Pi was 1.26 ±0.03, 1.14 ±0.03 and 1.23 ±0.03 (mmole/L, p=0.0033), whereas plasma iCa remained unchanged. Among subjects adherent to the dietary changes (27/29), FGF-23 levels decreased by 29 ±6% and increased by 31 ±9% on low and high Pi diets, respectively, compared to regular diet (p<0.0001), and were positively correlated with 24 hr. UPi excretion (p=0.0003) but not with 24 hr. UCa excretion. In contrast, PTH increased non-significantly on both low and high diets. FGF-23 was negatively correlated with tubular Pi reabsorption (TmPi/GFR, p=0.0028) and plasma calcitriol (p=0.05), whereas PTH was not. By multiple regression analysis, plasma Pi and FGF-23 were both negatively correlated to calcitriol (p=0.0021 and 0.04, respectively), whereas PTH was not.
In conclusion, FGF-23 plasma levels vary in response to changes in dietary Pi. FGF-23 negatively correlates with both renal Pi reabsorption and plasma calcitriol, suggesting that this phosphaturic factor plays a physiological role in Pi homeostasis.

Parathyroid Hormone (1-34; Teriparitide) Enhances Experimental Fracture Healing. Y. M. Alkhiary[1], L. C. Gerstenfeld[2], D. M. Cullinane[2], D. Nathanson*[1], E. Krall[2], M. Sato*[3], B. Mitlak*[3], T. A. Einhorn[2]. [1]Restorative Sciences & Biomaterials, Boston University School of Dental Medicine, Boston, MA, USA, [2]Boston University Medical Center, Boston, MA, USA, [3]Lilly Research Laboratories, Indianapolis, IN, USA.

Substantial progress has been made in the use of surgically implanted recombinant proteins to enhance fracture (fx) healing where there is nonunion or substantial loss of bone. However, a systemically administered therapy that could promote fracture healing would be desirable. We therefore tested the hypothesis that a once-daily subcutaneous injection of teriparatide could enhance fx healing. Two hundred fifty-two male Sprague Dawley rats underwent standard, closed mid-diaphyseal femoral fxs. Immediately post-fx, animals were divided into three groups and administered daily injections of 5 ug/kg teriparatide, 30 ug/kg teriparatide, or aqueous vehicle (control) for a maximum of 35 days treatment. Each group was further divided into three subgroups, which were euthanized on day 21, 35, or 84 post fx respectively. At necropsy, bones were harvested and the calluses subjected to QCT and mechanical torsion testing to failure. Additionally, calluses from three animals in each group were analyzed by histomorphometry. The 30 ug dose produced significant increases on day 21 post-fx for bone mineral content (BMC; p=0.006), bone mineral density (BMD; p=0.001), and percent cartilage in the callus (p=0.004) relative to controls. On day 35, both the 30 ug (p=0.001) and the 5 ug (p=0.01) groups showed increases in BMC and BMD. At this time, the 30 ug group also showed a significant increase in torque strength (p=0.001). While dosing was discontinued after day 35, analyses performed after 84 days in rats previously treated with 30 ug showed sustained increases over control for BMC (p=0.001) and BMD (p=0.002). Histological analysis and geometric measurements of the calluses further showed that there was no change in osteoclast number, while overall cortical diameters in the teriparatide treated animals were greatest at 84 days. These data show that daily subcutaneous administration of low-dose teriparatide, PTH (1-34), enhances fracture healing by increasing BMD, BMC, and strength, and produces a sustained anabolic effect throughout the remodeling phase of fracture repair.

MEPE Regulates Bone Mineralization and Phosphate Transport: PHEX and the MEPE ASARM-Peptide. P. S. N. Rowe[1], Y. Kumagai[2], G. Gutierrez[3], I. R. Garrett[3], R. Blacher*[2], D. Rosen*[2], D. Chen[3], M. K. Drezner[4], L. D. Quarles[5], G. R. Mundy[6]. [1]Periodontics, UTHSCSA, San Antonio, TX, USA, [2]Acologix, Emeryville, CA, USA, [3]Osteoscreen, San Antonio, TX, USA, [4]Univ of Wisconsin, Madison, WI, USA, [5]Duke Univ, Durham, NC, USA, [6]UTHSCSA, San Antonio, TX, USA.

Matrix extracellular phosphoglycoprotein (MEPE) expression is markedly elevated in X-linked hypophosphatemic rickets (Hyp) osteoblasts and in oncogenic hypophosphatemic osteomalacia (OHO) tumors. It is also expressed exclusively in osteoblasts, osteocytes, and odontoblasts. Since the Hyp defect is associated with osteoblast-secreted factors that impair mineralization and renal phosphate excretion and OHO has many phenotypic similarities to Hyp, we examined the effects of recombinant full-length human-MEPE (Hu-MEPE) on serum and urinary phosphate in-vivo, 33PO4-uptake in renal proximal-tubule-cultures and mineralization of osteoblast cultures. Dose dependent hypophosphatemia and hyperphosphaturia occurred in mice following intraperitoneal (IP) administration of Hu-MEPE (up to 400 ug/kg/31h), similar to mice given the phosphaturic hormone PTH (80 ug/kg/31h). Also the fractional excretion of phosphate (FEP) was stimulated by MEPE (65.0% (P<0.001)) and PTH groups (53.3% (P<0.001) relative to the vehicle group (28.7% (SEM 3.97)). In addition, Hu-MEPE significantly inhibited 33PO4-uptake in primary human proximal-tubule renal-cells (RPTEC) and a human renal cell-line (Hu-CL8) in vitro (Vmax 53.4% inhibition; Km 27.4 ng/mL, and Vmax 9.1% inhibition; Km 23.8 ng/mL respectively). Moreover, Hu-MEPE dose dependently (50 to 800 ng/mL) inhibited BMP2 mediated mineralization of a murine osteoblast cell-line (2T3) in vitro. Inhibition of mineralization was localized to a cathepsin-B released carboxy-terminal acidic MEPE-peptide containing the acidic-serine-aspartate-rich motif (ASARM-peptide). We have demonstrated previously that PHEX and a carboxy-terminal fragment of PHEX protects MEPE from cathepsin B cleavage and subsequent release of the acidic ASARM-peptide. Also, PHEX is defective in HYP and there is a marked increase in expression of MEPE and specific proteases (cathepsin D, ECEL1/DINE and neprilysin), potentially resulting in elevated levels of ASARM-peptide and in consequence rickets/osteomalacia. We propose that a novel PHEX-MEPE cell-surface protective-interaction is responsible for modulating mineralization and renal phosphate-handling. The distinct activities of these MEPE-peptides may be of use for the treatment of phosphate-handling and mineralization disorders in teeth, bone, kidney and also in the prevention of ectopic-mineralization.

Glitazones, the Anti-Diabetic PPAR-gamma Agonists, Pose a Significant Risk of Bone Loss; Differential Effects of Rosiglitazone and Netoglitazone. B. Lecka-Czernik, L. J. Suva, D. Gaddy, S. O. Rzonca*. Geriatrics, Orthopaedic Surgery, and Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

Glitazones compose a new class of oral anti-diabetic agents that are used for treating type 2 diabetes. These compounds sensitize cells to insulin through specific activation of PPAR-γ nuclear receptor. One of its isoforms, PPAR-γ2, is expressed in marrow mesenchymal stem cells and controls osteoblast and adipocyte development. PPAR-γ2 activated with rosiglitazone, an FDA-approved anti-diabetic glitazone, inhibited osteoblast and promoted adipocyte differentiation *in vitro* and *in vivo*. Rosiglitazone administration to non-diabetic C57BL/6 adult mice (6 mo) at a dose of 20 μg/g body weight/day for 7 weeks led to a significant decrease in bone mineral density (BMD) and bone mineral content (BMC). Detailed analysis of the microarchitecture of the proximal tibia using microcomputed tomography (microCT) revealed a significant decrease in BV/TV (32%), trabeculae number (22%) and connectivity (21%), and an increase in the spacing between trabeculae (33%) (p<0.05). Changes in bone structure were accompanied by changes in the expression of adipocyte and osteoblast marker genes measured in the whole tibia using real time PCR. The expression of fatty acid binding protein aP2 was increased 3-fold, whereas expression of osteoblast-specific genes, such as Runx2/Cbfa1, Dlx5, osteocalcin and collagen I, was decreased by 50%. Interestingly, although rosiglitazone administration to animals did not change the *ex vivo* potential of isolated marrow mesenchymal stem cells to differentiate toward osteoblasts and adipocytes, it significantly decreased the fraction of osteoblastic precursors that are sensitive to rosiglitazone in culture. These cells may represent plastic precursors capable of interconversion between adipocyte and osteoblast phenotypes. A similar decrease in the same cell fraction was seen in non-treated 24 mo old, compared to 6 mo old animals. Another agonist, netoglitazone, which binds to PPAR-γ with lower affinity, yet its anti-diabetic efficacy is 50-times greater than rosiglitazone, was examined. Netoglitazone was over 100-times less effective than rosiglitazone in both the inhibition of osteoblastogenesis and induction of adipogenesis in the model of marrow mesenchymal cell differentiation, U-33/γ2 cells. Netoglitazone administration to mice led to much smaller decreases in BMD and BMC, compared to the similar rosiglitazone dose. These results indicate that glitazones induce changes in bone that resemble age-related bone loss, and suggest that there may be effective anti-diabetic PPAR-γ agonists with little or no adverse effects on bone.

Transgenic Mice Overexpressing Human FGF23(R176Q) Recapitulate a Severe Form of the ADHR Phenotype. X. Y. Bai*[1], D. S. Miao[2], J. R. Li*[2], D. Goltzman[2], A. C. Karaplis[1]. [1]Medicine, SMBD-Jewish General Hospital, McGill University, Montreal, PQ, Canada, [2]Medicine, MUHC, McGill University, Montreal, PQ, Canada.

Renal phosphate wasting is associated with the hereditary disorders X-linked (*XLH*) and autosomal dominant (ADHR) forms of hypophosphatemic rickets and the acquired condition of tumor-induced osteomalacia (TIO). In addition to hypophosphatemia, patients with these diseases exhibit decreased or inappropriately normal serum levels of 1,25-dihydroxy vitamin D3 [1,25$(OH)_2D_3$], as well as rickets/osteomalacia. The genes responsible for XLH and ADRH have been identified as *PHEX* and *FGF23*, respectively. In ADHR, mutations in FGF23 prevent proteolytic cleavage, increase stability, and enhance the biological potency of the circulating protein. Elevated circulating serum levels of FGF23 have now been reported in XLH patients and FGF23 is abundantly expressed in tumors associated with TIO. To explore the biological actions of FGF23 in the intact organism, the cDNA encoding the R176Q form of FGF23 described in patients with ADHR, was introduced in a transgenic mouse model by targeting its expression in the liver.

The transgene was constructed in the pLIV.7 plasmid, which contains 3-kb of 5' flanking sequence, exon 1, part of exon 2, a 254-bp fragment of the 3' end, including the poly(A) signal, and 1.7-kb hepatic control region (HCR) of the human apolipoprotein E3 gene. Human FGF23-myc tag was mutated to encode FGF23(R176Q)-myc, and ligated into pLIV.7. The transgene was then microinjected into C57B/6J x CBA single cell embryos.

Animals carrying the transgene developed features characteristic of rickets and osteomalacia, such as shortened long bones and tail, whose severity correlated with the copy number of the transgene. Biochemically, they exhibited marked elevation in serum FGF23 levels, serum alkaline phosphatase activity, and PTH, while demonstrating normocalcemia with hypophosphatemia and increased urinary phosphate excretion. Histologically, in the long bones there were widened metaphyses, smaller epiphyses, thicker growth plates with irregular chondrocyte columns, disorganized hypertrophic zone lacking mineralization, and thickened trabeculae with large amount of unmineralized osteoid, consistent with extensive rickets/osteomalacia. Analysis of other tissues identified diffuse parathyroid hyperplasia and renal cysts in the mice carrying the transgene.

These animals recapitulate the morphological and biochemical features characteristic of a severe form of AHDR and will serve as a useful tool for dissecting the molecular signals that alter renal phosphate handling and vitamin D metabolism in the renal phosphate wasting states of XLH, ADHR, and TIO.

Expression of the Measles Virus Nucleocapsid (MVNP) Gene in Osteoclasts Increases Osteoclast Formation and Activity In Vitro and In Vivo. G. D. Roodman[1], N. Kurihara[1], S. V. Reddy[1], F. Singer[2], T. Cundy[3], H. Zhou*[4], D. Dempster[4], J. Windle*[5]. [1]Medicine-Hematology/Oncology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Endocrine, John Wayne Cancer Ctr, Santa Monica, CA, USA, [3]Medicine, University of Auckland, Auckland, New Zealand, [4]Pathology, Helen Hayes Hospital, New York, NY, USA, [5]Human Genetics, Virginia Commonwealth University, Richmond, VA, USA.

We reported that OCL from Paget's patients (PD) express MVNP and that OCL formed by human OCL precursors transfected with the Edmonston (Ed) strain of MVNP gene express a pagetic phenotype (increases in OCL numbers, nuclei/OCL, and sensitivity to 1,25-$(OH)_2D_3$). We recently reported the full-length MVNP sequence from a PD, which contained mutations in the C-terminus that differed from the Ed-MVNP and were also present in three other PD. To determine the effects of expressing MVNP and the PD mutations on OCL in vivo, we targeted the Ed or the PD-MVNP to cells in the OCL lineage in transgenic mice using the tartrate resistant acid phosphatase promoter (TRAP). Bone marrow from transgenic mice or nontransgenic littermates (controls) were tested for their capacity to form OCL, their sensitivity to 1,25-$(OH)_2D_3$, and their bone resorbing capacity in vitro. Both TRAP-PD -MVNP and Ed-MVNP marrow formed increased numbers of highly multinucleated OCL (30-50 nuclei/OCL). Interestingly, TRAP-PD-MVNP marrow required only 10^{-11}M 1,25$(OH)_2D_3$ to form large numbers of OCL while TRAP-Ed-MVNP marrow cells required 10^{-10}M. Marrow from both types of transgenic mice formed more OCL (three to fourfold) and were hyper-responsive to 1,25$(OH)_2D_3$ than marrow from nontransgenic littermates. Furthermore, $TAF_{II}17$, a potential coactivator of the vitamin D receptor that confers hyperresponsivity to 1,25-$(OH)_2D_3$ in OCL precursors from PD, was increased more than 50% in TRAP- PD-MVNP marrow cells than TRAP-Ed-MVNP mice but was not increased in control mice. Histomorphometric analysis of vertebrae, femurs and tibiae from TRAP-PD-MVNP mice showed increased OCL/mm bone (1.99 ± 0.8 vs. 0.89 ± 0.26 mean $\pm$ SD $p < .01$) and OCL surface ($5.04 \pm 2.11\%$ vs. $2.56 \pm 0.26\%$ $p < .01$) compared to nontransgenic littermates. Similar results were seen with TRAP-Ed-MVNP mice. Bone resorption lacunae were deeper and more numerous in both types of transgenic mice than controls. These data demonstrate that expression of the MVNP gene in OCL increases OCL formation and bone resorption in vivo, and mutations in the MVNP sequence present in PD increase the capacity of OCL precursors to respond to 1,25-$(OH)_2D_3$. These data support an important role for the MVNP gene in the pathogenesis of Paget's disease, and suggest that the "pagetic" mutations in MVNP may have physiologic significance.

Stimulation of Cyclooxygenase-2 Expression by TGF-Beta Enhances Bone Metastases in Breast Cancer. T. Hiraga, T. Yoneda. Dept Biochem, Osaka Univ Grad Sch Dent, Osaka, Japan.

Cyclooxygenase-2 (COX-2) is the rate-limiting enzyme of prostaglandin (PG) synthesis. Recent studies have shown that COX-2 is involved in angiogenesis, growth, apoptosis and invasiveness in breast cancer, suggesting the importance of COX-2 in malignant behavior of breast cancer. However, the role of COX-2 in distant metastasis in breast cancer is still unclear. Bone is one of the commonest sites of metastasis in breast cancer patients. Clinical studies have shown that the PG production by breast cancer cells positively correlates with the occurrence of bone metastases. These data raise the possibility that COX-2 expression in breast cancer cells contributed to the pathophysiology of bone metastases. To approach this, we studied the MDA-MB-231 (MDA-231) human breast cancer cells that caused bone metastases following heart inoculation. Immunohistochemical examination showed that MDA-231 cells in the close vicinity of residual bone expressed intense COX-2 in bone metastases. In contrast, COX-2 expression was undetectable in MDA-231 tumors developed in orthotopic site. Histomorphometrical examination revealed that a selective COX-2 inhibitor NS-398 (20mg/kg/day for 3weeks, ip) significantly reduced bone metastases with decreased number of osteoclasts, suggesting a critical role of COX-2 in bone metastases. Of note, the bisphosphonate ibandronate reduced COX-2 expression in MDA-231 cells in bone metastases, suggesting that COX-2 expression is dependent on bone resorption. Since evidence is accumulating that bone resorption releases bone-stored growth factors which in turn modulate the metabolism of metastatic cancer cells in bone, we next determined the effects of TGF-beta (TGFb), one of the most abundant growth factors stored in bone, on COX-2 expression in MDA-231 cells in culture. TGFb increased COX-2 expression in MDA-231 cells, whereas IGF, FGF and PDGF that are also stored in bone showed no effects. ELISA demonstrated that TGFb significantly increased PGE2 production and NS-398 inhibited PGE2 production in a dose-dependent manner in MDA-231 cells. Conditioned medium harvested from TGFb-treated MDA-231 cells significantly stimulated osteoclast-like cell formation in mouse bone marrow cultures, while the conditioned medium of MDA-231 cells treated with TGFb in the presence of NS-398 exhibited no effects. In conclusion, our results suggest that bone-derived TGFb up-regulates COX-2 expression in breast cancer cells colonizing bone, thereby increasing PG production, which in turn stimulates osteoclastic bone destruction, leading to the progression of bone metastases. Our results also suggest that suppression of COX-2 is a potential therapeutic intervention for bone metastases in breast cancer.

Lymphoproliferative Disease Induces Spontaneous Osteolytic Bone Lesions in Tax Transgenic Mice. L. Gao*[1], H. Zhao[2], H. J. Deng*[1], S. Kaushik*[1], J. Harding*[1], L. Ratner*[1], K. Weilbaecher[1]. [1]Department of Medicine, Washington University School of Medicine, St. Louis, MO, USA, [2]Department of Pathology, Washington University School of Medicine, St. Louis, MO, USA.

Adult T-cell leukemia/lymphoma (ATLL) is associated with expression of the HTLV-1 viral oncogene, tax, and with hypercalcemia and bone invading (osteolytic) lesions in 70% of patients. Tax transgenic mice have been previously generated utilizing the human granzyme B promoter that limits tax gene expression to the mature T-cell. Tax mice develop LGL leukemia and soft tissue tumors. We found that 70% of Tax mice developed numerous osteolytic bone lesions throughout the tail vertebre identified by X-ray analysis, between the ages of 4-12 months (Fig.1A). Bone mineral density measured by DEXA in the affected tail regions showed significant bone loss. TRAP staining on paraffin embedded tissue sections showed increased number of osteoclasts (indicated by arrows) at the interface of tumor and bone (Fig.2). Tax and wild type cultured osteoclasts were indistinguishable for the ability to form multinucleated TRAP positive cells capable of resorbing calcium phosphate matrix. Soft tissue tumor expression of osteoclast activating factors such as IL-6, PTHrP, M-CSF, and TNFa were similar in mice with and without osteolytic bone lesions. However, we detected higher RANKL expression by RT-PCR in soft tissue tumors associated with osteolytic bone lesions compared to soft tissue tumors without bone lesions. Furthermore, Tax+/Interferon gamma null mice developed widespread bone lesions and soft tissue tumors at earlier ages associated with more severe bone destruction compared to Tax+/Interferon gamma wild type mice (Fig.1B). We conclude that Tax mice develop spontaneous osteolytic bone metastases that are associated with enhanced tumor expression of RANKL. Interferon gamma gene deletion resulted in enhanced osteolytic tumor formation. Tax mice provide a new animal model for dissecting the pathogenesis of spontaneous bone osteolysis and for screening of new therapeutics targeted against tumor associated bone destruction.

PTHrP Stimulates New Bone Formation by Molecular Mimicry of Endothelin-1. K. S. Mohammad, T. A. Guise, J. M. Chirgwin. Medicine/ Endocrinology, Univ of Virginia, Charlottesville, VA, USA.

Prostate cancer metastases to the skeleton are frequently osteoblastic, despite abundant expression of the osteolytic factor parathyroid hormone-related protein, PTHrP. We propose a new explanation for this paradox: N-terminal fragments of PTHrP stimulate new bone formation by activating the endothelin A (ETA) receptor. Endothelin-1 (ET-1) is a 21 aa peptide which potently stimulates new bone formation via the ETA receptor. ET-1 residues 6-9 [LMDK] and PTHrP residues 8-11 [LHDK] share strong sequence homology. We tested PTHrP 1-16 in an ex vivo assay. Hemi-calvariae [n=4] of 4 day old mice were cultured on grids in medium + 0.1% BSA and test factor for 4 or 7 days. They were then fixed, decalcified, and embedded in paraffin. Sections were cut parallel to the sagittal suture, stained with H&E;, and analyzed by computerized histomorphometry to determine new bone area and osteoblast number. Inclusion of 100nM PTHrP 1-16 caused a 3-fold stimulation of new bone area at 4 days (0.0095 vs 0.0035mm2 for untreated control, $p<0.05$) and 7 days (0.014 vs 0.0035mm2 for untreated control, $p<0.001$). Osteoblast numbers were correspondingly increased. The response was equivalent to that caused by 100nM ET-1 positive control. There was no additional response to 1000nM PTHrP 1-16 or to the combination of 100nM each PTHrP 1-16 and ET-1. The effects on new bone area and osteoblast number were blocked by the inclusion of 0.01mM ABT627, a selective ETA receptor antagonist, which did not block new bone formation stimulated by FGF-2. We found similarly strong anabolic responses to 25nM PTHrP 1-20 and 1-23, while PTHrP 1-34 instead caused extensive osteolysis. Our data demonstrate that N-terminal peptides of PTHrP exert potent anabolic effects on bone via the ETA receptor. The sequence of PTHrP 18-23, RRRFF, is cleaved by prostate-specific antigen. Proteolysis at this site frees residues 8-11 to bind to ETA, providing a molecular explanation for the osteoblastic phenotype of PTHrP-positive prostate cancer bone metastases. The mimicry of ET-1 by PTHrP N-terminal peptides suggests that ETA receptor antagonists could be effective in treating prostate cancer, both against the actions of endothelin itself and against the anabolic effects of PTHrP fragments.

A Novel 25-Hydroxyvitamin D_3 Analog for Prostate Cancer. R. Ray*[1], N. Swamy*[1], T. Chen[1], S. Peleg[2], S. Christakos[3], N. Weigel*[4]. [1]Endocrinology, Diabetes and Nutrition, Department of Medicine, Boston University School of Medicine, Boston, MA, USA, [2]M.D. Anderson Cancer Center, Houston, TX, USA, [3]New Jersey Medical School, Newark, NJ, USA, [4]Baylor College of Medicine, Houston, TX, USA.

25-hydroxyvitamin D_3 (25-OH-D_3) is not considered to be therapeutically important due to its low vitamin D receptor (VDR)-binding affinity. Recently we developed an analog of 25-OH-D_3, 25-hydroxyvitamin D_3-3-bromoacetate (25-OH-D_3-3-BE) which engages VDR by cross-linking to its hormone-binding pocket. Preliminary studies with 25-OH-D_3-3-BE demonstrated that it inhibited the growth of prostate cancer cells (LNCaP, PC-3. LAPC-4), immortalized normal prostate cells (PZ-HPV-7), breast cancer cells (MCF-7), and primary skin cells (keratinocytes) similar to 1,25-dihydroxyvitamin D_3 (1,25$(OH)_2D_3$). Furthermore, we observed that 25-OH-D_3-3-BE was cytotoxic only towards PC-3, LNCaP and LAPC-4 cells. DNA-fragmentation and caspase assays showed that 25-OH-D_3-3-BE induced apoptosis. VDR-transfection assays in COS-7 cells demonstrated that 25-OH-D_3-3-BE modulated 24-hydroxylase promoter activity similar to 1,25$(OH)_2D_3$. Furthermore, in a pull-down assay 25-OH-D_3-3-BE stimulated interaction of VDR with RXR and GRIP-1 in PC-3 cells. These results strongly suggested that prostate cancer cell-specific effects of 25-OH-D_3-3-BE were mediated by VDR. Serum calcium measurement of CD-1 mice dosed with various amounts of 25-OH-D_3-3-BE showed that at least 3.3µg/20 gm of this compound did not raise serum calcium beyond control. Furthermore, 25-OH-D_3-3-BE drastically changed the cellular structure of tumor-cells in nude mice bearing PC-3-induced prostate tumor without eliciting significant systemic toxicity. Tissue-specific effects of 1,25$(OH)_2D_3$ and its analogs are not common due to the ubiquitous nature of VDR. We have demonstrated that 25-OH-D_3-3-BE, a non-calcemic analog of 25-OH-D_3 displayed strong prostate cancer cell-specific effects. It is also noteworthy that various human prostate cancer cells respond to 1,25$(OH)_2D_3$ differently, potentially limiting their use. In contrast, 25-OH-D_3-3-BE was equally effective in AR-positive LNCaP and AR-negative PC-3 and LAPC-4 cells. Therefore, 25-OH-D_3-3-BE could potentially be developed as a therapeutic agent for androgen sensitive and androgen-refractory prostate cancer

Tumor Suppressor Smad4/*DPC4* as a Corepressor for Estrogen Receptor α. L. Wu[1], Y. Wu[1], Q. Li*[1], W. Gathings*[2], X. Cao[1]. [1]Univ. of Alabama at Birmingham, Birmingham, AL, USA, [2]Univ. of Alabama in Huntsville, Huntsville, AL, USA.

Antiestrogen compounds are widely used for the treatment of osteoporosis, breast cancer and other diseases. Recent studies suggest that novel yet unidentified cofactors for the estrogen receptor may contribute to the tissue-specific activity of antiestrogens. We have demonstrated that Smad4, a common signal transducer in the TGF-β/BMP signaling pathway, functions as a transcription corepressor for estrogen receptor α (ERα). Endogenous ERα co-immunoprecipitates with Smad4 and the interaction can be induced by the antiestrogen ligands, tamoxifen, raloxifene and droloxifen. The observation was confirmed in chromatin immunoprecipitation assays. Smad4 and ERα form a complex when ERα binds to an estrogen responsive element in the estrogen target gene promoter. Importantly, overexpression of Smad4 enhances the antiestrogens inhibitory effect on luciferase reporter activity and down regulates the estrogen target gene transcription in breast cancer cells. Mapping of the interaction domains indicates that the N-terminal activation function domain 1 (AF1) of ERα and the N-terminal Mad homologous domain 1 (MH1) and Linker region of Smad4 are essential for their interaction. Estrogen receptor β (ERβ), however, does not interact with Smad4, and neither TGF-β nor Smad4 has any effect on ERβ-mediated transcription, suggesting that ERβ is not involved in the cross-talk between estrogen and TGF-β. We have also developed MCF-7 cell lines that overexpress Smad4 (MCF-7_Smad4) or GFP (MCF-7_GFP) mediated by retrovirus. By using a cell proliferation assay, we observed that overexpression of Smad4 enhances antiestrogen-induced cell growth arrest. Smad4 overexpression also enhances antiestrogen-mediated apoptosis as demonstrated in TUNEL assay. We also examined the effect of Smad4 on breast tumor growth in nude mice. MCF-7_GFP and MCF-7_Smad4 cells were inoculated into the flanks of 15 mice with 1×10^5 cells per site. The formula, length × width × height ×0.5236, was used to calculate tumor volume. As shown in the figure, Smad4 significantly inhibited tumor growth. In summary, we found that Smad4 functions as a transcription corepressor for ERα, and that Smad4 repression activity is differentially regulated by antiestrogens. Thus, TGF-β may regulate cell fate through Smad4-mediated cross-talk with the estrogen signaling pathway.

Ectopic Runx2 Regulates Breast Cancer Metastasis Associated Osteolytic Disease. G. L. Barnes[1], K. E. Hebert*[1], A. Javed[2], M. H. Kamal*[1], T. A. Einhorn[1], J. B. Lian[2], G. S. Stein[2], L. C. Gerstenfeld[1]. [1]Department of Orthopaedic Surgery, Boston University Medical Center, Boston, MA, USA, [2]Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA.

Metastatic breast cancer cells preferentially localize to skeletal sites and predominantly produce osteolytic disease. Metastasis associated lytic bone disease is the result of cancer cell mediated disruptions of the normal homeostatic interactions between osteoblasts and osteoclasts. We have recently reported that human breast cancer cells ectopically express the transcription factor Runx2, a factor associated with skeletal cell differentiation. We propose that the ectopic expression of Runx2 by human breast cancer cells is a key regulator of the interactions between cancer and bone cells that lead to osteolytic disease. In order to test this hypothesis we have disrupted the endogenous ectopic Runx2 activity in human

breast cancer cells through the use of several independent Runx dominant-negative constructs. In an in vivo intramedullary injection model system 90% of animals injected with control MDA-MB-231 breast cancer cells, which constitutively express Runx2, produce large lytic lesions associated with TRAP+ osteoclasts. In contrast, only 15% of mice injected with the dominant-negative Runx expressing MDA-MB-231 cells display detectable lesions. Furthermore, the lesions that do appear are smaller in size and are not associated with active osteoclasts. We have used an in vitro co-culture system with marrow stromal cells to assess the homeostatic interactions between osteoblasts and osteoclasts in the presence of human breast cancer cells. These studies demonstrate that breast cancer cells disrupt normal skeletal cell homeostasis and produce lytic disease by inhibiting new osteoblast differentiation and enhancing osteoclast differentiation and activity. In these co-cultures we observe a greater than 60 % reduction in osteoblast associated mineralized nodule formation and osteoblast gene expression (BSP, OC and Col I) together with a 2-3 fold increase in osteoclast associated TRAP expression and the expression of the pro-resorptive cytokines TNFa, RANKL and IL-6. Over-expression of the Runx dominant-negative construct in these cancer cells abolishes these cancer cell mediated effects in our in vitro system. Together both the in vivo and in vitro studies demonstrate that Runx2 is a central regulator of breast cancer cell mediated disruptions in normal skeletal homeostasis, specifically those that lead to osteolytic disease.

Cystatin 10, a Novel Chondrocyte-Specific Protein, Contributes to Pathogenesis of Osteoarthritis and Ectopic Ossification through Chondrocyte Calcification. T. Yamada[1], H. Kawano[1], T. Fukuda*[2], K. Yoshimura*[2], T. Nakamura*[2], Y. Koshizuka[1], S. Kamekura*[1], U. Chung[1], S. Kato[2], H. Kawaguchi[1]. [1]Orthopaedic Surgery, Univ. of Tokyo, Tokyo, Japan, [2]IMCB, Univ. of Tokyo, Tokyo, Japan.

In efforts to elucidate the molecular mechanisms of endochondral ossification, we recently identified a novel gene, cystatin 10 (Cst10), which was upregulated with ectopic ossification of the mouse auricular cartilage. Expression of Cst10 was specific to cartilage, especially to hypertrophic chondrocytes of the growth plate. In the culture of mouse chondrogenic ATDC5 cells, Cst10 expression was seen simultaneously with that of type X collagen, and increased in synchrony with maturation thereafter. Overexpression of Cst10 cDNA in ATDC5 cells induced calcification as determined by Alizarin red and von Kossa stainings. To further investigate the physiological role of Cst10, we created mice lacking the Cst10 gene ($Cst10^{-/-}$ mice). $Cst10^{-/-}$ mice developed normally without abnormalities of major organs. Immunohistochemical and in situ hybridization analyses of the growth plate showed no abnormality in proliferation or hypertrophy of chondrocytes; however, calcification of hypertrophic chondrocytes was impaired in the $Cst10^{-/-}$ growth plate and the height of calcified layer was about 60% that of wild-type (WT) littermates at 8 weeks of age. Bone densitometry, histomorphometry and 3D-μCT analyses revealed a significant decrease in the volume of primary spongiosa adjacent to the growth plate by Cst10 deficiency. In the culture of primary chondrocytes derived from the growth plate, calcification of $Cst10^{-/-}$ cells was suppressed compared to that of WT cells although their proliferation and earlier differentiation determined by Alcian blue staining were normal. Despite these *in vivo* and *in vitro* abnormalities, bone growth and turnover of $Cst10^{-/-}$ mice remained similar to those of WT during the observation period up to 52 weeks of age. However, when osteoarthritis was induced by producing instability in the knee joint of 8-week-old mice through ligament transection and menisectomy, substantial osteophyte formation due to endochondral ossification was seen in the WT knee 10 weeks after the operation, while this was rarely seen in the $Cst10^{-/-}$ knee. In addition, although all WT mice exhibited ossification of the tendon insertion of patella and calcaneus at 52 weeks of age, none of the $Cst10^{-/-}$ mice showed this disorder (n=4, each). We thus conclude that Cst10, an inducer of chondrocyte calcification, contributes to the pathogenesis of osteoarthritis and ectopic ossification without affecting the physiological bone growth or turnover, suggesting that this molecule could be a therapeutic target for these disorders.

In Vivo Characterization of Human SOST: SOST-Transgenic Mice Exhibit Skeletal Defects and are Osteopenic. M. S. K. Sutherland[1], C. Yu*[1], J. C. Geoghegan*[1], M. Jonas*[2], D. G. Winkler[1], B. R. Kovacevich*[2], A. Snell*[3], M. Appleby*[3], M. E. Brunkow*[4], J. A. Latham[1]. [1]Gene Function & Target Validation, Celltech R & D, Inc., Bothell, WA, USA, [2]Molecular Biology, Celltech R & D, Inc., Bothell, WA, USA, [3]Discovery Biology, Celltech R & D, Inc., Bothell, WA, USA, [4]Genomics, Celltech R & D, Inc., Bothell, WA, USA.

Sclerosteosis is a severe skeletal disorder characterized by progressive bone overgrowth and high bone mineral density due to a loss of function of the SOST gene. The gene product, sclerostin, which shares homology to the DAN family of BMP antagonists, is highly expressed in osteocytes. To explore the role of sclerostin in bone homeostasis in an *in vivo* animal model, SOST-transgenic mice were generated by selectively targeting the expression of human SOST to bone with the mouse osteocalcin gene 2 (OG2) promoter. We hypothesized that overexpression of human SOST in mice would result in decreased deposition of mineral and lower bone mineral density. A series of four independent transgenic founders were identified with gene copy numbers ranging from 4 to 30. Bones from the mice were shown to express the transgene by RT-PCR analysis and sclerostin protein was detectable by Western blot. SOST-transgenic mice exhibited kinky tails and were smaller at birth compared to age-matched wildtype littermates. All other visible phenotypes were normal. Alizarin red staining of the developing skeleton (E15.5 to 1 week of age) as well as X-ray analyses of weaned and adult mice revealed that the transgenic mice had extra floating ribs along with collapsed and fused vertebral bodies in the lumbar and sacral regions. Histological analyses of cross-sections of the lumbar vertebrae showed that the bones of SOST-transgenic mice had thinner cortices and reduced amounts of trabecular bone. The lumbar vertebrae (L3 to L5) and femurs of transgenic mice also displayed a significant reduction in bone mineral density as measured by PIXImus. Biomechanical testing of the vertebrae and femur by compression and 4-point bending, respectively, revealed that the bones of the transgenic mice were more fragile and less resistant to fracture compared to normal littermates. This is the first data bridging the role of sclerostin in rodents with man where the gene was originally characterized. These results highlight the important role that sclerostin plays in bone formation and maintaining the integrity of bone, and suggests that agents that neutralize this protein may be of therapeutic benefit in clinical indications associated with loss of bone.

Gender Dependent Neuroregulation of Bone Mass: Evidence from the Neuropeptide Y Y2/Y4 Double Knockout Mouse. P. A. Baldock[1], A. Sainsbury*[2], R. F. Enriquez*[1], M. Couzens*[2], H. Herzog*[3], E. M. Gardiner[1]. [1]Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney NSW, Australia, [2]Neurobiology Program, Garvan Institute of Medical Research, Sydney NSW, Australia, [3]Neurobiogy Program, Garvan Institute of Medical Research, Sydney NSW, Australia.

Neuropeptide Y (NPY) Y2 receptor has previously been shown to regulate cancellous bone formation in the mouse by a centrally mediated mechanism. However, the manner in which this elevation takes place is unknown. Elevated circulating levels of pancreatic polypeptide, the major ligand for NPY Y4 receptor, implicated the Y4 in the Y2 knockout (KO) bone phenotype.

This study compared the effect of NPY Y2 KO, Y4 KO and Y2/Y4 double KO on the regulation of bone mass in male and female mice. Distal femora from 4 month old knockout and wildtype mice were examined. Values [units] are given: mean (SEM).

Y4 KO in male mice did not affect cancellous or cortical bone mass. BV/TV [%] in Y4 KO mice 8.2 (1.2) did not differ from wildtype 6.6 (1.4). Both these values were lower than in Y2 KO mice 12.4 (1.7). In contrast, cortical bone was not different from wildtype in either Y4 or Y2 KO mice. Cortical area [mm2] in Y4 knockout 1.1 (0.1) did not differ from wildtype 1.2 (0.1) or Y2 KO mice 1.1 (0.1).

Y2/Y4 KO in male mice had a synergistic effect on cancellous bone. BV/TV in Y2/Y4 KO mice 17.4 (2.1) was elevated compared to Y4 KO 8.2 (1.2) and Y2 KO 12.4 (1.7), ($p< 0.06$). In contrast, cortical area was reduced in Y2/Y4 KO 0.92 (0.03) compared to Y4 KO 1.12 (0.04) and Y2 KO 1.09 (0.05). This effect was associated with reduced cortical thickness.

Interestingly, in female Y2/Y4 KO mice, there was no synergistic increase in cancellous BV/TV, with Y2/Y4 mice 10.6 (0.6) not different from Y2 KO females 10.8 (2.1), but with both greater than wildtype 5.9 (0.3). Moreover, cortical area 0.91 (0.2), femoral length [mm] 16.0 (0.1) and mid-femoral circumference [mm] 5.2 (0.1) in female mice were not different from male Y2Y4 KO mice 0.92 (0.03), 16.0 (0.1) and 5.2 (0.1), despite significant sex differences in cortical bone in both Y2KO and Y4KO mice.

Although the Y4 receptor pathway does not independently regulate bone mass, these data suggest that in males there is an interaction between the Y2 and Y4 pathways to reduce cancellous bone volume and increase cortical bone mass. Furthermore these data suggest an interaction between the control of bone mass by sex hormones and the NPY pathways.

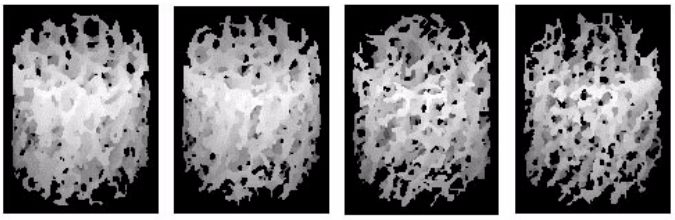
Longitudinal Changes in Trabecular Bone Architecture Detected by Micro-MRI Based Virtual Bone Biopsy. F. W. Wehrli[1], A. M. Popescu*[1], B. Vasilic*[1], B. R. Gomberg*[1], P. K. Saha*[1], B. Zemel[2], B. Bunker*[1], A. C. Wright*[1], P. J. Snyder[3], H. Peachy*[3]. [1]Radiology, University of Pennsylvania, Philadelphia, PA, USA, [2]Nutrition and Growth, Children's Hospital of Philadelphia, Philadelphia, PA, USA, [3]Department of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

Estrogen depletion following menopause is accompanied by bone loss and architectural deterioration of trabecular bone (TB). Conversely, hormone replacement therapy (HRT) protects against such bone loss. Here we report preliminary data on the first in vivo detection of such skeletal changes in an ongoing study involving early postmenopausal women, half of whom are getting HRT and half who do not (controls), using a protocol whereby BV/TV as well as parameters expressing TB topology are quantified at the distal radius and tibia by means of a MRI-based virtual bone biopsy. DXA BMD at the spine and hip were measured as well. From the MR images acquired at 137x137x410 μm3 voxel size, bone volume fraction maps were generated which were subvoxel processed to yield a final voxel size of 62x62x103 μm. These images were binarized, skeletonized and subjected to 3D topological analysis. Skeletonization converts rods to curves and plates to surfaces. Parameters extracted comprised the volume density of curves (CURV) and surface voxels (SURF) as well as composite parameters surface/curve ratio (S/C) and "erosion index" (EI). Apparent TB thickness (Tb.Th) was derived as well. Subjects were imaged at baseline and 11-13 months later. So far, 11 control and 5 HRT subjects afforded images of adequate quality. Relative differences from baseline were computed for each subject and the mean differences compared between groups. Measurements at the wrist indicated a relative decrease in CURV ($p=0.01$) and decrease in EI ($p=0.05$) in HRT relative to controls. Tb.Th was suggestive of being greater in the HRT group ($p=0.08$). Other structural parameters were not different. These preliminary findings are consistent with the known protective effects of HRT ensuring maintenance of a more plate-like TB architecture. The observations in the radius were not paralleled by similar findings in the tibia. BMD, though not statistically significant, indicated the same protective effect of HRT. This work suggests that MRI-based in vivo micromorphometry of trabecular

bone may be useful for monitoring osteoporosis treatment.



Virtual bone biopsy cores in a HRT (a, b) and control subject (c, d) taken at baseline (a, c) and one year later (b, d).

Identification of *Alox15* as a Gene that Regulates Peak Bone Mass in Mice. R. F. Klein[1], J. D. Allard*[2], A. S. Carlos*[1], Z. Avnur*[2], D. A. Olson*[1], R. Waters*[2], D. Dinulescu*[1], T. Nikolcheva*[2], M. Shea[1], B. Hansen*[1], J. Kansagor*[1], J. D. Belknap*[1], G. Peltz*[2], E. S. Orwoll[1]. [1]Oregon Health & Science University, Portland, OR, USA, [2]Roche Bioscience, Palo Alto, CA, USA.

The identification of genes underlying quantitative-trait loci (QTL) for complex diseases, such as osteoporosis, is a challenging and difficult task. We have previously identified a major QTL on chromosome 11 that is associated with variation in peak bone mineral density (BMD) in C57BL/6 (B6) and DBA/2 (D2) mice. In the present study, we used complementary genetic and genomic approaches to identify a novel molecular pathway affecting peak BMD. Selective breeding was used to transfer the chromosomal fragment containing the chromosome 11 QTL interval from B6 onto a D2 genetic background. Comparison of the resulting congenic mouse strain with the background D2 strain established that a 30 megabase B6 genomic interval on chromosome 11 in isolation confers increased BMD (68.3 ± 0.6 mg/cm^2 *vs*. 65.4 ± 0.4 mg/cm^2, $p < 0.0001$). Genome-wide microarray expression profiling identified a significant reduction (~20-fold) in the expression of *Alox15* in the high BMD congenic strain compared to the background D2 strain. *Alox15* encodes a lipid-peroxidizing enzyme of previously unknown biological function (leukocyte 12-lipoxygenase; L-12-LO or 12/15-LO). Sequencing of the *Alox15* cDNA revealed several differences between the D2 and B6 strains. Compared to B6 mice, calvarial cells isolated from D2 mice exhibited increased mRNA expression for *Alox15* and *CD36* (a gene induced by naturally-occurring lipid oxidation products of 12/15-LO activity). Cross-breeding experiments employing *Alox15* knockout mice with absent *Alox15* expression rescued mice from the low bone mass phenotype associated with the *Alox15* D2 allele. Moreover, pharmacological inhibition of 12/15-LO *in vivo* resulted in higher BMD and improved bone strength in a murine model of osteoporosis. These results provide strong presumptive evidence that 12/15-LO is an important determinant of peak bone mass in mice, raise the possibility that inherited variation in the 12/15-LO signaling pathway contributes to the pathogenesis of osteoporosis in humans, and suggest that pharmacological modulation of 12/15-LO activity may be useful in the prevention/therapy of osteoporosis.

TGFβ1 Prevents Ovariectomy Induced Bone Loss by Repressing T Cell Activation. Y. Gao[1], G. Toraldo[1], W. Qian*[2], K. Dark*[2], R. Shepherd*[1], M. N. Weitzmann[2], D. A. Towler[1], R. Pacifici[2]. [1]Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA, [2]Division of Endocrinology and Metabolism, Emory University School of Medicine, Atlanta, GA, USA.

Enhanced production of TNF and RANKL by activated T cells plays a pivotal role in ovariectomy (ovx) induced bone loss but the responsible mechanism is unknown. TGFβ1 may be a key regulator of ovx-induced T cell activation since estrogen (E) stimulates its production and TGFβ1 represses T cell function. To investigate the role of TGFβ in ovx induced bone loss we blocked the decrease in TGFβ1 induced by ovx by injecting mice IM with pCMV-TGFβ1 plasmid which elevates serum TGFβ levels. Injection of this plasmid led sham and ovx mice to attaine equally high levels of serum TGFβ1 for 4 weeks. Ovx induced significant bone loss and increased bone turnover in mice injected with mock plasmid, but not in mice treated with pCMV-TGFβ1, suggesting a role for TGFβ1 in preventing ovx-induced bone loss. Ovx increases T cell activation through enhancement of macrophage antigen presenting cell (APC) activity and expression of the APC regulating gene CIITA (ASBMR 2002). We thus investigated if E suppresses APC activity and CIITA through TGFβ. Our data shows that E effects on APC activity and CIITA were abolished by a neutralizing TGFβ1 antibody, thus suggesting that E regulates CIITA expression and APC activity through a TGFβ1 dependent mechanism. To further implicate TGFβ in the mechanism by which E represses T cell activation and bone loss we adoptively transferred T cells, insensitive to TGFβ due to a dominant negative TGFβ receptor type II (dnTGFβRII) transgene, into T cell-deficient nude mice. As expected, no bone loss was detected in ovx and sham nudes and in sham nudes reconstituted with WT T cells. In contrast, transplantation of T cells from either WT or dnTGFβRII mice into ovx nudes was followed by increased T cell activation and a bone loss equal to that of WT ovx mice. Importantly, transplantation of T cells from dnTGFβRII mice into sham nudes was also followed by T cell activation and bone loss equal to those observed in WT ovx mice. These findings demonstrate that silencing the repressive effects of TGFβ1 on T cells renders them insensitive to E and capable of inducing bone loss in vivo. Further attesting to the relevance of TGFβ signaling in T cells, the bone density of intact dnTGFβRII mice was significantly lower than that of WT littermates. In summary, the data confirm that T cells play an essential role in ovx induced bone loss and suggest that one mechanism by which E prevents bone loss is by stimulating the production of TGFβ. This cytokine mediates the repressive effect of E on T cell activation thus preventing T cell production of bone wasting cytokines.

Induction of Osteoblast Lineage Commitment and Differentiation by 4-estren-3α,17β-diol (Estren), but Not 17β-estradiol:A Putative Explanation of the Bone Anabolic Properties of ANGELS. S. Kousteni, L. Han, M. Almeida, J. Chen, H. Peng*, R. Jilka, S. C. Manolagas. Div Endo/Metab, Center for Osteoporosis and Metabolic Bone Diseases, CA Veterans Healthcare System, Univ of Arkansas for Med Sciences, Little Rock, AR, USA.

Estren, a compound that reproduces the nongenotropic effects of sex steroids without affecting classical transcription, increases BMD, mechanical strength and serum osteocalcin, in ovariectomized mice above the level of the estrogen-replete state, without affecting reproductive organs. As shown elsewhere in this meeting estren potentiates Wnt signaling in osteoblasts, by a) suppressing the activity of c-jun, and thereby decreasing the transcriptional activity of the Wnt antagonist Dickkopf-1 (Dkk-1) and b) increasing the expression of Wnt-1 and Wnt-2 and their receptor Frizzled-10. These actions in turn lead to the potentiation of β-catenin mediated transcription. Here, we report that estren, but not 17β-estradiol (E2), at 10-8M induced alkaline phosphatase (AP) activity and osteocalcin in the uncommitted mesenchymal progenitor cell line C2C12. These effects were blocked by either ICI 182,780 or flutamide as well as inhibitors of each one of 3 different cytoplasmic kinases known to be activated by estren: the Src kinase inhibitor PP1, the PI3 kinase inhibitor wortmannin, and the JNK kinase inhibitor SP600125. Further, estren, but not E2, induced Runx2 expression, increased AP activity and also induced mineralization (in the presence of ascorbic acid and β-glycerophosphate) in cultures of the committed pre-osteoblastic cell line MC3T3-E1. The potency of all these effects of estren was similar to that produced by a maximal dose of BMP-2 (300 ng/ml). Most strikingly, induction of AP and osteocalcin by estren in C2C12 cells was completely abrogated by the BMP-2 antagonist noggin (100 ng/ml) as well as the Wnt antagonist Dkk-1 (50 ng/ml), indicating that estren exerts its pro-differentiating effects on osteoblast precursors by stimulating both BMP-2 and Wnt signaling. Consistent with this contention and the possibility that Wnt signaling is a downstream effector of BMP-2 action, the BMP-2-induced stimulation of AP and osteocalcin in C2C12 cells was blocked by Dkk-1. Based on these findings, as well as the evidence that Wnt signaling is a critical determinant of bone mass in rodents and humans, we conclude that the anabolic effects of ANGELS, as distinguished from the anti-remodeling/anti-catabolic effects of estrogens and androgens, may result in part from the ability of ANGELS to induce lineage commitment and differentiation towards osteoblasts via kinase-mediated potentiation of a BMP-2/Wnt signaling cascade.

The *Wnt* Signaling Pathway Modulates *TWIST* Expression to Maintain and Expand Osteoprogenitor Populations during Osteogenesis. T. Yan*[1], S. D. Flanagan*[2], T. Linkhart[3], D. D. Strong[3], C. A. Glackin[1]. [1]Molecular Medicine, City of Hope Beckman Research Institute, Duarte, CA, USA, [2]Neurosciences, City of Hope Beckman Research Institute, Duarte, CA, USA, [3]Musculoskeletal Disease Center, JL Pettis VA Medical Center, Loma Linda, CA, USA.

Osteoblasts originate from a common osteoprogenitor or from mesenchymal stem cells (MSCs). The formation of osteoblasts requires that MSCs differentiate into mature osteoblasts through the process of osteogenesis. Osteogenesis requires that a series of transcriptional events take place to induce bone specific signaling pathways and gene expression, resulting in the development of the mature osteoblast phenotype in remodeling bone. We have focused on how the basic helix loop helix (bHLH) transcription factor family (e.g. *TWIST*) regulates gene expression in the early stages of osteogenesis and how signaling mechanisms (e.g. *Wnt* signaling) affect bHLH factors to stimulate or inhibit osteoblast differentiation. Since *Wnt-11* is highly expressed in the developing human skeletal system, we have examined the role of *Wnt-11* in the regulation of *TWIST* expression during osteogenesis. We have obtained evidence that *TWIST* is a positive regulator of important osteoprogenitor genes such as periostin and collagen, proteins required for cell adhesion, spreading and matrix formation. Based on our recent findings, we hypothesize that *Wnt* signaling molecules (including *Wnt-11*) play a significant role in inhibiting *TWIST* expression, which allows Runx2/Cbfa1 to facilitate osteoblast differentiation. To examine our hypotheses, murine 2T3 cells were stably transfected with plasmid vectors that over or under-express *TWIST*, periostin, *Wnt-11*, and sFRP2 and their phenotypes characterized. Runx2/Cbfa1 and *TWIST* promoters has been analyzed using *in vivo* footprinting techniques by LMPCR. Our preliminary data indicate that over-expressing *Wnt-11* in murine 2T3 cells causes a dramatic reduction of *TWIST* and an increase in Runx2/Cbfa1, ALP, and osteocalcin expression. By contrast, reduced *Wnt-11* expression prevents osteoblast differentiation by up-regulating *TWIST* and maintaining Runx2/Cbfa1 expression. The cellular morphology of the anti-sense *Wnt-11* is similar to that observed for the *TWIST* over-expressing osteoblasts suggesting that both *TWIST* and Runx2/Cbfa1 together with *Wnt-11* signaling may be important for the recruitment and maintenance of osteoprogenitors in remodeling bone. Based on these findings, we propose that *Wnt* signaling affects *TWIST* and Runx2/Cbfa1 expression to either maintain osteoprogenitor populations or, in the absence of *TWIST*, to enable positive activation by Runx2/Cbfa1 of downstream genes leading to osteoblast differentiation.

Δ2ΔFosB, a Truncated Isoform of ΔFosB Lacking Transactivation Domains, is Sufficient to Induce Osteosclerosis and Decreased Adipogenesis in Transgenic Mice. M. Kveiborg, R. Chiusaroli, G. Sabatakos, M. Wu*, W. M. Philbrick, W. C. Horne, R. Baron. Yale University School of Medicine, New Haven, CT, USA.

The AP-1 family of transcription factors consists of Fos- and Jun-related proteins, which play important roles in bone cell differentiation. As reported previously, ΔFosB and Δ2ΔFosB are naturally occurring splice isoforms of FosB. Although both maintain the ability to heterodimerize with Jun proteins and bind consensus AP-1 sites, they lack the major C-terminal transactivation domain of FosB. In addition, a potential N-terminal transactivation domain is absent in Δ2ΔFosB. Transgenic mice overexpressing ΔFosB under the control of the neuron-specific enolase (NSE) promoter develop an osteosclerotic phenotype as well as decreased adipose tissue. Furthermore, transgenic mice overexpressing ΔFosB specifically targeted to osteoblasts demonstrated that these effects are mediated by cell autonomous and independent mechanisms.

To determine the relative importance of Δ2ΔFosB versus ΔFosB in mediating the fat and bone phenotypes, we have generated transgenic mice overexpressing only Δ2ΔFosB under the control of the NSE-promoter. Overexpression of Δ2ΔFosB in bone and adipose tissues was confirmed by western blotting and histomorphometric analysis showed that the mice develop a severe osteosclerosis, characterized by a more than 4-fold increase in trabecular bone volume, doubling of trabecular thickness and number, and increased dynamic bone formation parameters. NSE-Δ2ΔFosB transgenic mice also exhibited a decrease in adipose tissue and serum leptin levels. Bone marrow cultures established from NSE-Δ2ΔFosB transgenic mice revealed a reduced ability of the cells to differentiate into adipocytes. Specifically, the expression levels of PPARγ and C/EBPα, two important adipogenic transcription factors were decreased, whereas the osteoblastic transcription factor, Runx2 was increased. Thus, overexpression of the Δ2ΔFosB isoform, which conserves the DNA-binding and heterodimerization capacity but lacks any known transactivation domains, is sufficient to induce both the osteosclerotic phenotype and the decreased adipogenesis to the same degree as previously observed in NSE-ΔFosB transgenic mice. These results suggest that the mechanisms by which ΔFosB affects osteoblast and adipocyte differentiation do not require intrinsic transcriptional activity. Since we have shown ΔFosB and Δ2ΔFosB interact with other AP-1 family members and with Smads, Runx2 and C/EBPβ, we conclude that they affect cell differentiation by interfering with the activity of other transcription factors or co-factors.

Osteopenia in Transgenic Mice with Osteoblast-Targeted ICER Expression. Y. Huang[1], G. Gronowicz[2], J. R. Harrison[3], B. E. Kream[1]. [1]Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]Orthopaedic Surgery, University of Connecticut Health Center, Farmington, CT, USA, [3]Orthodontics, University of Connecticut Health Center, Farmington, CT, USA.

ICER is a cAMP inducible member of the CREM transcription factor superfamily. Alternative splicing of the ICER transcript gives rise to 4 isoforms: ICER I, Iγ, II, and IIγ. Since ICER contains predominantly the basic leucine zipper region for DNA binding and dimerization, it acts as a dominant negative regulator of cAMP-dependent gene transcription in most systems. Previously, we reported that ICER mRNA and protein are induced by PTH via the cAMP-PKA signaling pathway in cultured osteoblasts and in calvariae *in vivo*. The goal of the present study was to assess the function of ICER in bone *in vivo* by overexpressing ICER in osteoblasts of transgenic mice. ICER I and ICER II cDNAs with an N-terminal FLAG epitope tag were cloned downstream of a fragment containing 3.6 kb of the rat Col1a1 promoter and 1.6 kb of the rat Col1a1 first intron to produce the pOBCol3.6-F-ICER I and II transgenes, respectively. The 3.6 kb Col1a1 promoter fragment targets ICER expression broadly to cells of the osteoblast lineage. Multiple lines of pOBCol3.6-F-ICERI and II transgenic mice were generated and characterized. In general, the phenotypes of ICER I and ICER II transgenic mice were similar. Transgenic mice at 8 weeks of age had a smaller body weight than wild-type littermates. At 8 weeks, all mice had significantly decreased bone mineral density of femurs and vertebrae as measured by DEXA. Static histomorphometry showed that transgenic mice had almost no trabecular bone and reduced cortical bone compared to non-transgenic littermates ($p<0.01$). There were no significant changes in osteoblast or osteoclast number per unit bone surface in the secondary spongiosa. However, transgenic calvariae and femoral cortical bone and primary spongiosa demonstrated exuberant TRAP staining. Dynamic histomorphometry showed a decreased bone formation rate in transgenic femurs. *Ex vivo* analysis of osteoblastic differentiation using bone marrow stromal cells revealed impaired formation of mineralized nodules under osteogenic differentiation conditions. Moreover, the formation of TRAP-positive multinucleated cells was enhanced in transgenic bone marrow stromal cells cultured for 5 days in the presence of M-CSF and RANK ligand. In summary, transgenic mice with osteoblast-targeted overexpression of ICER demonstrated osteopenia characterized by a profound loss of trabecular architecture and a reduction in cortical bone width. We speculate that osteoblast-targeted ICER overexpression caused dysregulation of both bone formation and resorption.

Regulation of G Protein Signaling in Osteoblasts In Vivo. R. A. Nissenson, M. Bencsik*, P. Nguyen*, J. Peng*, B. Halloran. Endocrine Research Unit, VA Medical Center/UCSF, San Francisco, CA, USA.

Intracellular signaling by G proteins is thought to provide critical regulation of osteoblast differentiation and function in response to extracellular signals. However, the presence of multiple G proteins and their cognate receptors has made it difficult to ascribe direct functional activities to specific G protein signals. We have initiated an effort to regulate G protein signaling by controlling the expression of an activated G protein coupled receptor (GPCR) in osteoblasts of transgenic mice. Several founder lines of mice expressing the tetracycline transactivator (tTA, tet off) gene driven by the 2.3 kb mouse α1Col I promoter were established. F1 mice from the line displaying the highest level of expression of tTA mRNA in bone (line 139) were mated with mice expressing a tTA driven gene encoding a GPCR (termed R01) known to activate Gi. Genotypic analysis of progeny demonstrated appropriate transmission of the tTA and R01 transgenes, but failed to identify any double transgenic pups (0/43), indicating that R01 expression during embryogenesis resulted in embryonic/perinatal lethality. However, if the mothers were maintained on doxycycline (doxy, 200 mg/kg chow) during the entire course of their pregnancy to suppress transgene expression, double transgenic pups were obtained at approximately Mendelian frequency (11/47). Only a very low level of expression of the R01 gene was detected in the bones of double transgenic pups when maintained on the +doxy diet. However, when the diet was switched to a –doxy diet at 4 weeks of age, R01 expression in bone was induced by 20 fold within 2 weeks. Phenotypic analysis of the skeleton of mice expressing the R01 transgene is currently in progress. These results suggest that excessive skeletal Gi signaling during embryogenesis results in lethality. Further, we have demonstrated the feasibility of controlling the expression of key osteoblast signaling pathways in vivo. This approach promises to allow direct investigation of the impact of specific G protein signals in osteoblasts on the structure and function of bone in vivo.

Inhibition of Glycogen Synthase Kinase-3β (GSK3β) Induces Bone Formation in a Mouse Calvarial Model. W. Zhao[1], B. Bhat[1], M. Wasko*[1], P. Yaworsky[2], Y. Kharode[1], P. Green*[1], J. Robinson[1], P. Zhang*[3], H. Fletcher*[3], V. Coleburn*[1], J. Wrobel*[3], F. Bex[1]. [1]Bone metabolism, Wyeth Research, Collegeville, PA, USA, [2]Genomics Division, Wyeth Research, Cambridge, MA, USA, [3]Chemical Sciences, Wyeth Research, Collegeville, PA, USA.

Glycogen Synthase Kinase-3 (GSK3β) is an important negative regulator of Wnt signaling through its action to destabilize β-catenin. Recent evidence from studies of the G171V LRP5 mutation suggests that activation of Wnt signaling may be involved in the resulting osteogenic skeletal phenotype. To determine in vivo whether Wnt pathway activation through GSK3β inhibition induces osteogenesis, the local administration of a GSK3β inhibitor (GSKi) on mouse calvariae were examined. We show here that inhibition of GSK3β induced expression of alkaline phosphatase(ALPase) activity in osteoblasts and increased calvarial thickness. GSKi at 1mg/kg or vehicle was injected sc daily for 18 days over the right side of the calvaria in 4 week-old male Swiss-Webster mice. The effect of GSKi on calvarial bone was assessed in histological sections by ALPase enzyme histochemical staining, quantitative histomorphometry and β-catenin expression by immunohistochemistry. Human PTH (1-34) at 20μg/kg/day, sc served as a positive control for the model and produced a significant increase in calvarial thickness. An increase in calvarial thickness was noted on the right hemicalvarium injected with GSKi when compared to either the left noninjected hemicalvarium of the same animal(11.8%, $p<0.005$) or calvaria from mice injected with vehicle alone (6%). ALPase was markedly enhanced in osteoblasts following either GSKi or PTH administration. Immunohistochemistry of calvaria injected with GSKi revealed strong β-catenin expression in pre-osteoblasts and osteoblastic cells lining the periosteum and the sagittal suture. In contrast, PTH had no effect on levels of β-catenin expression. Thus inhibition of GSK3β by local injection of GSKi has a bone anabolic effect that is associated with an increase in the level of β-catenin leading to the induction of osteoblast function. These results further support the significance of the Wnt signaling pathway in bone and the therapeutic potential of regulating this pathway in treating osteoporosis.

Regulation of Mouse Osteoprotegerin Gene Expression by 1α,25 dihydroxyvitamin D_3. T. Kondo*, R. Kitazawa, S. Maeda*, S. Kitazawa. Division of Molecular Pathology, Kobe University Graduate School of Medicine, Kobe, Japan.

Osteoclastogenesis is regulated by an integrated network of numerous bone metabolic factors, among which 1α,25 dihydroxyvitamin D_3 ($1\alpha,25(OH)_2D_3$) promotes osteoclastogenesis by reciprocally upregulating the expression of the receptor activator of NF-κB ligand (RANKL) gene and downregulating that of the osteoprotegerin (OPG) gene. To analyze the mechanism of OPG gene suppression by $1\alpha,25(OH)_2D_3$, we characterized cis-acting elements of the mouse OPG gene, and assessed the posttranscriptional modification process by actinomycin D studies. Both Northern blot and transient transfection analyses revealed that OPG gene expression was rapidly and transiently suppressed by $1\alpha,25(OH)_2D_3$ treatment. Additionally, actinomycin D studies revealed that $1\alpha,25(OH)_2D_3$ significantly shortened the half-life of OPG mRNA by 4 hours. Deletion mutant studies and electrophoretic gel motility shift assay revealed that mainly the c-Jun homodimer bound to the AP-1 binding site (TGACTGA, -293/-287) and maintained the steady-state

transcription of the OPG gene. Furthermore, the construct with the mutated AP-1 site (TGACTGA to CTCCCTC) was resistant to $1\alpha,25(OH)_2D_3$ -driven OPG gene suppression. In agreement with transient transfection studies, the amount of phosphorylated c-Jun protein (phospho-c-Jun) was decreased by vitamin D_3 treatment of ST2 stromal cell lines by 6 hours, while keeping the total amount of c-Jun protein constant. The amounts of the phosphorylated Jun N–terminal kinase (JNK) and the phosphorylated SAPK/Erk kinase (SEK1), on the other hand, were almost unchanged by vitamin D_3 treatment. Taken together with the fact that the OPG promoter has no consensus negative vitamin D-responsive elements, these data suggest that vitamin D_3 transrepresses the mouse OPG gene by reducing the proportion of the phospho-c-Jun protein in a JNK-independent manner. Our data indicated that short-term treatment with vitamin D_3 effectively downregulated OPG gene expression both by accelerating the degradation of OPG mRNA and by transrepressing the OPG gene through the AP-1 binding site in the catabolic phase. The OPG gene became insensitive to vitamin D_3 treatment, however, and reverted to its steady-state expression level in the long run, leading to the anabolic phase of the effect of $1\alpha,25(OH)_2D_3$ on bone.

1,25-Dihydroxyvitamin D3 Stimulates Dynamic Vitamin D3 Receptor/ Retinoid Receptor DNA-Binding and Coactivator Recruitment in Intact Osteoblasts. S. Kim*, H. Yamamoto, N. K. Shevde, J. W. Pike. Biochemistry, University of Wisconsin-Madison, Madison, WI, USA.

Hormonal 1,25-dihydroxyvitamin D3 (1,25(OH)2D3) induces gene expression through the vitamin D receptor (VDR), which binds as a retinoid X receptor (RXR) heterodimer to specific DNA sequences within target gene promoters and facilitates the recruitment of protein complexes essential for transcriptional modulation. In these studies, we explore the dynamics of this 1,25(OH)2D3-induced process on the 25-hydroxyvitamin D3-24-hydroxylase (Cyp24) and osteopontin (OPN) gene promoters in intact osteoblastic MC3T3-E1 target cells using chromatin immunoprecipitation techniques. 1,25(OH)2D3 rapidly stimulates the production of mRNA for both Cyp24 and OPN through direct actions on each gene's promoter. 1,25(OH)2D3 also induces rapid association of the VDR with both the Cyp24 and the OPN gene promoters. This DNA binding appears to cycle at early stages of transcriptional initiation with a periodicity of approximately 1 hr. Proteosome inhibitors such as MG132 reduce this cycling, suggesting that proteolysis is essential to the cycling process and transcriptional activation. VDR binding correlates directly with the accumulation of RXR on both promoters and double immunoprecipitations indicate the presence of both VDR and RXR on the same DNA fragment. 1,25(OH)2D3 treatment is also associated with rapid recruitment of coregulators such as the p160 coactivators SRC-1, 2 and 3 and the histone acetyltransferases p300 and CBP. The pattern of retention of these coactivators on the two promoters differs from that of VDR, however. DRIP205 is also rapidly recruited to these promoters, a process that correlates directly with the presence of RNA polymerase II. Interestingly, cotreatment of osteoblasts with 1,25(OH)2D3 and ZK159222, a vitamin D antagonist that blocks transcriptional activation by 1,25(OH)2D3, significantly reduces VDR DNA binding, limits the recruitment of coactivators such as SRC-1 and blocks the recruitment of RNA polymerase II. Lack of coactivator recruitment does not appear to be accompanied by increased association of corepressors such as SMRT or NCoR indicating that this antagonist may be a passive blocker of transactivation. These studies establish that 1,25(OH)2D3-induced transactivation in intact cells is a dynamic process that involves both RXR and a surprising number of coactivator complexes previously believed through molecular biological studies to associate with the VDR.

Expression of the Pagetic Phenotype in Osteoclasts (OCL) Requires VDR Dependent Transcription. N. Kurihara[1], S. V. Reddy[1], P. Friedman[2], A. W. Norman[2], G. D. Roodman[1]. [1]University of Pittsburgh, Pittsburgh, PA, USA, [2]University of California, Riverside, CA, USA.

OCL in Paget's disease (PD) are abnormal morphologically and contain paramyxoviral transcripts. OCL precursors from Paget's patients are hyper-responsive to 1,25-dihydroxyvitamin D_3 (1,25-$(OH)_2D_3$) and can form OCL at concentrations of 1,25-$(OH)_2D_3$ that are at least 1 to 2 logs less than those required for normal marrow cultures. We found that the hyper-responsivity to 1,25-$(OH)_2D_3$ was not due to increased vitamin D receptor (VDR) numbers or a VDR mutation. This hyper-responsivity to 1,25-$(OH)_2D_3$ allows increased OCL formation at physiologic levels of 1,25-$(OH)_2D_3$ that do not induce RANK ligand (RANKL), something that occurs at very low levels in normals. This hypothesis suggests that VDR dependent gene transcription is required for expression of the Paget's phenotype in OCL. In support of this, we have recently shown that transduction of normal CFU-GM with retroviral constructs containing the cDNA for the measles virus nucleocapsid (MVNP) gene, can induce these cells to form OCL that express a pagetic phenotype and are hyper-responsive to 1,25-$(OH)_2D_3$. Using a GST-VDR chimeric protein with lysates from MVNP transduced normal OCL precursors (CFU-GM derived cells) and marrow cells from involved bones from Paget's patients, we have isolated a potential coactivator of VDR, TAF_{II}-17, that was not expressed in empty vector (EV) transduced normal cells. The data suggested that VDR plays a key role in the abnormal OCL activity in PD. To test this hypothesis, OCL precursors from VDR -/- and VDR +/+ mice were transfected with the MVNP gene, and the characteristics of OCL formed examined. GST-VDR pull-down assays of MVNP transduced VDR-/- and VDR+/+ osteoclast precursors demonstrated that both cell types expressed high levels of TAF_{II}-17, a potential coactivator of VDR, which did not occur in EV transduced VDR-/- and VDR+/+ cells. OCL formation was significantly decreased in bone marrow cultures from VDR -/- mice treated with RANKL and M-CSF compared to the marrow cultures from VDR +/+ mice (32 ±7 vs. 61 ±6). The OCL that formed in marrow cultures of VDR -/- mouse transfected with the MVNP gene were small and did not express a pagetic phenotype (increased rate of formation, increased nuclear number, hyperresponsivity to RANKL). In contrast, MVNP transfected VDR +/+ mouse cells treated with RANKL/M-CSF formed large numbers of abnormal OCL that expressed a pagetic phenotype. As expected VDR -/- marrow cells did not form OCL in response to 1,25-$(OH)_2D_3$. These data suggest that VDR mediated gene transcription is required for optimal levels of OCL formation and that VDR mediated gene transcription is required for expression of a pagetic phenotype in OCL.

Vitamin D Receptor Isoforms Mediate the Cell-Selective Actions of the Vitamin D Analog Ro-26-9228. A. Ismail*[1], C. V. Nguyen*[1], M. R. Uskokovic*[2], S. Peleg[1]. [1]Endocrine Neoplasia & HD, M. D. Anderson Cancer Center, Houston, TX, USA, [2]Roche Inc., Nutley, NJ, USA.

The vitamin D analog Ro-26-9228 is tissue- and gene-selective in vivo. In culture, the vitamin D receptor (VDR)-mediated transcriptional activities of this analog were 30 to 100 times greater in human osteoblastic cell lines (MG-63 and hFOB) than in the human colon carcinoma cell line, Caco-2. We found that analog-bound VDR from hFOB cells had significant ability to interact with the p160 coactivator, GRIP, whereas analog-bound VDR from Caco-2 cells did not. We hypothesized that the cellular environment in the two cell types may differently regulate the events associated with acquisition of conformational changes that promote recruitment of coactivators of transcription to the VDR-ligand complexes. This activity was examined in the cytoplasmic and in the chromatin-bound receptor subpopulations of the two cell types. We found that in hFOB cells, unoccupied VDR was cytoplasmic and both 1,25-dihydroxyvitamin D3 (1,25D3) and the analog Ro-26-9228 induced a rapid accumulation of VDR in the chromatin. The ligand-bound (1,25D3 or Ro-26-9228) VDR from either cytoplasm or chromatin of hFOB cells had the ability to interact with GRIP. In contrast, the VDR in Caco-2 cells was present in both the cytoplasm and the chromatin in a ligand-independent manner. However, the treatment of Caco-2 cells with 1,25D3 selectively induced an accumulation of a smaller VDR form (form B) in the chromatin, whereas the analog's ability to induce accumulation of form B was poor. Examination of GRIP-interacting ability of VDR from Caco-2 cells revealed that the cytoplasmic and chromatin-associated large receptor form (form A) had ligand binding activity but did not have the ability to interact with GRIP, although the chromatin-bound form B did. To determine if form B was a proteolytic product of form A, we treated Caco-2 cells with the proteasome inhibitor MG132 and found, unexpectedly, that it caused a chromatin-exclusive accumulation of form B of VDR. Ligand treatment together with MG132 treatment appeared to promote a transformation of form A into form B. Furthermore, MG132 restored the coactivator-binding ability of the analog-treated VDR from Caco-2 cells to the same level as that induced by 1,25D3. Similar experiments with hFOB cells suggested that their VDR existed in a single, proteasome-sensitive form B. We hypothesize that the cell selectivity of Ro-26-9228 action is due to its limited ability to transform the inactive, proteasome-resistant form A of hVDR in Caco-2 cells into an active proteasome-sensitive form B, whereas in hFOB cells this step is not rate-limiting for VDR activation by the analog.

Evidence for a Role of C/EBP Beta in the Cross Talk between Parathyroid Hormone and $1,25(OH)_2D_3$ that Involves Enhancement of Protein Kinase a Mediated Induction of Vitamin D Receptor Transcription. P. Dhawan*[1], X. Peng*[1], M. Huening*[1], M. Centrella*[2], T. L. McCarthy*[2], S. Christakos[1]. [1]Depart ment of Biochemistry, University of Medicine and Dentistry of New Jersey, Newark, NJ, USA, [2]Yale University Medical School, New Haven, CT, USA.

C/EBP beta is a newly identified target of $1,25(OH)_2D_3$ action in osteoblastic cells. The induction of C/EBP beta in osteoblastic cells by $1,25(OH)_2D_3$ precedes the induction of 25-hydroxyvitamin D_3 24-hydroxylase [24(OH)ase] mRNA, consistent with a role of C/EBP beta as a mediator of the $1,25(OH)_2D_3$ response of the 24(OH)ase gene. In previous studies we showed that C/EBP beta cooperates with the vitamin D receptor (VDR) in the activation of 24(OH)ase transcription. A C/EBP beta site was identified in the rat 24(OH)ase promoter at –395/-388. Mutation of this site inhibited C/EBP beta binding and markedly attenuated the transcriptional response to C/EBP beta. In addition we have found cooperation of CBP/p300 with C/EBP beta by direct protein-protein interaction in regulating VDR mediated 24(OH)ase transcription. We now report that not only $1,25(OH)_2D_3$ but also parathyroid hormone (PTH) can induce C/EBP beta expression in osteoblastic cells. A peak induction of 9 fold is observed at 1h after PTH treatment (25 nM; first significant induction at 10 nM) in UMR106 osteoblastic cells with a return to basal levels by 9h. A similar induction of C/EBP beta by PTH was observed in primary osteoblasts. Treatment with $1,25(OH)_2D_3$ (10^{-8}M) for 16h followed by 4h with PTH (25nM) results in a 3-4 fold enhancement of C/EBP beta mRNA and 24(OH)ase mRNA as well as a 3-4 fold enhancement of VDR mediated 24(OH)ase transcription over the levels observed with $1,25(OH)_2D_3$ alone. Our data using the hVDR promoter (-1500/+60 that contains 2 putative C/EBP beta sites) indicate that C/EBP beta (5µg) can enhance PKA mediated transcription of hVDR 4 fold. Dominant negative C/EBP beta was found to inhibit the C/EBP beta mediated enhancement of VDR transcription. Thus, C/EBP beta plays an important role as an activator of $1,25(OH)_2D_3$ induced 24(OH)ase transcription as well as in PTH modulation of $1,25(OH)_2D_3$ action in osteoblastic cells. Our findings indicate, for the first time, a role for C/EBP beta in the cross talk between PTH and $1,25(OH)_2D_3$ that involves enhancement of PKA induced VDR transcription. Our findings also suggest that C/EBP beta may be a mediator of other PTH actions that affect skeletal integrity and osteoblast function.

Functional Cooperation Between Cbfa1 and the Vitamin D Receptor in the Regulation of Osteopontin Transcription. Q. Shen*, S. Christakos. Dept. of Biochemistry, UMDNJ-New Jersey Medical School & GSBS, Newark, NJ, USA.

Osteopontin (OPN) is a glycosylated phosphoprotein present in bone extracellular matrix that has been reported to modulate both mineralization and bone resorption. In osteoblastic cells the transcription of OPN is stimulated in response to 1,25dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) via the VDR/RXR complex. OPN expression is also regulated by the osteoblast specific differentiation regulator, Runx2/Cbfa1. Targeted disruption in mice of the vitamin D receptor (VDR) or Cbfa1 results in a marked inhibition of OPN expression in osteoblasts. In this study we addressed possible cross talk between VDR and Cbfa1 in regulating OPN transcription. Studies were done using COS-7 cells (that lack endogenous VDR and Cbfa1) transfected with the OPN promoter (-777/+79; VDRE –757/-743) and hVDR and/or Cbfa1 expression vectors. In $1,25(OH)_2D_3$ treated (10^{-8}M, 24h) VDR transfected COS-7 cells OPN transcription is induced 4.2±1.1 fold ($p<0.05$ compared to basal). OPN transcription was maximally induced 8.3±1.4 fold ($p<0.05$) by co-transfection of Cbfa1 expression vector in the absence of $1,25(OH)_2D_3$. Coexpression of Cbfa1 and VDR and treatment with $1,25(OH)_2D_3$ (10^{-8}M, 24h) resulted in a 20.1±1.6 fold induction of OPN transcription, suggesting functional cooperation between Cbfa1 and VDR. In COS-7 cells, the enhancement of the inductive action by $1,25(OH)_2D_3$ and Cbfa1 was dose dependently inhibited by AML1-ETO that acts as a repressor of Cbfa1. In ROS17/2.8 cells, that contain endogenous Cbfa1, 300ng pCMV AML1-ETO significantly diminished the $1,25(OH)_2D_3$ induction of OPN transcription ($p<0.05$). A Cbfa1 site was noted in the OPN promoter (AACCACA at –136/-130). Gel shift assays demonstrated that Cbfa1 binds to this site. A protein-DNA complex was not observed using a mutated Cbfa1 site (AAGAACA) as a probe. Using a mutant OPN promoter with the Cbfa1 site mutated as described for the gel shift assay and Cbfa1 and VDR co-transfected COS-7 cells, we found that cooperative activation between $1,25(OH)_2D_3$ and Cbfa1 was not observed. Our study demonstrates for the first time that the osteoblast specific transcription factor Cbfa1 has cooperative effects and cross talk with the VDR/RXR complex in $1,25(OH)_2D_3$ induced OPN transcription and suggests that Cbfa1 and VDR may cooperate in vivo to regulate the expression of the OPN gene.

Effect of PTH, Alendronate, or PTH Plus Alendronate on Biochemical Markers of Bone Turnover: One Year Results of the PaTH Study. D. C. Bauer[1], P. Garnero[2], J. P. Bilezikian[3], S. L. Greenspan[4], J. A. McGowan[5], L. Palermo*[1], D. M. Black[1]. [1]UCSF, San Francisco, CA, USA, [2]Synarc, Lyon, France, [3]Columbia University, New York, NY, USA, [4]University of Pittsburgh, Pittsburgh, PA, USA, [5]NIAMS, Bethesda, DC, USA.

Parathyroid hormone (PTH) promotes and bisphosphonates inhibit bone remodeling, yet both agents increase bone mass and reduce fracture risk. The effects of combined PTH and bisphosphonate therapy on markers of bone turnover have not been reported.

We randomized 238 postmenopausal women (not currently using bisphosphonates) with low hip or spine BMD (T-score <-2.5 or <-2.0 with a risk factor) to a daily regimen of: 100 µg rhPTH(1-84) (NPS)(n=119); alendronate (ALN) 10 mg (Merck)(n=60); or PTH and ALN together (n=59). BMD at the spine and hip were assessed by DXA. Fasting serum levels of N-terminal propeptide of type 1 collagen (P1NP, Roche) and C-terminal telopeptide of type 1 collagen (sCTX, Roche) were used to monitor formation and resorption, respectively, at baseline and 1, 3, and 12 months after randomization. An uncoupling index (z-score for P1NP minus z-score for sCTX) was calculated at each visit. Follow-up was complete in 95% of those randomized; analyses are by ITT.

Bone formation and resorption increased with PTH treatment and decreased with ALN treatment (Figures). For combination therapy at 1 month, bone resorption decreased close to levels observed with ALN alone, and formation increased close to levels observed with PTH alone. By 3 months, marker response to combination therapy mirrored changes observed with ALN therapy alone, but to a lesser extent. In each treatment group, correlations with 12 month change in spine BMD were higher with 1 month uncoupling index (r=0.43-0.61, $p<0.05$) than with 1 month change in P1NP or sCTX, or any parameter measured at later time points.

We conclude that after 1 month of combined PTH/ALN therapy the predominant effect on bone turnover is an increase in bone formation (PTH-driven) and a reduction in bone resorption (ALN-driven), but thereafter ALN blunts the anabolic effects of PTH. One month uncoupling index may best predict the 1 year change in spine BMD.

A Rapid and Profound 6-Month Suppression of Bone Turnover Is Seen with a Single SC Dose of AMG 162 in Postmenopausal Women. P. J. Bekker[1], D. L. Holloway[1], A. S. Rasmussen*[1], R. Murphy*[2], P. Leese*[3], G. Holmes*[4], C. R. Dunstan[5], A. M. DePaoli*[1]. [1]Clinical Research, Amgen Inc, Thousand Oaks, CA, USA, [2]Biostatistics, Amgen Inc, Thousand Oaks, CA, USA, [3]Quintiles, Lenexa, KS, USA, [4]SFBC International, Inc., Miami, FL, USA, [5]ANZAC Research Institute, Concord NSW, Australia.

RANKL (Receptor Activator of NF kappa B Ligand) is an essential osteoclastic differentiation and activation factor. The bone anti-resorptive activity, safety and tolerability of AMG 162, a fully human monoclonal antibody to RANKL, were evaluated in postmenopausal women in this randomized, double-blind, placebo-controlled, single-dose, dose escalation study.

Six cohorts of 8-9 women randomly received a single subcutaneous (SC) injection of either AMG 162 or placebo (3:1 ratio). AMG 162 doses were 0.01, 0.03, 0.1, 0.3, 1.0, and 3.0 mg/kg. Adverse events, chemistry, hematology, urinary N-telopeptide/creatinine (uNTX; Osteomark®), serum N-telopeptide (sNTX), and serum bone-specific alkaline phosphatase (BSAP, Ostase®) were followed for 6 months in all cohorts and 9 months in the 3 highest dose cohorts.

Forty-nine women were enrolled. uNTX mean % changes (+/- SE) from baseline are displayed.

	AMG 162, mg/kg single SC dose

* $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$ vs. placebo

Similar results were observed for sNTX. At Month 6, the mean change was 2%, –43 % and –56% in the placebo, 1.0 and 3.0 mg/kg AMG 162 groups, respectively. BSAP levels did not decrease remarkably until after the third week. Intact PTH levels increased up to ~4-fold by Day 5 in the 3.0 mg/kg dose group, but returned towards baseline with follow-up. Albumin-adjusted serum calcium did not decrease more than 10% on average in any group and no subject had values below 2 mmol/L. AMG 162 was very well tolerated. No related serious adverse events occurred; there was no evidence of an increased infection risk. No clinically meaningful laboratory changes, other than those described above, occurred. No subject had evidence of anti-AMG 162 antibodies.

In summary, a single SC dose of AMG 162 resulted in a dose-dependent rapid and sustained decrease in bone turnover from baseline. The tolerability profile was excellent. AMG 162 has potent anti-resorptive activity and could be a convenient treatment for osteoporosis.

The Risk vs. Benefit Profile of Estrogen Plus Progestin Does Not Differ by Underlying Risk of Osteoporosis. The Women's Health Initiative. J. Cauley[1], J. Robbins[2], Z. Chen[3], S. Cummings[4], R. Jackson[5], A. LaCroix*[6], M. LeBoff[7], C. Lewis[8], J. McGowan[9], J. Neuner*[10], M. Pettinger*[11], M. Stefanick*[12], J. Wactawski-Wende[13], N. Watts[14]. [1]U Pitt, Pittsburgh, PA, USA, [2]UC Davis, Sacramento, CA, USA, [3]U AZ, Tucson, AZ, USA, [4]UCSF, San Francisco, CA, USA, [5]OSU, Columbus, OH, USA, [6]FHCPC, Seattle, WA, USA, [7]Harvard, Boston, MA, USA, [8]UAB, Birmingham, AL, USA, [9]NIAMS, Bethesda, MD, USA, [10]U WI, Milwaukee, WI, USA, [11]FHCRC, Seattle, WA, USA, [12]Stanford, Palo Alto, CA, USA, [13]SUNY, Buffalo, NY, USA, [14]U Cincinatti, Cincinnati, OH, USA.

In the Women's Health Initiative Estrogen plus Progestin (E+P) trial, the overall benefit vs. risk profile, summarized in a global index, was a central focus. The global index was defined as the first occurrence of coronary heart disease, invasive breast cancer, stroke, pulmonary embolus, endometrial and colorectal cancer, hip fracture or death due to other causes. Overall, the global index showed a nominally significant 15% increase in the E+P group indicating more harm than benefit. The reduction in fractures and colorectal cancer were not sufficiently large to counterbalance the increased risk of heart disease and breast cancer. In the current analysis, we tested the hypothesis that the risk-benefit profile differs in women who are at "high" risk of fracture. We formed a summary risk score factor score using age (≥70), race (White/Asian), weight (<127 lbs), current smoking, positive family history of fractures, positive personal history of fractures; low calcium intake (<600 mg/day), self report of ≥2 falls in the past year; and never use of HRT prior to the trial. We assigned a score of one to each risk factor and summed the total number of risk factors (0-9). We divided the groups into tertiles (number of risk factors 0-2, 3, 4-9). The annual incidence of all fractures in placebo subjects was 1.4%, 1.8%, and 2.6% from tertile 1 (lower risk) through tertile 3 (higher risk), showing the validity of the scores. There was no evidence that the global index was more favorable in women who were considered at high risk of fractures. (Table) We conclude that the benefit of fracture reduction does not outweigh risks for heart disease and breast cancer even in women at higher risk of fracture.

Table: Relative Hazard of Global Index by Randomization Assignment, Stratified by Summary
Osteoporosis Risk Score
N = number with event
ann% = annualized incidence (%)

	E+P (N = 8506)		Placebo (N = 8102)		Hazard Ratio	95% CI	
						Lower	Upper
Summary risk score (9 items)	N	(ann. %)	N	(ann. %)			
Low (0-2 factors)	202	(1.27%)	182	(1.28%)	1.02	0.83	1.24
Mid (3 factors)	282	(1.87%)	233	(1.59%)	1.18	0.99	1.40
High (4-9 factors)	369	(2.16%)	304	(1.87%)	1.16	1.00	1.35

Changes in BMD at Different Skeletal Sites After Discontinuation of Treatment With rhPTH (1-34) in Postmenopausal Osteoporotic Women. J. R. Zanchetta, L. Rubio*, A. Mango*, C. E. Bogado*. Clinical Research, IDIM, Buenos Aires, Argentina.

Treatment with rhPTH (1-34) induces dramatic bone density increases in postmenopausal osteoporotic women. Assessment of the effects of treatment discontinuation on BMD is not easy. Patients remain free of treatment for different periods of time and thereafter receive different medications, making difficult the follow-up of BMD changes.
Ninety three patients who participated in a large, international rhPTH (1-34) vertebral fracture prevention trial at our site were follow-up with DXA measurements during 18 months. They have been randomly assigned to receive daily, self-injected doses of 20 (n=37) or 40 (n=25) ug of rhPTH or placebo (n= 31), plus 1000 mg calcium and 400 to 1,200 IU of vitamin D. After a media of 21 months of treatment, rhPTH treatment was stopped and patients entered in an observational follow-up study, receiving calcium and vitamin D supplements only. BMD measurements at lumbar spine (LSBMD)and femoral neck (FNBMD) and whole body bone mineral content (TBMC)were performed 6 and 18 months after treatment discontinuation.
rhPTH administration significantly increased BMD at all skeletal sites evaluated. LSBMD increased by 12.9 % (p< 0.001) and 9.0% (p<0.001), while FNBMD increased by 5.1% (p<0.001) and 4.3% for the 40 and 20 ug doses respectively. TBMC increased 5.6% (p<0.01) in the 40 ug group and by 3.3% in the 20 ug group. There were no significantly changes in the placebo group.
During follow-up LSBMD decreased by –3.04% and –3.42% after 6 months and by –4.32% and –0.88% after 18 months, in the 40 and 20 ug groups respectively. Despite bone loss, LSBMD remained significantly higher by 4.6% (40 ug group) and 3.8% (20 ug group) as compared with baseline after 18 months without treatment. FNBMD decreased by –1.2% after 6 months and –1.1 after 18 months in the 20 ug group. In the 40 ug group it changed by +1.03 and –2.4 after 6 and 18 months respectively. After 18 months FNBMD values remained 3.4% and 1.8% higher as compared with baseline in the 40 and 20 ug groups respectively. TBMC decreased by –2.3% and –1.79 after 6 months in the 40 and 20 ug groups respectively, but did not change significantly thereafter. No significantly changes were evident in the placebo group.
Our results confirm that patients loss bone after rhPTH(1-34) treatment is discontinued. However, 18 months after discontinuation, BMD remains significantly increased as compared with baseline at lumbar spine and femoral neck. The differences in the pattern of bone loss between lumbar spine and femoral neck or whole body, might reflect a different response of trabecular and cortical bone tissue after treatment discontinuation.

Effects of Simvastatin Treatment in Postmenopausal Osteopenic Women: A Randomized Controlled Trial. L. Rejnmark[1], N. H. Buus*[2], P. Vestergaard[1], F. Andreasen*[2], L. Heickendorff*[3], M. L. Larsen*[4], L. Mosekilde[1]. [1]Dept. of Endocrinology and Metabolism, Aarhus Amtssygehus, Aarhus, Denmark, [2]Center for Clinical Pharmacology, Aarhus University, Aarhus, Denmark, [3]Dept. of Clinical Biochemistry, Aarhus Amtssygehus, Aarhus, Denmark, [4]Dept. of Medicine and Cardiology, Aarhus Amtssygehus, Aarhus, Denmark.

Statins have been suggested as potential agents in the management of osteoporosis as statins have been reported to cause bone anabolic as well as antiresorptive effects.
In a double-blinded design, 82 healthy postmenopausal women with osteopenia or osteoporosis (T-score < -1), aged 53 to 74 years, were randomized to one-year of treatment with simvastatin 40 mg/day or placebo. Participants were recruited from the general population. None of the participants had known hyperlipidemic diseases. Bone mineral density (BMD) and plasma levels of cholesterol, PTH and biochemical markers of bone turnover were measured at baseline, after one year of treatment (week 52), and 26 weeks after withdrawal of treatment (week 78). Calcium supplements (400 mg/day) were administrated to all participants during the entire 1.5-year study period. Seventy-eight women completed the one-year of treatment. After one year, plasma cholesterol was reduced with simvastatin but not placebo (-27% vs. +0.7%, p<0.001). After withdrawal of treatment (week 78), plasma cholesterol returned to baseline levels in the simvastatin group and did no longer differ from the placebo group (p=0.83). However, plasma PTH levels as well as plasma levels of biochemical markers of bone formation (osteocalcin and bone-specific alkaline phosphatase) and bone resorption (CTx) did not differ between groups at week 52 or at week 78. Compared with placebo, simvastatin did not cause significant changes in BMD at the lumbar spine, total hip, femoral neck or whole body at week 52 or at week 78. Only at the forearm, BMD increased in response to simvastatin. At the total forearm, BMD was increased by 1.1% in the simvastatin group at week 52 (vs. –0.3% in the placebo group, p=0.01) and by 1.8% at week 78 (vs. +0.4% in the placebo group, p=0.02). At the ultradistal forearm, BMD was increased by 2.9% in the simvastatin group at week 52 (vs. +0.1% in the placebo group, p=0.02) and by 3.4% at week 78 (vs. +1.1% in the placebo group, p=0.04). Within the statin group, changes in cholesterol levels did not correlate to BMD changes at any measurement site. Thus, our results do not support a general beneficial effect of simvastatin on bone metabolism. Therefore, statin treatment is most likely not a therapeutic option in the treatment of osteoporosis.

Daily versus Cyclic PTH Combined with Alendronate versus Alendronate Alone for Treatment of Osteoporosis. F. Cosman[1], J. W. Nieves[2], M. M. Luckey[3], M. Zion*[2], L. Woelfert*[1], R. Lindsay[1]. [1]Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [2]Clinical Research Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [3]St. Barnabus Hospital, Livingston, NJ, USA.

During the early response to PTH administration, bone formation is stimulated more dramatically than bone resorption, which catches up by 6 months. Therefore, it is possible that repeated 3 month cycles of PTH therapy could produce an equal or greater skeletal response to that produced by daily PTH treatment. We embarked on a 15 month treatment trial involving 126 patients (mean age 67.7 years) with osteoporosis, already treated with alendronate for at least 1 year (mean = 3.2 years). While alendronate was continued (70mg/week), patients were randomly assigned to receive (1-34)hPTH 25 mcg by subcutaneous injection daily (DAILY PTH), 25 mcg PTH daily for cycles of 3 months on and 3 months off (CYCLIC PTH), or alendronate alone (A). Data are presented from the first 83 patients completing 9 months of the trial. Baseline demographic, biochemical and BMD variables were similar in the 3 groups. Serum levels of bone formation (osteocalcin, bone alkaline phosphatase, and aminoterminal propeptide of Type I procollagen); the urinary bone resorption marker, crosslinked n-telopeptide (NTX); and BMD were measured every 3 months. Bone turnover markers did not change significantly in the A group throughout the 9 months. In the DAILY PTH group, bone formation markers increased rapidly during the first 3 months and continuously throughout the 9 months (increases ranging from 80-300% for different markers, all p<0.001). In the CYCLIC PTH group, bone formation markers increased within the first 3 months of treatment similarly to the DAILY PTH group, declined during the off PTH cycle, and then rose again robustly during the second PTH cycle (60-270% from baseline, all p<0.001). NTX increased more modestly than bone formation markers in the PTH groups at 3 months and thereafter followed a similar pattern to bone formation markers in DAILY PTH vs CYCLIC PTH groups. Lumbar spine BMD rose progressively in the DAILY PTH group. In the CYCLIC PTH group, lumbar BMD rose to 3 months, declined slightly to 6 months and rose again from 6 to 9 months. At 9 months, there were no significant differences in BMD change between the 2 PTH groups; spine BMD increased 4.3% in the DAILY PTH group (p<0.0001), and 3.8% in the CYCLIC PTH group (p<0.0001). There was a smaller increase in BMD in patients in the A group (2%, p<0.04). These data indicate that PTH stimulates bone formation and increases BMD in the presence of long-term established alendronate. Furthermore, short cyclic challenges with PTH might be an efficient and economical way to use PTH for treatment of osteoporosis.

Delayed Fracture and Osteotomy Healing in Pediatric Osteogenesis Imperfecta Patients Receiving Pamidronate. C. F. J. Munns, F. Rauch, L. Zeitlin, F. Fassier*, F. H. Glorieux. Shriners Hospital for Children and McGill University, Montreal, PQ, Canada.

Treatment with cyclical intravenous pamidronate infusions has led to marked improvements in the clinical management of children and adolescents with osteogenesis imperfecta. However, the effect of treatment on fracture healing is not well characterized. In the present study we evaluated bone healing following radiologically confirmed lower limb fractures and after osteotomies performed for the placement of intramedullary rods. Delayed healing was defined as the radiographically apparent persistence of a fracture or osteotomy line 12 months following the event. A total of 197 fractures (132 femur, 65 tibia) in 85 patients with moderate to severe forms of OI (median age at the time of fracture 4.8 years; range 0.0 to 19.9 years; 45 girls) were evaluated. Incomplete fracture healing was more than twice as frequent when pamidronate therapy had been started before the fracture occurred (42 of 155 (27%) vs 5 of 42 (11%); P=0.04 by Chi square test). During pamidronate treatment, fractures that subsequently demonstrated delayed healing occurred at an older age (8.1 vs 4.3 years), a taller height (107 vs 85 cm), a heavier weight (19.3 vs 12.2 kg) and after a longer duration of treatment (2.1 vs 1.1 years) than fractures that healed normally (P<0.001 for all comparisons by U-test). 48% of fractures in OI type IV patients and 19% of fractures in OI type III patients showed delayed healing (P<0.001 by Chi square test). Osteotomy healing was assessed after 200 intramedullary rodding procedures in 79 OI patients with moderate to severe forms of OI (median age at the time of surgery 5.4 years; range 1.2 to 19.8 years; 42 girls). Delayed osteotomy healing was almost four times more frequent when pamidronate had been started before surgery (97 of 162 (60%) vs 6 of 38 (16%); P<0.001 by Chi square test). During pamidronate treatment, factors associated with delayed osteotomy healing were older age (6.5 vs 3.9 years), taller height (94 vs 82 cm) and heavier weight (15.9 vs 12.2 kg) (P<0.001 for all comparisons by U-test). Duration of pamidronate treatment was not associated with delayed osteotomy healing (1.4 vs 1.7 years; P=0.4 by U-test). Delayed osteotomy healing occurred after 83% of rodding procedures in OI type IV patients compared to 45% in OI type III patients

(P<0.001 by Chi square test). This study demonstrates that cyclical intravenous pamidronate therapy is associated with a significant delay in fracture and osteotomy healing in children and adolescents with OI. The clinical sequelae of the delay in healing require investigation.

Treatment of OIM Mice with Osteoprotegerin. J. Quenzer*[1], K. Boachie-Adjei*[1], A. Hao*[1], C. Dunstan[2], C. L. Raggio*[1], N. P. Camacho[1]. [1]Research Division, Hospital for Special Surgery, New York, NY, USA, [2]Amgen Corp., Thousand Oaks, CA, USA.

Osteogenesis imperfecta (OI) is a heritable disease caused by molecular defects in type I collagen that can result in severe bone fragility. Several studies have established that bisphosphonates are effective in reducing fracture risk and improving bone properties in OI. The purpose of the current study was to explore the possibility that treatment of an animal model of OI with the anti-resorptive agent osteoprotegerin (OPG) would also improve bone properties and reduce fractures. Mice homozygous for the *oim* mutation *(oim/oim)* are deficient in proα2(I) collagen and model moderate-to-severe OI. *Oim/oim* (n = 7) and *oim/+* mice (n = 9) were treated with 1 mg/kg/day recombinant OPG fusion protein (Fc-OPG) (generously supplied by Amgen Corp., Thousand Oaks, CA) injected s.c. 3x/week from 6 weeks to 14 weeks of age. At sacrifice, whole body AP radiographs were taken and fractures counted. Dissected femora were radiographed with a density standard, digitized, and analyzed with SigmaScan software (Jandel Scientific). The mineralized phase was evaluated histologically in tibial metaphyses with alcian blue staining. Data from this study were compared to data from saline-treated (control) mice. All the mice tolerated the OPG treatment very well, with consistent weight gain throughout the study. There was variability in response of both the *oim/+* and *oim/oim* mice to OPG, as evidenced by the quantity of new metaphyseal bone formation. Histologically, some mice exhibited little new bone growth, while some mice had metaphyseal bone with persistent calcified cartilage and thickened trabeculae. This was also reflected in the radiographic densities, which ranged from 1.19 to 3.14 (mean = 2.26 $\pm$.73) for the *oim/+* mice, and from 0.84 to 2.09 (mean = 1.17 $\pm$.48) for the *oim/oim* mice. The OPG *oim/oim* mice sustained between 1 – 4 fractures/mouse, compared to 1 – 7 fractures/mouse in the saline-treated *oim/oim* mice. *Oim/+* mice do not typically fracture, and consistent with that phenotype, sustained no fractures with OPG treatment. Previous studies have shown that Fc-OPG, which contains a human OPG domain, can be antigenic in mice after some time. Thus, the variability of response in the current study could be attributed to that fact. Nevertheless, these preliminary results support the notion that optimization of the dosing regime of OPG could result in consistent new bone formation and fracture reduction in the *oim/oim* mice.

The Effects of a Lifestyle Intervention for Teen Girls on Bone Mineral Density. C. Ritenbaugh*[1], L. DeBar*[1], M. Aickin*[1], P. J. Elmer*[1], D. Elliott*[2], E. Orwoll[2]. [1]Kaiser Permanente Center for Health Research, Portland, OR, USA, [2]Oregon Health and Science University, Portland, OR, USA.

YOUTH is a lifestyle intervention for increasing bone mineral density (BMD) among adolescent women (14-16 years of age), with a primary end point of change in BMD by DEXA at two years. Higher risk female adolescents (Body Mass Index between 16 and 23) and their parent(s)/guardian(s) were individually recruited among members of a large HMO in the Pacific Northwest. Eligible teens (N=228) were randomized into a lifestyle intervention or to general health education (control). The intervention targets are: (1) improving diet (increasing consumption of fruits, vegetables, and high calcium foods; and decreasing soft drink consumption), and (2) increasing high-impact physical activity and spinal motion. The control group receives general health information.

Interim results of the intervention on BMDare shown below for the first 140 girls (72 control, 68 intervention) who had BMD assessment at one year (Hologic 4500). At baseline (mean $\pm$ S.D.): overall age = 14.9 $\pm$ 0.6 yrs.; overall bmi = 20.0 $\pm$ 1.6; months since menarche 26.7 $\pm$ 14.5. In both groups, 76% of girls self-identified as white. There were significant 1-year differences in diet changes for the intervention group compared to control (intervention group: increased fruits and vegetables and calcium, decreased soda), but no significant differences in changes in high-impact or total activity levels or spinal motion. The table below shows baseline BMD values by group, the adjusted mean difference at one year, and the p-value for the 1-year difference. The adjusted mean difference is estimated from a conditional change regression (ANCOVA), adjusting for BMD at baseline and time since menarche.

Bone Mineral Density Site	Baseline Control X $\pm$ S.E.	Baseline Intervention X $\pm$ S.E.	Adjusted mean difference	p value
Total body	1.1 $\pm$ 0.08	1.11 $\pm$ 0.07	.0023 $\pm$. 0035	0.513
Femoral neck	0.89 $\pm$ 0.12	0.89 $\pm$ 0.12	-.0006 $\pm$ .0054	0.906
Trochanter	0.77 $\pm$ 0.10	0.75 $\pm$ 0.11	.0097 $\pm$ .0042	0.021
Ward's Triangle	0.88 $\pm$ 0.14	0.88 $\pm$ 0.14	-.0067 $\pm$ .0076	0.382
Total hip	0.96 $\pm$ 0.11	0.96 $\pm$ 0.12	.0060 $\pm$ .0039	0.130
Spine L1-L4 (mean)	0.97 $\pm$ 0.10	0.95 $\pm$ 0.09	.0177 $\pm$ .0043	0.000

Conclusion: Teenage girls can achieve lifestyle dietary changes for one year that result in enhanced bone mineral density at predominantly trabecular bone sites.

Interdependence between Calcium Intake and Menarcheal Age on Bone Mass Gain: A 8 Years Follow-up Study from Pre-puberty to Post-menarche. T. Chevalley[1], J. P. Bonjour[1], D. Hans*[2], D. Slosman*[2], R. Rizzoli[1]. [1]Div. of Bone Diseases, Geriatric and Internal Medicine, Univ. Geneva, Switzerland, [2]Div. of Nuclear Medicine, Radiology, University of Geneva, Switzerland.

Both early menarche and high Ca intake during growth are considered as factors reducing the risk of osteoporosis, probably by increasing peak bone mass. Recent observation suggests a possible interdependence between these two factors. We investigated whether Ca intake could influence menarcheal age (MENA) and, conversely, whether the response of bone mineral mass accrual to increased Ca intake could vary according to MENA. 144 girls aged 7.93±0.04 yrs (mean±sem) were randomized in a double blind controlled trial to receive either a Ca supplement (Calsup) of 850mg/day (n=77) or placebo (n=67) during one year. Areal bone mineral density (aBMD) was determined by DXA at 6 skeletal sites: radius metaphysis, radius diaphysis, femoral neck, trochanter, femoral diaphysis and L2-L4 vertebrae. The mean yearly aBMD gains at these 6 sites were 21±2 and 27±2 (p<0.005) in the Placebo and Calsup group, respectively (intention to treat cohort). The subjects were reexamined at 1.0, 3.5 and 7.5 yrs after the end of intervention and MENA was recorded. Spontaneous Ca intake was assessed by frequency questionnaires at baseline, 6 and 12 months allowing us to calculate the total Ca intake (spontaneous±Calsup, in g/yr) during the intervention phase, taking into account the individual degree of compliance in the Calsup group. Further frequency questionnaires made at each follow-up visit indicated a steady individual position within the spontaneous Ca intake range. We now report on results obtained when the subjects were 16.38±0.07 and 16.34±0.06 yrs in the placebo (n=58) and Calsup (n=67) groups, respectively. A highly significant negative correlation was found between Ca intake and MENA (R=-0.35, p<0.0001), and between MENA and gain in aBMD from age 8.0 to 16.4 yrs at all 6 skeletal sites (R range: from - 0.41 to - 0.22, p<0.0001- p<0.016). The positive effect of Calsup on mean axial and appendicular aBMD gain from baseline remained significantly greater in girls below (Early) but not in those above (Late) the median of MENA: Early, placebo (MENA=12.2±0.2 yrs) 286±8 mg/cm^2, Calsup (MENA=12.1±0.1 yrs) 317±8, p<0.01. Late, placebo (MENA=13.9±0.1 yrs) 284±10 mg/cm^2, Calsup (MENA=13.9±0.1yrs) 276±16, p>0.05. In conclusion, our study shows for the first time a relationship between Ca intake during pre-puberty and menarcheal age. It also indicates that early menarche is associated with lasting bone mass gain in response to Ca supplementation. Thus, both early menarcheal age determinants and high Ca intake appear to positively interact on bone mineral mass accrual.

Femoral Neck Bone Strength Changes in Prepubertal Boys: A Randomized Controlled Trial of a 2-Year, School-Based Exercise Intervention. K. J. MacKelvie[1], M. A. Petit*[2], K. M. Khan[1], H. A. McKay[1]. [1]University of British Columbia, Vancouver, BC, Canada, [2]Pennsylvania State University, Hershey, PA, USA.

Exercise during growth has a positive influence on bone mineral accrual, yet little is known about how bone structure and bone strength adapt to loading during growth. Our previous work has shown that, in early pubertal girls, the primary response to loading was bone accrual at the endosteal surface of the femoral neck, conferring a significant increase in bone bending strength over 8 months. Our objective was to compare changes in proximal femur bone structure and bone strength between 31 prepubertal (Tanner Stage 1) boys who participated in a school-based, high impact circuit intervention (12 minutes, 3x/week) for 20 months and 33 maturity-matched controls. We assessed structural variables and bone strength at the narrow neck (NN), intertrochanteric region and femoral shaft regions by applying the Hip Structural Analysis program to dual energy x-ray absorptiometry scans (DXA, Hologic QDR 4500) of the proximal femur. We derived total body lean mass and fat mass from DXA total body scans, and measured height and weight by standard methods, physical activity by questionnaire (PAQ-C), calcium intake by a food frequency questionnaire, and maturity by Tanner staging self-assessment of pubic hair. Intervention boys (10.2±0.5 years old) and control boys (10.1±0.5 years old) had similar baseline height (140.8 vs 141.3 cm) and weight (36.9 vs 35.4 kg) and similar average 20-month physical activity scores and calcium intakes (861 vs 850 mg/day). Twenty-month height and weight changes did not differ between groups; lean mass changed more (P<0.05) in intervention (22.8%) than control boys (18.6%). We compared 20-month bone changes with ANCOVA, adjusting for height change, final Tanner stage and baseline bone values. At NN region, intervention boys had greater expansion at both the periosteal (+2.6%, P=0.1) and endosteal (+2.7%, P=0.2) surfaces, resulting in significantly greater changes in section modulus (bone bending strength) (+7.5%, P=0.02). Changes at the intertrochanteric and femoral shaft regions did not differ significantly between groups. Twenty-month change in NN bone bending strength was correlated positively with change in lean mass (r=0.47, P<0.001), but negatively with change in fat mass (r=-0.33, P=0.01). A 2-year school-based, high impact exercise program implemented 3 x/week for 12 minutes is an effective strategy for site-specific gains in bone strength at the femoral neck region of the proximal femur. The bone structural adaptation may be mediated by changes in lean body mass. These data further highlight the surface-, site- and sex-specific bone adaptation to loading during growth.

Influence of Sex Hormones on Bone Geometric Properties and Mineral Density in Early Pubertal Girls. Q. Wang*[1], P. Nicholson*[1], M. Suuriniemi[2], A. Lyytikäinen[1], E. Helkala*[1], M. Alen*[3], H. Suominen[1], S. Cheng[1]. [1]Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland, [2]Department of Cell Biology, University of Jyväskylä, Jyväskylä, Finland, [3]PEURUNKA-Medical Rehabilitation Center, Jyväskylä, Finland.

The effects of sex hormones on bone geometric properties and density in early adolescent girls are not yet fully understood. The present study aimed to evaluate the correlations among serum 17β-estradiol (E2), testosterone, bone geometric properties and mineral density in pre- and early pubertal girls. E2, testosterone, and sex hormone binding globulin (SHBG) were measured using time-resolved fluoroimmunoassays (Delfia, Wallac Oy, Turku) in 245 10-12 year-old Finnish girls without history of disease or medication known to affect bone metabolism. The left tibial shaft was measured by peripheral quantitative computed tomography (Stratec XCT-2000). The cortical bone area and marrow cavity area were measured and expressed as proportions of the total tibial cross sectional area (CSA). Cortical thickness and total volumetric BMD (vBMD) were also determined. These tibial geometric and densitometric measures were correlated against the serum sex hormone concentrations controlling for age, body weight and height. The results showed that E2 was significantly associated negatively with marrow cavity proportion ($r = -0.19$, $p = 0.003$), positively with cortical proportion and thickness as well as total vBMD ($r = 0.24$, $p < 0.001$; $r = 0.18$, $p = 0.004$, and $r = 0.23$, $p < 0.001$, respectively). Free E2 showed similar correlations with these bone variables as total E2. However, testosterone and free testosterone were not associated with these bone variables. On the other hand, SHBG was associated negatively with vBMD, cortical thickness, and cortical proportion ($r = -0.18$, $p = 0.005$; $r = -0.22$, $p <0.001$; and $r = -0.16$, $p = 0.012$, respectively), positively with marrow cavity proportion ($r = 0.16$, $p = 0.010$). Total bone CSA did not correlate with E2, testosterone or SHBG. These results suggest a positive effect of E2 on bone cortical development by suppressing bone turnover at the endosteum during the early pubertal period, and that the effects of E2 on bone are more pronounced than that of testosterone.

The Paternally Imprinted Autosomal Dominant Form of Pseudohypoparathyroidism Type-Ib Is Associated With a 2998-bp Deletion Centromeric of *GNAS1*. M. Bastepe, L. Fröhlich*, H. Jüppner. Endocrine Unit/Medicine, Mass. General Hosp., Harvard Med. Sch., Boston, MA, USA.

Most cases of pseudohypoparathyroidism type-Ib (PHP-Ib), unlike some other PHP forms, are not caused by coding Gs-alpha mutations. However, a familial form of PHP-Ib with autosomal dominant inheritance and paternal imprinting (AD-PHP-Ib) has been mapped to a ~2.5-Mb locus on 20q13.3 comprising a portion of *GNAS1*, the gene encoding Gs-alpha. Moreover, sporadic and familial PHP-Ib cases show a loss of methylation at *GNAS1* exon A/B, and recent studies have shown that the mutation leading to this epigenetic abnormality in AD-PHP-Ib kindreds resides at least 56 kb upstream of exon A/B. Taken together, these findings implicate a mutation affecting a long-range, *cis*-acting element that controls imprinting of *GNAS1*. We have now refined the AD-PHP-Ib locus to an ~280 kb interval based on a new recombinant individual in kindred W. Subsequent analysis of markers in this region revealed a heterozygous 2,998-bp deletion in kindred F, which was present only in affected members and unaffected carriers. The same deletion was also found in patients and healthy carriers of 12 other unrelated AD-PHP-Ib kindreds, but not in 114 healthy controls. For each patient affected by AD-PHP-Ib, the deletion was inherited maternally and associated with loss of methylation at exon A/B without defects at other DMRs of *GNAS1*. The deletion was also found in two apparently sporadic PHP-Ib cases with the exon A/B methylation defect. These cases, on further analysis of clinically unaffected parents, appeared to have inherited the mutation from their mothers. Many other sporadic PHP-Ib cases, despite having the exon A/B methylation defect, lack the deletion or any similar mutations. Interestingly, kindred W, which strongly links to the *GNAS1* region (lod score: 2.53), also does not show the deletion or any mutations within the deleted region, although the epigenetic abnormality in this kindred is identical to that in kindreds in whom the deletion is present. It is thus likely that, while the identified deletion disrupts a *cis*-acting regulatory element necessary for establishment and/or maintenance of the methylation imprint at exon A/B, there are additional imprinting control elements at *GNAS1*. *In vivo* studies will help elucidate the relationship between the identified mutation and the loss of exon A/B methylation.

Noncoding Deletion Present in van Buchem Patients Removes Essential Regulatory Elements Required for Bone-specific Expression of BMP-antagonist Sclerostin. G. G. Loots*[1], M. Kneissel*[2], H. Keller[2], M. Brunkow*[3], J. Chang*[4], D. Ovcharenko*[4], I. Plajzer-Frick*[4], V. Afzal*[4], E. M. Rubin*[5]. [1]Genomics Division, LLNL, Livermore, CA, USA, [2]Bone Metabolism Unit, Novartis Pharma, Basel, Switzerland, [3]Celltech Inc., Bothell, WA, USA, [4]Life Sciences Division, LBNL, Berkeley, CA, USA, [5]DOE, Joint Genome Institute, Walnut Creek, CA, USA.

Sclerosteosis is a generalized progressive bone overgrowth disorder due to the loss of function of the *SOST* gene product sclerostin. Van Buchem disease is a similar skeletal disorder characterized by milder sclerosteosis-like phenotypes and is associated with the presence of a 52 kb deletion (VBDel) located ~35kb downstream of the *SOST* transcript and ~10kb upstream of the *MEOX1* gene on human chromosome 17p21. Human-mouse comparative sequence analysis revealed several highly conserved noncoding elements present in the VBDel region suggesting that van Buchem disease is caused by the removal of essential *SOST*-specific regulatory elements. Using in vitro BAC-recombination techniques we have engineered a ~160kb human BAC containing the *SOST* and *MEOX1* transcripts by removing the ~52kb intergenic region absent in patients suffering from van Buchem Disease. We have generated several lines of transgenic animals carrying either the wildtype human *SOST* BAC or the VBDel modified BAC. Following the expression pattern of the endogenous sost mouse gene, we have investigated the expression pattern of the human transgenes in these two types of transgenic animals. Similar to the murine *SOST* expression, the human sost transcript from the wildtype BAC is predominantly expressed in the mineralized bones of fetal, neonatal and adult mice, as well as in the apical ectodermal ridge of the developing embryo. Transgenic animals carrying the modified VBDel BAC fail to express the human sost transcript in mineralized bone, while the embryonic expression of this transgene is unaffected. Using comparative sequence analysis, transient transgenic technology and transient transfection experiments in osteoblastic cells we are currently in the process of testing all the evolutionary conserved noncoding elements present in the VBDel for the potential to drive expression in the adult skeletal structures. Our findings suggest that van Buchem disease is caused by a regulatory mutation that diminishes osteoblast-specific expression of the BMP-antagonist sclerostin.

Engraftment of Wild-Type Bone Marrow Stromal Cells in Akp2-/- Mice: A Potential Therapy for Infantile Hypophosphatasia. D. Harmey, S. Narisawa*, J. L. Millan. The Burnham Institute, La Jolla, CA, USA.

Hypophosphatasia is a rare heritable disease for which there is currently no treatment. This disease results from loss-of-function mutations in the tissue non-specific alkaline phosphatase (TNAP) gene. TNAP hydrolyzes the mineralization inhibitor inorganic pyrophosphate (PP_i) and thereby promotes mineralization. There is wide variation in the severity of this disease, the most severe form of which is perinatal/infantile hypophosphatasia. We have developed a mouse model of infantile hypophosphatasia by ablating the TNAP (*Akp2*) gene. *Akp2*$^{-/-}$ mice have poorly mineralized bones, suffer spontaneous fractures and display elevated levels of PP_i. These mice appear normal at birth but are growth retarded from day 5, suffer epileptic seizures and do not survive weaning. The mineralization defects in these mice lies with the bone forming osteoblasts, which are unable to mineralize matrix. Given that bone marrow stromal cells (BMSCs) are a source of multipotential progenitors that under osteogenic conditions can differentiate into mature osteoblasts, we hypothesized that BMSCs from wild-type (WT) mice may be used as donor cells to treat the hypophosphatasia mice. BMSCs were isolated from the long bones of 6-week old WT mice. To ensure that these cells successfully differentiated into osteoblast-like cells, we cultured BMSCs in the presence of ascorbic acid (50 μg/ml) and β-glycerophosphate (10 mM). Under these conditions BMSCs differentiated into osteoblastic-like cells expressing characteristic osteoblast markers, *i.e.,* TNAP, osteocalcin (OCN) and core binding factor (CBFA-1). Based on these observations, we performed bone marrow transplants into *Akp2*$^{-/-}$ mice. To aid BMSC engraftment in the host mice, we sub-lethally irradiated 4-day old *Akp2*$^{-/-}$ mice. Following a 24-hour recovery period the mice were injected with a mixture of BMSCs that had been cultured under osteogenic conditions, along with freshly isolated BMSCs, these injections were performed daily for 3 weeks. Mice were sacrificed and long bones dissected and longitudinal frozen sections were examined for TNAP activity to determine whether engraftment of donor cells had occurred. Clusters of donor-derived TNAP positive cells were observed within the bone marrow cavity in some of the treated mice. While clearly we need to optimize the conditions for engraftment, these findings are encouraging in terms of the potential use of BMSCs as a means of replacing TNAP-deficient osteoblasts by wild-type osteoblasts with the goal of ameliorating the hypomineralization of infantile hypophosphatasia.

Osteoporosis Pseudoglioma Syndrome: 3 Siblings with a Novel LPR5 Mutation. E. A. Streeten[1], H. Morton*[2], D. J. McBride*[1]. [1]Endocrinology, Diabetes and Nutrition, University of Maryland School of Medicine, Baltimore, MD, USA, [2]Pediatric Genetics, Clinic for Special Children, Strasburg, PA, USA.

Osteoporosis-pseudoglioma syndrome (OPPG) is a rare autosomal recessive disorder of severe juvenile osteoporosis and congenital blindness, due to mutations in the LRP5 gene. Approximately 30 cases of OPPG are known worldwide. We report 3 siblings with OPPG, members of a conservative Mennonite church in Pa. The proband (A) is an 11 9/12 yo boy who was noted to be blind at 7 weeks of age and bilateral retinal detachments were diagnosed. At age 6 yrs, he had his first fracture, of a clavicle after a mild fall. At 7 9/12 yo, he fractured his proximal R femur after a mild fall, and over the next 7 months, had atraumatic fractures of the left femur and tibia and spine at multiple levels. At age 8 9/12, DXA showed a Z score of –6.1 in the spine and metabolic evaluation was normal. He was started on oral risedronate and over the next year, his BMD improved 78% and he had no fractures. In the 2nd year on risedronate, BMD increase was smaller, total 103% in the first 2 years (Z score –7.25 to –4.27), and he had another 3 femur fractures. His treatment was then changed (8 months ago) to IV pamidronate 1 mg/kg x 3 every 4 months and he has had no fractures since then. Rods have been placed in both femurs but he has been non-ambulatory since age 7 ½ yo. The proband's brother (B), now 7 yo, had congential blindness due to retinal detachment and at age 4 9/12 yo, DXA showed a spine Z score of -5.0. He was started on oral risedronate, and after 2 years, his Z score increased to -3.7. Now aged 7 yo, he has had no fractures to date. The 3rd affected sibling (C), a girl now 12 mos old had congenital blindness due to bilateral retinal detachment and has not yet had a DXA.

A DXA study on the father was normal (spine T score -0.5, hip +0.3); the mother had mild osteopenia (spine T score -1.2, hip -0.6). There are 5 unaffected siblings to the proband.
To study the LRP5 gene in this family, primers were designed to include flanking intron sequence for each of the 23 LRP5 exons. PCR products were generated from a control sample, both parents, and an affected child using genomic DNA. Sequence analysis demonstrated a novel exon 6 allelic variant (Trp-425-X) in the affected child. The parents were heterozygous for the variant allele; the control sample was homozygous for the wild type allele.
In summary, we report 3 siblings with OPPG and a novel LRP5 mutation. The heterozygote mother has mild osteopenia and further studies on heterozygotes in this family may help to clarify whether heterozygotes in OPPG have low bone mass.

Variation in Bone Brittleness Among Chromosome Substitution Mouse Strains. J. Ryan*[1], A. Hill*[2], J. Nadeau*[2], K. Jepsen[1]. [1]Orthopaedics, Mount Sinai School of Medicine, New York, NY, USA, [2]Center for Computational Genomics, Case Western Reserve University, Cleveland, OH, USA.

Genetic background is an important determinant of bone mechanical properties; these properties are complex both genetically (multigenic) and mechanically (dependent upon many traits). To understand how genes interact to create a mechanically functional bone, we examined a set of 21 B6.AJ-Chr Chromosome Substitution Strains, CSS, (19 autosomes, x, y) that were developed for complex trait analysis [1]. Each of the B6.AJ-Chr(i) strains is a homozygous inbred strain that is identical to the B6 strain except that chromosome 'i' has been replaced (intact) with the corresponding AJ chromosome. If B6.AJ-Chr(i) differs from B6 for a trait, there must be at least one QTL on chromosome 'i' related to the trait. We tested for variation in bone brittleness among the CSS panel given that femurs from AJ (brittle) and B6 (ductile or tough) differ significantly for this clinically relevant trait [2]. Femurs from 14-16 wk old male and female B6 and AJ mice (n=10-25/group) and from each of the chromosome substitution strains (n=7-16/group), except for chromosomes 5, 7, and 13 (female), were failed in 4-point bending. Post-yield deflection (PYD), the deformity before failure, was calculated as a measure of bone brittleness. The data revealed that for females, the B6.AJ-Chr12, -Chr16, -Chr18, and -ChrX strains have PYD values significantly smaller (more brittle) than B6 ($p<0.05$, ANOVA). For males, B6.AJ-Chr18 was the only strain to show a significantly reduced PYD relative to B6 ($p<0.01$, ANOVA). In contrast to females, male B6.AJ-Chr16 showed reduced PYD compared to B6, but the difference was not significant, and male B6.AJ-Chr12 and B6.AJ-ChrX showed similar PYD values compared to B6. Analysis of the CSS panel revealed that genes on certain chromosomes of the AJ background interacted with the remaining genes of the B6 background and this lead to a brittle phenotype. Importantly, variation in brittleness among the CSS panel was gender specific; our data suggest there are important genes on chromosomes 12, 16, 18, and X for females and 18 for males that contribute to bone brittleness. Variation in femoral PYD among inbred strains correlates with mineral content [3]; thus, variation in PYD among the CSS panel may indicate that certain genes within the AJ background contributed to an alteration in matrix composition and consequently material quality. Future work will quantify these matrix changes that accompany the chromosome substitutions and determine how these changes are responsible for the increased bone fragility. Fine Mapping *Igfsl1*, a QTL with Low BMD and Low Serum IGF-1, Using Two Different Breeding Strategies. C. L. Ackert-Bicknell[1], K. L. Shultz[1], R. Klein[2], E. Orwoll[2], E. C. Akeson*[3], W. G. Beamer[1], C. J. Rosen[4]. [1]The Jackson Laboratory, Bar Harbor, ME, USA, [2]Oregon Health Sciences University, Portland, OR, USA, [3]The Jackson Laboratory, Bangor, ME, USA, [4]Maine Center for Osteoporosis, St. Joseph Hospital, Bangor, ME, USA.

Serum IGF-1 levels are correlated with BMD, femoral cross-sectional area and fracture risk. We have previously reported that serum IGF-1 level is a polygenic trait, with Quantitative Trait Loci (QTLs) on Chr 1, 6, 10 and 15. The B6.C3H-6T (6T) congenic strain is a C57BL/6J (B6) mouse carrying a portion of the C3H/HeJ (C3H) Chr 6 (*D6Mit93* to *D6Mit150*), and has a 20% lower serum IGF-1, reduced periosteal circumference, shorter femurs and reduced trabecular bone as compared to B6. There was no difference in IGF-1 transcript levels in either the liver or long bone, as measured by RT-PCR and RNase protection assay, in 6T as compared to B6. Two congenic sublines were created in an attempt to fine map this QTL. The B6.C3H-6-1 subline, (*D6Mit93* to *D6Mit124*) does not contain this QTL, whereas the B6.C3H-6-2 (6-2) subline (*D6Mit124* to *D6Mit150*) does. To further fine map, 584 offspring from a 6T by B6 cross were generated but no recombination in the 6-2 congenic region was found, a phenomenon also seen in the original B6xC3H F2 genome wide scan. Fluorescent in situ hybridization was performed on chromosome spreads from the 6T and control strains to find an explanation for this lack of recombination. Probes were generated from BACs selected from the Roswell Park Cancer Institute B6 Female mouse BAC library. BACs were chosen based on chromosomal location in relation to the above three D6Mit markers as determined from the Ensembl published mouse genome. An inversion on Chr 6 in the B6.C3H-6T strain of mouse was discovered, explaining the lack of genetic recombination. As an alternate strategy, the serum IGF-1 levels in 23 of the B6 by DBA/2J (D2), recombinant inbred (BXD RI) strains were measured and a strong QTL for serum IGF-1 was mapped to the region of *D6Mit10* (LOD 6.0), 2.4 cM proximal to *D6Mit150*. As in the C3H cross, it was the B6 allele that conferred higher serum IGF-1 in the B6xD2 cross. Coincidentally, this same region contained a previously published QTL for femoral cross-sectional area. We are now exploring this D2 Chr 6 region for low serum IGF-1 in order to fine map *Igfsl1* and to complement previous gene expression data from B6.C3H-6T. As work towards the goal of producing a B6.D2-6 congenic progresses, it has been noted that this region will undergo genetic recombination, indicating that D2 does not carry the chromosomal inversion. The similarity in phenotype between mice D2-like or C3H-like for this region on Chr 6 suggests that *Igfsl1* is not a function of the inversion, but rather is a gene or genes with multiple alleles.

Anti-IL-8 Therapy Inhibits Breast Cancer Growth and Osteolysis *In Vivo*. M. S. Bendre[1], R. A. Skinner*[1], R. Singh*[2], D. Gaddy[1], L. J. Suva[1]. [1]Orthopaedic Surgery, UAMS, Little Rock, AR, USA, [2]Pathology and Microbiology, University of Nebraska Medical Center, Omaha, NE, USA.

Bone is one of the most common sites for breast cancer metastasis. Skeletal metastases connote a dramatic change in the prognosis for the patient and significantly increase the morbidity associated with breast cancer. Understanding the factors contributing to the metastatic behavior of breast cancer cells to bone is essential for the development of interventions that may prevent or impede the progression of these lesions. Recently we reported that elevated levels of the chemokine interleukin 8 (IL-8) but not parathyroid hormone related protein (PTHrP) correlate with increased bone metastasis in a population of human breast cancer cells (MDA-MET; Bendre et al, 2002). When added to cultures of human peripheral blood mononuclear cells, IL-8 stimulates osteoclastogenesis and bone resorption by both RANKL dependent and independent mechanisms. This process is presumably associated with the expression of the IL-8 specific receptor CXCR1 by human osteoclasts and their precursors (Bendre et al., 2003). Thus, we hypothesized that IL-8 may be responsible for the osteolysis induced by breast cancer cells colonizing bone. To test this hypothesis in vivo, MDA-MET cells were injected in the tibia of nude mice. The mice were treated with either a monoclonal antibody directed against IL-8 (35ug), or a control IgG (35ug), or no treatment every alternate day for 28 days following tumor cell inoculation. Mice were sacrificed and tibiae evaluated radiologically and histologically. All injected mice receiving no treatment (7/7) or treated with control IgG (6/6) developed large osteolytic bone tumors. In the IL-8 antibody treated group 44% did not show any tumor (3/7). Small tumor foci with no demonstrable osteolysis were observed in 2 mice (28 %) and 2 /7 (28%) of mice developed osteolytic tumor. The total area of osteolytic lesions and tumor burden was significantly lower in mice treated with IL-8 antibody compared with mice receiving control IgG or no treatment. These data suggest that IL-8 may have an important pathogenic role in the development and growth of osteolytic bone lesions. The efficacy of anti IL-8 antibody provides a strong rationale for the utility of anti-IL-8 therapy in the inhibition of tumor growth in bone, and suggests a novel therapeutic opportunity for the treatment of bone metastasis.

Increased Survival and Decreased Metastasis Formation after Ten Years in Patients with PTHrP-positive Breast Cancer; a Prospective Study in 526 Patients. M. A. Henderson*[1], J. A. Danks[2], J. Slavin*[3], T. Harris*[2], J. L. Hopper*[4], T. J. Martin[2]. [1]Surgical Oncology, Peter MacCallum Cancer Institute, Melbourne, Australia, [2]St Vincent's Institute of Medical Research, Melbourne, Australia, [3]Pathology, St Vincent's Hospital, Melbourne, Australia, [4]Public Health and Community Medicine, University of Melbourne, Melbourne, Australia.

The aim was to determine in a prospective clinical study whether PTHrP production by primary breast cancers is predictive of skeletal metastases. In a prospective study of 526 consecutive patients with operable breast cancer, the significance of positive PTHrP staining by immunohistology has been evaluated with respect to other prognostic factors, and to the pattern of metastatic disease and overall survival. 79% of tumors stained positively for PTHrP. Ten year survival of patients with PTHrP positive tumors (median follow-up 7.5 years) was 74% (95% CI 68-80%), and for those with PTHrP negative tumors was 47% (95% CI 35-56%) ($p<0.0001$). Patients with PTHrP negative primary tumors were more likely to develop metastases at all sites, including bone ($p=0.008$), lung ($p=0.002$), liver ($p=0.016$) and soft tissue ($p=0.002$). Multivariate analysis using a Cox Proportional Hazards Model identified the following as independently significant prognostic variables: tumor size (RR 1.01, $p<0.0001$), node status (RR 1.1, $p<0.0001$), PTHrP status (RR 0.43, $p<0.0001$), PR (RR 0.6, $p = 0.02$) and vascular invasion (RR 1.74, $p = 0.006$). PTHrP status was associated with ER ($p = 0.001$), PR ($p = 0.03$) and menopausal status ($p = 0.01$); not significantly associated were tumor size ($p = 0.06$), vascular invasion, tumor grade and patient age. Other clinical studies that relate PTHrP expression by the primary tumor to development of bone metastases are characterized by any or all of small numbers, case selection, limited follow-up and retrospective accrual. The present study is the only long-term, prospective study of consecutive patients which investigated primary tumor PTHrP status and skeletal complications and survival. The conclusion is that increased production of the multifunctional protein, PTHrP, by breast cancers confers upon them a less invasive phenotype. Possible mechanisms for this are being actively explored. The likely contribution of PTHrP to establishment of bone metastases represents a specific, separate mechanism of PTHrP action, by which cancer cells in bone marrow are able to promote osteoclast formation and activity, thereby providing the specific property necessary to complement the general invasive properties of the cancer cells.

Wnt/beta-catenin Signaling Antagonist DKK1 Is Secreted by Plasma Cells and Contributes to Osteoblast Dysfunction and Osteolytic Lesions in Multiple Myeloma. J. D. Shaughnessy*[1], F. Zhan*[1], E. Tian*[1], R. Walker*[1], E. Rasmussen*[2], B. Barlogie[1]. [1]Myeloma Institute for Research and Therapy, University of Arkansas for Medical Sciences, Little Rock, AR, USA, [2]Cancer Research and Biostatistics, Seattle, WA, USA.

Background: Multiple myeloma (MM) is a plasma cell (PC) malignancy that grows in the bone where it causes osteolytic lesions, which lead to intractable bone pain, life-threatening hypercalcemia, and a risk for pathological fractures. Lytic lesions are only found adjacent to medullary plasmacytoma, suggesting that PC secrete factors that directly affect osteoclast and/or osteoblast biology and function.
Methods: Oligonucleotide microarray profiling and biochemical analyses were used to identify molecular determinants of osteolytic lesions in 174 cases of newly diagnosed MM.
Results: Logistic regression and permutation analysis of global gene expression patterns in patients with no MRI-defined focal lesions (n = 36) and those exhibiting >= 1 focal lesions (n = 137) identified 58 genes distinguishing the two groups. The soluble Wnt/b-catenin signaling antagonist, dickkopf-1 (DKK1), represented the only gene coding for a secreted factor in 28 genes significantly (P < .0001) over-expressed in PC from patients with focal lesions. Immunohistochemistry and immunofluoresence microscopy showed DKK1 expression to be unique to PC in both MM and normal bone marrow. Elevated DKK1 protein in MM bone marrow plasma was strongly correlated with both gene expression patterns and MRI-focal lesions. Incubation of osteoblast precursor cells with bone marrow plasma from patients with elevated serum DKK1 could inhibit BMP-2 induced alkaline phosphatase production in a DKK1-dependent fashion.
Conclusions: Given the critical role of Wnt/b-catenin signaling in osteoblast development and function, data presented here suggests that malignant PC contribute to the lytic bone destruction process in MM, in part, through the secretion of the Wnt signaling antagonist DKK1. These data also provide support for the notion that DKK1 represents a potential target for the prevention or treatment of malignancy-related osteolysis, as well as osteoporosis.

Antibody to CXCR4 Blocks Prostate Cancer Metastasis to Osseous Sites *In Vivo*. N. Osman*, Y. X. Sun*, A. J. Koh-Paige*, A. Schneider*, K. Cook*, J. Wang*, L. K. McCauley, R. S. Taichman. Periodontics/Prevention/Geriatrics, University of Michigan Dental School, Ann Arbor, MI, USA.

Previously we determined that the SDF-1/CXCR4 chemokine axis is activated in prostate cancer (CaP) metastasis to bone. Moreover, SDF-1 triggers the adhesion of CaPs to marrow endothelial cells and is related to increasing tumor grade.
To delineate the role of SDF-1/ CXCR4 receptor in CaP disease, two experiments were performed. First, to establish a positive correlation between SDF-1 expression and tumor metastasis, SDF-1 tissue levels were characterized for a variety of murine tissues by ELISA. Expression of SDF-1 was highest in the pelvis, tibia, femur, liver, adrenal/kidneys and lungs of those tissues examined with concentrations of SDF-1 ranging from 5-25 µg/mg total protein.
Second, an *in vivo* metastasis model was examined with two experimental groups. PC-3^{luc+} cells ($2x10^5$) were either pre-incubated with neutralizing antibody to CXCR4 (R&D Systems (MBA173)) at 10 µg/animal, or an isotype matched control. Bone metastases were established by administering the cells into the left cardiac ventricle in HSD:athymic nu/nu mice. Equal doses of the antibodies were administered I.P. at 2 and 24 h post inoculation. At 4 weeks, the mice were injected with luciferin. Bioluminescence generated by the luciferin/luciferase reaction served as a locator for cancer growth and was used for quantification using a Xenogen IVIS system and LivingImage™ software. Signal intensity was quantified as the sum of all detected photons within the region of interest during a 1 min. luminescent integration time. The animals were subsequently radiograph and sacrificed. Bones were evaluated by histomorphometric analysis to confirm cancer involvement.
Antibody to CXCR4 significantly reduced the total metastatic load compared to IgG control. Examination of individual sites of bone metastasis also demonstrated that antibody to CXCR4 significantly reduced the luminescent signal further demonstrating that the SDF-1/CXCR4 in part regulates osseous metastasis including femur/tibia regions, spine and maxilla/mandible areas (not presented). Preliminary histology and radiographic analyses confirm these findings. These *in vivo* metastasis data directly provide critical proof of principle to support a role for SDF-1/CXCR4 in osseous metastasis.

Hypogonadism Causes Bone Loss and Increased Bone Metastasesin a Model of Mixed Osteolytic/Osteoblastic Metastases: Prevention by Zoledronic Acid. S. S. Padalecki, M. R. Carreon*, B. G. Grubbs*, T. A. Guise. University of Texas Health Science Center, San Antonio, TX, USA.

There is accumulating evidence that bone resorption is an important component of osteoblastic metastases. The precise role of this bone resorption, whether it is essential in the pathophysiology of the osteoblastic response and whether inhibiting it would block the development of osteoblastic metastases, is of practical clinical importance. Bone is a repository for growth factors, which are released as a consequence of osteoclastic bone resorption. In men with advanced prostate cancer, gonadal ablation increases systemic bone resorption, thereby releasing these growth factors. Therefore, gonadal ablation may also make bones of a more fertile environment for prostate cancer metastasis.
To test the hypothesis that increased osteoclastic bone resorption due to hypogonadism causes a more fertile environment for mixed osteolytic/osteoblastic bone metastases, we developed a mouse model which mimics the clinical situation of men rendered hypogonadal as a result of treatment for prostate cancer. Surgical castration of male nude mice resulted in reduced trabecular bone volume and increased osteoclast numbers over a 4-week period compared with eugonadal controls. To investigate the role of hypogonadism in the development of mixed osteolytic/osteoblastic bone metastases, male nude mice underwent orchiectomy or sham surgery 4 weeks prior to intracardiac inoculation with TSU-PR1 bladder cancer cells that cause mixed metastases. Mice were treated daily with zoledronic acid or vehicle from the time of surgery. Radiographs, bone mineral density and bone histomorphometry were used to assess bone mass and tumor osteolysis. Hypogonadism resulted in lower bone mineral density compared with sham-controls. This was prevented by zoledronic acid. TSU-PR1 bone metastases were increased and developed faster in hypogonadal mice treated with vehicle compared to sham-controls. Zoledronic acid decreased bone metastases in hypogonadal TSU-PR1-inoculated mice but had no effect on soft tissue metastases or survival.
This work provides in vivo evidence that hypogonadism causes bone loss and may increase metastases to the skeleton that are mixed in nature. Treatment with zoledronic acid not only prevented bone loss due to androgen deprivation but also reduced bone metastases in this model. These data support the hypothesis that increased bone resorption due to androgen deprivation may result in a more fertile environment for the development of bone metastases. Bone resorption inhibitors, such as bisphosphonates, may benefit hypogonadal men with advanced prostate cancer to prevent bone loss as well as skeletal metastases.

Osteoclasts Enhance Angiogenesis in Concert with Myeloma Cells through Osteopontin and VEGF. M. Abe, T. Hashimoto*, T. Oshima*, H. Shibata*, E. Sekimoto*, Y. Tanaka*, T. Hara*, K. Kitazoe*, S. Ozaki*, S. Kido*, D. Inoue, T. Matsumoto. Department of Medicine and Bioregulatory Sciences, University of Tokushima Graduate School of Medicine, Tokushima, Japan.

Multiple myeloma (MM) develops in the bone marrow, and causes devastating bone destruction by enhancing osteoclastic bone resorption. We have reported that osteoclasts (OCs) induced by MM cells in turn enhance survival and growth of MM cells. Similarly, angiogenesis has been demonstrated to be enhanced in the bone marrow in patients with MM, which has drawn considerable attention as a potential therapeutic target. Both angiogenesis and osteolysis develop in the MM bone marrow in parallel with the tumor expansion, suggesting a link between OC and vascular cell activities. In addition, we previously demonstrated that OCs constitutively secrete high levels of an angiogenic noncollagenous matrix protein, osteopontin (OPN), and that MM cells secrete VEGF, a potent angiogenic factor. We therefore investigated a role of OCs in enhancement of angiogenesis in MM with a particular focus on OPN and VEGF.
Vascular tubule formation was assayed using Angiogenesis Kit (KZ-1000) obtained from KURABO (Osaka, Japan). Conditioned media (CM) from either peripheral blood mononuclear cell-derived OCs or MM cell lines (ARH77, U266 and RPMI8226) at 10 % enhanced vascular tubule formation equipotently 1.5-fold. Interestingly, CM from co-cultures of both cells further enhanced it 2.5-fold, suggesting a role of the interaction between OCs and MM cells in angiogenesis. Although no MM cell lines secreted detectable OPN, MM cell contact enhanced OPN production by OCs beyond the already high basal levels (about 10 vs. 7 microg / 10E5 cells for 3 days). On the other hand, all MM cell lines secreted VEGF whose levels were not changed when co-cultured with OCs. Since VEGF has been demonstrated to induce an OPN receptor, alphaVbeta3 integrin, on endothelial cell surface and to enhance OPN-induced endothelial cell migration, we next examined the effects of OPN and VEGF on angiogenesis. OPN (1 microg/ml) or VEGF (10 ng/ml) alone enhanced vascular tubule formation 1.3- and 1.5-fold, respectively, and both in combination further enhanced it 2-fold, suggesting cooperative action of both factors on angiogenesis. Consistently, antibodies against alphaVbeta3 integrin and VEGF each alone partially and both in combination completely abrogated tubular formation enhanced by CM from the co-cultures of OCs and MM cells.
In conclusion, OCs enhance angiogenesis in concert with MM cells, which is largely mediated by OPN and VEGF derived from OCs and MM cells, respectively. Therefore, impairment of OCs may inhibit MM progression not only directly but also through suppression of angiogenesis.

Calcitonin/Calcitonin Gene-related Peptide Protect the Maternal Skeleton from Excessive Resorption During Lactation. J. P. Woodrow*[1], C. S. Noseworthy*[1], N. J. Fudge*[1], A. O. Hoff*[2], R. F. Gagel[2], C. S. Kovacs[1]. [1]Memorial University of Newfoundland, St. John's, NF, Canada, [2]MD Anderson Cancer Center, Houston, TX, USA.

Surgical models of calcitonin deficiency had suggested that lack of calcitonin lowered bone mass after a cycle of pregnancy and lactation, leading to the hypothesis that calcitonin protects the maternal skeleton from excessive resorption during pregnancy and lactation. That postulated role has never been fully accepted because of inconsistent results, confounding effects of thyroid ablation, and recognition that extrathyroidal sources of calcito-

nin were not obliterated.
We utilized the CT/CGRP gene ablation model (*Ct*-null mice) to re-explore the possible role of calcitonin (and CGRP) in regulating maternal bone metabolism during pregnancy and lactation.
Ct-het mice were back-crossed into outbred *Black Swiss* strain. *Ct*-het males and females were mated to generate wt, *Ct*-het and *Ct*-null females. These mice were studied after 10 weeks of age and were mated to *Ct*-het males. Serial daily measurements of bone mineral content (BMC) and density were made during pre-pregnancy, pregnancy, lactation, and after weaning (approx 60 day cycles). A PIXIMUS densitometer (DXA scaled for mice) assessed total and regional BMC and density. A baseline BMC was determined for each mouse from her pre-pregnancy measurements, to which all subsequent readings were normalized (expressed as % of baseline). Ionized calcium was measured during pre-pregnancy, pregnancy, and lactation.
Baseline BMC trended higher in *Ct*-null (0.360 ± 0.01 g vs 0.333 ± 0.02 g in *Ct*-het and 0.301 ± 0.03 g in wt, p=NS). BMC increased in pregnancy to a significantly lower peak in *Ct*-null (112.1 ± 1.6 % vs. 120.4 ± 2.1 % in *Ct*-het and 132.7 ± 3.7 % in wt, p< 0.01). During lactation, BMC plummeted to 45.7 ± 3.3 % of baseline in *Ct*-null versus 94.4 ± 0.4 % of baseline in *Ct*-het and wt (p< 0.02). Within 2 weeks of weaning, BMC returned to baseline in *Ct*-null, *Ct*-het and wt. Maternal ionized calcium did not change between pre-pregnancy to late pregnancy. Ionized calcium rose significantly post-delivery in *Ct*-null to 1.42 ± 0.02 mmol/l but not in *Ct*-het or wt, and returned to normal (1.29 ± 0.02 mmol/l) by one week post-delivery.
In summary, *Ct*-null mice gained less BMC during pregnancy and plummeted to 45% of baseline BMC during lactation, a net excursion (from peak to trough) of 67% of BMC. This excess bone resorption was accompanied by maternal hypercalcemia. BMC returned to baseline after weaning in *Ct*-null as promptly as in wt and *Ct*-het.
We conclude that calcitonin/CGRP prevent severe drops in maternal BMC and increased skeletal fragility during lactation, but are not required in the long-term because the maternal skeleton recovers to baseline.

Inhibition of Vascular Calcification In LDLR -/- Mice by Treatment With Human PTH(1-34). J. S. Shao, N. Charlton-Kachigian*, Y. Gao, S. L. Cheng, D. A. Towler. Division of Bone and Mineral Diseases, Washington University School of Medicine, St. Louis, MO, USA.

Vascular calcification is a common response to dysmetabolic stimuli such as diabetes and hypercholesterolemia. We identified that high fat diets induce insulin - resistant diabetes, hyperlipidemia, and aortic calcification in LDL receptor knockout (LDLR -/-) mice. Diabetes and aortic calcification are more pronounced in male animals, with vascular calcification dependent upon BMP2 - Msx2 signaling that promotes osteogenic differentiation of aortic myofibroblasts. We examined the regulation of vascular calcification and aortic osteogenesis by human PTH(1-34), a prototypic osteoanabolic hormone, in LDLR -/- mice fed diabetogenic diets. Methods: Six week old male LDLR -/- mice (n= 5 / arm) were fed mouse chow or high fat diet (42% calories from fat; 0.15% cholesterol by weight) for 4 weeks. Mice were treated s.c. with vehicle, or 0.4 mcg / kg of PTH(1-34) dosed 5 days / week. At sacrifice, bone mineral content (BMC) was determined by DXA. Osteogenic gene expression was quantified in RNA from single aortas and hind limbs by fluorescence RT-PCR. Vascular calcification was determined by Alizarin red (AR) staining of cardiac valve sections, using image analysis to quantify leaflet mineralization. Circulating regulators of inflammation and mineral deposition (osteopontin/OPN; osteoprotegerin/OPG; leptin) were measured by ELISA. Results: Serum glucose and lipid levels increased significantly in response fatty diets. These diets upregulated aortic expression of BMP2, Msx2, and OPN. As in humans, diabetes upregulated circulating OPG and leptin levels ca. 4-fold; no change in circulating OPN was noted. PTH(1-34) increased BMC in diabetic LDLR-/- mice, with concomitant induction of osseous Msx2, osseous OPN, and serum OPN; no change in lipids, glucose, OPG, or leptin was noted. By contrast, PTH(1-34) treatment suppressed aortic OPN and Msx2 mRNA accumulation > 50%, indicating reciprocal regulation of orthotopic vs. heterotopic osteogenic programs. Valve calcification mirrored vascular osteogenic gene expression responses. As compared to vehicle, PTH(1-34) decreased cardiac valve calcification ca. 80% (8.3 +/- 1.5 % vs. 1.5 +/- 0.5 % valve area calcified; p < 0.001). Analyses of spleen cells showed that PTH(1-34) decreased CD68+ OPN+ monocytes by 50% (p = 0.08), suggesting that anti-inflammatory actions may contribute to vascular PTH responses. Summary: PTH(1-34) inhibits valve calcification and aortic osteogenic differentiation during the initiation of diabetic vascular calcification. Intermittant PTH(1-34) may exert beneficial actions on vascular calcium homeostasis at the early stages of macrovascular responses to diabetes.

PTH Receptor Internalization by Inactive PTH Fragments. Regulation by NHERF1 (EBP50). W. Sneddon[1], C. Syme*[1], A. Bisello[1], C. E. Magyar*[1], E. J. Weinman*[2], P. A. Friedman[1]. [1]Universities of Pittsburgh, Pittsburgh, PA, USA, [2]and Maryland, Baltimore, MD, USA.

PTH effects on kidney and bone are mediated by the Type 1 PTH receptor (PTH1R). PTH1R is internalized in a cell- and ligand-specific manner. In kidney distal tubule (DCT) cells and some bone cell lines (e.g. ROS17/2.8), both the agonist PTH(1-34) and the antagonist PTH(7-34) induce PTH1R internalization. In contrast, in renal proximal tubule (PCT) and SaOS2 cells, only PTH(1-34) internalizes the PTH1R. Mahon and Segre reported (Nature '02) that Na/H exchanger regulatory factors (NHERFs) bind to the PTH1R through a C-terminal PDZ recognition domain and have a role in signaling. NHERF1 is a cytoplasmic adapter protein that has been implicated in both protein targeting and the assembly of protein complexes. NHERF1 possesses tandem PDZ domains and an ERM domain that binds to the actin-associated proteins, ezrin, radixin, and moesin. NHERF1 is expressed by proximal tubules and by SaOS2 cells, but not by distal tubules or ROS17/2.8 cells. We mutated the PTH1R PDZ domain from ETVM to ETVA to determine the role of NHERF1 on PTH1R internalization. In cells lacking NHERF1, the ETVA/PTH1R internalized after challenge with PTH(1-34) or PTH(7-34). However, in cells expressing NHERF, PDZ mutation abolished the ability of NHERF1 to interact with the PTH1R. PTH(7-34) now efficiently internalized the PTH1R/ETVA receptor. We hypothesized that NHERF1 mediates the cell- and ligand-specific pattern of PTH1R internalization. Heterologous expression of full-length NHERF1 in DCT or ROS17/2.8 cells inhibited PTH(7-34)-stimulated PTH1R internalization without affecting PTH(1-34)-induced endocytosis. To determine if the ERM domain is involved in ligand-induced PTH1R internalization, we expressed ERM-deficient NHERF1 (NHERFdERM) in DCT cells. NHERFdERM did not inhibit PTH(7-34)-induced receptor endocytosis suggesting that the ERM domain is required for tethering the PTH1R. Because the ERM domain binds actin-associated proteins, we theorized that disrupting the actin cytoskeleton would release the PTH1R from NHERF and permit PTH(7–34) to internalize the receptor. As predicted, cytochalasin D, PTH(7–34) promoted receptor internalization in cells expressing NHERF1. Cytochalasin did not affect PTH(1-34)-induced endocytosis or EVTA/PTH1R sequestration. We conclude that NHERF1 acts as a molecular switch for the conditional efficacy of PTH fragments. Cells expressing NHERF do not internalize the PTH1R in response to PTH(7-34), whereas the PTH1R is internalized in cells lacking NHERF. The magnitude and pattern of NHERF expression may have important implications for understanding PTH1R function in kidney and bone in states of calcium wasting and aging.

Parathyroid Hormone-Induced Recruitment of Osteoblasts from Bone Marrow Fibroblasts. R. T. Turner, S. Lotinun. Orthopedic Research, Mayo Clinic, Rochester, MN, USA.

Pulsatile administration of parathyroid hormone (PTH) to rats results in a rapid increase in cancellous bone formation, largely due to modulation of existing bone lining cells to express the osteoblast phenotype. In contrast, continuous infusion of PTH results in hypercalcemia, focal bone resorption and severe peritrabecular marrow fibrosis (parathyroid bone disease). The purpose of the present study was to determine the origin of the PTH-induced fibroblasts as well as their fate following termination of PTH treatment. Studies were performed in which PTH was continuously infused into adult female rats for 1 w (40 µg/kg/d) using sc implanted osmotic pumps. The animals were co-infused with 3H-thymidine (2 mCi/rat) to label cells progressing through the cell cycle. Groups of PTH-treated and control rats were sacrificed 0 d and 7 d following termination of PTH treatment. In spite of a dramatic increase in osteoblast (OB) number and cancellous bone formation in PTH-treated rats, negligible numbers of OB and osteocytes (OCy) were labeled at d 0 in either treated or control animals. This result indicates that continuous as well as pulsatile PTH induces modulation of bone lining cells to osteoblasts. Peritrabecular fibroblasts were not present in the controls. In the PTH-treated rats, 85% of the fibroblasts, which formed multiple cell layers and lined 70% of the cancellous bone surface, were labeled with thymidine, indicating proliferation. Gene array analysis revealed significant PTH-induced increases in mRNA levels for genes associated with fibroblast differentiation and migration (e.g., PDGF-A, lysyloxidase, collagen XII, frizzled and phosphodiesterase 1). Fibroblasts were absent on bone surfaces in the PTH-treated rats on d 7, and 85% of the OB on and 73% of the OCy within active remodeling sites were labeled, numbers dramatically greater than in the controls (15% and 4%, respectively, p<.01). These data provide evidence that fibroblasts recruited to bone surfaces in response to continuous PTH are capable of differentiating to osteoblasts. To further test this possibility we performed an experiment in which PTH was infused for 1 w and bone histomorphometry and mechanical properties evaluated after 4 w. At the end of the study, the PTH-treated animals had normal serum Ca and PTH, no evidence of parathyroid bone disease, increased bone volume and increased strength. These findings demonstrate that continuous PTH can recruit osteoblasts by at least two mechanisms; 1) modulation of lining cells; and 2) recruitment of marrow fibroblasts to bone surfaces where they undergo proliferation and subsequent differentiation to osteoblasts. The latter mechanism represents a novel target for development of new therapies to treat osteoporosis.

Targeted Overexpression of G protein-coupled Receptor Kinase 2 in Osteoblasts Promotes Bone Loss. L. Wang*, L. D. Quarles, R. F. Spurney. Department of Medicine, Duke University Medical Center, Durham, NC, USA.

G-protein coupled receptors (GPCR's) play a key role in bone remodeling. The osseous effects of GPCR systems may be regulated by the rate of receptor desensitization in osteoblasts. GPCR desensitization is largely mediated by direct phosphorylation of GPCR proteins by a family of enzymes termed GRK's. To investigate the role of GRK's in regulating bone formation in vivo, we overexpressed the potent GPCR regulator GRK2 in osteoblasts using the osteocalcin gene 2 (OG2) promoter to target expression to mature osteoblasts. Four founder lines were established that expressed enhanced levels of GRK2 mRNA in calvaria. Overexpression of GRK2 in osteoblasts resulted in a significant reduction in bone mineral density (BMD) in transgenic (TG) mice (40.1 ± 0.6 mg/cm2) compared to non-TG littermate controls (42.7 ± 0.4 mg/cm2; P<0.005). The decrease in BMD affected predominantly trabecular bone and was most pronounced in female mice. To investigate the mechanism of GRK-dependent bone loss, we assessed parathyroid hormone (PTH)-induced cAMP generation by the PTH/PTH-related peptide (PTHrP) receptor in mouse calvaria ex-vivo. Calvaria from GRK2 TG mice had an attenuated response to PTH-induced cAMP generation. This reduction in GPCR responsiveness was associated with an increased osteoprotegrin (OPG) to OPG ligand (OPGL) mRNA ratio in calvaria consistent with

reduced osteoblast coupling to osteoclasts. In support of the lack an osteoclastic effect, urinary deoxypyridinoline (DPD) excretion was similar in TG mice (20 ± 1.4 nM DPD/mM creatinine) and control animals (22 ± 3.6 nM DPD/mM creatinine; P=NS). Taken together, these data suggest that enhancing GRK activity in mature osteoblasts diminishes the anabolic effects of GPCR systems leading to bone loss.

PTH/PTHrP Receptor Delays Chondrocyte Hypertrophy via both Runx2-dependent and Independent Pathways. J. Guo, U. Chung, A. Szczepanik*, D. Yang*, F. R. Bringhurst, H. M. Kronenberg. Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

Targeted disruption of either the PTHrP or PTH/PTHrP receptor (PTHR) genes in vivo leads to acceleration of chondrocyte differentiation, while chondrocyte hypertrophy is delayed or severely disturbed in Runx2 deficient mice. Because the effect of the Runx2 knockout on chondrocyte differentiation is opposite to that of the PTHR or PTHrP knockout, we considered the possibility that the delayed differentiation induced by PTHR activation might be mediated in part by downregulation of Runx2 expression. To examine this possibility, cultured embryonic tibia and femur were acutely treated with PTH, and Runx2 expression then was analyzed by in situ hybridization. Treatment of cultured rudiments with rat PTH(1-34) at a dose of 100 nM dramatically suppresses Runx2 mRNA levels in hypertrophic chondrocytes; Runx2 mRNA in adjacent bone collar was unchanged. The maximal effect occurred at 4-8 hr of treatment. Similar repression of (mutated) Runx2 mRNA by PTH was observed in Runx2-deficient tibia (in which inactive but detectable mRNA is found), indicating that Runx2 action is not needed for the regulation of Runx2 mRNA by PTH. Runx2 protein levels in wild type tibia, measured by Western blot, were not affected by 6-hr treatment with PTH. PTH treatment exhibited no effect on Runx2 expression in the presence of Actinomycin D, an inhibitor of RNA synthesis; addition of Actinomycin D alone led to a rapid fall in Runx2 mRNA levels. These data suggest that the effect of PTH on Runx2 expression was mainly due to altered transcription. Moreover, the same effect of PTH on Runx2 mRNA levels was also found in PLC-defective PTHR mutant rudiments.

To explore Runx2-independent effects of PTHrP on chondrocyte hypertrophy we examined E17.5 femurs from littermates with or without PTHrP and/or Runx2 gene deficiency. Vascular invasion and many chondrocytes that express collagen type X and osteopontin mRNA were observed in the double knockout femurs, whereas no vascular invasion and no cells expressing either collagen type X or osteopontin were found in Runx2-deficient femurs.

Our data indicate that Runx2 promotes but is not required for chondrocyte hypertrophy and that the delayed hypertrophy induced by PLC-independent PTHR activation may be mediated by both Runx2-dependent and independent mechanisms.

Biglycan Mediates the WNT Signaling Pathway in Osteoblastic Cells. S. Wadhwa, X. D. Chen, M. F. Young. Craniofacial and Skeletal Diseases Branch, NIDCR, Bethesda, MD, USA.

Biglycan (bgn) is a member of the small leucine-rich proteoglycan family and is abundantly expressed in the extracellular matrix of bone. Previous work has indicated that mice who are deficient in bgn have low bone mass. However, the mechanism for this effect is relatively unknown. We suspect that changes in bone's extracellular matrix leads to altered cell signaling. It was recently found that bgn directly binds to a wnt induced soluble protein, wisp-1, suggesting that there exists a relationship between bgn and the wnt signaling pathway. In addition, studies have shown that defects in the wnt signaling pathway leads to decrease bone mass. In this study, we wanted to test the hypothesis that bgn is directly involved in the regulation of the wnt signaling pathway. In order to determine which components of the wnt signaling pathway might be affected we examined changes in mRNA profiles in osteoblastic cultures obtained from the calvaria of newborn wild type and bgn deficient mice. Using a microarray database we had previously designed, comparing bgn deficient and wildtype osteoblastic cells, we discovered that wnt-1, wnt-3a and wisp-1 mRNA levels were lower in bgn deficient osteoblasts compared to osteoblasts from wild type mice. These results were confirmed in three independent experiments using semi quantitative RT-PCR. In contrast, also by three independent experiments, we found by western blot analysis that beta catenin, a central player in the wnt signaling pathway, was upregulated in osteoblasts from bgn deficient mice. To test whether bgn effects were direct, we constructed an adenovirus encoding the full-length murine bgn gene. The adenovirus was then used to isolate native recombinant protein, which was added back to bgn deficient osteoblastic cultures. The addition of bgn (2ug/ml) for 24 h caused wnt-1, wisp-1 and beta catenin levels to approach the levels of wild type osteoblastic cultures. Interestingly, in a gain of function approach, the addition of recombinant bgn (2ug/ml) for 24 h to MC3T3-E1 cells caused a significant reduction in beta catenin levels. Taken together these results suggest that the wnt signaling pathway maybe modulated by proteoglycans in the extracellular matrix and that biglycan and wnt may act cooperatively to regulate bone mass.

The Heritage of Cells within Postnatal Tendon and Bone Formation. D. L. Glaser*[1], R. Ramachandran*[2], X. Jiao*[1], T. W. Lin*[1], L. J. Soslowsky*[1], E. M. Shore[1], F. S. Kaplan[1], D. J. Goldhamer*[3]. [1]Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, USA, [2]University of Pennsylvania, Philadelphia, PA, USA, [3]Molecular & Cell Biology, University of Connecticut, Storrs, CT, USA.

A fundamental question in the cellular pathogenesis of postnatal tissue repair and cell differention is the identity of progenitor cells responsible for new tissue. In fibrodysplasia ossificans progressiva (FOP), heterotopic ossification affects both tendon and muscle. While several stem cell populations could contribute to this process, the lineages of these cells remain undefined. This study examined the identity of progenitor cells responsible for post-natal tendon repair and ectopic bone formation.

To generate animal models with tagged cells of specific lineages, transgenic mice that express Cre recombinase under control of a tissue-specific promoter/enhancer were mated to Rosa26-LacZ reporter mice, resulting in cell-specific LacZ expression. Once activated, LacZ expression remains constitutive for the life of the cell and its descendants, regardless of phenotypic changes. Transgenic mouse lines with the following promoters (and cell specific expression) were generated: MyoD (satellite cells); Smooth Muscle Myosin Heavy Chain (smooth muscle cells, pericytes); and Tie2 (endothelial cells, hematopoietic stem cells, side population cells). To determine the role of bone marrow-derived cells, chimeric mice were produced by transplanting bone marrow (BMT) from constitutive Rosa26-LacZ mice into irradiated C57BL/6 hosts. The fates of the LacZ tagged cells were followed during BMP induced ectopic ossification and in a patellar tendon injury model. Animals were examined histologically at various intervals from 4 days to 12 weeks. Specimens were stained for beta-galactosidase activity to identify participation of specific cell lineages.

In MyoD-cre/R26R mice, labeled cells were consistently found in cartilage and bone but not in tendon. In SMMHC-cre/R26R mice, labeled cells were found in healing tendon but not in heterotopic ossification. In Tie2-cre/R26RA, labeled cells were abundant in fibroproliferative tissue that proceeds both bone and tendon formation. In BMT animals, labeled inflammatory cells were observed early in both models, however, fibroproliferative, cartilage, bone and tendon cells were not labeled; the bone marrow elements within ectopic bone ossicles were labeled.

Taken together, these lineage tracing studies provide the first definitive evidence of the heritage of cells in postnatal tendon repair and ectopic ossification and provide direct cellular targets for therapeutic approaches that regulate the regenerative response in these tissues.

Expression of mCSF-1 in op/op Mice Leads to Amelogenesis Imperfecta Phenotype. S. L. Abboud[1], K. Woodruff*[1], J. Dickson*[2], N. Ghosh-Choudhury[1], J. Schulze*[2], L. Cardenas*[2], M. MacDougall*[2]. [1]Pathology, University of Texas, San Antonio, TX, USA, [2]Pediatric Dentistry, University of Texas, San Antonio, TX, USA.

CSF-1-mediated osteoclastogenesis is critical for tooth eruption. In op/op mice, absence of soluble (s) and membrane-bound (m) forms of CSF-1 decreases osteoclasts and leads to osteopetrosis and failure of tooth eruption. Using a transgenic approach, we showed that human (h) mCSF-1, expressed in bone of op/op mice (op/opT) using the osteocalcin promoter, caused significant regression of osteopetrosis and restored tooth eruption. However, the biologic effect of each isoform on tooth formation is unknown. To determine the role of CSF-1 in tooth development, teeth from 3 wk op/op, op/opT and wt mice were compared for enamel/dentin integrity and matrix protein expression. The osteocalcin promoter targets odontoblasts and high hCSF-1 protein was detected in op/opT teeth. At 3 wks, op/opT showed an amelogenesis imperfecta (AI) phenotype characterized by malaligned, chalky white incisors, with twisted tips prone to breakage. By scanning EM (SEM), morphology of op/opT molars was similar to wt. However, SEM of fractured molars in op/op mice showed abnormal enamel and dentin. The enamel was thin, lacked normal parallel crystals and fractured on a different plane than dentin, indicating a faulty dentin/enamel junction. In contrast, op/opT molars showed normal dentin and thicker more organized enamel that fractured in the same plane as dentin similar to wt. Although op/opT enamel was improved, it was thinner and less organized than wt enamel. To determine if the AI phenotype was associated with altered dental matrix proteins, their expression profile was assessed using real time PCR. Compared to wt, op/op mice showed a decrease in dentin-enriched proteins, DSPP and Dmp-1 and an increase in enamel-enriched proteins, enamelin, ameloblastin and EMSP-1. Expression of mCSF-1 in op/opT increased DSPP and Dmp-1 close to wt levels. Expression of enamelin was almost normalized, whereas expression of ameloblastin and EMSP-1 remained similar to that in op/op mice. Regulation of enamelin in op/opT likely occurred via interaction of mCSF-1 on the surface of odontoblasts with its cognant receptor on ameloblasts. By RT-PCR, ameloblast, but not odontoblast, cell lines expressed the c-fms receptor. These findings indicate that CSF-1 is essential for normal tooth matrix development. Expression of mCSF-1 in op/opT partially corrected the enamel defect seen in op/op mice and likely contributed to the AI phenotype; sCSF-1 may be required for complete resolution. Targeting CSF-1 to teeth may provide a useful therapeutic strategy for regulating enamel/dentin matrix proteins and eruption in dental disorders.

Dentin Matrix Protein-1 (Dmp1) Mice Display Multiple Abnormalities during Early and Late Skeletal Development. L. Ye*[1], H. Huang*[1], Y. Xie*[1], Y. Lu*[1], D. Chen[2], S. L. Dallas[1], L. F. Bonewald[1], Y. Mishina*[3], J. Q. Feng[1]. [1]School of Dentistry, UMKC, Kansas City, MO, USA, [2]Molecular Medicine, UTHSCSA, San Antonio, TX, USA, [3]NIEHS/NIH, Research Triangle Park, NC, USA.

Previously we reported that adult mice lacking Dmp1 gene exhibit the characteristics of chondrodysplasia, osteoarthritis, and show severe defects in mineralization. Although newborns appear grossly normal, upon further detailed examination it was found that these animals also exhibit skeletal abnormalities, including increased trabecular bone in metaphysis as well as a delay in secondary ossification.
To gain a complete understanding of temporal roles of Dmp1 in skeletal development and the potential mechanisms for the observed skeletal defects, Dmp1 null mice from embryonic day 3 to 1 year old were examined. Radiographs showed osteopetrosis-like changes in metaphyses of mutants starting from day 10, which were confirmed by von kossa and alizarin red/alcian blue staining as well as alkaline phosphatase histochemistry. Dmp1 mutants also showed abnormalities in the length and diameter of their long bones as well as a failure in remodeling to form the normal hour glass shape as seen in WT littermates. In addition, Dmp1 nulls showed a dramatic delay in secondary ossification in long bones, vertebrae and tails. To determine the mechanisms underlying these skeletal abnormalities, we first examined expression of markers of bone formation as well as bone ECM proteins by both in situ hybridization and/or immunohistochemistry at 3-wk after birth. Cbfa1 expression as well as proteoglycans, such as decorin, biglycan and fibromodulin was increased in metaphyses. This suggests that one of the major abnormalities in Dmp1 mice may be overexpression of ECM proteoglycans. We also examined expression of caspase 3 and found a dramatic reduction in the number of hypertrophic chondrocytes expressing this marker of apoptosis. To examine the role of Dmp1 in mineralization, double calcein labeling was performed at 3-wk and 3-mo after birth. In WT animals a clear double label was observed on the endosteal surface. In contrast in Dmp1 null mice, calcein label was incorporated diffusely on both the endosteal and the periosteal surfaces. This aberrant periosteal mineralization may contribute to the bony protrusions observed in mutants. To examine if delayed secondary ossification was due to impaired vascular invasion, PECAM was used as a marker. The mutants showed reduced numbers of blood vessels in epiphyses.
These data show that in addition to its role in the adult skeleton, Dmp1 plays critical roles in early bone development through its effects on vascular invasion, chondrocyte apoptosis, mineralization and expression of bone ECM molecules.

Genome-wide Generation of Knock-out Mice and in vivo Expression Profiling using VelocigeneTM, a New High-throughput Method, Identifies Novel Genes Expressed in Bone and Cartilage. R. Raz*, N. C. Adams*, P. Kraus*, N. W. Gale*, D. Frendewey*, W. Auerbach*, W. T. Poueymirou*, H. Su*, Y. Xue*, T. M. DeChiara*, D. M. Valenzuela*, G. D. Yancopoulos*, A. N. Economides*. Regeneron Pharmaceuticals, Tarrytown, NY, USA.

A novel method, termed VelocigeneTM, has been developed which allows for the rapid generation of genetically modified mice. This method utilizes bacterial homologous recombination for precise engineering of modified genes in bacterial artificial chromosomes (BACs), to generate BAC-based targeting vectors (BACvecs). ESC clones targeted by homologous recombination with BACvecs are identified using quantitative PCR. Use of BACvecs in place of traditional targeting vectors affords many advantages, such as increased targeting frequency, ability to make very large deletions in a single step, and bypass the need for negative selection and isogenicity. In addition, the whole process is highly scalable, automated, and industrialized, allowing the generation of 500 *knock-out* lines per year at our current throughput. Since the targeted gene is typically replaced by a reporter such as *lacZ*, its expression pattern can be visualized. We have used this technology to target more than 425 genes to date. Among them, 225 have been surveyed for expression. Of those, 24 are expressed in cartilage but not in bone, 5 are expressed in bone and not cartilage, whereas 8 are expressed in both. Detailed analysis has revealed intricate expression patterns. For example, the Monocyte Chemotactic Protein-3 (MCP3) is expressed only in the vertebral disks but not in other cartilagenous structures, whereas the Placental Growth Factor (PLGF) is only present in the growth plates of the long bones. This expression profiling has also shown that genes widely characterized in other systems are also expressed in cartilage or bone, where their function had been largely ignored; examples are EphA2, Angiopoietin Y1, Pigment Epithelium Derived Factor (PEDF) and Cocaine/Amphetamine-Regulated Transcript (CART). Detailed expression profiling for these genes will be presented. Additionally, *knock-out* mice have been generated for a number of these genes and their phenotypes are being analyzed in bone and cartilage. In conclusion, our high-throughput approach for generating and analyzing *knock-out* mice where genes of interest are replaced by a reporter provides precise and comprehensive information about their expression patterns, to an extent superior to other methods.

Dynamic Imaging of Extracellular Matrix Molecules in Osteoblasts and Role of Fibronectin as an Orchestrator of Extracellular Matrix Assembly. P. Sivakumar*[1], A. Czirok*[2], B. J. Rongish*[2], D. M. Peters*[3], S. L. Dallas[1]. [1]Univ. Missouri, Kansas City, MO, USA, [2]Kansas Univ. Med. Ctr., Kansas City, KS, USA, [3]Univ. Wisconsin, Madison, WI, USA.

The extracellular matrix (ECM) has classically been viewed as a static three dimensional scaffold whose role is to hold tissues together and act as a barrier to cell movement. However, recent dynamic imaging studies in early embryos and fibroblast cultures have demonstrated that the ECM is not static and that ECM molecules form structures that continually undergo movement and deformation. Here we have used time lapse fluorescence imaging to study the dynamics of ECM proteins in living osteoblast cultures.
Latent TGFβ binding protein-1 (LTBP1) is an ECM protein that binds TGFβ and regulates its bioavailability in bone. LTBP1 time dependently co-localizes with fibronectin, which is one of the earliest ECM proteins to be assembled and is critical for osteoblast differentiation. Dynamic imaging, using fluorescently labeled fibronectin or LTBP1 antibodies as probes, revealed a large amount of cell movement in postconfluent FRC cultures. This resulted in large displacements of the LTBP1 and fibronectin-positive fibrils, which continually stretched and contracted to accommodate cell movements. Occasionally, stretched fibrils were seen to break, followed by contraction of the fibrils to 25% of their extended length. These studies suggest that fibronectin fibrils are highly stretched in living osteoblast cultures and have elastic properties. Stretching of fibronectin molecules has been proposed to expose cryptic self assembly sites as well as binding sites for other ECM proteins. We hypothesized that a major pathway by which fibronectin regulates bone cell function is by orchestrating the assembly of other ECM proteins. To examine this a fibronectin-null cell model was used. Fibronectin-null embryonic fibroblasts failed to incorporate LTBP1 and fibrillin-1 into their ECM as shown by immunofluorescent staining, immunogold EM, and Western blotting. Incorporation of type I collagen was also dramatically impaired. Addition of 10μg/ml plasma fibronectin rescued incorporation of all three ECM molecules. Rescue experiments using a panel of fibronectin fragments showed that only fragments which assembled into ECM fibrils were able to rescue LTBP1 incorporation.
These data show that fibronectin may act as a template for assembly of a number of ECM proteins, which may explain in part the importance of fibronectin in osteoblast differentiation. Time lapse imaging studies have highlighted the dynamic nature of fibrillar bone ECM proteins, which undergo surprisingly large movements and distortions associated with osteoblast movement.

Differential Effects of Teriparatide and Alendronate on Markers of Bone Remodeling and Areal and Volumetric Bone Density in Women with Osteoporosis. M. McClung[1], P. Miller*[2], R. Civitelli[3], M. Warren*[4], S. Greenspan*[5], L. Haddock*[6], J. Tamayo*[7], D. Donley*[8], J. San Martin[8]. [1]Oregon Osteoporosis Center, Portland, OR, USA, [2]Colorado Center for Bone Research, Lakewood, CO, USA, [3]Washington University School of Medicine, St. Louis, MO, USA, [4]Physicians East, Greenville, NC, USA, [5]University of Pittsburg Medical Center, Pittsburg, PA, USA, [6]University of Puerto Rico, San Juan, Puerto Rico, [7]COMOP Osteoporosis Research Center, Mexico D.F., Mexico, [8]Eli Lilly and Company, Indianapolis, IN, USA.

Teriparatide (rDNA origin) injection [TPTD; rhPTH (1-34)], a stimulator of bone formation, and alendronate (ALN), a bisphosphonate, both increase bone mineral density (BMD) and decrease fracture risk. We conducted an 18-month randomized, double-blind, prospective clinical trial comparing the effects of TPTD or ALN on markers of bone remodeling, lumbar spine, hip areal and volumetric BMD in postmenopausal women with osteoporosis. Final patient visits will occur in May 2003 and full 18-month data will be presented. During a 6-month interim analysis, double-labeled iliac crest bone biopsies were obtained from a subset of patients: TPTD (n=8) or ALN (n=9). Histomorphometric analysis revealed pronounced stimulation of formation in patients on TPTD, while patients on ALN revealed pronounced suppression. This was reflected in significant differences in mineralizing surface (8.1±4.4% (mean ± SD) vs. 0.2 ± 0.3%, P<.001), bone formation rate (0.062 ± 0.036 vs. 0.002 ± 0.002 μm/d, P<.05) and activation frequency (0.99±0.57/yr vs. 0.02±0.03/yr, P<.001)(TPTD vs. ALN). Markers of bone formation revealed a 217% increase in serum N-terminal procollagen type I extension peptide (PINP) in the TPTD group (n=76) versus a 67% decrease (P<.001) in ALN treated patients (n=85). Markers of bone resorption revealed a similar trend, urinary N-telopeptide (NTx) increased by 59% with TPTD treatment (n=73) compared to a 72% decrease with ALN treatment (n=84)(P<.001). Contrasting effects on bone remodeling between TPTD and ALN translated into increases in BMD. A greater increase in areal lumbar spine BMD, measured by DXA, was present in the TPTD group (n=84) compared with the ALN group (n=87), 4.7% vs. 3.2%, respectively (P<.01). Volumetric lumbar spine trabecular BMD was measured by QCT in a subset of patients and results showed even more drastic differences between therapies. Volumetric BMD was 5-fold higher with TPTD (n=16) than with ALN (n=19), 14.6% vs. 2.9%, respectively (P<.01). In conclusion, our results underscore the different mechanisms of action between TPTD and ALN, and confirm that stimulation of bone formation with TPTD increases areal and volumetric BMD more than suppression of bone turnover with ALN.

Teriparatide (rhPTH [1-34]) Treatment Improves the Structure of the Proximal Femur in Women with Osteoporosis. L. M. Semanick*[1], K. Uusi-Rasi*[1], J. R. Zanchetta[2], C. E. Bogado*[2], E. F. Eriksen[3], M. Sato[3], T. J. Beck[1]. [1]Department of Radiology, The Johns Hopkins University School of Medicine, Baltimore, MD, USA, [2]IDIM and USAL University, Buenos Aires, Argentina, [3]Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN, USA.

Postmenopausal women with osteoporosis enrolled in the Fracture Prevention Trial who received daily injections of teriparatide (rhPTH [1-34]) showed significantly lower rates of vertebral and non-vertebral fragility fractures compared to placebo controls. These observations suggest that teriparatide improves bone mechanical strength. A subset of postmenopausal women (n=558) in the randomized double-blind multicenter study (mean age 70 ± 7 years) were randomized to a once-daily self-administered subcutaneous injection of placebo (n=189), teriparatide 20 μg (TPTD20; n= 86) or teriparatide 40 μg (TPTD40; n=183) for a median of 20 months. Dual energy x-ray absorptiometry (DXA) hip scans were analyzed with the Hip Structure Analysis (HSA) program to derive structural geometry. This HSA program measures BMD and the geometric properties of cortical bone within narrow regions across the femoral neck, intertrochanter and femoral shaft from images acquired by DXA. Linear models were used to assess the effects of teriparatide treatment on bone structure using baseline values as covariates. There were no significant differences in body size or age between treatment groups at any time point. At the femoral neck, teriparatide increased bone mass and improved bone strength in a dose-related manner, compared to placebo. The mean increase (95% CI) in bone mineral density was 4.2% (2.4% to 6.0%) in the TPTD20 group and 7.2% (5.4% to 9.1%) in the TPTD40 group, compared to placebo. The mean differences in axial strength (bone cross-sectional area) were 3.5% (1.8% to 5.3%) and 6.3% (4.5% to 8.2%), and in bending strength (section modulus) 3.6% (1.4% to 5.8%) and 6.8% (4.6% to 9.1%) in the TPTD20 and TPTD40 groups respectively. The mean increase in cortical thickness was 4.5% (2.6% to 6.4%) and 7.7% (5.7% to 9.7%), while buckling ratio (local cortical instability) decreased by 5.5% (3.5% to 7.5%) and 8.6% (6.6% to 10.5%) in the TPTD20 and TPTD40 groups respectively. Changes at the intertrochanteric region were comparable to those at the narrow neck. Teriparatide treatment effects did not reach significance at the cortical shaft. In conclusion, compared to placebo, teriparatide treatment increased bone mass, improved bone strength, increased cortical thickness and reduced the buckling ratio at the intertrochanteric region and the femoral neck.

A Novel Vitamin D Analogue Restores Bone Mass and Adds Extra Bone by Markedly Stimulating Bone Formation in Ovariectomized Rats with Established Osteopenia. H. Z. Ke[1], H. Qi*[1], D. T. Crawford*[1], G. Xu*[1], M. Li[1], L. plum[2], M. Clagett-Dame[2], H. F. DeLuca[2], D. D. Thompson[1], T. A. Brown[1]. [1]Cardiovascular and Metabolic Diseases, Pfizer Global Research and Development, Groton, CT, USA, [2]University of Wisconsin-Madison/Deltanoid Pharmaceutical, Inc., Madison, WI, USA.

It has been reported that a novel vitamin D analogue, 2-methylene-19-nor-(20S)-1-a,25(OH)2D3 (2MD), stimulates osteoblastic bone formation in vitro and increases bone mass in ovariectomized (OVX) rats with minimal effect on serum calcium. The purpose of this study was to test whether 2MD can restore bone mass in OVX rats with established osteopenia. Sprague-Dawley female rats were sham-operated (sham) or OVX at 4 months of age. Beginning at 8 weeks post-surgery, OVX rats were orally dosed with 2MD at 0.5, 1, 2.5, 5 or 10 ng/kg/d for 16 weeks. Compared with sham and OVX controls, serum calcium did not differ in OVX rats treated with 2MD at 0.5 or 1 ng/kg/d, while slightly but significantly increased at 2.5, 5 or 10 ng/kg/d. Treatment with 2MD in OVX rats significantly increased total body bone mineral density by 4%, 7%, 14%, 23% and 31% at 0.5, 1, 2.5, 5 or 10 ng/kg/d, respectively. These observations were confirmed by pQCT analysis of distal femoral metaphysis (DFM) and femoral shafts (FS). Total bone density in DFM dose-dependently increased in 2MD-treated OVX rats (up to +73%) at doses equals to or greater than 1 ng/kg/d compared with OVX controls. Similarly, total bone content in FS increased significantly at all doses of 2MD treated OVX rats (up to +33%). Compared with OVX controls, there were significant increases in trabecular bone volume and trabecular connectivity determined by micro-CT analysis of DFM in 2MD treated OVX rats at doses as low as 1 ng/kg/d. Furthermore, bone formation on periosteal, endocortical and trabecular surfaces determined by histomorphometric methods dose-dependently increased in OVX rats treated with 2MD compared with OVX and sham controls. Interestingly, 2MD induced new trabecular bone formation in the marrow cavity of tibial shafts where there was no trabecular bone in sham or OVX rats, indicating that the pre-existing bone surface was not required for 2MD induced bone formation. This differs from parathyroid hormone, another bone anabolic agent, which requires pre-existing bone surface for its bone anabolic effect to be manifested. In summary, we found that 2MD not only restored both trabecular and cortical bone mass but also added extra bone to the osteopenic, OVX rats by stimulating bone formation on all bone envelopes. These data indicate that 2MD may have therapeutic potential in human skeletal disorders such as osteoporosis.

Proteasomal Degradation of Runx2 Shortens the Anti-apoptotic Signal of PTH in Osteoblasts: Why Intermittent Administration is Needed for Bone Anabolism. T. Bellido, L. I. Plotkin, A. A. Ali, C. A. O'Brien, S. C. Manolagas, R. L. Jilka. Div. Endo&Metab, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. of Arkansas for Medical Sciences, Little Rock, AR, USA.

Intermittent PTH causes bone anabolism, whereas sustained elevation of the hormone has a catabolic effect. However, an explanation for this dichotomy has remained elusive. Based on earlier evidence that the anabolic effect of intermittent PTH in mice is due at least in part to attenuation of osteoblast apoptosis, we examined whether continuous elevation of the hormone also reduced osteoblast death. We report that administration of PTH to Swiss Webster mice with an osmotic pump, or feeding them a calcium-deficient diet to increase the level of endogenous hormone, did not affect the prevalence of osteoblast apoptosis as determined 6 days after initiation of treatment by in situ end labeling. Consistent with this *in vivo* evidence, PTH (or dibutyryl-cAMP) provided only temporary (6-12 h) protection against etoposide- or anoikis-induced death of osteoblastic calvaria cells or OB-6 cells. The anti-apoptotic effect of PTH on OB-6 cells required Runx2-mediated transcription of genes like Bcl-2. Remarkably, PTH also caused an increase in ubiquitinated Runx2 marked for proteasomal proteolysis, and a decline in total Runx2 that reached 30% of controls at 3-6 h as determined by Western blot analysis. Acceleration of Runx2 degradation by overexpression of Smurf1 (the ubiquitin E3 ligase that targets Runx2 for degradation) blocked the anti-apoptotic effect of PTH. Conversely, abrogation of the PTH-induced decline in Runx2 using the proteasome inhibitor lactacystin, or by transfection of a dominant negative mutant of Smurf1, extended the anti-apoptotic effect of PTH to at least 24 h. Overexpression of either wild type Runx2, or a Runx2 mutant lacking the Smurf1 recognition site, also extended the anti-apoptotic effect of PTH. Moreover, Smurf1 reversed the prolonging effect of wild type Runx2 but not that of the mutant Runx2. We conclude that the duration of the anti-apoptotic effect of PTH is short-lived because it depends on the level of Runx2, which in turn is decreased by PTH via Smurf1-mediated proteasomal proteolysis. The self-limiting nature of PTH-induced survival signaling in osteoblasts explains why intermittent administration of the hormone is required for bone anabolism.

Isosorbide Mononitrate Increases Bone Formation and Decreases Bone Resorption in Postmenopausal Women: A Randomized Trial. S. A. Jamal[1], S. R. Cummings[2], G. A. Hawker[3]. [1]Endocrinology, St. Michael's Hospital, University of Toronto, Toronto, ON, Canada, [2]San Francisco Coordinating Center and Research Institute at the California Pacific Medical Center, San Francisco, CA, USA, [3]Rheumatology, Women's College Ambulatory Care Centre, University of Toronto, Toronto, ON, Canada.

Nitric oxide (NO) both stimulates bone formation and inhibits bone resorption in vitro. NO donors (nitrates) are inexpensive, safe, and widely available but their value for postmenopausal osteoporosis has never been evaluated in a randomized trial.

We enrolled women who were at least 3 years postmenopausal with hip bone mineral density (BMD) T-score between 0 and -2.5. We randomly assigned them to 5 mg or 20 mg per day of oral isosorbide mononitrate (ISMO), or placebo for 12 weeks. We measured changes in urine N-Telopeptide, (NTx), a marker of bone resorption and serum Bone Specific Alkaline Phosphatase (BSAP), a marker of bone formation.

Compared with women randomized to placebo, women randomized to 20mg of ISMO had a 45.4 % decrease in NTx (95% confidence interval [CI]: 25.8 to 64.9) and a 23.3% increase (95% CI: 8.9 to 37.8) in BSAP. Women randomized to 5mg of ISMO had a 36.3% decrease in NTx (95% CI: 14.8 to 57.8) and a 15.9% increase in BSAP (95% CI: 1.1 to 30.7) (Figure 1). 21% of women taking ISMO stopped treatment because of quickly reversible headache.

We conclude that ISMO decreases bone resorption to a degree similar to estrogen but also increases bone formation. This suggests that nitrates may substantially reduce fracture risk in postmenopausal women.

Figure 1. Changes in urine NTX and serum BSAP in women randomly assigned to 5 or 20 mg of ISMO daily compared with change in women assigned to placebo.

Estren Is a SERM with the Capacity to Excert Genomic Effects. S. Movérare[1], J. Dahllund*[2], N. Andersson[1], S. Nilsson*[2], J. Gustafsson[3], C. Ohlsson[1]. [1]Centre for Bone Research at the Sahlgrenska Academy (CBS), Department of Internal Medicine, Göteborg University, Göteborg, Sweden, [2]KaroBio AB, Huddinge, Sweden, [3]Department of Biosciences at Novum & Department of Medical Nutrition, Karolinska Institute, Huddinge, Sweden.

It was recently reported that 4-estrene-3α,17β-diol (estren) increases bone mass without affecting classical transcription (1). The aim of the present study was to compare the physiological effects of estradiol and estren on a variety of physiological responses in ovariectomized (ovx) wild type (WT) and estrogen receptor (ER) inactivated mice ($ER\alpha^{-/-}$, $ER\beta^{-/-}$ and $ER\alpha^{-/-}\beta^{-/-}$). Ovx mice of the different genotypes were treated for four weeks with estradiol (0.7µg/mouse/day) or estren (75 µg/mouse/day). As expected, estradiol increased the uterine weight (816 ± 97 %), the trabecular BMD (88 ± 21 %) and the cortical BMC (17 ± 4 %) while it decreased the gonadal fat weight (-62 ± 5 %) compared with vehicle in WT mice. Estren exerted a clear effect on the uterine weight (132 ± 28 %) and the trabecular BMD (19 ± 4 %) but no effect on the gonadal fat weight or the cortical BMC in WT mice. Comparison of the effect of estren in WT mice and ER inactivated mice demonstrated that the effects on uterus and trabecular BMD were exerted via ERα.

The effect of estren on the activation of an estrogen-responsive element (ERE)-driven reporter gene (ALP) was tested in ERα and ERβ reporter cell lines (2). Estren activated the reporter gene both via ERα (EC_{50} 70 nM) and via ERβ (EC_{50} 77 nM). Both the effect via ERα and the effect via ERβ were completely blocked by the estrogen receptor antagonist ICI 182780. Thus, estren has *in vitro* the capacity to exert genomic effects via both ERα and ERβ.

In conclusion, estren is a SERM with effects on trabecular BMD and uterus and these effects *in vivo* are mediated via ERα. Furthermore, *in vitro* data demonstrate that estren has the capacity to exert genomic effects.

Severely Decreased Bone Formation and Cortical Bone Content in Mice Lacking the Protein Kinase Akt2. H. Z. Ke, G. Xu*, D. T. Crawford*, H. Qi, H. A. Simmons, T. A. Brown, D. D. Thompson. Cardiovascular and Metabolic Diseases, Pfizer Global Research and Development, Groton, CT, USA.

The phosphoinositide-dependent serine-threonine protein kinase Akt (also known as PKB) has been proposed to be a key mediator of cell proliferation and survival. However, the regulatory role of Akt on trabecular and cortical bone development is not known. The purpose of this study was to elucidate the effects of knockout of Akt2 (PKB-beta), one of the three isoforms of Akt, on cortical and trabecular bone in female and male mice. Skeletal phenotypes of knockout (KO) female mice at age of 4, 8 and 12 months and KO male mice at 8 months of age were characterized and compared with their wild-type (WT) littermates. Compared with WT controls, body weight was significantly lower by 10%, 20% and 17% at 4, 8 and 12 months of age, respectively, in KO females and by 28% at 8 months of age in KO males. At 8 months of age, fat body mass decreased significantly by 50% and 55% in KO females and males, respectively, compared with WT. Femoral length did not differ between KO and WT in females and males, indicating that Akt2 does not regulate longitudinal bone growth. PQCT analysis of the distal femoral metaphysis (DFM) showed that KO females had significantly lower total bone content (-19%), total bone density, cortical bone content and cortical bone area compared with WT at 4 months of age. These parameters increased with age between 4 and 8 months of age, while they decreased with age between 8 and 12 months of age in both KO and WT females. However, these parameters remained significantly lower in KO compared with WT in all age groups. Similarly, PQCT analysis of the femoral shaft (FS) showed that KO females had significantly lower total bone content, total bone area, cortical bone content, cortical bone area, periosteal and endocortical circumferences compared with WT at 8 and 12 months of age. In 8-month-old KO male mice, total bone content and cortical bone content decreased significantly by 36% and 38% in DFM, and 23% and 22% in FS, respectively, compared with WT. Cortical bone histomorphometric analysis indicated that there was a 90% decrease in periosteal bone formation rate and a 57% decrease in endocortical bone formation rate in KO males compared with WT. There was a 59% decrease in trabecular bone formation rate determined by histomorphometric analysis of DFM and a 44% decrease in trabecular bone volume determined by micro-CT analysis of DFM in 8-month-old KO males compared with WT. In summary, Akt2 knockout severely decreased bone formation and bone mass in mice. Thus, activation of Akt2 may provide therapeutic potentials for skeletal disorders such as osteoporosis.

Capsaicin Sensitive Sensory Neurons Maintain Normal Bone Integrity. W. S. Kingery[1], S. Offley*[1], T. Guo*[1], A. Joseph*[1], D. P. Lindsey*[2], C. R. Jacobs[2]. [1]PM&R Service (117), VAPAHCS, Palo Alto, CA, USA, [2]Rr&d, VAPAHCS, Palo Alto, CA, USA.

Familial dysautomia is an autosomal recessive disease in which patients suffer from extensive unmyelinated sensory neuron loss, reduced bone density, and frequent fractures. It has been proposed that the loss of neuropeptides synthesized by unmyelinated neurons adversely affects bone integrity in this hereditary syndrome. To determine whether unmyelinated neurons can contribute to bone density and strength we treated skeletally mature male rats with either capsaicin (250mg/kg s.c.) or vehicle. Capsaicin activates the vanilloid receptors (VR1) that are expressed by many of the small diameter sensory afferents, including most of the neuropeptide containing neurons. Activation of the VR1 causes an influx of cations into the neuron resulting in the excitotoxic destruction of unmyelinated and small myelinated afferents. Four weeks after capsaicin treatment bone mineral density (measured by DXA scanning) in the metaphyses of the tibia and femur was reduced. There was also a reduction in distal femur density and a loss of bone strength (41% decrease in ultimate stress on biomechanical testing). No changes occurred in body weight, 24 h grid-crossing activity, hindpaw weight bearing, or gastrocnemius and soleus muscle mass after capsaicin treatment, data indicating that skeletal unloading did not contribute to the loss of bone density and strength. Peroneal nerve histomorphology was evaluated by light and electron microscopy 4 weeks after capsaicin treatment. Capsaicin treatment caused a 57% loss of unmyelinated sensory axons and a 8% loss of myelinated axons. Capsaicin also reduced the substance P content (measured by EIA) of the sciatic nerve by 78% and diminished sciatic nerve stimulation evoked extravasation responses by 64%. There was also a 68% reduction of substance P content in the proximal tibia at 4 weeks after capsaicin treatment. These results support the hypothesis that capsaicin sensitive afferent neurons contribute to the maintenance of metaphyseal bone density and strength. Capsaicin sensitive neurons have efferent functions in the tissues they innervate, effects mediated by the release of neuropeptides from the peripheral nerve terminals. We postulate that the deleterious effects of capsaicin treatment on cancellous bone density and strength are mediated by reductions in local neuropeptide content and release.

Aromatase Inhibition Does not Alter Bone Turnover, Serum OPG or Bone Density in Elderly Men with Mild Hypogonadism. B. Z. Leder[1], J. L. Rohrer*[1], S. D. Rubin*[2], J. Gallo*[3], J. S. Finkelstein[1]. [1]Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA, [2]AstraZeneca Pharmaceuticals, Wilmington, DE, USA, [3]Eximias Pharmaceuticals, Berwyn, PA, USA.

The reduction in serum gonadal steroid levels that occurs in aging men may contribute to various aspects of age-related physiological decline, including bone density. Recent studies suggest that estradiol (E) may be a crucial regulator of bone turnover in elderly men though testosterone (T) likely also plays a role. Thus, the effects of aromatase inhibition in men are difficult to predict. To assess the skeletal effects of aromatase inhibition in elderly men with mild hypogonadism (screening T < 350 ng/dL), we randomized 37 subjects (ages 62-74) to receive either anastrozole (a potent aromatase inhibitor) 1 mg QD, anastrozole 1 mg twice weekly, or placebo for 12 wk. Gonadal steroid levels, biochemical markers of bone turnover, osteoprotegerin (OPG), and total body bone density (TBBD) were measured at baseline and after 12 wk of treatment.

Both doses of anastrozole increased serum bioavailable T (BioT) levels (and total T- data not shown) in these men and decreased serum estradiol (E) levels. (*p<0.01 vs Group 3. **p <0.01 vs Group 3 and P<0.05 vs Group 2)

Changes in hormone levels (mean ± SD)

	Baseline BioT (ng/dL)	Week 12 BioT (ng/dL)	Baseline Estradiol (pg/mL)	Week 12 Estradiol (pg/mL)
Group 1 (anastrozole 1 mg QD) (n=12)	99 ± 31	207 ± 65**	26 ± 8	17 ± 6*
Group 2 (anastrozole 1 mg 2/wk) (n=11)	115 ± 37	178 ± 55*	27 ± 8	17 ± 5*
Group 3 (placebo QD) (n=14)	100 ± 35	97 ± 30	23 ± 4	25 ± 6

Despite these hormonal changes, no changes in osteocalcin (OC), bone specific alkaline phosphatase, or amino-terminal propeptide of type I procollagen were observed in any group. Similarly, no changes were observed in serum N-telopetide (NTX) or urinary deoxypyridonoline. (Data shown below for NTX and OC only.)

Changes in bone turnover markers (mean ± SD)

	Baseline NTX (nmol/L)	Week-12 NTX (nmol/L)	Baseline OC (ng/mL)	Week-12 OC (ng/mL)
Group 1	10.8 ± 2.3	11.0 ± 2.1	17.5 ± 3.8	17.8 ± 3.0
Group 2	11.8 ± 2.9	11.2 ± 3.0	18.9 ± 5.4	18.0 ± 5.4
Group 3	11.2 ± 3.0	10.9 ± 2.3	20.5 ± 6.8	21.5 ± 6.5

Serum OPG and TBBD also did not change in any group. These data suggest that increasing T and decreasing E for 12 weeks in mildly hypogonadal elderly men does not adversely affect bone metabolism. Furthermore, despite published reports that E increases and T decreases OPG expression *in vitro*, serum OPG levels are also unaffected by aromatase inhibition. Additional study is needed to assess the long-term effects of this method of T replacement on the skeleton and other gonadal steroid responsive tissues.

Leptin Modulates both Resorption and Formation while Preventing Disuse-Induced Bone Loss in Tail-Suspended Female Rats. T. Thomas, A. Martin*, R. de Vittoris*, M. Lafage-Proust, C. Alexandre, L. Vico. INSERM E0366, Saint-Etienne, France.

We previously demonstrated that peripheral administration of leptin was able to prevent disuse induced bone loss over 2 weeks of tail-suspension in female rats. In accordance with in vitro data, we tested the hypothesis that leptin preventive action on bone loss could be related to effects on both resorption and formation activities taking advantage of the uncoupling pattern of bone remodeling in this model. One hundred female Wistar rats were randomly assigned to 1 of the following groups: tail-suspended or non-suspended rats treated either with leptin or vehicle for 3, 7 and 14 days, and 2 baseline groups. After 1 week of adaptation, rats were suspended and human recombinant leptin was continuously administered using intraperitoneal Alzet pumps. Animals were measured at baseline, day 7 and day 14 using PIXImus (Lunar Corp.), and tibia samples were collected for histomorphometry after sacrifice. After 7 and 14 days, suspension induced a decrease in bone mineral density measured at the tibial metaphysis, a trabecular bone site, as compared to baseline (0.162±0.003 vs 0.173±0.004 and 0.147±0.003 vs 0.181±0.004; P<0.01, respectively) whereas leptin administration for 7 and 14 days prevented this decrease (0.181±0.005 and 0.177±0.014, respectively; NS). These data were confirmed by histomorphometry. This preventive effect of leptin on disuse-induced bone loss was partly explained by a significant prevention of the transient increase in bone resorption observed in the suspended group at day 7 (N.Oc/B.Ar: 43.0±5.3 vs 124.3±6.7; P<0.01). These leptin effects could be mediated by the osteoprotegerin (OPG) pathway as suggested by the 3-fold increase in OPG gene expression under leptin administration, as measured by direct RT-PCR in tibial osteoblastic cells harvested at day 3 from the 2 suspended groups. Only at day 14, leptin prevented the decrease in bone formation rate induced by suspension (BFR/BS: O.21±0.02 vs 0.11±0.01 um3/um2/d; P<0.05). The latter effects could be related to leptin role, in mediating the reciprocal differentiation between adipocytes (Ad) and osteoblasts demonstrated in vitro. Indeed, we observed no significant difference in mineral apposition rate whereas leptin prevented the concurrent increase in adipogenesis observed in the suspended group treated with vehicle (Ad.S/B.Ar: 3.1±2.0 vs 4.9±2.1 %; P<0.05). In summary, these data suggest that peripheral administration of leptin could prevent disuse-induced bone loss with combined effects on both bone resorption and bone formation. Further studies are now needed to clarify the putative dual leptin effects on bone depending on its central brain-mediated vs peripheral effects.

PPAR-Alpha Agonists Increase Bone Mineral Density in Female Rats. U. Syversen, I. Bakke*, G. Aune*, L. Thommesen*. Institute of Cancer Research and Molecular Medicine, Norwegian University of Science and Technology, Faculty of Medicine, Trondheim, Norway.

Peroxisome proliferator-activated receptors (PPARs) are members of the steroid nuclear superfamily of receptors that have been shown to modulate the expression of genes involved in lipid metabolism and fat storage. Recently, the presence of PPARs has also been demonstrated in bone cells and a role in bone metabolism has been postulated. In the present study we have examined the effect of the PPAR alpha agonists Wyeth 14,643 and fenofibrate, the gamma agonist pioglitazone and the combined PPAR alpha, gamma and delta agonist tetradecylthioacetic acid (TTA) on bone mineral density (BMD) in female rats.

Fifty female Fischer rats were divided into 5 groups and were given methocel (control group), Wyeth 14,643, fenofibrate, TTA and pioglitazone (50 mg/kg body weight) for 4 months. BMD was measured by double x-ray absorptiometry. Body weight was registered throughout the study. There was no difference in body weight between control rats and the treatment groups. After 4 months femoral BMD was significantly higher in rats treated with Wyeth 14,643 (7%, p=0.0002), fenofibrate (5.7%, p=0.0035) and TTA (5%, p=0.0116) than in control rats. In rats treated with pioglitazone, femoral BMD tended to be lower than in control rats (-3%, p=0.1591). Total body BMD was significantly lower in the pioglitazone treated group compared to controls (p<0.0001), while there was no difference between the control group and the other groups. Wyeth 14,643 was found to inhibit the differentiation of monocytes into osteoclasts in a dose-dependent manner, and also inhibited the proliferation of the preosteoclast cell line.

In conclusion, treatment with the PPAR-alpha agonists Wyeth 14,643 and fenofibrate, and the combined PPAR alpha, gamma and delta agonist TTA, significantly increased femoral BMD in female rats, while treatment with the PPAR gamma agonist pioglitazone resulted in a significantly decrease in total body BMD.

β2-Adrenergic Agonists Have Negative Effects on Bone Architecture and Density in Rat. N. Bonnet*, B. Brunet-Imbault*, C. J. Parnaud*, G. Lemineur*, A. Arlettaz*, C. Chappard, D. Courteix, C. L. Benhamou. Inserm ERIT-M 0101, Orleans, France.

β2-receptors have recently been demonstrated to influence bone metabolism and bone mass via the central nervous system. β2-agonists have shown a negative effect on bone mass (1), but the effect on bone architecture has not been studied. The aim of this study is to quantify the effects of two β2-agonists (clenbuterol and salbutamol) on bone mass, bone length, morphological and topological trabecular bone parameters and bone strength.

34 ten weeks old Wistar female rats were studied. During 6 weeks SC daily injections were performed : 10 control rats receiving normal saline (2mg/kg/day) were compared to 13 rats receiving salbutamol (4mg/kg/day) and 11 rats receiving clenbuterol (2mg/kg/day). High-resolution BMD was measured by dual-energy X-ray absorptiometry on the *ex-vivo* rat femurs. The femur lengths were measured with a digital calliper. Trabecular bone microarchitecture was characterized by X-ray micro-computed tomography(μCT) (Skyscan 1072) : morphological (BV/TV, Tb.N, Tb.Th) and topological (SMI, TBPf, connectivity, degree of anisotropy (DA)) parameters were measured on the femur distal metaphysis. The radiological projections obtained by μCT were used to measure the cortical thickness at the mid diaphysis. The mechanical strength was measured using three-point bending tests.

Compared to controls, salbutamol and clenbuterol respectively induced significant reductions of 6.6% and 6.9% in BMD (p<0.001), 3.7% and 3.7% in the length (p<0.001) and 6% and 4.7 % in the cortical thickness (p<0.01). Salbutamol had no significant effect on morphological and topological parameters nor fracture load whereas clenbuterol induced a significant reduction of 45.8% of BV/TV (p<0.001), 46.6% of Tb.N (p<0.001), 18.5% of connectivity (p<0.02), 9.9% of fracture load (p<0.04) and a significant increase of TBPf (p<0.04). DA and SMI are not significantly influenced.

These results indicate that clenbuterol had an additive effect on microarchitecture. BV/TV, TbN were reduced whereas TbTh remained constant suggesting a predominant mechanism of trabeculae removal. The TBPf evolution in the clenbuterol group also indicates changes in the trabecular network shape. Salbutamol doesn't modify significantly the trabecular microarchitecture whereas the salbutamol concentration has been doubled compared to clenbuterol.

These data confirm the negative influence of β2-agonists on bone mass, and show the deleterious effect of the clenbuterol on trabecular bone microarchitecture, with potential pharmacological consequences in medicine and doping.

Role of TGF-β and Menin in the Proliferation and Secretion of Human Parathyroid Cells. H. Sowa[1], H. Kaji[1], R. Kitazawa[2], S. Kitazawa[2], T. Tsukamoto*[1], S. Yano*[1], G. N. Hendy[3], T. Sugimoto[1], K. Chihara*[1]. [1]Endocrinology, Kobe University, Kobe, Japan, [2]Molecular Pathology, Kobe University, Kobe, Japan, [3]Medicine, McGill University, Montreal, PQ, Canada.

Primary hyperparathyroidism is a common endocrine disorder caused by parathyroid tumor and an excess of parathyroid hormone (PTH) secretion. However, the mechanism of tumorigenesis in parathyroids is still unknown. Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominant disorder with multiple endocrine tumors, and somatic mutations of the MEN1 gene have also been found in 10-20 % of sporadic primary parathyroid tumors. We previously demonstrated that menin, a product of the MEN1 gene, interacts with Smad3, and that inactivation of menin blocks TGF-β-signaling (PNAS, 2001). The present study was therefore performed to clarify the role of TGF-β and menin in the proliferation and PTH secretion of parathyroid cells by employing human parathyroid cells from the patients with secondary hyperparathyroidism. Western blot analysis of parathyroid tissues demonstrated that parathyroid cells express TGF-β. TGF-β significantly inhibited the proliferation of parathyroid cells in MTT assay and ^{3}[H]-thymidine incorporation. Menin inactivation by menin antisense (AS) oligonucleotides (oligo) abrogated TGF-β-inhibited proliferation and PCNA expression in these cells. Moreover, the staining of PCNA and PTH by immunocytochemistry of parathyroid cells showed that menin inactivation with AS oligo antagonized TGF-β-inhibited proliferation in PTH-positive cells. As for secretion of PTH, TGF-β inhibited the expression of PTH (Western blot) and its level in the medium (RIA) of parathyroid cells. Inactivation of menin with AS oligo increased basal PTH secretion and TGF-β-inhibited PTH secretion On the other hand, control sense oligo did not affect the proliferation and PTH secretion of parathyroid cells. The present study demonstrates that menin inactivation antagonizes TGF-β-inhibited proliferation and PTH secretion in human parathyroid cell cultures. These findings suggest that TGF-β functions as an autocrine- or paracrine- inhibitory factor of growth and PTH secretion in parathyroid tissues, and that blockage of TGF-β signaling by menin inactivation results in tumor formation.

COX-2 Inhibitors and Fracture Healing: Reversibility of Effects After Short Term Treatment. L. C. Gerstenfeld[1], D. M. Cullinane*[1], E. A. Krall*[1], J. Fitch*[1], M. Thiede[2], T. A. Einhorn[1]. [1]Boston University Medical Center, Boston, MA, USA, [2]Pharmacia Corp, Chesterfield, MO, USA.

Reports have suggested inhibition of experimental fracture (fx) healing with both COX-2-specific inhibitors (coxibs) and nonspecific non-steroidal anti-inflammatory drugs (NSAIDs). Because drug specificity, dose, and duration may influence fx healing, and because patients with fxs require analgesia for only short periods of time after initial stabilization, we tested the hypothesis that short-term dosing is reversible. Two experiments were conducted: in the first, 150 male SD rats underwent production of standard closed mid-diaphyseal femoral fx. Animals were then divided into three treatment gps and dosed by daily gavage with either the NSAID, ketorolac (4 mg/kg/d); the coxib, valdecoxib (5 mg/kg/d); or vehicle. In each gp, rats were administered drugs or vehicle for the first 7 days post-fx and euthanasia was performed on half of the animals on day 21 and the other half on day 35. In a second experiment, rats (n=150) were administered drug or vehicle for the first 21 days post-fx and euthanized on days 21 and 35. Methods of data analysis included manual testing of the integrity of the fx calluses, mechanical torsion testing to failure, and histomorphometry. Fisher's exact test was used to measure the association of % of nonunions with treatment. In rats treated for 7 days, there were no significant differences in % of nonunions after 21 days (16% of ketorolac, 22% of valdecoxib, and 8% of vehicle-treated animals, p=0.47), nor after 35 days (5% of ketorolac, 0% of valdecoxib, and 9% of

vehicle-treated, p=1.0). In rats treated for 21 days, there were differences in % of non-unions after 21 days (13% of ketorolac, 36% of valdecoxib, and 4% of vehicle-treated, p=0.01), but the differences disappeared by 35 days (0% in ketorolac and valdecoxib gps, 5% in vehicle-treated, p=1.0). Torsional strength in the bones which had united showed no significant differences among any of the treatment gps at either 21 or 35 days. Histomorphometry showed a strong correlation between non-union rate and percent cartilage in the calluses. These data suggest that both coxibs and NSAIDs delay fx healing and the magnitude of the effect as measured by non-union in this study is related to the duration of treatment. However, upon discontinuation of treatment, healing normalizes and if treatment is administered for up to 3 weeks post-fx, healing will occur within the expected time-frame (35 days in rats). Extrapolation of these findings to a clinical setting further suggests that management of fracture-associated pain with inhibitors of COX-2 should neither impair nor delay healing as long as the duration of treatment is consistent with current standards of care.

Clinical Characteristics of 94 Subjects with Autosomal Dominant Osteopetrosis Type II (ADO2) and Chloride Channel 7 Gene Mutations. S. G. Waguespack[1], K. A. Buckwalter*[2], M. J. Econs[3]. [1]Endocrine Neoplasia and Hormonal Disorders, U.T. M.D. Anderson Cancer Center, Houston, TX, USA, [2]Radiology, Indiana University, Indianapolis, IN, USA, [3]Medicine, Indiana University, Indianapolis, IN, USA.

ADO2 is caused by mutations in the chloride channel 7 (ClCN7) gene. The clinical characteristics of this disease remain poorly understood. We studied 94 individuals with ClCN7 gene mutations from 11 ADO2 families. We collected clinical data through patient interviews, medical records, and/or self-reported responses on a questionnaire. We assessed for a history of fractures (FX), osteomyelitis (OM), visual loss (VL), and bone marrow (BM) failure in adults and children. A score of "severe" for the fracture category was given if there was a history of > 10 fractures or > one hip/femur fracture. We compared the data between clinically affected, unaffected gene carriers and normal control subjects. Individuals were defined as affected or unaffected based on the presence or absence of classic radiographic findings and/or abnormal serum biochemistries, respectively.

Subjects <18 yrs. of age

	N	Age ± SD	FX (Any)	FX (Severe)	OM	VL	BM failure
Affected	19	8.9 ± 4.5	11 (58%)	3 (16%)	1 (5%)	8 (42%)	1 (5%)
Carrier	3	7.9 ± 7.3	0 (0%)	0 (0%)	0 (0%)	0 (0%)	0 (0%)
Control	67	7.7 ± 4.2	11 (16%)	0 (0%)	0 (0%)	0 (0%)	0 (0%)

Subjects >18 yrs. of age

	N	Age ± SD	FX (Any)	FX (Severe)	OM	VL	BM failure
Affected	43	47.1 ± 16.4	42 (98%)	14 (33%)	10 (23%)	4 (9%)	1 (2%)
Carrier	29	43.3 ± 15.6	17 (59%)	0 (0%)	0 (0%)	0 (0%)	0 (0%)
Control	150	42.7 ± 15	68 (45%)	0 (0%)	2 (1%)	0 (0%)	0 (0%)

In this cross sectional analysis, almost all patients with ADO2 have a fracture at some point of their lives. Although fractures occur in all groups, the presence of a severe fracture history was identified only in affected patients. As expected, fractures in unaffected gene carriers did not differ from controls. Osteomyelitis was most commonly identified in the mandible and/or maxilla (8/10 affected adults); the other cases involved the lower extremity, two of which occurred after surgical repair of a fracture. Visual loss appears to occur at a relatively high rate, particularly in the pediatric age group. Finally, although rare, BM failure can occur in ADO2 patients. In conclusion, ADO2 is a disease of significant morbidity that can be quite severe in its clinical course; given the high rates of visual loss in subjects < 18 yrs., it is paramount to completely assess vision in any child with ADO2.

Long-term Infusion of Secreted Frizzled Related Protein 4 (sFRP-4) Reduces Serum Phosphate Concentrations without a Compensatory Change in Vitamin D Metabolism. T. Berndt*[1], T. A. Craig*[1], A. E. Bowe*[2], J. Vassiliadis*[2], D. Reczek*[2], R. Finnegan*[2], S. M. Jan De Beur[3], S. C. Schiavi[2], R. Kumar[1]. [1]Medicine, Mayo Clinic, Rochester, MN, USA, [2]Receptor Ligand Therapeutics, Genzyme Corporation, Framingham, MA, USA, [3]Division of Endocrinology, Johns Hopkins University, Baltimore, MA, USA.

Tumor induced osteomalacia (TIO) is a syndrome associated with hypophosphatemia, excessive phosphate excretion, osteomalacia, and abnormal vitamin D metabolism. Recent studies have identified sFRP-4 as a protein that is over expressed in tumors from patients with TIO. Therefore, the present studies were performed to determine the effects of long-term intravenous infusion of sFRP-4 on renal phosphate handling and vitamin D metabolism in rats. Normal rats were anesthetized and prepared for solute clearance studies. After a 90-minute stabilization period, a control clearance was taken and then either vehicle (n=5) or sFRP-4 (0.3 microgram/kg/hr, n=7) was infused. After a 1-hour equilibration period, one-hour clearances were taken at 4 and 7 hours after the initiation of the infusion. At the end of the experiment, blood was collected for the measurement of 1 alpha, 25-dihydroxyvitamin D, and the kidneys were removed for the isolation and assessment of 25-hydroxyvitamin D 1 alpha hydroxylase cytochrome P450 and 25 hydroxyvitamin D 24-hydroxylase cytochrome P450 mRNA concentrations by quantitative real-time RT-PCR. In the vehicle infused group, basal fractional excretion of phosphate (FEPi) was 7 ± 2% and plasma Pi was (2.0 ± 0.2 mM) and were stable throughout the experiment. With long-term infusion of sFRP-4, FEPi significantly increased from 9 ± 3% to 20 ± 4%, p<0.05 four hours after initiation of the sFRP-4 infusion and was 18 ± 4% at 8 hours. Infusion of sFRP-4 decreased serum Pi from 2.0 ± 0.1 mM to 1.5 ± 0.1 mM, p<0.05, at 4 hours and to 1.5 ± 0.1 mM, p<0.05, at 8 hours. Serum 1 alpha, 25-dihydroxyvitamin D concentrations and renal 25-hydroxyvitamin D 1 alpha-hydroxylase cytochrome P450 mRNA were similar in both groups. We conclude that long-term infusion of sFRP-4 is associated with increased phosphate excretion, hypophosphatemia, and that the vitamin D endocrine system fails to respond to the hypophosphatemic stimuli following sFRP-4 infusion. Sodium and calcium excretions were not changed. Thus, sFRP-4 has the biological properties of "phosphatonin".

The Role of Local Corticosteroid Generation in Inflammation-Associated Bone Loss. M. S. Cooper, P. Emery*, M. Hewison, P. M. Stewart*. Division of Medical Sciences, University of Birmingham, Birmingham, United Kingdom.

Generalized and periarticular osteoporosis are common features of inflammatory arthritis. These effects appear to be mediated by high levels of pro-inflammatory cytokines. 11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1) is an intracellular enzyme that generates active cortisol from inactive cortisone. By generating active glucocorticoids locally, osteoblastic 11β-HSD1 is an important determinant of the effects of glucocorticoids on osteoblasts. In vitro, osteoblastic 11β-HSD1 expression is induced by pro-inflammatory cytokines. We thus hypothesized that inflammation-associated bone loss may reflect a localized form of corticosteroid-induced osteoporosis. Corticosteroid metabolism was examined in patients presenting with early rheumatoid arthritis (age 59±13 (mean±SD), n=31) or mechanical, non-inflammatory, joint conditions (n=9). None of the patients had been treated with glucocorticoids or bone active medications. Serum markers of inflammation and clinical measures of disease severity were measured. Corticosteroid metabolite profiles were determined by gas chromatography/ mass spectrometry on urine samples giving measures of total corticosteroid metabolite production, 11β-HSD1 activity ((THF+alloTHF)/THE ratio), 11β-HSD2 activity (urinary free cortisol/urinary free cortisone (UFF/UFE)) and 5α-reductase activity (THF/THE ratio).

The (THF+alloTHF)/THE ratio (indicating 11β-HSD1 activity) was significantly increased in patients with inflammatory arthritis compared with controls (1.54±0.08 (mean±SE) vs 1.20±0.11; p<0.05). There was no difference in total corticosteroid metabolite production, 11β-HSD2 activity or 5α-reductase activity. Amongst patients with inflammatory arthritis significant correlations between inflammatory markers and 11β-HSD1 activity were found with high inflammatory markers predicting increased 11β-HSD1 activity (r=0.40 for ESR, r=0.39 for CRP, both p<0.05). In contrast, there was no correlation of inflammatory markers with corticosteroid metabolite production or 5α-reductase activity.

11β-HSD1 activity is elevated in patients with early untreated inflammatory arthritis and increases with the level of disease activity. This activity appears to reflect local generation of active corticosteroids from circulating inactive precursors. Increased 11β-HSD1 activity and thus chronic local corticosteroid excess may account for the periarticular and generalized osteoporosis seen in inflammatory arthritis.

Increased Circulating Level of FGF-23 in Patients with McCune –Albright Syndrome. T. Yamamoto[1], Y. Imanishi[2], H. Koshiyama*[3], Y. Miyoshi*[4], N. Shimizu[5], E. Kinoshita*[6], Y. Nakagomi[7], A. Miyauchi[8], K. Satomura[5], M. Inaba[2], T. Sugimoto[9], Y. Nishizawa[2], H. Juppner[10], K. Ozono[4]. [1]Pediatrics, Minoh City Hospital, Minoh, Japan, [2]Metabolism, Endocrinology & Molecular Medicine, Osaka City University Graduate School of Medicine, Osaka, Japan, [3]Medical Research Institute, Kitano Hospital, Osaka, Japan, [4]Pediatrics, Osaka University Graduate School of Medicine, Suita, Japan, [5]Second Division of Pediatrics, Osaka Medical Center and Research Institute for Maternal and Child Health, Izumi, Japan, [6]Pediatrics, Nagasaki University School of Medicine, Nagasaki, Japan, [7]Pediatrics, Yamanashi University School of Medicine, Kofu, Japan, [8]Medicine, National Hyogo-Chuo Hospital, Sanda, Japan, [9]Division of Endocrinology/Metabolism, Department of Clinical Molecular Medicine, Kobe University Graduate School of Medicine, Kobe, Japan, [10]PediatricEndocrine Unit, Department of Medicine, Mass. General Hospital and Harvard Medical School, Boston, Boston, MD, USA.

McCune-Albright syndrome (MAS) is sometimes complicated with hypophosphatemia. We previously reported the presence of a humoral factor which inhibited intestinal phosphate transport (Yamamoto T et al : J Bone Miner Metab 19:287,2001). Recently, fibroblast growth factor 23(FGF23) was reported as a phosphaturic factor and we recently reported increased circulating serum FGF23 levels in patients with oncogenic and X-linked hypophosphatemia. Thus, we measured serum FGF23 levels in patients with MAS accompanying hypophosphatemia. As a control for hypophosphatemia, we also investigated the serum FGF23 levels in 2 patients with hereditary hypophosphatemic rickets with hypercalciuria(HHRH).

Serum phosphate levels were clearly decreased in 7 MAS patients with hypophosphatemia compared with 14 normal controls. Mean serum phosphate values for MAS and normal controls were 3.0 and 4.5 mg/ml respectively (P=0.0002). Mean serum ALP and plasma FGF23 levels were clearly increased in MAS patients respectively (ALP:1357 vs 732 IU/l ; P=0.0251, FGF23: 307 vs 81 RU/ml ; P=0.0104). In HHRH, plasma mean FGF23 levels were within normal range(67 RU/ml). In MAS patients, plasma FGF23 levels were negatively correlated to serum phosphate levels (r= -0.553, P=0.0127) but positively correlated

to serum ALP levels(r=0.668, P=0.0052). Serum ALP levels were not correlated to serum phosphate levels. Oral phosphate loading test in two MAS patients revealed impaired maximal increase of serum phosphate levels compared to normal controls. These data suggest that FGF23 is a possible causal factor for hypophosphatemia in MAS patients. However, the mechanism of FGF23 on the regulation of serum phosphate levels in MAS patients remains further investigation.

Mechanical Stimulation Promotes Osteocyte Survival: Requirement of Nuclear Targets of the Src/ERK Pathway. L. I. Plotkin, J. I. Aguirre, B. Strotman*, S. C. Manolagas, T. Bellido. Endocrinology, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. Arkansas for Med. Sci., Little Rock, AR, USA.

Mechanical signals activate the extracellular signal regulated kinases (ERKs) in osteocytes. Since mechanical loading might regulate osteocyte apoptosis *in vivo* and ERKs are required for osteocyte survival induced by systemic factors, we investigated whether mechanical stimulation influences the response of osteocytic cells to pro-apoptotic stimuli and whether ERKs are involved. MLO-Y4 osteocytic cells stably expressing nuclear green fluorescent protein (GFP) were first stretched for 10 min at 5% elongation, and subsequently treated with the proapoptotic stimuli etoposide or dexamethasone. Whereas either pro-apoptotic agent increased the percentage of cells exhibiting apoptotic features after 6 h in unstretched cultures, cells subjected to mechanical stimulation were protected from the effect of the pro-apoptotic agents. Inhibition of ERKs with PD98059 or with a dominant negative (dn) form of MEK (the kinase responsible for ERK activation) abolished the protection from apoptosis induced by stretching. On the other hand, inhibition of PI3K or p38 MAPK, two other kinases activated by mechanical signals, had no effect. Consistent with the previously demonstrated involvement of Src in ERK activation induced by stretching, cells treated with the inhibitor of Src kinases PP1 or transfected with a Src mutant lacking kinase activity did not exhibit the protective effect of stretching. Strikingly, cells transfected with a dn Src mutant lacking the SH2 domain (which mediates Src interaction with the estrogen receptor) also lost the responsiveness to stretching, whereas cells transfected with a dn Src mutant lacking the SH3 domain (which mediates Src interaction with the androgen receptor) remained responsive. These results are consistent with evidence (shown elsewhere in this meeting) that the transduction of mechanical signals into ERK activation involves the estrogen receptor, but not the androgen receptor. In addition, mechanical stimulation induced rapid translocation and nuclear accumulation of ERK2 fused to GFP, which increased between 1-20 min of stretching, and lasted for about 1 h after 10 min of stimulation, declining to control levels by 3 h. Furthermore, the anti-apoptotic effect of mechanical signals was abolished by actinomycin D or cycloheximide, inhibitors of RNA or protein synthesis, respectively. Taken together, these results indicate that mechanical signals promote osteocyte survival via transcription-dependent mechanisms downstream of the Src/ERK signaling pathway.

Blockade of Anabolic Mechanotransduction Pathway in COX-2 Deficient Mice. Y. Mikuni-Takagaki[1], H. Sekiya[2], K. Naruse*[3], M. Itoman*[3], K. Seto*[2]. [1]Oral Biochemistry, Kanagawa Dental College, Yokosuka, Japan, [2]1st Dept. of Oral and Maxillofacial Surgery, Tsurumi University School of Dental Medicine, Yokohama, Japan, [3]Orthopedic Surgery, Kitasato University School of Medicine, Sagamihara, Japan.

Cyclooxygenase-2 (COX-2) has been shown to play an essential role in bone formation during fracture repair.
We have reported that low-intensity pulsed ultrasound (US), which mechanically accelerate fracture healing 40% by time, targets osteoblasts but not osteocytes. The anabolic response of osteoblasts was obliterated either by blocking COX-2 with NS398 or by inhibiting p38 with SB203580 (JBMR, 2003). In order to substantiate a fundamental role of COX-2 in the mechanotransduction pathways, acceleration of fracture repair by US was studied in ***COX-2***$^{-/-}$ mice (B6; 129S7-*Ptgs2*^{tm1Jed}, Jackson Laboratories), which were subjected to the mid-diaphyseal femoral fracture with intramedullary fixation at relatively old age of 52±2 weeks. Half of the animals in each group were exposed to the ultrasound for 20 min a day, from the fourth day of surgery. Both exposure and control groups were anesthetized prior to the treatment using a SAFHS (Smith & Nephew Inc.) ultrasound generator equipped with probes 13-mm across (Teijin Limited). Conditions were identical to those used for patients and the bone cell cultures. Homozygous mutant and control mice were maintained on a mixed genetic background of 129S/C57BL/6J, and neither COX-2 mRNA nor protein was detected in tissues from homozygous mutant mice. Bone formation during the skeletal repair was monitored by contact X-ray, microCT, histochemical analyses, and real-time PCR. Radiographs and histologic sections of ***COX-2***$^{-/-}$ and wild-type mice after 10-day postfracture point showed detectable delay in healing of ***COX-2***$^{-/-}$ femora with and without the exposure to US. By day 21, the difference became apparent: 1) All wild-type femora exposed to US attained bony union. 2) If not treated with pulsed ultrasound, ***COX-2***$^{-/-}$ femora did not produce union. Only some of them resulted in mineralized callus formation. 3) Untreated wild-type and ***COX-2***$^{-/-}$ femora exposed to US were in between 1) and 2) in that order. Furthermore, we found that the amplified late upregulation of mRNAs such as IGF-I, which we reported in mechanically loaded cells, was lost in ***COX-2***$^{-/-}$ osteoblasts. The defect in upregulation, however, was at least in part rescued by the added PGE_2 at 1 hr, when the immediate early induction of COX-2 results in PGE_2 secretion. Taken together, these results suggest that COX-2 not only plays an important role in fracture repair, but also functions as an essential mediator of mechanotransduction leading to bone formation.

Unloading-induced Bone Loss Occurs though the Central Control via Sympathetic System. H. Kondo[1], K. Tsuji[1], K. Kitahara[1], S. Rittling[2], A. Nifuji[1], D. Denhardt[3], G. Karsenty*[4], M. Noda[1]. [1]Dept of Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Rutgers University, Piscataway, NJ, USA, [3]Dept of Nutritional Sciences, Rutgers University, New Brunswick, NJ, USA, [4]Dept of Molecular and Human Genetics, One Baylor Plaza, Huston, TX, USA.

Unloading in bed-ridden patients results in disuse osteoporosis, the number of which is soaring in our modern aging society. Although, it is well known that unloading causes rapid bone loss in vivo, the mechanisms underlying this phenomenon are not fully understood. Tail suspension enhances excretion of deoxypyridinoline into urine suggesting that not only bones in the hind limb but also systemic skeletal elements would be subjected to central control which would be regulated by tail suspension. One of the candidates for such systemic control may be central nervous system that stimulates sympathetic nerve to suppress bone formation. This paper examined whether sympathetic nervous system is involved in unloading-induced bone loss in tail suspension. Adult 129 mice were treated either with vehicle or with guanethidine which depletes noradrenaline and chemically impairs sympathetic system. Guanethidine alone did not affect bone volume levels. Tail suspension reduced cancellous bone volume (BV/TV) in vehcle-treated mice. In contrast, in guanethidine treatmented mice, such reduction in BV/TV was no longer observed even after tail suspension. Furthermore, propranolol, an antagonist against beta adrenergic receptor, prevented tail suspension-induced cancellous bone loss. Propranolol by itself did not alter basal levels of cancellous bone volume. Propranorol treatment prevented tail suspension-induced reduction in bone mineral density in the proximal end of tibia. In order to examine the cellular mechanisms underlying these observations, we conducted bone marrow cell cultures in the presence of ascorbic acid and beta glycerophosphete. Tail suspension suppressed mineralized nodule formation in the cultures of bone marrow cells compared to the cells oblained from control loaded mice. In contrast, bone marrow cells obtained from mice treated with propranolol no longer exhibited suppression of nodule formation by tail suspension. Similarly, bone marrow cells obtained from guanethidine treated mice did not show tail suspension-induced suppression in the levels of mineralized nodule formation in culture. These data indicated that central sympathetic control mediates the unloading–induced bone loss.

Rescuing the Phenotype of Biglycan-Deficient Mice via Exercise. D. H. Kohn*[1], J. M. Wallace*[2], R. M. Rajacher*[2], X. Chen[3], S. Shi*[3], M. R. Allen*[4], S. A. Bloomfield*[4], P. G. Robey[3], M. F. Young[3]. [1]Biologic & Materials Sciences, University of Michigan, Ann Arbor, MI, USA, [2]Biomedical Engineering, University of Michigan, Ann Arbor, MI, USA, [3]Nidcr, NIH, Bethesda, MD, USA, [4]Health and Kinesiology, Texas A & M University, College Station, TX, USA.

Biglycan-deficient mice exhibit lower bone volume than wild types, due to a deficiency in bone forming cells. We hypothesized that mechanical stimulation could rescue the phenotype of these knock-outs. At 8 wk of age, bgn-deficient and wild type male mice (C57BL6/129 background; 10 mice/group; NIDCR animal approval 001-151) were randomly assigned to control or exercise (treadmill running 10 m/min, 30 min/day, 21 days) groups. Bones were harvested for QCT and mechanical testing (4 point bending). Phenotypic changes in bgn-deficient mice were primarily exhibited in the tibia (Table). KO mice also have a trend towards a larger cortical area that is more isotropically distributed. However, this material is of lower quality, causing the bone to have lower strength and energy dissipation. This phenotype may be due to an upregulation of other matrix proteins responsible for promoting mineralization, causing over-mineralization and weaker, more brittle bone. This hypothesis is supported by the QCT data showing a significant increase in BMC and BMD in the KOs. Exercise lead to an increase in cross sectional area and post-yield deformation in the wild types, at the expense of strength. Exercise had a less significant effect on the geometry of the knockouts, but was accompanied by increases in yield force (p=0.005), post-yield displacement (p=0.044), total displacement (p=0.045), and ultimate energy (p=0.045). These properties were greater or equal to wild type control values, and the increase in properties due to exercise was at least as large in KOs as wild types. Exercise was therefore able to rescue the phenotype of bgn knockouts.

Knockout of Cyclooxygenase-2 (COX-2) in Mice Results in a Skeletal Phenotype, but Does not Influence Mechanical Responsiveness. I. Alam[1], S. J. Warden*[1], A. G. Robling[2], C. H. Turner[1]. [1]Orthopaedic Surgery, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Anatomy & Cell Biology, Indiana University School of Medicine, Indianapolis, IN, USA.

Cyclooxygenase-2 (COX-2) is inductively expressed to control a rate-limiting step in the production of prostaglandins (PGs). PGs have effects on both bone formation and resorption, which are mediated through the proliferation and differentiation of osteoblasts and the regulation of osteoclast differentiation. Previous studies have shown that COX-2 mediated production of PGs is essential for the healing of fractures, and that inhibition of COX-2 interferes with skeletal mechanical responsiveness. This study compared adult COX-2 knockout (COX-2-/-) mice to wild-type (COX-2+/+) littermate controls to investigate the effect of COX-2 on bone mass and size, and explored the role of COX-2 in mechanotransduction. We identified that COX-2-/- mice had 11% lower body weight compared to COX-2+/+ mice ($p<0.01$). They also had smaller bones with long bone length being 4-5% shorter ($p<0.01$). On bone mass assessment, whole femoral and tibial BMC (normalized by body weight) was 22-29% lower in COX-2-/- mice by DXA ($p<0.01$), and femoral, tibial and humeral midshaft vBMD was 8-11% lower by pQCT ($p<0.05$). Similarly, vBMD in the proximal femur, tibia and humerus was 6-10% lower in COX-2-/- mice ($p<0.05$). Exposing ulnas of COX-2-/- and COX-2+/+ mice to an identical mechanical stimulus, no influence of genotype was observed on histomorphometric measures of bone formation (relative BFR/BS— COX-2+/+ 134.0±28.1 mm3/mm2/yr; COX-2-/- 180.8±41.1 mm3/mm2/yr). The results of this study are interesting from a couple of perspectives. Firstly, COX-2 is not believed to have a role in homeostasis as it is inductively expressed. However, we found COX-2-/- mice to be lighter and to have greater mortality than COX-2+/+ mice suggesting a role in normal physiological functioning. Secondly, we found the deletion of the gene that encodes for COX-2 to have no effect on skeletal mechanical responsiveness. This contradicts previous findings using COX-2 specific inhibitors. One explanation for this opposing finding is that COX-2-/- mice may have developed compensatory pathways for the absence of COX-2, pathways not developed when COX-2 is blocked temporarily using inhibitors. These findings highlight the need for further exploration of the role of COX-2 in the skeleton.

OPN Deficiency Increases Bone Formation and also Protects Tooth from Severe Root Resorption during Mechanical Stress-Induced Tooth Movement. C. Chung*[1], K. Kitahara[1], S. R. Rittling*[2], K. Tsuji[1], A. Nifuji[1], K. Soma*[3], D. T. Denhardt[2], M. Noda[1]. [1]Molecular pharmachology, Tokyo Medical and Dental Univ., Tokyo, Japan, [2]Rutgers Univ., Piscataway, NJ, USA, [3]Orthodontic Science, Tokyo Medical and Dental Univ., Tokyo, Japan.

Previously we have developed a new mechanical stress-induced tooth movement model in mice, which induces a reproducible mesial directed movement of the maxillary first molar accompanied by bone resorption on the pressure (mesial) side, and new bone apposition on the tension (distal) side resulting in a reverse pattern of bone remodeling within the alveolar bone. Since OPN, a major non-collagenous bone matrix protein, is induced by mechanical stress, affecting osteoclastic bone resorption and also bone formation, we have applied this model to an OPN-deficient mice to elucidated the direct role of OPN during mechanical stress induced tooth movement along with the underlying alveolar bone remodeling. Even though OPN is a well-known chemotactant of osteoclast precursors *in vitro*, OPN-deficiency did not affect the number of osteoclasts nor delay the tooth movement *in vivo*. On the contrary, tooth movement within the alveolar socket was significantly increased ($p<0.05$) and the tooth was protected from severe root resorption, with significantly less odontoclasts ($p<0.05$) in the OPN-deficient mice. Because OPN was also shown to regulate osteoblastic bone formation in calvaria to mechanical stress, we have also investigated bone formation during mechanical stress-induced tooth movement in the alveolar bone by using calcein/xylenol orange triple labeling. As the tooth moved within the alveolar socket, new bone apposition was detectable in the distal tension side in both WT and OPN-deficient mice, while the unloaded internal control did not. Mineral apposition rate (MAR) and bone formation rate (BFR) was significantly increased ($p<0.05$) in the OPN-deficient mice, suggesting increased movement to mechanical stress was in part due to increased bone apposition. We further investigated the mineral contents using energy dispersive spectrometer (EDS) attached to scanning electron microscope (SEM), however the basal level of Ca/P in tooth, alveolar bone, and periodontal ligament was similar in both group.

During clinical orthodontic treatment and in case of traumatic occlusion, root resorption is one of the most common and serious complications, because unlike bone, tooth cannot undergo remodeling and recover once it is severely destroyed. Since our data shows OPN deficiency to protect tooth from root resorption without disturbing the movement itself and to even increases bone formation to mechanical stress, regulation of OPN may be a way to secure smoother tooth movement *in vivo*.

Functional Modulation of LRP5-Wnt-Dkk1 Activity by Various Mutations in LRP5 Beta-Propeller1. B. M. Bhat[1], K. M. Allen*[2], J. Graham*[3], W. Liu*[3], A. Morales*[2], A. Anisowicz*[2], H. Lam*[1], C. McCauley*[1], V. Coleburn*[1], M. Cain*[3], E. Fortier*[3], H. Wang*[2], F. J. Bex[1], P. Yaworsky*[3]. [1]Women's Health and Bone, Wyeth Research, Collegeville, PA, USA, [2]Human Genetics, Genome Therapeutics Corp., Waltham, MA, USA, [3]Genomics, Wyeth Research, Cambridge, MA, USA.

Allelic forms of low-density lipoprotein receptor-related protein 5 (LRP5) have been identified in a spectrum of human bone density traits. A single point mutation (G to T) in the LRP5 gene results in a glycine to valine amino acid change (G171V) that is responsible for an autosomal dominant High Bone Mass (HBM) trait in two independent kindreds. Recently, 6 additional amino acid changes in LRP5 have been associated with increased bone mineral density in several sclerosing bone disorders. Loss of function mutations in LRP5 result in an autosomal recessive disorder of reduced bone mass, osteoporosis pseudoglioma syndrome (OPPG). LRP5 acts as a co-receptor with Frizzled family members to propagate cellular signals upon Wnt protein binding. This signaling can be antagonized by Dickkopf 1 (DKK1), a known LRP5 ligand. In the presence of Wnt, expression of LRP5 or the HBM variant, (LRP5-G171V mutant), induces nuclear translocation of beta-catenin and T cell factor (TCF)-luciferase reporter activity. When DKK1 is introduced, the HBM variant-mediated TCF activity is inhibited to a lesser degree than that with LRP5. Structural analysis of LRP5 revealed that the HBM mutation lies in the first beta-propeller domain. Additional substitutions of G171 to 171K, F, I or Q also resulted in HBM-like activity in the presence of Wnt and DKK1. This indicates the importance of this position to LRP5 receptor function. In order to determine if other amino acid changes might similarly affect function, we modeled the effect of the HBM mutation within beta-propeller1. Interestingly, mutations A65V, A214V and M282V but not E128V and G199V resulted in an HBM–like TCF-activity. We also simulated the G171V mutation in the other beta-propellers of LRP5, as well as LRP6. These substitutions all function as the wild type receptor. In conclusion, by mutation analysis and in vitro Wnt-Dkk1-TCF-functional studies, we have identified other mutations in beta-propeller1 that result in HBM-like properties. Interestingly, all the mutations associated with increased bone density lie in the first beta-propeller. Structural analysis of the LRP5 family member LDLR suggests that this first beta-propeller domain interacts with the ligand binding domains. Therefore, further analysis of additional mutations in the molecule may lead to a better understanding of the function of LRP5, and its interaction with Wnts and Dkks.

The Osteoblast Homeoprotein Msx2 Promotes Osteogenic Differentiation of Aortic Myofibroblasts. S. Cheng, J. Shao, N. Charlton-Kachigian*, D. A. Towler. Div. of Bone and Mineral Diseases, Dept. of Int. Med, Washington University School of Medicine, St. Louis, MO, USA.

Calcific vasculopathy is prevalent in diabetes, contributing to cardiovascular mortality. In a murine model of type II diabetes, diabetogenic diets heterotopically activate an aortic osteogenic gene regulatory program that includes expression of the bone morphogen BMP2 and its genomic target Msx2 in aortic adventitial myofibroblasts. To evaluate the roles of BMP2 and Msx2 signaling in aortic calcification, we studied effects of BMP2 and Msx2 on primary aortic adventitial myofibroblasts. These myofibroblasts express vascular smooth muscle cell (VSMC) markers, and respond to BMP2 by upregulating Msx2 mRNA accumulation and enhancing osteogenic differentiation. Transduction of primary aortic myofibroblasts with a retrovirus expressing Msx2 also promotes osteogenic differentiation. Expression of osteoblast-specific differentiation factor osterix is upregulated 10-fold by Msx2, and mRNA level for the early osteoblast phenotypic marker alkaline phosphatase (ALP) increases >50-fold. ALP enzyme activity is also stimulated, and mineralized matrix nodule formation is enhanced 30-fold by Msx2. Whereas osteopontin and Runx2 gene expression is unchanged by Msx2, SM22α and VSMC α-actin are stimulated 3-4 fold. In contrast, PPARγ expression is drastically down regulated by Msx2 to 5% of the control level. Msx2 actions were further studied in the C3H10T1/2 model of mural mesenchymal lineage allocation. As in primary aortic myofibroblasts, Msx2 enhances osteogenic differentiation of C3H10T1/2 cells. Adipogenesis – revealed by lipid accumulation and expression of PPARγ and adipsin – is completely inhibited by Msx2 (confirmed in 3T3-L1 preadipocytes). While Msx2 activation of early osteogenesis is cell-autonomous, inhibition of adipogenesis occurs in part via a secreted adipostatic activity. In conclusion, Msx2 regulates lineage allocation of aortic myofibroblasts. Migratory adventitial myofibroblasts capable of adipogenic and osteogenic differentiation can be diverted to the mineralizing osteogenic lineage by Msx2, and thus contribute to the medial and neointimal calcification of diabetes.

Osteoblast Gene Transcription from Connexin-Response Elements (CxREs) is Regulated by the PKC/Raf/MEK/ERK Pathway. J. P. Stains, R. Civitelli. Bone and Mineral Diseases, Washington University, St. Louis, MO, USA.

We have previously demonstrated that recessive (gene deletion) or dominant (connexin45 overexpression) disruption of connexin43 (Cx43) function results in osteoblast dysfunction and abnormal expression of osteoblast genes, including downregulation of osteocalcin and type I collagen transcription. Using ROS17/2.8 cells, which are highly coupled by Cx43, and ROS/Cx45 cells, where gap junctional communication is altered by

Cx45 overexpression, we have identified transcription elements in the osteocalcin and collagen (I)α1 proximal promoters which sense changes in gap junctional communication. These connexin-response elements (CxREs) provide gap junction sensitivity to heterologous promoters, and in non-osteoblastic cell contexts as well. Transcription via CxREs is regulated by recruitment of the ubiquitous transactivator Sp1 and the repressor Sp3. By chromatin immunoprecipitation, we demonstrate that perturbation of gap junctional communication by overexpression of Cx45 in an endogenous Cx43 background results in transcriptional repression consequent to increased Sp3 bound to the CxRE, while in a highly coupled environment (where Cx43 prevails) Sp1 is preferentially bound to the CxRE. We find that gap junctional communication alters Sp1/Sp3 recruitment via post-translational effects. Immunoprecipitations reveal decreased serine/threonine phosphorylation of Sp1 in Cx45 overexpressing cells, while acetylation of Sp3 is increased; both modifications affect Sp1/Sp3 binding affinity and transcriptional activity in a fashion compatible with transcriptional downregulation via CxRE. Since such post-translational modifications are modulated by MAPK activities, we used anti-phospho-PKC, -Raf and -ERK antibodies to show that PKC/Raf/ERK activation is reduced in a communication-deficient background. Furthermore, using luciferase reporter assays we show that inhibition of the Raf/MEK/ERK signal pathway with the MEK inhibitor U0126 results in markedly reduced transcription from the CxRE, whereas overexpression of a constitutively active MEK1, or treatment with PMA, an activator of the PKC pathway, increase CxRE-driven transcription. In contrast, p38 MAP Kinase and JNK/SAPK pathways do not regulate transcription from CxREs. Thus, gap junctional communication controls gene transcription by specifically modulating the PKC/Raf/MEK/ERK signal transduction cascade, which controls the activity of CxRE-binding transcription complexes. These findings offer a molecular mechanism by which intercellular communication via gap junctions modulate the response of bone forming cells to hormonal or local signals.

Regulation of the Anabolic Action of Calcineurin. L. Sun[1], H. C. Blair[2], B. S. Moonga[1], P. J. R. Bevis*[1], E. Abe[1], S. Epstein[1], M. Zaidi[1]. [1]Medicine, Mount Sinai School of Medicine and the Bronx VA GRECC, New York, NY, USA, [2]Pathology, University of Pittsburgh and Pittsburgh VA Medical Center, Pittsburgh, PA, USA.

Calcineurin, a ubiquitous calcium/calmodulin activated phosphatase, is inhibited by the commonly used immunosuppressants, cyclosporine A and FK506, both of which cause dramatic bone loss. Deletion of the calcineurin Aα gene thus resulted in severe osteoporosis arising mainly from a ~40% reduction in bone formation evident in tetracycline double labeling studies. Over-expression of calcineuirn Aα, in contrast, stimulated osteoblast differentiation. Profound, up to ~300-fold increases in osteoblast differentiation markers, namely, Runx-2, osteocalcin, bone sialoprotein, and alkaline phosphatase, were noted upon transduction of MC3T3.E1 osteoblasts with a calcineurin Aα-TAT fusion protein. All three isoforms of calcineurin A, α, β and γ, as well as those of calcineurin B, B1 and B2, were expressed in both primary osteoblasts and MC3T3.E1 cells. Traditionally, calcineurin dephosphorylates and *permits* the nuclear translocation of the transcription factor, NFATc. Here, we establish a new pathway for calcineurin action – its dephosphorylation of IκBβ, the inhibitory subunit of NFκB family of transcription factors. Dephosphorylated IκBβ binds to and *prevents* the nuclear translocation of p65, p50, and c-Rel. Through the use of complementary techniques – co-immunoprecipitation, chemical cross-linking, and phosphatase assays – we have demonstrated that calcineurin Aα binds to and dephosphorylates IκBβ, and that both effects are inhibited by NFATc. To understand the mechanism of calcineurin Aα-IκBβ binding, we used (a) peptide RII that selectively inhibits calcineurin's phosphatase activity by acting on its 18 amino acid-long, protein kinase domain, and (b) several IκBβ mutants either lacking the PEST domain (ΔPEST) or containing single amino acid substitutions within it (S313A and S315A). Peptide RII potently inhibited the calcineurin-induced dephosphorylation of IκBβ. Likewise, the ΔPEST and S313A mutants, but not the S315A mutant, blocked calcineurin-IκBβ binding and enhanced the nuclear translocation of the NFκB heterodimers, p65, p50 and c-Rel. Finally, whereas transfection with calcineurin Aα up-regulated the expression of ryanodine receptors, a family of Ca^{2+} release channels, the IκBβ mutant, S313A, when co-transfected with calcineurin Aα, blocked this effect. Together, the evidence appears compelling that calcineurin binds to, and dephosphorylates IκBβ, as an alternate substrate, *via* its PEST domain (Ser313). This selective dephosphorylation of IκBβ might, in fact, regulate the extent of calcineurin's novel anabolic action.

MSG-Sensitive Hypothalamic Neurons Contribute to the Control of Bone Mass. F. Elefteriou*[1], S. Takeda[1], X. Liu*[1], D. Armstrong*[2], G. Karsenty[1]. [1]Molecular and Human Genetics and Bone Disease Program of Texas, Baylor College of Medicine, Houston, TX, USA, [2]Pathology, Baylor College of Medicine, Houston, TX, USA.

Using chemical lesioning we previously identified hypothalamic neurons that are required for leptin antiosteogenic function. In the course of these studies we observed that destruction of neurons sensitive to monosodium glutamate (MSG) in arcuate nuclei did not affect bone mass. However MSG treatment leads to hypogonadism, a condition inducing bone loss. Therefore the normal bone mass of MSG-treated mice suggested that MSG-sensitive neurons may be implicated in the control of bone mass. To test this hypothesis we assessed bone resorption and bone formation parameters in MSG-treated mice. We show here that MSG-treated mice display the expected increase in bone resorption and that their normal bone mass is due to a concomitant increase in bone formation. Correction of MSG-induced hypogonadism by physiological doses of estradiol corrected the abnormal bone resorptive activity in MSG-treated mice and uncovered their high bone mass phenotype. Since Neuropeptide-Y (NPY) is highly expressed in MSG-sensitive neurons and since Y2-receptor deficient mice display a high bone mass phenotype, we tested whether NPY regulates bone formation. Surprisingly, NPY-deficient mice had a normal bone mass. This study reveals that distinct populations of hypothalamic neurons are required for the control of bone mass and demonstrates that MSG-sensitive neurons control bone formation in a leptin-independent manner. It also indicates that NPY deficiency does not affect bone mass.

Evidence that the Mechanism Whereby Insulin-Like Growth Factor Binding Protein (IGFBP)-6 Markedly Inhibits Osteoblast Differentiation Is Through Sequestration of an Activator of Osteoblast Differentiation, the LIM Mineralization Protein-1 (LMP-1). D. D. Strong, T. A. Linkhart, Y. Gunn*, R. Kim*, J. Rung-Aroon*, S. Mohan, D. J. Baylink, Y. Amaar. Musculoskeletal Disease Center, Jerry L. Pettis VA Medical Center, Loma Linda, CA, USA.

Recent *in vitro* studies to overexpress IGFBP-6 (BP-6) in human osteoblasts, or to suppress BP-6 expression with antisense RNA have shown that this IGFBP strongly inhibits osteoblast differentiation (ie. it can completely halt osteoblast differentiation and it does so through an IGF-independent action). BP-6 is located primarily in the nucleus by virtue of its novel nuclear localization sequence. Thus we sought to test the hypothesis that BP-6 mediates its actions through inhibitory interactions with transcription factors or co-activator proteins that regulate osteoblast marker gene expression. To test this hypothesis, we utilized a yeast two-hybrid screen to identify intracellular proteins that bound to BP-6. BP-6 fused to the Gal-4 DNA binding domain was expressed in a yeast 2-hybrid bait vector and used to screen a U2 human osteosarcoma cDNA yeast library. BP-6 strongly interacted with a protein encoded by a cDNA fragment containing the LIM domain regions of LMP-1. Most importantly, LMP-1 was shown previously to induce osteoblast differentiation *in vitro* and induce bone formation *in vivo* (Boden et al., 1998). Northern blot analysis indicated that LMP-1 was expressed in human osteoblasts suggesting the hypothesis that BP-6 inhibits osteoblast differentiation by blocking the differentiation actions of LMP-1. Co-immunoprecipitation studies with lysates from SaOS-2 cells overexpressing HA-tagged-LMP-1 with recombinant BP-6 protein confirmed that BP-6 bound to the LMP-1 in mammalian cells. Co-immunoprecipitation studies also revealed that LMP-1 interacted strongly with BP-6 but not with IGFBP-5, demonstrating BP-6 specificity for this inhibitory interaction. When BP-6-red-fluorescent and LMP-1-green fluorescent fusion protein expression vectors were transiently co-transfected into osteoblasts, LMP-1 protein and BP-6 co-localized in the nucleus. In conclusion, the present findings that LMP-1 strongly binds to BP-6, is a strong inhibitor of osteoblast differentiation and past findings that LMP-1 is a positive regulator of osteoblast differentiation is consistent with the hypothesis that BP-6 sequesters LMP-1 to inhibit osteoblast differentiation.

Different Roles of Integrin Subunits to Stimulate Proliferation and Differentiation by Mechanical Stress in Osteoblasts. P. Müller*[1], C. Schmidt*[1], B. Nebe*[1], J. Rychly[2]. [1]Department of Internal Medicine, University of Rostock, Rostock, Germany, [2]Experimental Research Center, University of Rostock, Rostock, Germany.

To evaluate the role of integrin receptors in the mechanisms that are involved in the regulation of osteoblast physiology by mechanical stress we used a magnetic drag force device to apply physical forces on defined integrin receptors without stretching the whole cell. Magnetic beads were coated with different antibodies to integrin receptors and attached to the receptors on the dorsal surface of adherent cells. Forces on the receptors were directed in parallel to the cell surface. Application of physical forces to the β1 integrin subunit in cells of the osteoblastic cell line MG-63 induced an enhanced expression of collagen I as well as of proteins involved in the cell cycle regulation. The effects were increased compared with only clustering the receptor by incubation with β1 integrin antibody coated beads. This indicates that β1 integrin mediates mechanical stress to induce both differentiation and proliferation and the effects depend on the force strength. To see, whether different α integrin subunits play a specific role to mediate mechanical stress we applied physical forces to α2, α3 and α5 integrin subunits which were expressed in similar densities on the cell surface. Forces applied to all three α subunits induced an increased expression of cyclin D1, cyclin E and induced the phosphorylation of Rb protein. This indicated that the three integrins which we tested transduced physical forces to stimulate cell proliferation. However, application of forces to these integrin subunits revealed that only α5 but not α2 and α3 induced an enhanced expression of collagen I. Further analyses of signalling events demonstrated that only stress to integrin α5 provoked an activation of MAP-kinases and this was required for collagen expression due to mechanical stress. In addition, we found that only stress on integrin α5 induced the activation of the adaptor protein Shc. In contrast, forces to all three α integrin subunits activated the focal adhesion kinase (FAK) and induced the cytoskeletal immobilization of this protein. In conclusion, we found differences in the function of integrins to mediate mechanical stress to stimulate cell proliferation and collagen I expression. We suggest that collagen expression due to mechanical forces is mediated by α5 and requires the Shc pathway, whereas for proliferation various α integrin subunits may function as mechanotransducers which involves the activation of FAK.

Caspase-3 Deficiency Causes Osteopenia by Attenuating Differentiation of Osteoblast Progenitors. M. Miura*[1], X. Chen[1], S. Gronthos[2], Y. Bi*[1], M. R. Allen*[3], S. Lakhani*[4], R. Flavell*[4], X. Feng*[5], P. G. Robey[1], M. Young[1], S. Shi*[1]. [1]Csdb, NIDCR, Bethesda, MD, USA, [2]Institute of Medical and Veterinary Science, South Australia, Australia, [3]3Texas A&M University, Galveston, TX, USA, [4]Yale University School of Medicine, New Haven, CT, USA, [5]Baylor College of Medicine, Houston, TX, USA.

Caspase-3 is a critical enzyme for apoptosis and cell survival. Apoptosis has important biological roles in the development, homeostasis of cell population, and in pathogenesis. Caspase-3 deficient (CPP32-/-) mice survive for 3-5 weeks and have various phenotypes including decreased apoptosis of neural cells and peripheral T cells and severely stunted growth. However, whether caspase-3 deficiency results in any bone defect is unclear. In this study, we tested the hypothesis that caspase-3 plays an important role in maintaining integrity of bone and found that both homozygous (CPP32-/-) and heterozygous (CPP32+/-) mice have reduced bone density. To determine the cellular basis for the reduced bone mass we examined pre-osteoblasts isolated from the calvarias of newborn normal and mutant mice and tested the relative levels of proliferation, differentiation and cell survival. Our results showed that caspase-3 deficient cells had increased proliferation rates, but decreased capacity to form a mineralized matrix. Examination of the intracellular signals elicited in response to TGF-beta revealed that caspase-3 deficient cells exhibited an increased expression of phospho-Smad2 and P21 as well as decreased expression of CDC2 and CDK4. Furthermore, caspase-3 deficient cells showed increased cell senescence and attenuated TGF-beta-regulated Cbfa1 expression. Inhibition of Smad2 expression by siRNA transfection was able to partially rescue TGF-beta-mediated down-regulation of CDK4 and CDC2, indicating that the Smad2 pathway is responsible for the TGF-beta-mediated cascade in caspase-3 deficient cells. In contrast, BMP2-induced phospho-Smad1 signaling was not impaired in pre-osteoblasts of CPP32-/- or CPP32+/- mice. Bone marrow stromal stem cells (BMSSCs), another population of osteogenic progenitors, showed similar results in terms of proliferation, differentiation and response to the TGF-beta induction. Moreover, the reduced bone density in caspase-3 deficient mice was not associated with an elevated osteoclast activity. Taken together, these findings demonstrate for the first time that caspase-3 is crucial for the proliferation and differentiation of osteogenic progenitors. Deficiency of caspase-3 may lead to osteopenia by attenuating differentiation of osteogenic progenitors through activation of the TGF-beta/Smad pathway.

c-Cbl-PI3-kinase Interaction Is Required for M-CSF-induced Osteoclast Migration and for Bone Resorption. A. Sanjay[1], T. Miyazaki[1], G. DeBlasi[1], K. Henriksen*[2], M. Ensig*[2], W. C. Horne[1], R. Baron[1]. [1]Orhtopaedics, Yale University School of Medicine, New Haven, CT, USA, [2]Nordic Biosciences, Copenhagen, Denmark.

The non-receptor tyrosine kinase Src and the proto-oncogene product c-Cbl, Src's major substrate in osteoclasts (OCs), are required for osteoclast motility and bone resorption. Phosphatidylinositol 3' kinase (PI3K), which is also necessary for normal OC migration and function, associates with c-Cbl. Both the SH2 and SH3 domains of the PI3K p85 regulatory subunit have been implicated in mediating the c-Cbl-PI3K interaction. c-Cbl's tyrosine 731 occurs in a sequence (YEAM) that is consensus motif for phosphorylation by Src and, when phosphorylated, for binding the SH2 domain of p85. In the present study, we show that mutating tyrosine 731 to phenylalanine, inhibiting Src kinase activity, by expressing a dominant-negative Src mutant or mutating the Src binding site on c-Cbl blocked the binding of PI3K to c-Cbl. Thus, the Cbl-PI3K association appears to require both the binding of Src to c-Cbl and the subsequent phosphorylation of tyrosine 731 of c-Cbl by Src. We then investigated the functional role of the c-Cbl-PI3K interaction in M-CSF-induced OC migration and in bone resorption, using c-Cbl-/- osteoclast-like cells (OCLs) reconstituted with various c-Cbl mutants. M-CSF (50 ng/ml), induced a 60% increase in migration of WT OCLs in a Boyden chamber migration assay. In contrast the migration of c-Cbl-/- OCLs, intrisically low, was not increased by the presence of M-CSF. As expected, expression of WT c-Cbl in c-Cbl-/- OCLs with the adenovirus system rescued the phenotype and M-CSF induced a 65% increase in migration, comparable to the response of WT OCLs to M-CSF. In contrast, over-expression of a c-Cbl molecule in which the tyrosine 731 is mutated, CblY731F, failed to rescue the M-CSF-induced motility of the c-Cbl-/- OCLs, demonstrating that the Src-dependent phosphorylation of Y731 and the recruitment of PI3-kinase by c-Cbl are required for osteoclast migration in response to M-CSF. Aws a consequence of impaired migration, the pit forming capability of Cbl Y731F-expressing-OCLs was also reduced to 30% of control. Taken together these results indicate that the Src kinase-dependent interaction of c-Cbl with PI3K is important for OC migration and bone resorption.

Regulation of Osteoclast Apoptosis and Bone-Resorbing Activity by Ubiqutination of Proapoptotic BH3-only Bcl-2 Family Member Bim. T. Akiyama[1], P. Bouillet*[2], U. Chung[1], A. Fukuda[1], H. Oda*[1], K. Nakamura*[1], A. Strasser*[2], S. Tanaka[1]. [1]Dept. of Orthopaedic Surgery, University of Tokyo, Tokyo, Japan, [2]The Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia.

Osteoclasts (OCs) are terminally differentiated cells with a short life span, and undergo rapid apoptosis without trophic factors such as macrophage colony-stimulating factor (M-CSF). There is accumulating evidence that pro-apoptotic and anti-apoptotic Bcl-2 family proteins play essential roles in regulating apoptosis, and we found that OC apoptosis was associated with a rapid and sustained increase in the pro-apoptotic BH3-only Bcl-2 family member Bim. This increase in Bim level was due to the reduced level of ubiquitination of Bim, and M-CSF treatment dramatically enhanced its ubiquitination. Overexpression of a degradation-resistant lysine-free Bim mutant in OCs completely abrogated the anti-apoptotic effect of M-CSF, while wild type Bim did not show such effects, suggesting that ubiquitination-dependent regulation of Bim levels is critical for regulating OC apoptosis.
In an attempt to clarify the role of Bim in the skeletal homeostasis, we analyzed the skeletal tissues of *bim-/-* mice. Histological examination and X-ray analysis revealed that *bim-/-* mice had mild osteopetrosis although the number of OCs was increased. Histomorphometry of *bim-/-* mice demonstrated that they showed low levels of both bone formation and bone resorption markers, leading to abnormally low bone turnover. In situ hybridization showed clear expression of *bim* gene in OCs but not in osteoblasts or chondrocytes in normal mice bone, indicating that the osteopetrosis of *bim-/-* mice is primarily caused by the abnormal function of OCs. Consistent with this in vivo observation, OCs differentiated from bone marrow cells of *bim-/-* animals showed significantly reduced bone-resorbing activity compared to *bim+/+* OCs in spite of their marked prolongation of survival, and adenovirus-mediated Bim introduction not only induced apoptosis of *bim-/-* OCs, but also normalized their bone-resorbing activity. These results show that Bim is regulated in a ubiquitination-dependent manner in OCs, and works as a key regulator of activation of OCs as well as their apoptosis.

Role of IKK Alpha in RANK-Mediated Osteoclastogenesis. M. L. Chaisson*, M. E. Tometsko*, A. P. Armstrong*, D. G. Branstetter*, W. C. Dougall. Cancer Biology, Amgen, Seattle, WA, USA.

Signaling through RANK is required for osteoclast, mammary gland, and lymph node development. However, the extent to which RANK utilizes similar signaling pathways in these different tissues remains to be determined. For instance, it has recently been shown that mice expressing a kinase inactive form of IκB kinase α (IKKα) have similar defects in mammary gland and lymph node development as RANK-null mice, but no apparent osteopetrotic phenotype. To further analyze the role of IKKα in RANK signaling in osteoclasts, we obtained fetal liver cells containing hematopoetic precursors from IKKα-null and wild-type E18.5 embryos. The fetal liver cells were cultured with CSF-1 and RANK ligand (RANKL) for 6 days and stained for TRAP activity. In wild-type fetal liver cells, this treatment led to formation of large, multinucleated $TRAP^+$ osteoclasts. However, in IKKα-null fetal liver cells, only small, primarily single-nucleated $TRAP^+$ cells were observed. TRAP expression, as assessed by quantitative RT-PCR, was 10-fold less in IKKα-null fetal liver cells treated with CSF+RANKL compared to wild-type cells. Similar decreases were observed for other osteoclast markers, including β3-integrin, MMP-9, and calcitonin receptor. Additionally, we observed a requirement for IKKα in RANK-mediated regulation of several chemokine genes. RANK upregulated expression of SDF-1 and MIP-1γ in wild type cells, and down-regulated expression of MIP-1β, MCP-1, and MIP-1α, effects that were dramatically decreased in IKKα-null cells. These effects were not due to a lack of osteoclast precursor potential in IKKα-null cells, as similar numbers of cells expressing macrophage markers F4/80 and CD11b were observed in wild-type and knockout fetal liver cultures after 1 week growth in CSF-1. As IKKα is a known regulator of NF-κB, we next analyzed the contribution of IKKα to RANK-mediated NF-κB activation in fetal liver cells grown in CSF-1. In both wild-type and IKKα-null cells, RANKL treatment caused complete degradation of IκBα by 15 minutes, followed by re-synthesis at 30 minutes, suggesting that osteoclastogenic defects observed in IKKα-null cells were not due to lack of classical NF-κB activation. Additionally, RANKL-treatment of IKKα-null cells resulted in normal phosphorylation of p38, JNK, and ERK, although a slight decrease in phospho-AKT was seen compared to wild-type. Although classical NF-κB activity was not impaired in IKKα-null cells, we did observe a 4-fold decrease in RANKL-mediated upregulation of p100 in IKKα-null cells compared to wild type. These data indicate that IKKα is required for RANK-mediated osteoclastogenesis *in vitro*, likely through activation of a non-canonical NF-κB pathway.

A New Mechanism for Osteoclast and Myeloma Cell Elimination. H. Das*, J. F. Bukowski*. Medicine, Harvard Medical School, Boston, MA, USA.

Mechanisms regulating osteoclast homoestasis in health and disease are not fully understood. Balance between bone formation and bone resorption is essential to maintaining healthy bone. Nitrogen-containing bisphosphonates (N-bisphosphonates) are directly toxic to osteoclasts, and act by blocking farnesyl diphosphate synthase, a key enzyme in the mevalonate pathway, thereby inhibiting prenylation of proteins important in intracellular trafficking. However, complete inhibition, and death of osteoclasts can take up to 72 hours. Gamma delta T lymphocytes comprise 2 to 5% of T lymphocytes in human blood and bone marrow. The predominant subset of these lymphocytes co-express V gamma 2 and V delta 2 T cell receptor chains on their cell surface, which uniformly recognize N-bisphosphonates. Engagement of this receptor by N-bisphosphonates triggers the secretion of large amounts of interferon gamma, a cytokine that inhibits osteoclast activity and inhibits tumor cell growth. These T cells can kill myeloma cells that have bound the N-bisphosphonate risedronate to their cell surface. Gamma delta T cells kill osteoclasts within 3 hours after contact, and pretreatment of osteoclasts with risedronate enhances this efficiency of killing by 3-fold.
Incubation of osteoclasts or monocytes on plastic plates coated with hydroxyapatite, then pretreated with risedronate and washed extensively, also renders these cells 3-fold more sensitive to killing by gamma delta T cells. Since monocytes do not resorb bone and do not

form pits in these hydroxyapatite plates as do osteoclasts, the data strongly suggest that bone resorption is not necessary for risedronate to release from hydroxyapatite and bind to cell surfaces in sufficient quantity to be detected by gamma delta T cells. In addition, direct exposure of osteoclasts, monocytes, or myeloma cells to soluble risedronate followed by extensive washing renders these cells susceptible to killing by gamma delta T cells.
Thus, a function of gamma delta T cells is to kill osteoclasts and myeloma cells. Exposure to N-bisphosphonates enhances the susceptibility of osteoclasts and myeloma cells to killing. These data suggest that N-bisphosphonates bound to bone can release from bone, and bind to osteoclasts or myeloma cells, rendering them susceptible to specific recognition and elimination by gamma delta T cells. This may be a mechanism whereby N-bisphosphonates inhibit bone resorption and decrease metastases to bone.

RGS12 Is Essential for Signaling by RANKL for Terminal Differentiation of Osteoclasts via Ca^{2+} Oscillation Pathway. S. Yang*, W. Chen*, Y. Abe*, Y. P. Li. The Forsyth Institute, Harvard School of Dental Medicine, Boston, MA, USA.

RANKL is essential for terminal differentiation of monocytes/macrophages into osteoclasts. Despite recent progresses in studies of the RANKL signaling mechanism, little is known about how RANKL specifically induces terminal differentiation of osteoclasts. To gain insight into RANKL signaling in differentiation of osteoclasts, we employed a genome-wide screening approach to identify genes that are specifically or predominately expressed in osteoclasts, using GeneChip. In particular, we focused on signaling factors in this screening. The most notable gene from the screening was RGS12. The expression of RGS12 in osteoclasts was found to be18 fold higher than that in stromal cell. Northern Blotting analysis confirmed the result obtained from Microarray assay. Immunocytochemistry using RGS12-specific antibodies showed that RANKL induced RGS12 expression in RAW264.7, monocyte progenitor cells. To demonstrate the importance of the RGS12 function in osteoclast differentiation, we used RNA interference (RNAi) technology to silence (knockdown) RGS12 expression in RAW264.7cells. Using a mammalian expression vector for small interfering RNA (siRNA), pAVU6+27 siRNA expression vector, we constructed mouse RGS12 siRNA vectors and introduced these into RAW264.7cells. The stable clones were tested for RGS12 expression by Immunostaining. In contrast to wild-type cells, those transfected with RGS12 siRNA contained undetectable RGS12 protein under conditions of RANKL induction. These RGS12 knockdown cells failed to differentiate into tartrate-resistant acid phosphatase positive multinucleated osteoclast like-cells. It was previously reported that RGS12 is a multifunctional protein capable of direct interactions through its PTB domain with the tyrosine-phosphorylated calcium channel. A recent study showed that RANKL induces terminal differentiation of monocyte/macrophage into osteoclasts by evoking Ca^{2+} oscillations via TRAF6 and c-Fos signaling pathways. These pervious works in other Laboratories led us to investigate RGS12 role in Ca^{2+} oscillations induced RANKL in osteoclast differentiation. Our data showed that strong Ca^{2+} oscillations occurred in RAW264.7 cells induced by RANKL for 24 hours. In contrast to RAW264.7 control cells, Ca^{2+} oscillations in RAW264.7 cells transfected with RGS12 siRNA-c6, which displayed a low level of RGS12 expression under RANKL induction, were markedly reduced. Furthermore, RAW264.7 cells transfected with RGS12 siRNA-c6 failed to form extracellualr acidification. Our results thus reveal that RGS12 is essential for terminal differentiation of osteoclasts induced by RANKL via Ca^{2+} oscillation pathway.

Mechanism of Action of TSH (Thyrotropin) on Bone. E. Abe[1], W. Yu[1], Y. Li[2], R. Marians*[1], T. Ando*[1], H. C. Blair[2], T. F. Davies*[1], M. Zaidi[1]. [1]Medicine, Mount Sinai School of Medicine, and the Bronx VA GRECC, New York, NY, USA, [2]Pathology, University of Pittsburgh and Pittsburgh VA Medical Center, Pittsburgh, PA, USA.

Deletion of the TSH receptor in mice resulted in a dramatic skeletal phenotype characterized by severe osteoporosis and focal sclerosis. Ex vivo bone marrow cultures showed enhancements in both osteoclast and osteoblast formation. Real time RT-PCR and FACS analysis revealed presence of TSH receptors on both osteoclast and osteoblast precursors and their concentration was increased during cell differentiation. Activation of these receptors by recombinant TSH resulted in a marked inhibition of the formation of mature cells. Together, the data point towards a primary role for TSH in the control of bone remodeling. Here, we have explored the molecular mechanism underlying the inhibition of osteoclast and osteoblast formation by TSH. For studies on osteoclast formation, we used TSH receptor-positive RAW-C3 cells, a sub-clone of RAW264.7 cells, which undergoes RANK-L-induced osteoclast differentiation. TSH inhibited both osteoclastogenesis and osteoclast survival in a concentration-dependent manner. TSH also attenuated the expression of several markers of osteoclast differentiation, namely cathepsin K, β_3 integrin, TRAP, and calcitonin receptor. Finally, TSH inhibited RANK-L-induced phosphorylation of Janus N-terminal kinase (JNK) within 15 minutes. This was accompanied by an equally impressive inhibition of the nuclear translocation of the transcription factor, c-jun. The other RANK-L-induced pathways involved in osteoclast formation and survival, namely, Akt, p38, and Erk1/2 remained unaffected, as did the nuclear translocation of c-fos. The anti-osteoclastogenic and pro-apoptotic actions of TSH thus appear to be exerted through reduced JNK phosphorylation, diminished c-jun nuclear translocation, and likely, the attenuated transcription of genes whose promoters have AP-1-binding sites. We next explored the mechanism of TSH-induced reduction in osteoblast differentiation using mouse calvarial osteoblasts. TSHR expression in the cells was confirmed by real time RT-PCR. TSH reduced the expression of the osteoblast differentiation markers alkaline phosphatase, bone sialoprotein and osteocalcin. It also potently inhibited the expression of osterix as well as Runx-2, a critical pro-differentiation transcription factors, whilst the expression of LRP-5 remained unchanged. Collectively, therefore, we have identified TSH as a powerful negative regulator of bone remodeling that inhibits osteoclast and osteoblast formation using distinct molecular pathways.

Identification of Three RANK Cytoplasmic Motifs Mediating Osteoclast Differentiation. W. Liu*, D. Xu, P. Patel*, H. Tsay*, X. Feng. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

RANKL and its receptor RANK play a pivotal role in osteoclast (OC) differentiation and function. As a member of the TNF receptor superfamily, RANK may mediate intracellular signaling by recruiting signaling molecules such as TRAFs. Several groups previously attempted to characterize the RANK domains that interact with various TRAFs. Collectively, these groups showed that distinct RANK cytoplasmic regions interact with TRAFs 1, 2, 3, 5 and 6 in transformed cells in the context of over-expression and/or in *in vitro* binding assays. However, the data from these studies are conflicting, undermining the biological significance of these data. Moreover, specific RANK cytoplasmic motifs mediating OC differentiation and function have not been functionally identified. We have previously developed a chimeric receptor approach that permits us to carry out a detailed structure/function study of the RANK cytoplasmic domain in OC differentiation and function using authentic OCs. RANK cytoplasmic domain contains six putative TRAF-binding motifs (PTM): PTM1, ILLMTREE at a.a.286-293; PTM2, PSQPS at a.a.349-353; PTM3, PFQEP at a.a.369-373; PTM4, VYVSQTSQE at a.a.537-545; PTM5, PVQEET at a.a.559-564; PTM6, PVQEQG at a.a.604-609. Using this chimeric receptor approach, we showed that mutation of only one PTMs in RANK cytoplasmic domain had no effect on the RANK's ability to mediate OC differentiation, suggesting that some of the PTMs may be functionally redundant in regulating OC differentiation. To test this possibility, we constructed a mutant in which all six PTMs are mutated. Osteoclastogenesis assays with this mutant showed that this mutant failed to mediate OC formation, confirming that some of the PTMs are indeed functionally redundant. To elucidate which PTM is functional, we further engineered six more mutants: W1, W2, W3, W4, W5 and W6. In each of these 6 mutants only one PTM is NOT mutated. Specifically, PTM1 is not mutated in W1 while PTM2 is not mutated in W2, and so forth. These mutants would allow us to determine which PTM alone is able to induce OC formation in osteolastogenesis assays. Our data showed that W3, W5 and W6 are capable of mediating OC formation while W1, W2 and W4 failed to do so, revealing that PTM3, PTM5 and PTM6 are functional RANK cytoplasmic motifs that are capable of inducing OC formation. Significantly, our work presented here represents the first study establishing a functional link between specific RANK cytoplasmic motifs and a physiologically relevant readout: OC formation. More importantly, the identification of these functional RANK motifs has laid the foundation for delineating the downstream signaling pathways leading to OC formation in a more physiologically relevant manner.

Rescue of the Phenotype of RANKL-Deficient Mice by Hepatic Expression of Soluble RANKL Transgene. H. Yasuda[1], A. Minamida*[1], J. M. Penninger*[2], Y. Iwakura*[1]. [1]Institute of Medical Science, University of Tokyo, Tokyo, Japan, [2]Princess Margaret Hospital, University Health Network, Toronto, ON, Canada.

RANKL, a member of the TNF family, is a key regulator of osteoclastogenesis, lymphocyte development and lymph node (LN) organogenesis. RANKL is a membrane-bound ligand but its soluble form is released from different type of cells by shedding. RANKL knockout (KO) mice showed severe osteopetrosis, with no osteoclasts, marrow spaces, or tooth eruption, and exhibited profound growth retardation. These mice also showed defects in early differentiation of T and B cells, and lacked all LNs. We previously reported that transgenic (TG) mice overexpressing soluble RANKL (sRANKL) only in the liver after birth showed severe osteoporosis with an increase of osteoclasts. In human increases of serum sRANKL level were reported in patients with rheumatoid arthritis and juvenile Paget's disease, but the physiological and pathological roles of sRANKL are unknown. To understand the bona fide roles of sRANKL, we analyzed the phenotype of KO mice aged 4 to 6 weeks with hepatic expression of sRANKL transgene (hereafter called TG/KO mice). Expression of sRANKL in KO mice rescued osteoclast development entirely in long bones with marrow cavities but failed to restore tooth eruption and growth retardation. Dual-energy X-ray absorptiometry revealed that bone mineral densities of femur and tibia in TG/KO mice were markedly decreased compared with those of TG, KO and wild-type mice. In TG/KO mice the defects in differentiation of T and B cells were partially restored. The expression of sRANKL restored LN organogenesis in KO mice and TG/KO mice developed all LNs examined; e.g. inguinal, axillary, mandibular, and mesentery LNs. It is of interest that the serum sRANKL concentrations in TG/KO mice were variable (0.3 to 50 ng/ml) in individuals. Rescue of osteoclastogenesis and LN organogenesis was observed in all TG/KO mice examined. Surprisingly there were sRANKL concentration thresholds required in restoration of the defects in differentiation of T and B cells in TG/KO mice. The sRANKL concentration in wild-type mice was about 0.1 ng/ml, ranging 0 to 0.2 ng/ml. Rescue of the phenotype of KO mice with the minimal concentration (0.3 ng/ml) of hepatic-expressed sRANKL suggests that sRANKL may play an important role in osteoclastogenesis and LN organogenesis in physiological conditions. Hepatic expression of sRANKL rescued most of the phenotype of KO mice, except for tooth eruption and growth retardation, indicating that the membrane-bound RANKL is not essential for the restorations. In addition, the strict regulation of time- and tissue-specific expression of the RANKL gene may not be important for the functions of RANKL or sRANKL.

Overexpression of a Human *SOST* BMP-antagonist Results in Severe Limb Deformities in Mice. G. G. Loots*[1], M. Kneissel*[2], M. M. Glatt*[2], M. Khokha*[3], R. M. Harland*[3], E. M. Rubin*[4]. [1]Genomics Division, LLNL, Livermore, CA, USA, [2]Bone Metabolism Unit, Novartis Pharma, Basel, Switzerland, [3]Department of Molecular and Cell Biology, University of California Berkeley, Berkeley, CA, USA, [4]DOE, Joint Genome Institute, Walnut Creek, CA, USA.

Sclerosteosis is a generalized progressive bone overgrowth disorder due to the loss of function of the *SOST* gene product sclerostin. Null mutations in the BMP-antagonist *SOST* result in occasional polydactyly and in a substantial progressive increase in bone mass. Accumulation of abnormal bone mass begins in adulthood and affected patients display increased bone formation, while bone resorption is undisturbed. To investigate the physiological function of this BMP antagonist, we generated several lines of transgenic mice carrying a ~160kb human *SOST* BAC. Following the expression pattern of the endogenous murine *SOST* gene, we investigated the expression pattern of the human transgene in several independent lines of transgenic animals. Similar to the murine *SOST* expression, the human *SOST* transcript was robustly expressed in the mineralized bones of fetal, neonatal and adult mice. Transgenic lines overexpressing human *SOST* grew to maturity with normal body size and weight and bone mass. Preliminary results from ongoing ageing studies revealed a small age-related decrease in bone mineral density in the appendicular and axial skeleton compared to non-transgenics from four to six months of age as evaluated by DEXA and pQCT. Further evaluations will show whether this trend will become more pronounced with ageing. When bred to homozygosity, transgenics showed congenital limb defects. The fore and hind limbs of these animals were severely deformed displaying a wide range of fused and missing digits as visualized by autoradiography and microCT. Since limb development is initiated prior to ossification of the skeleton, we examined the expression of the endogenous mouse *SOST* gene and the human transgene in the developing embryo. We found *SOST* to be expressed as early as E9.5dpc, predominantly in the mesenchyme tissue of the developing limb bud. In addition first results from a limited number of animals demonstrated decreased bone mineral density in the tibia of young adult homozygous mice. These initial characterizations suggest that excessive production of *SOST* can cause limb defects and possibly osteoporotic phenotypes and that transgenic mice overexpressing this BMP-antagonist could serve as a useful animal model for studying limb development and potentially bone formation.

Hox Proteins as BMP Downstream Transcription Factors. X. Li*, X. Cao*. Department of Pharmacology, University of Alabama at Birmingham, Birmingham, AL, USA.

BMPs are potent growth factors that induce osteoblast differentiation and bone formation. BMPs transduce their signals into the cell through a family of mediator proteins, Smads. Upon phosphorylation by BMP receptor, R-Smads such as Smad1 interact with Smad4 and translocate into the nucleus where it activates gene transcription and induces osteoblast differentiation. We have reported that Hoxc-8 acts as a transcription repressor. Smad1 interaction with Hoxc-8 dislodges Hoxc-8 from its element, resulting in the induction of gene expression leading to bone cell differentiation. Smad6 interacts with Hoxc-8 as a heterodimer when binding to DNA, and Smad6/Hoxc-8 complex inhibits interaction of Smad1 with Hoxc-8 and Smad1-induced transcription activity. There are 39 members within the Hox gene family arranged into four clusters. Based on the sequence similarity and position on the chromosomes, genes in the four clusters are divided into 13 paralogs. In this study, we systematically examined the potential interactions of Smad1, Smad4 and Smad6 with 13 Hox proteins that were chosen from each of the 13 paralogs including HoxA1, HoxA2, HoxB3, HoxB4, HoxA5, HoxB6, HoxB7, HoxA9, HoxD10, HoxA11, HoxD12 and HoxD13. We generated the 13 Hox expression vectors in both bacteria and mammalian cells. Each of the 13 purified GST-Hox proteins was examined for its interaction with Smad1, Smad4, and Smad6. Just like Hoxc-8, all of the Hox formed heterodimers with Smad6 when binding to osteopontin Hox binding element. Both Smad1 and Smad4 interact with all of the 13 Hox proteins and block binding of these Hox proteins to DNA element. These data suggest that all of the 39 Hox proteins interact with Smad1, Smad4 and Smad6, not TGF-β specific R-Smads, as major BMP downstream transcription factors. Furthermore, we examined the potential function of the interactions between Smads and Hox proteins in gene transcription and BMPs stimulated Osteoprotegrin (OPG) transcription. It has been shown that Hox sites mediate both OPG promoter construct activity and endogenous OPG gene expression in response to BMP stimulation. OPG promoter reporter construct was co-transfected with HoxA1, HoxB4 and HoxB7 expression plasmids in C3H10T1/2 cells treated with BMP-2. As expected, BMP-2 stimulated OPG promoter transcriptional activity, and Hox proteins inhibited BMP-2-mediated transactivation. Thus, our data indicate a fundamental Smad-mediated transcription mechanism, which likely is involved in all of the 39 Hox transcription factors. Our findings may help to understand the mechanism of BMP-regulated tissue patterning and bone development.

Menin Is Required for BMP2-Induced Osteoblastic Differentiation Through the Interaction with Smad1/5 and Runx2. H. Sowa[1], H. Kaji[1], L. Canaff[2], G. N. Hendy[2], T. Tsukamoto*[1], T. Komori[3], K. Miyazono[4], T. Sugimoto[1], K. Chihara*[1]. [1]Endocrinology, Kobe University, Kobe, Japan, [2]Medicine, Mc Gill University, Montreal, PQ, Canada, [3]Molecular Medicine, Osaka University, Osaka, Japan, [4]Molecular Pathology, University of Tokyo, Tokyo, Japan.

Menin is the product of the MEN1 gene, which is responsible for multiple endocrine neoplasia type1. Menin is ubiquitously expressed, and homozygous menin knockout mice exhibit cranial and facial hypoplasia, suggesting the importance of menin in the regulation of bone formation. We previously demonstrated that menin interacts with the TGF-β signaling molecule, Smad3 (PNAS, 2001). Moreover, our recent study indicated that menin is required for the commitment of multipotential mesenchymal stem cells into the osteoblast lineage and inhibits the later differentiation of osteoblasts (JBC, 2003). In that study, inactivation of menin antagonized BMP-2-induced osteoblast differentiation in C3H10T1/2 cells, mouse mesenchymal cells, but not in mouse osteoblastic MC3T3-E1 cells. Smad1/5 and Runx2 are critical components of the BMP signaling pathway in osteoblast differentiation. The present study was therefore performed to clarify the mechanism by which menin inactivation antagonizes BMP-2-induced osteoblast differentiation. In mouse bone marrow stromal cell-lines, ST-2 and PA-6 cells, inactivation of menin with menin antisense oligonucleotides antagonized BMP-2-induced expression of osteocalcin and Runx2, and ALP activity, although it did not affect the chondrogenic and adipogenic differentiation induced by BMP-2. Menin was co-immunoprecipitated with Smad1 and Smad5 in ST-2 and MC3T3-E1 cells. Inactivation of menin with transfection of menin antisense DNA (AS) abrogated the Smad1/5-driven luciferase expression of 3GC2-lux in ST-2 cells but not in MC3T3-E1 cells. These results suggest that menin physically and functionally interacts with Smad1/5 in uncommitted mesenchymal stem cells, but not in well-differentiated osteoblasts. Secondly, menin was also co-immunoprecipitated with Runx2 in ST-2 cells but not in MC3T3-E1 cells. Moreover, AS antagonized the Runx2-driven luciferase expression of OSC-luci in ST-2 cells but not in MC3T3-E1 cells. These results indicate that menin interacts with Runx2 physically and functionally in uncommitted mesenchymal cells but not in well-differentiated cells. In conclusion, the present study suggests that menin is involved in BMP-2-induced commitment of multipotential mesenchymal stem cells into the osteoblast lineage, and this may be mediated by its interaction with Smad1/5 and Runx2.

Regulation of FGF23 Expression but Not Metabolism by Phex. S. Liu, R. Guo*, Z. Xiao, L. D. Quarles. Medicine, Duke University, Durham, NC, USA.

Inactivating mutations of the type II cell-surface protease Phex is the cause of X-Linked Hypophosphatemia (XLH) and the disease phenotype in the Hyp-mouse homologue. FGF23, a phosphaturic factor, is increased in subjects with XLH and correlates with the degree of hypophosphatemia. Increments in FGF23 could result either from inactivating mutations of Phex that prevent the normal degradation of FGF23 or from increased biosynthesis of FGF23 caused by intermediate steps downstream of Phex. To distinguish between these two possibilities, we assessed Phex-dependent metabolism of FGF23 and measured FGF23 message levels in various tissues derived from normal and Hyp mice. We generated recombinant FGF23 and Phex proteins in COS-7 cells and translated FGF23 and Phex in rabbit reticulocyte lysates in vitro. In COS-7 cells full-length FGF23 was present in total cell lysates, but N-terminal and C-terminal fragments generated from cleavage at the RXXR site predominated in conditioned media (CM). Decanoyl-Arg-Val-Lys-Arg-chloromethyl-ketone (CMK) added to the culture media resulted in a dose-dependent inhibition of FGF23 processing in COS-7 cells, indicating that an endogenous furin-type convertase is responsible for FGF23 metabolism. Co-transfection of Phex with FGF23 in COS-7 cells did not result in additional metabolism of FGF23, either in the presence or absence of CMK. In addition, CMK did not inhibit Phex-dependent cleavage of the synthetic substrate ZAAL-pNa. Using in vitro translated proteins, a reduction in band intensity of FGF23 occurred after incubation with reticulocyte lysates expressing wild-type Phex, the inactive Phex-3'M mutant or vector alone, indicating that the apparent cleavage was non-specific. Since we could not demonstrate Phex-dependent cleavage of FGF23 either in vivo or in vitro, we examined the alternative possibility that FGF23 expression is increased in Phex-deficient Hyp mice. Using real-time PCR we found that FGF23 expression was highest in bone compared to other tissues. In addition, Hyp mice displayed significantly higher levels of FGF23 transcripts than normal controls in bone but not in bone marrow. Differential expression of FGF23 was also observed in Hyp compared to normal osteoblasts, but the overall abundance of FGF23 was very low in cultured osteoblasts compared to bone tissue. Although further studies are needed to determine the cell-type in bone that expresses FGF23, our findings indicate that FGF23 is not a direct Phex substrate, but its expression may be indirectly regulated in bone by the actions of Phex on unidentified substrates.

Gremlin, a Bone Morphogenetic Protein Antagonist, Causes Severe Osteopenia I*n Vivo* by Distinct Mechanisms. E. Gazzerro[1], R. C. Pereira[1], V. Jorgetti*[2], A. N. Economides[3], E. Canalis[1]. [1]Department of Research, Saint Francis Hospital and Medical Center, Hartford, CT, USA, [2]Laboratoria de Fisibatologia Renal, Universidade de Sao Paulo, Sao Paulo, Brazil, [3]Functional Genomics, Regeneron Pharmaceuticals, Inc., Tarrytown, NY, USA.

Bone morphogenetic proteins (BMP) induce differentiation of stromal cells toward osteoblasts and enhance osteoblastic function. As such, they play a key role in bone development and in the maintenance of skeletal homeostasis. However, BMPs in excess are detrimental and their actions need to be tempered by intracellular and extracellular proteins. Extracellular antagonists bind BMPs with high affinity and prevent their binding to specific cell receptors. Although BMP antagonists share this common mechanism of action, specific activities are likely for each antagonist. Gremlin, a member of the DAN family of BMP antagonists, plays a role in the control of limb outgrowth, but its activity in postnatal skeletal formation is not known. *In vitro* gremlin prevents the effects of BMPs on osteoblastic function. To define the function of gremlin *in vivo*, we created transgenic mice overexpressing gremlin under the control of the rat osteocalcin promoter. Gremlin overexpression was confirmed by Northern blot analysis of RNA from calvaria of transgenic mice. The growth of gremlin transgenics was severely impaired and their weight was reduced by 30% compared to wild type littermates. The femoral length was half the length of control mice. Transgenic mice displayed tooth fragility. Histomorphometric analysis, performed at 3.5 weeks of age, revealed up to 50% reduction in trabecular bone volume and number in the femurs of gremlin overexpressing mice compared to age matched controls. Trabecular thickness was normal. The decrease in trabecular bone volume was accompanied by a marked decrease in the number of osteoblasts, whereas osteoclast number was normal. Since the osteocalcin promoter becomes active in mature osteoblastic cells, the effect of gremlin is probably due to increased osteoblastic apoptosis and not due to a decrease in osteoblastic cell formation. Gremlin overexpression induces a skeletal phenotype different from that displayed by transgenic mice overexpressing the BMP antagonist noggin under the control of the same osteocalcin promoter. Noggin overexpressing mice have a marked reduction in trabecular bone volume with no changes in osteoblast number, suggesting that the effect is secondary to a decrease in osteoblastic function and not number. These differences underline that different functions of BMPs are regulated by different antagonists. In conclusion, gremlin overexpression *in vivo* causes severe osteopenia secondary to a decrease in osteoblast number.

Overexpression of BMP4 in Osteoblasts Causes Severe Osteopenia in Transgenic Mice. N. Tsumaki*, M. Horiki*, Y. Hashimoto*, K. Kuriyama*, H. Yoshikawa. Orthopaedic Surgery, Osaka University Medical School, Suita, Japan.

Bone morphogenetic protein (BMP) family members such as BMP2, BMP4, and BMP7 are known to induce ectopic bone formation when implanted subucutaneusly. Extensive studies have revealed that BMPs promote non-committed cells to enter into osteoblastic lineage. These proteins thus have been candidates for medicine to treat bone diseases such as nonunion of fractures and osteoporosis. However, it remains to be clarified how BMPs control osteoblast differentiation, bone formation, and bone remodeling. To understand *in vivo* effect of BMPs on bone formation, we generated transgenic mice expressing BMP4 and Noggin to osteoblasts using the α1(I) collagen chain gene promoter sequence. Noggin is an antagonist of BMPs and believed to bind to various BMPs, preventing them to interact with their receptors.

[Materials and Methods] Transgene constructs were prepared by ligating BMP4 cDNA or Noggin cDNA to the 2.3 kb promoter sequence form the α1(I) collagen chain gene. By microinjecting these transgene inserts, transgenic mice were generated and analyzed.[Results and Discussion] Both the BMP4 and Noggin transgenic mice showed severe skeletal abnormalities and died at birth. Therefore we analyzed pleural generation zero (G_0) embryos at 18.5 d. p. c.. Histological analysis showed that normal mice limbs underwent endochondral ossification with solid bone formation in the center of each skeletal component at this stage. Limb skeleton of Noggin transgenic mice consisted of proliferative and hypertrophic chondrocytes, but lacked bone. In Noggin transgenic bone rudiments, BMP signals seemed to be blocked by excess amount of Noggin. These results may suggest that BMP signals are essential for bone development. BMP4 transgenic mice, on the other hand, showed bone formation. Analysis of longitudinal sections of humerus by using micro-CT showed that trabecular bone was significantly reduced in BMP4 transgenic mice than in Normal mice (Figure). Histological analysis revealed that BMP4 transgenic bone contained much less amount of blood vessels and larger number of TRAP-positive cells per bone than that of normal mice. Our results indicate that persistent expression of BMP4 in osteoblasts may cause osteopenia.

Interferon γ Receptor Knock-Out Induces Bone Loss Through a Decrease in Bone Formation. G. Duque*[1], M. Macoritto*[1], N. Dion*[2], L. Ste Marie*[2], R. Kremer[1]. [1]Department of Medicine, Calcium Research Lab, McGill University, Montreal, PQ, Canada, [2]Centre Hospitalier de l'Universite de Montreal, Montreal, PQ, Canada.

Mesenchymal stem cells (MSCs) have the ability to differentiate into osteoblasts, adipocytes, chondrocytes or myocytes. In this study we first determine the genes involved in human MSC differentiation into osteoblasts by cDNA microarray analysis. We examined 12,000 human genes on the array Human Genome U95A (Affymetrix). In addition to the previously described pathways of osteoblast differentiation we found that a new set of genes known as "interferon-inducible genes" were rapidly and transiently up-regulated between 2.9 to 16.9 fold during this process. Furthermore we found that addition of interferon γ to human MSCs stimulates the expression of RunX2/Cbfa1, a key regulator of osteoblast differentiation. We next assessed the role of interferon γ on bone turnover in mice expressing the interferon gamma receptor knock-out phenotype ($IFGR^{-/-}$). $IFGR^{-/-}$ mice had over 40% reduction in bone mass at both hip and spine as compared to $IFGR^{+/+}$ mice. We also noted a significant decrease in structural parameters of trabecular mass by 3D micro-CT surface/volume (BS/BV) and trabecular thickness (Tb.Th) and a significant increase in trabecular separation (Tb.Sp), $p<0.01$. Histomorphometric analysis confirmed the decrease in BS/BV and Tb.Th and also demonstrated a significant decrease in cortical thickness (Ct.Wi) in $IFGR^{-/-}$ mice, $p<0.01$. Histological analysis of bone sections indicated a marked reduction of osteoblast staining (alkaline phosphatase and osteopontin) as well as a reduction in Cbfa1 and TRAPP staining ($p<0.01$) in $IFGR^{-/-}$ mice. Circulating levels of N-telopeptide RANKL and osteocalcin were also reduced by over 40% ($p<0.01$) in $IFGR^{-/-}$ mice. Finally bone marrow cells obtained from $IFGR^{-/-}$ mice and induced to differentiate into osteoblasts showed over 70% reduction in the number of mineralized nodules as compared to bone marrow cells obtained from $IFGR^{+/+}$ mice ($p<0.01$). Our data therefore demonstrate that interferon γ signaling regulates bone formation and that its deficiency results in low bone turnover osteoporosis.

Marrow Stromal Cells and Osteoclast Precursors Differentially Contribute to TNF-α Induced Osteoclastogenesis In Vivo. H. Kitaura, K. Aya, P. Zhou, S. Takeshita, F. P. Ross, S. L. Teitelbaum. Department of Pathology, Washington University, School of Medicine, St. Louis, MO, USA.

As documented primarily by in vitro experiments, marrow stromal cells, macrophages and T-cells are believed to participate in TNF-induced osteoclast recruitment. The relative contributions of each of the three cell types to inflammatory osteoclastogenesis and their roles as direct TNF targets, in vivo, are however unknown. To assess the role of stromal cells in TNF-induced osteoclast recruitment we generated two species of chimeric mice. Thus, wild type (WT) bone marrow, immunodepleted both T-cells and stromal cells was transplanted into irradiated mice lacking both TNF receptor type1 and type2 (WT to KO). In this condition osteoclast precursors but not stromal cells are capable of responding to TNF. As control, WT marrow was transplanted into WT mice (WT to WT). In each cir-

cumstance we prevented T-cell development by injection of anti-CD4 and anti-CD8 antibodies. Both groups of chimeric mice were administered increasing doses of TNF. At all doses of the cytokine the number of OCs measured histomorphometrically in vivo, is markedly reduced in WT to KO as compared to WT to WT chimeras (p<.001). Hence, TNF-responsive marrow stromal cells are essential for optimal TNF-induced osteoclastogenesis. Confirming this in vivo observation, a similar decrease in osteoclastogenesis occurs when marrow of TNF-injected WT to KO mice is cultured ex vivo in the presence of TNF (p<.001). TNF induces stromal cells to express RANKL (this meeting) suggesting the defect in OC formation in TNF-treated WT to KO mice reflects a relative paucity of RANKL. Consistent with this hypothesis, addition of RANKL to marrow cultures derived from TNF-treated WT to KO mice completely rescues their osteoclastogenic capacity. We have previously shown that RANKL sensitizes OC precursors to TNF-induced osteoclastogenesis. In the present exercise we find the converse, namely TNF sensitizes OC precursors to RANKL-induced osteoclastogenesis is also true. Thus, marrow derived from TNF treated both WT to WT and WT to KO mice generates substantially more osteoclasts in response to RANKL than does marrow from untreated mice (p<.001). The fact that the event is indistinguishable in marrow derived from WT to WT and WT to KO mice establishes that in contrast to TNF-induced RANKL production, TNF-induced RANKL sensitization is a stromal cell independent event. Thus, optimal TNF-induced osteoclastogenesis requires stromal cells which produce RANKL in response to TNF. On the other hand, TNF-induced RANKL sensitivity reflects direct targeting of TNF to OC precursors.

Hip Fracture Risk is Increased in Men at Both High and Low Levels of Serum Vitamin A. A. R. Opotowsky*, J. P. Bilezikian. Medicine, Columbia University, College of Physicians and Surgeons, New York, NY, USA.

One recent Swedish study suggests that high serum vitamin A levels are associated with increased risk of hip fracture among men. However, the population studied was notable for its generally high vitamin A intake and serum vitamin A levels. Therefore, it is unclear if these results apply to the US population in which the range of vitamin A is likely to be greater. We investigated the hypothesis that both high and low serum vitamin A predispose men to hip fracture. The NHANES I Epidemiologic Follow-up Study included 3,219 men 40 to 74 years old, of whom 51 had an incident hip fracture during the 22-year (μ=13.7±6.3) follow-up. As expected, vitamin A levels in this national sample were lower than those in the Swedish sample. The mean vitamin A level of the lowest quintile in this sample was 1.45 μmol/l compared with 1.72 μmol/l in the Swedish study. The relative risk (RR) of hip fracture for each quintile of baseline serum vitamin A as compared with the middle quintile was determined using Cox regression. There were 17 (2.6%), 12 (2.0%), 5 (0.8%), 4 (0.6%), and 13 (2.0%) incident hip fractures in the lowest to highest quintiles respectively. Controlling for age at exam, weight, height, and history of previous fractures, the RR (95% CI) of hip fracture for each quintile, compared with the middle quintile, respectively were 3.8 (1.4-10.6, p<0.01), 2.8 (1.0-8.1, p=0.06), 1.0 (reference), 0.7 (0.2-2.8, p=0.65), and 3.3 (1.2-9.5, p=0.03). We repeated the analysis using the parameters cited in the Swedish study linking high serum vitamin A to increased hip fracture risk. Those in the NHANES I sample who would have been classified in the highest quintile in the Swedish study (>2.64 μmol/l) were much more likely to sustain a hip fracture than those who would have been in the middle quintile in that study (2.17-2.36 μmol/l), RR=7.5 (1.7-33.8, p<0.01). However, subjects who would have been classified in the highest quintile in the Swedish study were no more likely to sustain a hip fracture than those in our lowest quintile, RR=0.8 (0.4-1.7, p=0.56). These results suggest that men with either high or low serum vitamin A are at increased risk of hip fracture. Prior studies concluding that only high serum vitamin A (or high vitamin A intake) confers increased risk may not be applicable to the general United States population. Rather, it appears that levels of vitamin A at both ends of the concentration range place men at significant risk for hip fracture.

Smoking Influences the Association Between Estrogen Receptor Alpha Gene Polymorphisms and Bone Mineral Density: A Gene-Environment Interaction in the Framingham Offspring Study. A. M. Shearman[1], D. Karasik[2], L. A. Cupples*[3], S. Demissie*[3], S. Coven*[1], K. Gruenthal*[1], D. E. Housman*[1], D. P. Kiel[2]. [1]Ctr for Cancer Research, MIT, Cambridge, MA, USA, [2]Hebrew Rehab Ctr for Aged & Harvard Med Sch, Boston, MA, USA, [3]Biostatistics, BU Sch of Public Health, Boston, MA, USA.

There are conflicting results regarding the role of estrogen receptor alpha (ESR1) polymorphisms in the regulation of bone mineral density (BMD). Also, smoking affects estrogen metabolism, is associated with lower BMD and greater risk of osteoporosis, and may affect ESR1 transcription. We hypothesized that smoking might influence the association between ESR1 and BMD.

We studied 732 men and 792 women (mean age 60 ys, range 29-86) from the Framingham Study Offspring Cohort. BMD (g/cm^2) was measured by DXA at the hip (femoral neck, FN, trochanter, TR, Ward's area, WA) and L2-L4 lumbar spine (LS). DNA samples were genotyped for six polymorphisms: the TA repeat upstream of exon 1, +30T/C in exon 1, PvuII and XbaI in intron 1, +975C/G in exon 4, and *D6S440.* The two microsatellite repeat polymorphisms were recoded as presence/absence of the most frequent allele.

Information on age, height, body mass index (BMI), current cigarette smoking (y/n), and current estrogen use in women (y/n) was obtained at the time of BMD examination. We used ANOVA/ANCOVA to estimate the main effects of each polymorphism, as well as haplotype probabilities derived using the expectation-maximization algorithm, on crude and covariate-adjusted BMD in each sex separately.

High linkage disequilibrium was observed between the first four polymorphisms (D' = 0.82 - 0.99). 12.4% of men and 15.0% of women were current smokers.

No significant main associations between ESR1 polymorphisms and BMD were observed for any skeletal site, in either sex. In contrast, significant interactions between PvuII and XbaI genotypes, current smoking, and BMD (p = 0.004 to 0.014) were found in men. Interactions were also found between smoking, haplotypes px (frequency 55%) and PX (36%), and BMD at the hip in men (p = 0.002 and 0.031, respectively).

A substantial additive effect of combined PvuII and XbaI genotypes was found among male smokers (n=78): BMD was higher in pp-xx compared to PP-XX, difference of 12.3% (FN), 13.5% (TR), 19.8% (WA), and 8.5% (LS), pANOVA=0.06, 0.07, 0.03, and 0.05, respectively. No association was found in non-smoking men. In women, no interaction was found between ESR1 polymorphisms, current smoking, and BMD. In conclusion, the polymorphisms in intron 1 of the ESR1 gene are significantly associated with BMD in male smokers. These findings highlight the importance of considering smoking status when examining associations between ESR1 polymorphisms and BMD.

Risk Factors of Hip Fracture in Women with High BMD: EPIDOS Study. J. A. Robbins[1], A. Schott*[2], P. Garnero[3], P. D. Delmas[4], P. J. Meunier[4]. [1]Internal Medicine, UC Davis, Sacramento, CA, USA, [2]Dept d'Info Med, Lyon, France, [3]Unit 403, INSERM/Synarc, Lyon, France, [4]Unit 403, INSERM, Lyon, France.

Older women with lower bone mineral density (BMD) are at greatest risk of hip fracture. Still, many fractures occur in those with higher BMDs. We used the EPIDOS data set to identify factors significantly predictive of hip fractures in women with high BMD but not those with low BMD. The cohort of 7562 non-institutionalized older French women, average age 80.5 (std, 3.8), was divided into 3 groups with equal numbers of incident hip fractures based on femoral neck BMD (97 ± 1 fractures/group). We did not make use of T-scores because of the many choices of available "normals". For this analysis follow-up averaged 3.6 years (std, 0.9) until study end, dropout, or hip fracture. All continuous variables were transformed to z-scores and were age adjusted to insure that the differences were not proxies for age. Cox proportional hazards examinations were carried out for each variable of possible interest in those in upper and lower ranges of BMD. A time dependent method was used to avoid confounding by mortality and/or drop out. Measures of strength, coordination, structures (ultrasound attenuation) and bone turnover, urinary deoxy pyridinoline (DPD) adjusted for creatinine in a sub-sample of the population, were investigated. Most factors traditionally associated with hip fracture were predictive in all groups; age, gait speed, right sided strength and coordination, and BMD measurements. The results for the extreme groups are presented in the table for those variables where they diverged. Hazards ratios (HR), and 95% confidence intervals (95% CI) for these HRs are shown.

	Low BMD (≤0.601gm/cm^2)				**High BMD (≥ 0.683 gm/cm^2)**			
Factor (per std or yes/no)	Sig	HR	95%CI		Sig	HR	95% CI	
Age	0.010	1.250	1.055	1.482	0.000	1.830	1.555	2.153
Urinary DPD	0.637	0.989	0.943	1.142	0.017	1.246	1.041	1.492
Ultrasound attenuation	0.160	0.818	0.618	1.083	0.000	0.577	0.453	0.734
Left foot coordination	0.226	1.119	0.933	1.342	0.017	1.246	1.040	1.492
Left grip strength	0.461	0.921	0.740	1.146	0.026	0.790	0.642	0.973
Couldn't heel/toe walk 4 steps	0.160	1.508	0.850	2.674	0.017	1.927	1.122	3.311
History of prior Fractures	0.140	0.738	0.493	1.105	0.031	1.550	1.042	2.309
Took sleeping pills regularly	0.006	1.786	1.183	2.697	0.083	0.702	0.407	1.048

In older women with what is usually accepted as non-osteoporotic range BMD, factors of weakness, in-coordination, and ultrasound, and bone turnover marker measurements, are associated with an increase in hip fractures. These factors are less important in those with lower BMDs. Sleeping pill use appears to be more associated with fractures in those with osteoporotic range BMDs. Low BMD remains the strongest associate of hip fracture but in those with higher BMD other factures related to fall risk and bone structure and turnover, which put women at risk for hip fractures, appear to play a role in hip fracture risk and may need to be addressed.

Altered Sensitivity to Mechanical Load: A Potential Osteoporosis Phenotype. K. Uusi-Rasi[1], T. J. Beck[1], J. M. Zmuda[2], T. A. Hillier[3], L. Lui*[4], K. L. Stone*[4], L. M. Semanick*[1], S. R. Cummings[4]. [1]Johns Hopkins University, Baltimore, MD, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]Kaiser Permanente Center, Portland, OR, USA, [4]University of California, San Francisco, CA, USA.

Family history of fracture is an important risk factor for osteoporotic fractures, but the mechanism is unclear. We hypothesized that reduced sensitivity to skeletal load may produce weaker bones with thinner cortices that reach instability faster as bones expand and cortices thin with age. Differences in mechanosensitivity should alter the relationship between bone strength and skeletal load; estimated as the ratio of bending strength (section modulus - Z) to fat free mass (FFM by bioelectric impedance) as a crude index of muscle load. We evaluated hip geometries at the proximal femur of 2836 women from the Study of Osteoporotic Fractures who had repeated hip DXA scans (mean follow-up 3.7 y) analyzed with the Hip Structure Analysis (HSA) program and information on family history of hip

fracture. We studied whether women with incident hip fractures (Hip-Fx, n = 281) or other osteoporotic fractures (Other-Fx, n = 1324) have impaired mechanosensitivity (Z/FFM) than fracture free women (Fx-Free, n = 1231). To evaluate familial predisposition, we compared women who had a parent or sibling with hip fracture (+Hx, n = 650) to women without such history (-Hx, n = 2186) adjusting for age, knee-height and weight by ANCOVA. Hip-Fx had 8.8% (95% CI 6.7 to 11.0%) and Other-Fx 5.4% (3.9 to 6.8%) lower Z/FFM at the neck than Fx-Free. The respective values at the shaft were 5.1% (3.1 to 7.1%) and 3.6% (2.3 to 4.9%). Buckling ratio was 19% (15 to 24%) greater in Hip-Fx than in Fx-Free at both femoral neck and shaft with Other Fx intermediate. In family Hx groups, mean difference in Z/FFM was 2.5% (0.8 to 4.1%) at the neck and 1.8% (0.3 to 4.1%) at shaft in favor of -Hx group independent of Fx category. Buckling ratio was 5.6% (3.3 to 8.0%) and 3.3% (0.6 to 6.1%) greater among +Hx at neck and shaft, respectively. Bending strength declined and buckling ratio increased faster in Hip-Fx than in Fx-Free, mean differences were -0.8% (-1.2 to -0.4%) for bending strength and 0.9% (0.4 to 1.3%) for buckling ratio. No differences in rate of change in geometry were apparent between Hx groups. Our results suggest that mechanosensitivity is impaired in women with osteoporotic fractures compared to women who remain fracture-free. The association of mechanosensitivity with family Hx of hip fracture suggests an inherited trait while lack of an effect on rates of change suggests that mechanosensitivity levels may be fixed. The geometric conditions underlying differences in mechanosensitivity appear to lead to cortical dimensions that are more prone to buckling.

Higher 25-Hydroxyvitamin D Levels are Associated with Better Lower Extremity Function in Active and Inactive Ambulatory Elderly in the US. H. A. Bischoff[1], T. Dietrich*[2], E. J. Orav*[3], Y. Zhang*[4], E. W. Karlson*[1], B. Dawson-Hughes[5]. [1]Robert B. Brigham Arthritis and Musculoskeletal Clinical Research Center, Brigham and Women's Hospital, Boston, MA, USA, [2]Periodontology, Charité, Berlin, Germany, [3]Biostatistics, Div. of General Internal Medicine, Brigham and Women's Hospital, Boston, MA, USA, [4]Clinical Epidemiology Research and Training Unit, Boston University School of Medicine, Boston, MA, USA, [5]Jean Mayer USDA Human Nutrition Research Center on Aging, Tufts University, Boston, MA, USA.

Purpose: The aims of this study were to determine whether there is an association between 25-hydroxyvitamin D (25-OHD) levels and lower-extremity function in ambulatory elderly, and, if so, whether the association differs by activity level and whether there is an identifiable threshold in this association.
Subjects and Methods: Cross-sectional, representative sample of the US population (NHANES III; 4100 adults age 60-90+ years). Linear regression analyses and regression plots were used to assess functional performance by 25-OHD serum levels controlling for sex, age, race/ethnicity, BMI, calcium intake, poverty income ratio, number of medical comorbidities, self-reported arthritis, use of a walking device, month of measurement and activity level (inactive vs. active and METs in active elderly). Inactive subjects did not walk one mile without stop, swim, jog, bicycle, dance, exercise or garden in the last month (25% of subjects). Separate analyses were performed for the 8-feet walking speed (mean of 2 trials; in seconds [s]) and the sit-to-stand speed (5 repetitions; in s).
Results: Walking speed: compared to the lowest quintile of 25-OHD the highest quintile showed an average increase by 0.25s (test for trend; $p < .0001$). Sit-to-stand speed: compared to the lowest quintile of 25-OHD the highest quintile showed an average increase by 0.66s (test for trend; $p = .049$). In the regression plots, performance speed in both tests show the most pronounced improvement in the lowest 25-OHD levels. In the 25-OHD reference range of 22.5 to 94 nmol/l most of the improvement occurred in 25-OHD levels going from 22.5 to approximately 40 nmol/l. Further improvement was seen in the range of 40-94 nmol, but the magnitude was much less dramatic. In the adjusted analyses active subjects were 0.34s quicker in the walking test ($p < .0001$) and 0.80s quicker in the sit-to-stand test ($p < .0001$) than inactive subjects. However, there was no effect modification by activity level.
Conclusion: In both active and inactive ambulatory elderly subjects, 25-OHD levels above 40nmol/l and as high as 90 nmol/l, the upper end of the reference range, are associated with better musculoskeletal function in the lower extremities.

Secular Trends in Hip Fracture Incidence in California 1983-2000 for Different Ethnic Groups. S. L. Silverman[1], D. Zingmond*[2]. [1]OMC Clin Res Ctr, Beverly hills, CA, USA, [2]UCLA, Los Angeles, CA, USA.

Background: Rates of hip fracture have decreased among Nonhispanic White women in Rochester since 1970 (Melton, 2000). However, trends in hip fracture rates for ethnic minorities are unknown. The state of California has an ethnically diverse population and has maintained detailed data documenting hip fractures over the past two decades.
Purpose: To study secular trends in the incidence of hip fracture in California 1983-2000 among women and men from four different racial/ethnic groups: Nonhispanic White (NHW); African-American (AfrA); Hispanic American (HispA) and Asian American (AsA).
Methods: We used the California Office of Statewide Health Planning and Development annual hospital Patient Discharge Database, to identify all hospitalizations for acute hip fracture among individuals at non-Federal California general acute care hospitals from 1983 to 2000. Individual patient race/ethnicity, gender, and age are reported for each hospital discharge. Population estimates for race/ethnicity, gender, and age by year were estimated using U.S. Census and state Department of Commerce annual population estimates. For each race and gender, age adjusted rates were calculated restricted to those 55 years and older and standardized to the overall 2000 U.S. population age distribution by gender. Secular trends were fitted using weighted linear regression with robust variance estimators.
Results: Adjusted baseline rates for hip fractures among women were 733 fractures / 100,000 for NHW, 274 for AfrA, 245 for HispA, and 381 for AsA and among men were 251 for NHW, 156 for AfrA, 111 for HispA, and 111 for AsA. Estimated changes in hip fracture rates differ by both gender and by ethnicity. Among women over the past 18 years, hip fracture rates decreased by 4.5 fractures / 100,000 individuals / year in NHW ($p < 0.001$) and 4.3 in AsA ($p < 0.001$), were unchanged in AfrA (0.46 , $p = 0.560$), but increased by 5.4 in HispA ($p < 0.001$). Among men, rates increased among NHW by 1.57 ($p = 0.001$) and among HispA by 1.79 ($p < 0.001$). Changes in fracture rates for AfrA and AsA men were not significantly different from 0.
Conclusion: While hip fracture rates have declined significantly among NHW and AsA women over the past decade, rates have been unchanged among AfrA women and have increased significantly among HispA women. Further study is indicated to understand why risk of hip fracture is increasing among HispA women.

Long-Term Effects of Poor Environmental Conditions During Early Life: Increased Prevalence of Hip Fractures among Holocaust Survivors. A. J. Foldes[1], J. Brodsky*[2], N. Bentur*[2]. [1]Osteoporosis Center, Hadassah University Hospital, Jerusalem, Israel, [2]JDC-Brookdale Institute of Gerontology, Jerusalem, Israel.

It has been suggested that senile osteoporosis is largely determined by peak bone mass which, in turn, is affected by a host of environmental factors. Comparing holocaust survivors to individuals of the same origin, who had not experienced the holocaust, provided us with a unique opportunity to test the relationship between detrimental conditions during early life and the prevalence of hip fractures (Fx) later in life.
Data were derived from a population survey that was conducted during 1997-8 on a sample of 2,669 Ashkenazi Jews (1,350 females, 1,319 males), 60 years of age or more (median age = 74), born in Europe before World War II. The prevalence of self-reported hip Fx (based on any previous diagnosis by a physician of a Fx at the pelvic bone or the femora) was recorded. Based on their personal history during World War II, the study participants were stratified into three groups: (1) Survivors of Nazi concentration or labor camps; (2) "Other" survivors, who lived under Nazi occupation, but did not experience camps; (3) Control group, consisting of those who did not live under Nazi occupation during WW II.

	Prevalence of hip Fx (%)				Odds ratio (camp survivors vs. controls)
	Total sample (n=2,669)	Camp survivors (n=452)	Other survivors (n=929)	Controls (n=1,288)	
Total sample	4.8	9.0	4.6	3.3	2.9
Females	5.7	11.4	5.5	3.9	3.0
Males	3.6	6.8	3.1	2.4	2.3
Age<75	2.8	9.4	2.2	0.8	13.1
Age≥75	8.1	7.9	9.5	7.3	NS

The following conclusions can be drawn: (1) An almost threefold higher prevalence of hip Fx was observed among survivors of Nazi camps (9.0%), as compared to controls (3.3%), with intermediate values for "other" survivors. The extent of this finding may even be underestimated, given the "survival of the fits" phenomenon. (2) The camp effect was limited to the younger cohort, which consisted of individuals who were 16-17 year-old or younger at the onset of WWII. This observation is also manifested by the unexpected finding, that among the camp survivors, hip Fx prevalence in the younger cohort exceeded that observed in the older cohort! (3) In the older cohort, that included individuals who were past the age of 16-17 at the onset of WW II, no camp effect was observed. (4) In the younger cohort, the prevalence of hip Fx in males (3.0%) approached that of females (2.7%), while in the older cohort, the expected higher prevalence of hip Fx in females (10.5%) compared to males (4.8%) was maintained.
The findings of this study support the notion that living under detrimental conditions during early life is associated with a higher risk of hip Fx later in life.

Homecysteine, Bone Density and Fractures in Healthy Elderly People: The LASA Study. R. A. M. Dhonukshe-Rutten*[1], P. Lips[2], S. M. F. Pluijm*[3], L. C. P. de Groot*[1], W. A. van Staveren*[1]. [1]Human Nutrition and Epidemiology, Wageningen University, Wageningen, Netherlands, [2]Endocrinology, VU University Medical Center, Amsterdam, Netherlands, [3]EMGO Institute VU University Medical Center, Amsterdam, Netherlands.

Hyperhomocysteinemia may contribute to the development of osteoporosis. Some in vivo and in vitro studies support disturbance of cross-linking of collagen type I in bone by homocysteine (Hcy) as a possible mechanism. The relationship between homocysteine, bone mass and fracture incidence was studied in the Longitudinal Aging Study Amsterdam (LASA), a prospective cohort study which started in 1992. Subjects were 615 men and 652 women (mean age ± SD 76 ± 6.6 yr). Plasma samples were obtained in 1996 and
stored frozen until analysis. Plasma Hcy was measured by fluorescent polarisation immunoassay, osteocalcin was measured by IRMA and urine deoxypyrodinoline was measured

by competitive immunoassay.
Broadband ultrasound attenuation (BUA) was assessed in the heel bone (CUBA Clinical). A prospective follow-up of falls and fractures was done until 1999. Age- and sex-specific quartiles for (log-transformed) Hcy were used to calculate risk ratios for fractures. These were adjusted for age, BMI, smoking status, creatinine levels, falling and physical performance. Mean plasma Hcy ± SD was 13.5 ± 5.2 µmol/l. 42% of the men and 26% of the women had a high Hcy concentration (≥ 15.5 µmol/l). Serum osteocalcin and urine deoxypyrodinoline were positively associated with Hcy ($p < 0.001$). BUA was negatively associated with plasma Hcy (ß –1.8, $p< 0.02$ for men and ß –2.4, $p < 0.001$ for women). 21 Fractures occurred in men and 36 fractures occurred in women during the 3-years fracture follow-up. The adjusted risk ratio (95% confidence interval) for the highest homocysteine quartile for fractures was 3.3 (1.1;1.9) for men and 1.8 (0.8;3.9) for women and 2.2 (1.2;4.1) for the sexes combined, all compared with the lower three age- and sex-specific Hcy quartiles. There was no association between plasma Hcy and falls.
In conclusion, a high plasma Hcy was significantly associated with low BUA, high markers of bone turnover and increased fracture risk.

Ultralow Estradiol Increases BMD and Decreases Bone Turnover in Older Women, Particularly those with Undetectable Estradiol: The ULTRA Trial. S. R. Cummings[1], V. Yankov*[2], K. Ensrud*[3], B. E. Ettinger[4], R. Wallace*[5], K. Johnson*[6], J. Macer*[1], E. Vittinghoff*[1], D. Grady*[1]. [1]Univ of Calif, San Francisco, CA, USA, [2]Berlex, Montville, NJ, USA, [3]Univ of Minn, Minneapolis, MN, USA, [4]Div of Research, Kaiser Permanente, Oakland, CA, USA, [5]Univ of Iowa, Iowa City, IA, USA, [6]Univ of Tennessee, Memphis, TN, USA.

Women with undetectable levels of estradiol (E2) have increased bone loss and fracture risk. Standard dose estrogen therapy reduces fracture risk but has serious adverse effects and, in women with a uterus, requires concomitant progestin to prevent endometrial cancer. We hypothesized that ultra low doses of E2 could be safely taken without a progestin and would improve bone resorption and BMD, particularly in those with undetectable E2 levels.
417 women age ≥ 60 years with hip BMD z-score >-2.0 and intact uteri were randomly assigned to ultra low TE2 (0.0125mg E2 daily via 3.25cm2 transdermal patch changed weekly) or placebo for 2 years. Follow-up measurements, including DXA and endometrial evaluation, were completed in 90% of participants and, of those, 99% used ≥75% of study patches. We measured pretreatment E2 by a double antibody assay that detects E2 ≥ 1.4 pg/ml, and measured SHBG by IRMA. We also analyzed outcomes stratified by undetectable vs. other quintiles of baseline E2/SHBG ratio, an index of bioavailable E2. We present results for undetectables vs. highest quintile of E2 at baseline.
In women assigned to ultra low TE2, E2 increased from a median of 4.8 pg/ml to only 7.5 pg/ml at 1 year (P<.001); E2 was undetectable in 13% at baseline and 4% at 1 year (P<.001). Overall, ultra low TE2 significantly decreased bone turnover and increased BMD (table). These effects were greater in women with undetectable baseline E2 than in those with higher E2/SHBG ratios (table). Safety and tolerability of TE2 was similar to that of placebo; there was no significant difference in incidence of endometrial proliferation or hyperplasia between groups.

		E2/SHBG Quintiles		*P-value for*
2-yr change*	All Women	*Undetectable*	*Highest*	*interaction†*
Osteocalcin	-15.6%	-33%	-9%	.005
Spine BMD	+2.4%	+3.5%	+1.2%	.10
Hip BMD	+1.5%	+2.4%	+0.9%	.11

*vs. placebo; P<.01 for all main effects. † Treatment-by-SHBG / E2 interaction

Ultralow TE2 decreased bone turnover and improved BMD in older women without causing endometrial proliferation. TE2 may produce greatest skeletal benefits in women with undetectable endogenous E2. Measurement of E2/SHBG may identify women with true 'estrogen-deficiency' who would substantially benefit from ultralow TE2.

Short Term Response to Parathyroid Hormone (1-34hPTH) in Human Iliac Crest Bone using a Unique Quadruple (Double Double) Tetracycline Labeling Regimen and Single Biopsy. R. Lindsay[1], H. Zhou[1], F. Cosman[1], M. Bostrom[2], J. D. Cruz*[1], J. W. Nieves[1], D. W. Dempster[1]. [1]Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [2]Medicine, Hospital for Special Surgery, New York, NY, USA.

We describe here the early dynamic response of iliac crest bone to treatment with 1-34hPTH using a technique of quadruple labeling with two sets of tetracycline labels that allows longitudinal information from a single biopsy. Biopsies were obtained in 16 postmenopausal women (10 treated with 1-34hPTH [25mcg sc./day] for 7 weeks and 6 controls). Prior to treatment with PTH each individual received tetracycline labeling, using 2 different tetracyclines, following a standard protocol. Four weeks after initiation of treatment with 1-34hPTH, labeling was repeated with reverse order of tetracyclines, and biopsy performed 7 days after last label dose. Controls received identical labeling, but without PTH. Double labels were identified as first or second set based upon color sequence. Demographic data, and structural parameters in cancellous (Cn) and cortical (Ct) bone, were similar in both groups. In PTH treated individuals mineral apposition rate (MAR) and bone formation rate (BFR) increased from pretreatment (Cn 0.42 ± 0.09 to 0.64 ± 0.15 µm/day; 0.007 ± 0.002 to 0.025 ± 0.006 µm/µm2/day; $p<0.05$ and endosteal (En) 0.44 ± 0.09 to 0.66 ± 0.09; 0.025 ± 0.007 to 0.069+/-0.014: $p<0.05$) with PTH, while MAR and BFR remained constant or declined slightly in controls. The percent bone surface covered by labels increased in all subjects after PTH but not in controls. The average length of individual labels in the second set was greater than the first in Cn (0.66 ± 0.14 to 1.11 ± 0.27mm $p<0.02$) and in En (0.35 ± 0.07 to 0.54 ± 0.14, $p=0.01$) in PTH treated subjects but not in controls. In Ct the second set of labels was shorter after PTH, consistent with more rapid completion of Haversian systems. In PTH treated subjects, quadruple labels always occurred on eroded surface, but second labels also occurred 25% of the time on smooth surfaces, without evidence of prior resorption ($p<0.05$). Estimates of eroded surface were similar in both groups, suggesting little PTH induced increase in remodeling activation at 7 weeks. These data demonstrate the utility of quadruple tetracycline labeling to evaluate longitudinal short term changes in bone formation in a single iliac crest biopsy. The data support early stimulation of bone formation following administration of therapeutic doses of 1-34hPTH, without significant stimulation of resorption, and suggest strongly that the early PTH effects represent either surface annexation by osteoblasts spilling from remodeling sites and/or formation of bone on previously quiescent surfaces.

Effects of Discontinuation of Teriparatide Treatment on Cortical Bone in Postmenopausal Women with Osteoporosis. C. E. Bogado*[1], A. Mango*[1], M. Sato[2], J. R. Zanchetta[1]. [1]Clinical Research, IDIM, Buenos Aires, Argentina, [2]Lilly Research Laboratories, Indianapolis, IN, USA.

We have previously reported the effects of teriparatide [rhPTH (1-34)] administration on cortical bone assessed by peripheral quantitative computed tomography (pQCT) in the distal radius of postmenopausal women with osteoporosis. Compared with placebo, patients showed significantly higher total bone mineral content, total and cortical bone areas, periosteal and endosteal circumferences and axial and polar moments of inertia.
Of the original study population, 93 women completed an 18-months observational study to determine the effects of discontinuation of teriparatide on the changes previously induced by the treatment on cortical bone. During the treatment phase patients received 1000 mg calcium and 400 IU vitamin D orally and either placebo (n= 26) or teriparatide at 20 (n= 37) and 40 ug (n= 28) as self-injected daily doses. Along the follow-up period patients did not receive any treatment for osteoporosis, or any drug that could affect bone metabolism other than the calcium and vitamin D supplements. Measurements were performed at the nondominant forearm, 6 and 18 months after discontinuation of therapy, at a site corresponding to 15% of the length of the ulna proximal to the radius distal end using a Stratec XCT 960 pQCT machine (Stratec Medizintechnik GmbH, Pforzheim, Germany).
There were no significant changes in the parameters of bone distribution and structural geometry during the study. Compared with placebo, total bone mineral content, total and cortical bone areas, periosteal and endosteal circumferences and axial and polar moments of inertia remained significantly higher 18 months after treatment discontinuation. There was a small, nonstatistically significant decrease in cortical density in the placebo group. In contrast, cortical bone density increased in the 40 ug group, although this change was not statistically significant. Cortical bone content did not change in any group.
In summary, there was no evidence of a detrimental effect on cortical bone density after treatment discontinuation. Moreover, the positive effects on bone distribution and structural geometry induced by teriparatide were still evident 18 months after teriparatide discontinuation. Since these favorable changes are associated with increased bone strength, our results are consistent with the reported evidence of durable effects of teriparatide for fracture risk reduction even after treatment is stopped.

Osteogenic Activity of a Novel Synthetic Peptide Fragment of Human MEPE. T. Hayashibara*[1], T. Hiraga[1], B. Yi[2], M. Nomizu[3], Y. Kumagai[4], R. Nishimura[1], T. Yoneda[1]. [1]Dept Biochem, Osaka Univ Grad Sch Dent, Osaka, Japan, [2]Div Endocrinol, Univ Texas Hlth Sci Ctr, San Antonio, TX, USA, [3]Div Biosci, Hokkaido Univ Grad Sch Environ Earth Sci, Hokkaido, Japan, [4]Acologix, Inc., Emeryville, CA, USA.

Co-occurrence of disturbed phosphate homeostasis and skeletal disorders including rickets and osteomalacia in X-linked hypophosphatemic rickets and oncogenic hypophosphatemic osteomalacia suggests that the phosphate metabolism is associated with ossification. Although the mechanism of these diseases is largely unknown, it has been proposed that the yet-unidentified phosphaturic hormone named phosphatonin plays a role in the pathophysiology of these disorders. Matrix extracellular phosphoglycoprotein (MEPE) is one of the recently-identified candidates for phosphatonin. MEPE expression was found in osteoblasts/osteocytes and mice deficient in a MEPE homologue gene OF45 showed increased bone density, suggesting that MEPE produced in osteoblasts inhibits bone formation. In the present study, we examined the effects of a synthetic 23mer peptide (AC-100) containing RGD motif that corresponds to the region of 242-264 of human MEPE on bone formation in vitro and in vivo. Histological and histomorphometrical examination demonstrated that AC-100 (1, 10mg/ml) significantly promoted new bone formation with increased numbers of osteoblasts in organ cultures of neonatal mouse calvariae. These effects of AC-100 were comparable to those of rhBMP-2 (40ng/ml). Of interest, AC-100 enhanced PTH-rP-stimulated osteoclast-like cell formation in mouse bone marrow cultures. Repeated daily subcutaneous injections of AC-100 (20, 200mg) onto the mouse calvariae increased bone thickness and stimulated new bone formation as determined by calcein double-labeling to a similar extent to FGF-1 (12.5mg). A synthetic peptide in which the RGD sequence was scrambled into DRG failed to stimulate new bone formation, suggesting the interactions of the RGD sequence to integrins in osteoblasts are critical to

the osteogenic activity of AC-100. In support of this notion, AC-100 activated the integrin signaling molecules FAK and ERK in the MG-63 human osteoblastic osteosarcoma cells. Our results show that AC-100, a synthetic 23mer peptide fragment of human MEPE, increases new bone formation through activating osteoblasts, raising the possibility that MEPE, when cleaved, exhibits osteogenic activity in contrast to the full length MEPE. The results also suggest that the activation of integrin signaling in osteoblasts via RGD sequence is crucial to the osteogenic activity of AC-100. The anabolic effects of AC-100 may be beneficial for bone defects, fractures and bone diseases associated with decreased local bone mass.

GLP-2 Is a Key Player in the Regulation of Bone Turnover: New Prophylaxis? D. B. Henriksen[1], P. Alexandersen*[2], T. L. Andersen*[1], I. Byrjalsen*[1], E. Gamwell Henriksen*[1], B. Hartmann*[3], C. Christiansen[2], J. Juul Holst*[3]. [1]Nordic Bioscience, Herlev, Denmark, [2]Center for Clinical & Basic Research, Ballerup, Denmark, [3]University of Copenhagen, Copenhagen, Denmark.

The circadian variation of bone resorption as derived from the collagen type I fragments measured in the CrossLaps (s-CTX) assay is significantly decreased in fasting individuals. This observation supports the idea that release of nutrients and minerals from the skeleton are tightly regulated to respond to food intake.

Studies of several gut hormones make it clear that these peptides are key regulatory hormones that transmit information generated during ingestion of food. Thus, the harvest from the skeletal reserve of both calcium and protein could be regulated by gut hormones to respond to ingestion of nutrition.

We have identified the gastrointestinal peptide, glucagon like peptide-2 (GLP-2) as a key factor in the regulation of bone resorption in response to food intake. This discovery lead to a placebo-controlled randomised study of the effect of single subcutaneous injection of GLP-2 in four different dosages or placebo (saline) in 60 postmenopausal women. GLP-2 caused a dose-dependent reduction in the s-CTX level from baseline. An area under the curve (AUC0-8h) analysis for s-CTX after GLP-2 injection confirm the dose-dependent decrease. Bone formation, as assessed by osteocalcin, was un-affected by the exogenous GLP-2 treatment.

The surprising acute effect of GLP-2 on bone resorption could indicate a direct action of the hormone on bone cells (osteoclasts and/or osteoblasts). We have located a GLP-2 receptor to be expressed by the osteoclast in both rat and human. Thus the mechanism of action for GLP-2 on bone turnover is most likely mediated through this bone tissue receptor.

These studies suggest that administration of GLP-2 results in a reduction of the bone resorption with no effect on the bone formation process and we interpret this action as a positive uncoupling of the bone turnover processes. A positive uncoupling of the bone turnover processes can potentially lead to a "passive" anabolic effect on the bone turnover, i.e. suppressing the bone resorption process and leave bone formation un-changed.

Thus, GLP-2 could provide a potential new drug for prevention and/or treatment of osteoporosis.

An Orally Available, Non-Steroidal, Selective Androgen Receptor Modulator (SARM) Has Anabolic Activity in Osteopenic Female Rats. E. G. Vajda[1], W. C. Chang[1], E. C. Talaoc*[1], K. Burnett*[1], K. Griffiths*[1], E. Martinborough*[2]. [1]Pharmacology, Ligand Pharmaceuticals, San Diego, CA, USA, [2]Medicinal Chemistry, Ligand Pharmaceuticals, San Diego, CA, USA.

Both androgens and estrogens play a role in skeletal biology. Estrogen decreases bone remodeling in humans and animal models, but the role of androgens is not as clearly defined, particularly in women. Androgens have both anabolic and anti-resorptive activity in different models and may be useful in the treatment of osteoporosis. The potential for undesired prostate stimulation in men and virilizing activity in women however, has been a major limitation for the clinical use of androgens. In these studies, we report a novel, non-steroidal selective androgen receptor modulator (SARM) with tissue selectivity in castrated male rats and bone anabolic activity in osteopenic female rats. Nine week old male SD rats were castrated and immediately began treatment with the SARM or vehicle for 14 days. At doses that were fully efficacious at maintaining the levator ani muscle weight at intact levels (1 mg/kg p.o.), efficacy in the ventral prostate and seminal vesicle were 10% and 6% relative to intact controls, respectively. Efficacy in the preputial gland, a modified sebaceous gland, was 5%. Serum osteocalcin was elevated by castration and was restored to intact levels with SARM treatment, indicating changes in bone metabolism. Two month old female SD rats were ovariectomized (OVX) in order to induce osteopenia. Treatment with the SARM (0.1, 1, or 10 mg/kg p.o.), estradiol, or testosterone propionate was initiated 8-weeks post-OVX and continued for 12 weeks. Serum osteocalcin was significantly increased by OVX and significantly decreased by treatment. Serum total alkaline phosphatase was significantly increased with respect to OVX controls. DEXA scans at the mid-femur showed increased bone mineral density (8.3%) with respect to OVX control animals. Dynamic histomorphometry at the mid-femur revealed significantly increased periosteal bone formation (73.9% increase) in a dose-dependent manner. Femur bending strength was also significantly increased in biomechanical testing. In contrast to the effects of SARM treatment, periosteal bone formation rates were decreased and bending strength was unaffected in estradiol treated rats, demonstrating a distinctly different mechanism of action. Collectively, these results indicate that a SARM with tissue selective and potent bone anabolic activity may be a promising compound for the treatment of osteoporosis in men and/or women.

10.000 IU of Oral Vitamin D Per Day Are Required to Rapidly (3 months) Reach Adequate 25OHD in Osteoporotic Women. S. Mastaglia*, B. Oliveri, M. S. Parisi*, A. Cristófari*, C. Mautalen. Sección Osteopatías Médicas, Hospital de Clínicas, Universidad de Buenos Aires, Buenos Aires, Argentina.

Recently Heaney et. al. (J Am Coll Nutr 2003 Apr ,22(2):142-6) reported that 25OHD serum levels should be above 34 ng/ml (86 nmol/l) for adequate calcium absorption and beneficial for the treatment of osteoporosis. The dose of vitamin D required to rapidly reach adequate serum 25OHD levels (above 34ng/ml) has not been established to date.

Thirty four women living in Buenos Aires (34° S) aged 61.7± 5.5 years, with 15.7± 6.1 years since menopause, average BMI: 27.7±4.7 and average T score of lumbar spine/ femoral neck: -2.5. The patients were randomized to receive placebo (G1) or vitamin D in a daily oral doses of 5.000 IU(G2) or 10.000 IU (G3). All the subjects received calcium supplementation (500mg/day/tablets).

Serum calcium, bone alkaline phosphatase (BALP), 25 hydroxivitamin D (25OHD), mm PTH, serum crosslaps (sCTX), and 24 hours urine calcium (uCa) and urine creatinine were measured at baseline and after 1, 2 and 3 months of treatment.

Average baseline 25OHD levels for the whole population was 14.2 IU ng/ml. All individual values were below 34 ng/ml. No differences in baseline measurements were found among the three groups. Serum and urinary calcium were within normal range. The average increments of 25OHD are shown in the figure.

At the end of 3 months 73% of group 3, 42% of group 2 and 0% of group 1 reached 25 OHD values above 34 ng/ml. Serum and urinary calcium values remained within normal range in all patients. No significant changes were observed in serum PTH, CTX or BAP.

In the light of the present results, the oral dose of vitamin D required to rapidly achieve adequate levels of 25OHD in osteoporotic postmenopausal females appears to be much higher than the usual recommended dose (800IU/day). Ten thousand units per day during 90 days was effective since 25OHD levels reached 39 ng/ml (range 28 to 55 ng/ml) and caused no side effects. Future studies should determine the maintenance dose, once the effective level has been achieved.

Pre-treatment Bone Turnover and Fracture Efficacy of Alendronate: The Fracture Intervention Trial. D. C. Bauer[1], P. Garnero[2], M. C. Hochberg[3], A. Santora[4], P. Delmas[5], S. K. Ewing*[1], D. M. Black[1]. [1]UCSF, San Francisco, CA, USA, [2]Synarc, Lyon, France, [3]Univerisity of Maryland, Baltimore, MD, USA, [4]Merck Research Laboratories, Rahway, NJ, USA, [5]INSERM, Lyon, France.

Previous trials have demonstrated that bisphosphonate treatment reduces bone turnover and fracture risk among osteoporotic women. The effect of bone turnover rate prior to therapy on treatment efficacy has not been studied in large trials.

In the Fracture Intervention Trial, women age 55-80 with femoral neck BMD<0.68 g/cm2 were randomized to alendronate (ALN), 5-10 mg/d (n=3105) or placebo (PBO)(n=3081). At baseline 56% were osteoporotic, defined as those with prevalent vertebral fracture and/or BMDfn t-score <-2.5. Among these osteoporotic women, during a mean follow-up of 3.2 years, 492 non-spine fractures were documented and 285 incident vertebral fractures were identified on paired lateral spine x-rays. We used archived serum to measure pre-treatment levels of bone specific alkaline phosphatase (Bone ALP, Hybritech), and N-terminal propeptide of type 1 collagen (P1NP, Orion). C-terminal telopeptide of type 1 collage (sCTX, Crosslaps) was also measured, but only 20% of the cohort was fasting.

To determine the effect of pre-treatment bone turnover on fracture risk reduction, the risk

of spine and non-spine fracture was compared among ALN and PBO-treated subjects stratified into tertiles of baseline bone marker levels. Interactions between continuous baseline levels of markers and ALN efficacy were tested in age-adjusted proportional hazard and logistic models.
At baseline, mean (±SD) P1NP and bone ALP levels were 52.1±20.3 mg/dl and 14.0±4.5 mg/dl, respectively. The reduction in non-spine fractures with ALN treatment differed significantly among those with low and high levels of P1NP levels at baseline (Table), and similar trends were observed with bone ALP. Treatment efficacy for hip and morphometric spine fractures did not differ significantly according to baseline marker levels.
We conclude that in the Fracture Intervention Trial, reductions in non-spine fracture risk with ALN therapy are greater among osteoporotic women with high pre-treatment levels of bone turnover as assessed by P1NP.

Relative Risk of Non-spine Fracture (95% CI) for ALN vs. PBO by Tertile of Baseline Marker

Marker	Lowest Tertile	Middle Tertile	Highest Tertile	Tx*marker interaction p value
P1NP	0.89 (0.65, 1.21)	0.74 (0.54, 1.01)	0.54 (0.39, 0.74)	0.02
Bone ALP	0.83 (0.61, 1.13)	0.68 (0.49, 0.94)	0.61 (0.45, 0.83)	0.70

Hip Structure Analysis (HSA) Predicts Risk for Incident Hip Fracture in the Nursing Home. L. B. Yates[1], T. J. Beck[2], K. E. Broe[3], M. L. Bouxsein[4], D. P. Kiel[3]. [1]Harvard Medical School, Boston, MA, USA, [2]Johns Hopkins University, Baltimore, MD, USA, [3]Hebrew Rehabilitation Center for Aged, Boston, MA, USA, [4]Beth Israel Deaconess Medical Center, Boston, MA, USA.

Hip Structure Analysis (HSA) has been studied in community-dwelling populations to understand age-related differences in femoral geometry over the lifespan and to predict risk for hip fracture. To our knowledge, no study has applied HSA in an elderly nursing home population. We hypothesized that in this population older individuals would have less favorable HSA indices, and that these indices would predict incident hip fracture. We therefore performed DXA scans (Hologic QDR 1000) on 232 long-term care residents (168 women, 64 men), aged 67-102 y (mean 88 ± 6 y), and followed them for hip fracture, death or end of study (median follow-up 3.1 y). We divided subjects into three age groups: 67-84 y (n=61); 85-90 y (n=95); 91-102 y (n=76). We applied HSA to the DXA images to derive measurements at the narrowest point in the femoral neck, including BMD, cross-sectional area (CSA), subperiosteal width (W), endocortical diameter (ED), section modulus (Z, bending strength), buckling ratio (BR, cortical instability), and cortical thickness (CT). We used linear regression to analyze the association between age groups and HSA variables, and Cox proportional hazards to model risk for hip fracture, adjusting all models for baseline age, sex, height, weight, and need for assistance in ambulation (yes/no). Adjusted mean BR, ED, and W significantly differed ($p \leq 0.007$) by age group (oldest vs youngest, 4 to 7% difference), with the oldest group having the least favorable indices. There were no age group differences in CSA (p=0.56), BMD (p=0.34), or CT (p=0.33), although a trend was seen for Z (p=0.06). During follow-up 39 residents (17%) had hip fracture. For each standard deviation (SD) decrease in HSA variable at the femoral narrow neck, the hazard ratio (HR) and 95% CI for hip fracture are shown below.

Hip Fracture HR per -1 SD in HSA Variable (95% CI)

CSA	Z	BMD	CT	BR	W	ED
2.01	1.82	1.74	1.74	0.71	0.96	0.88
(1.14,3.53)	(1.03,3.21)	(1.09,2.77)	(1.09,2.77)	(0.53,0.95)	(0.58,1.57)	(0.56,1.40)

Our results indicate that age-related changes in hip structure occur even in very old persons and that measurements of femoral geometry predict risk for hip fracture in nursing home residents.

Hip Section Modulus, but not Bone Density, Shows the Effects a Decade Later of a Two-year Calcium Supplement Taken at the Time of Attainment of Peak Bone Mass. R. I. Price[1], N. K. Briffa[2], T. J. Beck[3], A. L. Mein*[2], B. C. C. Khoo*[1], R. L. Prince[1], S. S. Dhaliwal*[1]. [1]Sir Charles Gairdner Hospital, Nedlands, Australia, [2]Curtin University, Perth, Australia, [3]Johns Hopkins University, Baltimore, MD, USA.

Maximising premenopausal BMD is important for preventing fractures in old age. Calcium (Ca) intake is a significant agent for increasing BMD, but there is uncertainty as to the long term beneficial effect of a limited period of Ca supplement around the time of attainment of peak bone mass (PBM). Unlike DXA-derived areal BMD (aBMD), Hip Structural Analysis (HSA; [1]) describes bone structural geometry, in particular section modulus (Z; an index of bone strength), and may augment BMD as an assessor of bone fragility. This study examined changes in HSA and BMD in young women, over the decade after attainment of PBM.
Sixty-two women of mean (SD) age 27.8 (1.0) years were re-measured for aBMD and HSA, 9.4 (0.9) years following baseline measurements, on recruitment at age 18 into a 2-year randomised, controlled trial of Ca supplement (2). aBMD was measured at femoral neck (FN), trochanter (Tr) and intertroch. (IT). HSA variables were measured in duplicate at the "narrow neck" (NN) of FN, IT and shaft (Sh), using identical DXA (QDR1000W) images. Serial HSA data were unobtainable for 2 subjects. Thus 29 and 31 subjects were in the "placebo" (Pl) and "prior Ca supplement" followup groups. Dietary Ca was assessed at followup by questionnaire. Mean (SD) Ca intake was 895 (228) mg/d.
Focusing on section modulus, changes in Z over the decade were treatment and site dependent. NN Z increased from Mean (95% CI) of 1.33 (1.25, 1.41) cm3 to 1.43 (1.33, 1.53) (+0.8%/yr, p<0.003) for the Ca group, with a nonsignificant (NS) trend of +0.4%/yr in Pl. IT Z changes were NS for the Ca group (-0.7%, p<0.13), but IT Z increased from 3.71 (3.49, 3.93) to 4.09 (3.85, 4.33) (+1.1%/yr, p<0.04) for Pl. Sh Z increased from 2.01 (1.90, 2.12) to 2.23 (2.10, 2.36) (+1.2%/yr, p<0.03) for Pl, with NS for Ca. Prior Ca supplement had no effect on aBMD changes at any site (p<0.35) so treatment groups were combined in the BMD analysis. Over the decade, aBMD at hip sites declined [FN; -0.40%/yr (SD=0.62) (p<0.001): Tr; –0.34 (0.60) (p<0.001)], or was unchanged [IT; +0.12 (0.58) (p=0.10); Sh (at HSA shaft site); +0.32 (0.32) (NS)].
We conclude that, unlike hip aBMD which generally declined in the decade following attainment of peak bone mass, hip section modulus (and thus likely bone strength) generally increased. In sites of high cancellous content (eg FN) this increase was linked to prior Ca supplement, but at more cortical sites (eg Sh) it was conversely linked to the absence of Ca supplement. 1. Measurements of Plate and Rod Thickness in Human Trabecular Femoral Bone in osteoporosis and Osteoarthritis. A. Bonnassie*[1], F. Peyrin*[1], B. Brunet-Imbault*[2], C. Chappard[2], C. Benhamou[2]. [1]CREATIS UMR CNRS 5515, Villeurbanne, France, [2]Inserm ERIT-M 0101, Orléans, France.

3D X-ray microtomography which is increasingly used to analyze trabecular bone micro-architecture, enables computing architecture parameters without any model assumption. We propose a new geometrical analysis to identify the plate and rod structures in the 3D image and compute additional morphometric characteristics on each type of structure.
We analyzed two groups of subchondral bone in femoral head from osteoporostic patients (OP, n=8), and osteoarthritic patients (OAsc, n=8). Cylindrical cores (diameter 8mm) were imaged using 3D synchrotron radiation microtomography at the ESRF. In each 3D image (voxel size : 10.13 µm) a region of interest avoiding boundary effects related to bone cutting was selected (diameter : 6mm). 3D morphometric parameters of trabecular bone micro-architecture were computed using the Mean Intercept Length method and model independent techniques. We applied our new technique to label each voxel in the bone structure as a rod, a plate or a branching element. The result is illustrated in figure 1 where colors are associated to the different structures. After labeling, we computed the volume of each structure on the total volume, denoted PV/TV, NV/TV, RV/TV respectively for the plates, the rods and the branches. In addition the thickness of each type was also estimated as P.Th*, R.Th*, N.Th*.

Figure 1 : 3D display of the labeling of plates (light gray), rods (black) and branching (dark gray) structures in a femoral head bone in an osteoarthritic patient.
The two groups were found significantly different for all morphologic parameters. In addition, the geometrical analysis showed that the OAsc group presented a significantly higher volume of rods and branching component than the OP group. The trabecular thickness was also found significantly larger both for rods and plates in the Oasc group. In each structure (OP and Oasc), the percentage of plate and rod volume to the total volume were not significantly different, but the rod thickness was found significantly larger than the plate thickness.
The proposed method gives new insight in the morphologic analysis of trabecular bone micro-architecture.

Correlation of 2D Trabecular Structure Parameters with 3D μCT and Measurements of Bone Strength in Femoral Bone Cores. C. D. Arnaud[1], S. Liew*[1], D. Steines*[1], A. Nazarian*[2], R. Mueller*[3], B. J. Linder*[1], P. Lang*[1]. [1]Imaging Therapeutics, Inc., San Mateo, CA, USA, [2]Orthopedic Biomechanics Laboratory, Harvard Medical School, Boston, MA, USA, [3]Swiss Federal Institute of Technology, Zurich, Switzerland.

Bone mineral density measurements (BMD) identify subjects at risk for fracture and can help select those individuals who will benefit most from therapy. However, overlap exists in the distribution of BMD of patients with and without osteoporotic fracture, and BMD does not accurately predict the *presence* of fractures. Thus, factors other than BMD influence fracture risk. Key among those factors are alterations of trabecular structure. Most procedures for assessing bone structure are invasive (i.e. histomorphometry, 3D μCT) or expensive (i.e. MRI). We developed automated hip radiographic imaging technology that measures a host of parameters of the geometry and connectivity of trabecular structure, using routine proximal hip radiographs. It involves x-ray digitization, identification of regions of interest, background subtraction, extraction of trabecular structures, and binarization and skeletonization of those structures. To verify our ability to use this 2D x-ray technology to quantitatively assess trabecular architecture, we compared it with 3D μCT, a gold standard for such measurements. Furthermore, results from our techniques were compared to biomechanical bone properties.

Bone cores (n=49) were harvested from cadaveric proximal femora. Specimen radiographs were obtained and 2D structural parameters were measured on the radiographs. Cores were then subjected to 3D μCT and biomechanical testing. The 2D structural parameters measured included trabecular area ratio (AR), length (L), intensity (I) and thickness (T). Pearson's correlation coefficients (r) between 2D structure parameters and biomechanical failure load, biomechanical stiffness, and corresponding 3D μCT parameters, respectively, are listed in the table below.

We conclude that measurements of bone structure on femoral bone core radiographs correlate highly with bone failure loads and stiffness as well as 3D μCT measurements. These results suggest that inexpensive proximal femoral trabecular structural analysis from hip radiographs may yield vastly improved diagnostic assessment of osteoporosis and estimation of fracture risk.

*p<0.001	AR	L	I	T
Failure load	0.74*	0.81*	0.83*	0.81*
Stiffness	0.69*	0.74*	0.77*	0.75*
μCT	0.90 (with BV/TV)	0.84* (with BV/TV)	0.96* (with TbTh)	0.87* (with TbTh)

Chemical Composition Distinguishes Fracture from Non-Fracture Subjects Matched by Bone Mass. B. R. McCreadie[1], M. D. Morris*[2], T. Chen*[2], W. F. Finney*[2], E. Widjaja*[2], S. A. Goldstein[1]. [1]Orthopaedic Surgery, University of Michigan, Ann Arbor, MI, USA, [2]Chemistry, University of Michigan, Ann Arbor, MI, USA.

Although bone mineral density is used clinically to evaluate fracture risk, a large overlap exists between those who go on to fracture and those who do not. This study sought to determine whether the chemical composition of the bone extracellular matrix influences fracture risk.

Trabecular bone specimens were obtained from two groups of females, fractured (undergoing arthroplasty) and unfractured at death, matched for age and bone volume fraction. All specimens were taken from a location adjacent to the fracture site in most of the fracture cases. An epi-illumination Raman microspectroscopic imaging system was used to obtain Raman scatter spectra from each specimen. Ratios of the band areas of phosphate ν_1, carbonate ν_1 and collagen amide I were used as measures of carbonate/phosphate and mineral/matrix (phosphate/amide I).

A clear relationship was found between the carbonate/phosphate and phosphate/amide I ratios. The carbonate/phosphate ratio is essentially constant over much of the range, but increases considerably at the extreme low end of the phosphate/amide I ratio. The fracture specimens are concentrated at the low end of the carbonate/amide I range. A statistical comparison of carbonate/phosphate ratio yielded a p-value of 0.08, while for carbonate/amide I was 0.28.

In groups matched for bone mass, we were able to make a distinct separation between many females who did not fracture compared to those who did. The modest overlap in specimens may be a result of difficulties in defining a true control population. Some of the individuals that died without fracture would likely have sustained a fracture had they lived longer.

It is unclear whether the differences seen at the fracture site are local or systemic. If the differences in chemical composition are limited to the fracture site, these results suggest a large increase in remodeling prior to overt fracture. If the differences are systemic, it suggests that some individuals may be more susceptible to fracture based on the chemical constituency of bone matrix.

This study is the first to demonstrate a relationship between carbonate/phosphate and phosphate /amide I ratios. In addition, the results suggest a novel and potentially robust method for predicting risk of fracture, either alone or in combination with bone mineral density. It should be possible to develop spectroscopic instrumentation to conduct convenient non-invasive or minimally-invasive measurement of the relevant chemical constituents.

Comparison of Areal and Volumetric Vertebral Bone Densities Measured by DXA and CT in Healthy Girls. T. A. L. Wren[1], A. Kovanlikaya*[2], X. D. Liu*[2], P. D. Pitukcheewanont*[3], V. Gilsanz[2]. [1]Orthopaedic Surgery and Radiology, Childrens Hospital Los Angeles, Los Angeles, CA, USA, [2]Radiology, Childrens Hospital Los Angeles, Los Angeles, CA, USA, [3]Endocrinology and Metabolism, Childrens Hospital Los Angeles, Los Angeles, CA, USA.

Dual-energy x-ray absorptiometry (DXA) is the most frequently used technique for measuring bone density in both children, although in growing subjects, areal bone mineral density (BMD) measurements are influenced by changes in bone size and soft tissue composition. The purpose of this study was to determine the agreement between DXA areal BMD values and CT volumetric bone density (BD) values. DXA areal BMD and Z-score (Z_{DXA}) were compared with CT volumetric BD and Z-score (Z_{CT}), and to CT measures of cross-sectional area (CSA) in 100 healthy girls, ages 5 - 20 years. Z-score represents the number of standard deviations (SD) the BMD or BD is above or below the mean for sex- and age-matched controls. Moderate correlations were observed between DXA and CT densities (r=.688, p<.0001) and between DXA and CT Z-scores (r=.624, p<.0001). A moderate correlation was also present between BMD and CSA (r=.662, p<.0001). The density correlations were weaker in subjects under 12 yr (r=.203, p=.54 for density; r=.449, p = .15 for Z-score) than subjects 12 yr and older (r=.668, p<.0001 for density; r=.652, p<.0001 for Z-score), while the correlations of BMD with CSA were stronger in subjects under 12 yr (r=.757, p=.0030) than older subjects (r=.394, p<.0001). Paired t-tests indicated that the DXA Z-scores were systematically lower than the CT Z-scores (p<.0001). We conclude that increases in DXA areal BMD of the lumbar vertebrae in girls under 12 yrs old are likely a reflection of changes in vertebral size rather than changes in density and that caution should be exercised before girls of any age are diagnosed with osteoporosis based on DXA measurements.

New Osteoporosis Screening Recommendations for Older Women: Targeted Screening May Be More Appropriate for Non-White Women. D. L. Broussard*, J. H. Magnus. Tulane University Health Sciences Center, New Orleans, LA, USA.

Universal osteoporosis screening in the U. S. is now recommended for all women ≥65 years of age, regardless of race/ethnicity. While some non-White women are at a greater risk of post-fracture disability and mortality than White women, non-White women have a lower overall fracture rate than White women. Furthermore, there is no consensus about what levels of bone mineral density (BMD) should be considered osteoporotic in different race/ethnic groups. Therefore, screening all older non-White women may not be cost effective, a circumstance that may be remedied by targeting screening only to those non-White women at high risk for osteoporosis. The purpose of this study was to determine if a set of low BMD risk factors for White women accurately identifies African American (AA) and Mexican American (MA) women with osteoporosis. Low body mass index, low calcium intake, current cigarette smoking, and no physical activity were found to be consistent low BMD risk factors for White women in published population-based studies. This set of four risk factors was evaluated among 252 AA, 232 MA, and 745 White women, aged 65 to 79 years, who participated in the Third National Health and Nutrition Examination Survey (NHANES III). Osteoporosis T-scores were calculated for each group as 2.5 SD below the race/ethnic specific young adult female (20-29 years) mean BMD for the total femur using published NHANES III data. The diagnostic accuracy of one or more of the four risk factors for identifying total femur osteoporosis in each of the race/ethnic groups of women was assessed by calculating sensitivity, specificity and positive and negative predictive values. Based on the race/ethnic group-specific T-scores, the prevalences of osteoporosis in this NHANES III population were 9.8%, 13.5%, and 13.1%, respectively, for AA, MA and White women. The sensitivities associated with the presence of one or more of the four risk factors were 87%, 92%, and 70%, respectively for AA, MA, and White women. Specificity was highest in White women (52%) while the specificities for AA and MA women fell below 50%. PPV ranged from 20% to 28%, and NPV ranged from 87% to 94%. About 23% of AA and 28% of MA women had no risk factors, and in a screening setting would not be referred to BMD testing. Of those with no risk factors, only 11% of AA and 6% of MA women had osteoporosis. Furthermore, the false negative rates for AA and MA women were low. These results suggest that applying the set of four risk factors studied as a prescreening risk assessment tool may be useful for identifying AA and MA women who are not likely to have osteoporosis and do not require a BMD measurement, which has the potential for reducing the economic burden of universal BMD screening.

The Use of BMD for Therapeutic Decision Making. J. A. Kanis, A. Oden*, H. Johansson*, C. De Laet*, E. V. McCloskey, K. Kayan*, T. Jalava*, A. Oglesby*, O. Johnell. WHO Collaborating Centre for Metabolic Bone Diseas, University of Sheffield Medical School, Sheffield, United Kingdom.

Clinical risk factors are poor predictors of fracture risk, but not useless. They may have more utility in categorising individuals above or below risk thresholds. If so, BMD may not be required in all patients to make recommendations about treatment. The aim of this study was to develop a methodology to optimise the role of bone mineral density (BMD) measurements in a case finding strategy. We studied 2113 women aged 75 years or more randomly selected from Sheffield UK. Baseline assessment included hip bone mineral den-

sity (BMD) and clinical risk factors. Outcomes included death and fracture in women followed for 6723 person years. Poisson models were used to compute fracture probabilities. Women were categorised by fracture probability with and without a BMD assessment. An arbitrary 10 year fracture probability threshold of 35% was taken as an intervention threshold. Age, prior fracture, use of corticosteroids and low body mass index (BMI) were identified as significant clinical risk factors. 16.8% of women were classified as high risk on the basis of these clinical risk factors. The average BMD in these patients was approximately 1 SD lower than in low risk women. 21.5% of women were designated to be at high risk with the addition of BMD. 15% of all women were re-classified after adding BMD to clinical risk factors, most of whom lay near the intervention threshold. When a high probability of re-classification was accepted (without a BMD test) for high risk to low risk ($P_1 \leq 0.8$) and a low probability accepted for low to high risk ($P_2 \leq 0.2$), BMD tests would be required in only 21% of the population and the proportion of re-classified women would be reduced from 15 to 8%. The proportion of high risk individuals not detected would decrease from 46 to 13% which is 2.8% of all women. We conclude that the use of clinical risk factors can identify elderly women at high fracture risk and such patients have a low average BMD. BMD testing is required, however, in a minority of women – a fraction that depends upon the probabilities accepted for misclassification and the thresholds of risk chosen.

Hypovitaminosis D in Healthy Adolescents. C. M. Gordon[1], K. DePeter*[2], E. Grace*[2], S. J. Emans*[2]. [1]Endocrinology & Adolescent Med., Children's Hospital, Boston, MA, USA, [2]Adolescent Medicine, Children's Hospital, Boston, MA, USA.

Vitamin D is essential for optimal bone accretion during adolescence. In a clinic sample of healthy adolescent girls and boys, we sought to determine the prevalence of hypovitaminosis D. We also examined whether the prevalence differed by gender, season or ethnicity, and examined anthropometric and lifestyle predictors of serum levels of 25-hydroxyvitamin D (25D). 282 adolescents (185 girls and 97 boys) who presented to an outpatient adolescent medicine practice in Boston, MA were evaluated at the time of a routine physical examination. Serum levels of 25D, parathyroid hormone (PTH), calcium, phosphorus and magnesium were obtained, and activity and nutritional questionnaires completed. The prevalence of hypovitaminosis D (<15 ng/ml) was 20% for the cohort. The problem was more prevalent in girls (22%) than boys (15%), and more prevalent in African- American (30%) than Asian (17%), Hispanic (18%), or White (2%) teenagers. There was a seasonal variation noted, with a prevalence of 9% during summer (July - Sept.) and 36% during winter (Jan.- March). The mean winter 25D level was significantly lower than that during summer (10.7 +/- 2.4 vs. 27.7 +/- 10.1 ng/ml, p<0.001), and PTH levels were higher (54.6 +/- 26.7 vs. 43.7 +/-19.9 pg/ml, p=0.006). There was a significant negative correlation between serum 25D and PTH (r= -0.27, p<0.001). There was a modest, but significant positive correlation between 25D levels and reported consumption of vitamins(r= 0.15, p=0.012) and calcium supplements (r= 0.15, p=0.013), and a negative correlation between 25D and both weight (r= -0.18, p=0.003) and body mass index (r= -0.17, p=0.004). There were no significant differences among boys and girls with respect to use of multivitamins or calcium supplements, but daily milk consumption was higher in the boys than girls (2.8 +/- 2.2 vs. 1.6 +/- 1.1 cups, p<0.001). Both the boys and girls with hypovitaminosis D reported significantly lower milk consumption than those who were replete (1.4 +/- 1.1 vs. 2.2 +/- 2.0 cups, p=0.039). Hypovitaminosis D occurred in 20% of otherwise healthy teenagers in a clinic sample from Boston, a city of northern latitude. The problem was more prevalent in girls than boys, and most prevalent among adolescents of African-American descent. These findings suggest that hypovitaminosis D is a significant problem among teenagers. Adolescent providers should take note of these findings, both of the high prevalence of this health problem and suboptimal nutritional practices, especially among girls and adolescents of certain ethnicities.

Umbilical Vein Calcium Concentration Predicts the Bone Mass of Children at Age Nine Years. M. K. Javaid[1], S. R. Shore*[1], P. Taylor*[2], C. Gale*[1], F. O'Callaghan*[1], N. K. Arden*[1], K. M. Godfrey*[1], C. Cooper[1], &. The Princess Anne Hospital Study Group*[1]. [1]MRC Environmental Epidemiology Unit, University of Southampton, Southampton, United Kingdom, [2]Medical Physics and Bioengineering, Southampton Univeristy Hospitals NHS Trust, Southampton, United Kingdom.

Osteoporotic fractures are a significant burden to society in the UK. Peak bone mass is a major determinant of bone strength in later life and epidemiological studies suggest that intrauterine and early postnatal environments influence skeletal trajectory and peak bone mass accrual. The aim of this study was to identify the specific maternal and neonatal determinants of bone mass in later childhood.

211 children (113 boys) were studied at age nine years. Their mothers anthropometry, diet and lifestyle had been characterized prospectively and the children were measured at birth. Now aged nine years, the children had their bone mass measured using DXA.

Boys were significantly taller (p=0.004) and had greater bone mass (p=0.002) than the girls. At nine years, birthweight remained a strong predictor of whole body bone mineral content (WBBMC) (r=0.40, p<0.001); lean mass (r=0.35, p<0.001) and fat mass (r=0.21, p=0.02) in both boys and girls. Lower maternal social class and educational attainment, smoking during late pregnancy, reduced prepregnant weight and height, and lower maternal fat stores during late pregnancy were significantly (p<0.05) associated with lower childhood WBBMC.

There were also strong positive associations between childhood WBBMC and umbilical venous calcium (p=0.002) and albumin (p=0.008) concentration. In contrast, umbilical venous phosphate, alkaline phosphate and creatinine did not predicted childhood WBBMC. In multivariate analyses, maternal smoking, socioeconomic status and fat stores were no longer associated with childhood WBBMC when umbilical calcium concentration was taken into account; male sex and tall maternal stature remained independent predictors of WBBMC.

These results suggest that umbilical venous calcium concentration is an important correlate of the trajectory of skeletal growth during the first nine years of postnatal life. The capacity to maintain a materno-fetal calcium gradient might be the physiological mechanism through which maternal smoking and nutrition adversely influence skeletal development in the offspring.

Physical Activity Intensities and Femoral Neck Strength in Young Children: The Iowa Bone Development Study. K. F. Janz*[1], T. L. Burns*[2], S. M. Levy*[3], J. C. Torner*[4], M. C. Willing[5], T. J. Beck*[6], J. M. Gilmore*[3], T. A. Marshall*[3]. [1]Health and Sport Studies, University of Iowa, Iowa City, IA, USA, [2]Biostatistics, University of Iowa, Iowa City, IA, USA, [3]Preventive and Community Dentistry, University of Iowa, Iowa City, IA, USA, [4]Epidemiology, University of Iowa, Iowa City, IA, USA, [5]Pediatrics, University of Iowa, Iowa City, IA, USA, [6]Radiology, Johns Hopkins, Baltimore, MD, USA.

Intervention studies suggest that a threshold of vigorous-intensity physical activity is needed to impact bone strength in children. However, quantifying this relationship in population-based studies is difficult since children are not cognitively capable of accurately reporting activity intensities. In this observational study, accelerometry was used to investigate associations between activity intensities and femoral neck (FN) bone strength (426 children, mean age 5.2 yr, range 4 to 6 yr). We tested the hypothesis that within the scope of children's usual activity patterns, vigorous activity is more strongly associated with bone strength than other activity intensities.

Physical activity was measured using 4-d accelerometry readings. This method produced minute-by-minute movement count data. Movement counts were calibrated to oxygen uptake as a multiple of resting metabolic rate (METs). The predictor variables were minutes per day in sedentary and light (< 2.9 METs), moderate (3 to 5.9 METs), and vigorous activity (≥ 6 METs). FN aBMD, cross-sectional area (CSA), and section modulus (Z) were calculated from DXA outputs (Hologic 2000). Associations were examined using partial correlation coefficients and stepwise linear regression after adjustment for weight and height.

Partial Correlations Coefficients		Femoral Neck		
*P < 0.05, **P < 0.01, NS = not significant		aBMD (g/cm^2)	CSA (cm^2)	Z (cm^3)
Sedentary and Light (min)	Boys	-0.20**	NS	NS
	Girls	-0.30**	-0.19**	-0.19**
Moderate (min)	Boys	0.NS	NS	NS
	Girls	0.26**	0.20**	0.16*
Vigorous (min)	Boys	0.28**	0.27**	0.22**
	Girls	0.30**	0.26**	0.19**

In boys, only vigorous activity entered regression models that included weight and height, the proportion of variance explained after adjustments ranged from r^2 = 3.9 to 5.8%. In girls, vigorous activity also entered all models explaining 1.2 to 4.4% of the variance and sedentary and light activity inversely entered the FN aBMD model (r^2 = 5.7%). During young children's "everyday" activity, vigorous activity is more highly associated with FN bone strength than other activity intensities. In girls, sedentary and light activity negatively impacts bone strength. Public health guidelines emphasizing moderate activity may not be appropriate for children's bone health.

BMP-3 Is a Negative Regulator of Cell Maturation during Skeletogenesis. L. W. Gamer*, J. Nove*, V. Rosen. Oral and Developmental Biology, HSDM and Forsyth Institute, Boston, MA, USA.

Although BMP-3 is the most abundant BMP in bone matrix, little is known about its specific role in the skeleton. In vivo, BMP-3 knockout animals possess twice the trabecular bone mass of their wild type littermates. In vitro, BMP-3 inhibits osteoblast differentiation in bone marrow stromal cell cultures and blocks BMP-2 and 7 mediated osteogenic activity, suggesting that unlike osteogenic BMPs, BMP-3 has an inhibitory effect on its target cells. In order to study where, when and how BMP-3 might act, we performed detailed in situ hybridization analysis of BMP-3 mRNA during skeletogenesis in mouse and chick. Initially, BMP-3 transcripts outline the prechondrogenic mesenchymal condensations, marking the future perichondrial surface. As individual skeletal elements form, BMP-3 transcripts become restricted to the perichondrium adjacent to the central region of the developing skeletal element, and then localize to osteoblasts. At all stages of endochondral bone formation, BMP-3 expression is excluded from chondrocytes. Since BMP-3 appears to be a negative regulator of osteoblast differentiation, we hypothesized that BMP-3 secreted by perichondrial cells may also exert an inhibitory effect on adjacent chondrocytes. Using the chick limb as a model, we implanted beads loaded with recombinant BMP-3 protein into stage 20-22 chick limb and found a consistent shortening and fusion of skeletal elements at d7 and 11. We also constructed a BMP-3 retrovirus and used it to infect stage 22 wing buds and micromass cultures from stage 23-24 limbs. Infection of wing buds with the BMP-3 virus resulted in an expansion of the skeletal elements. In BMP-3 infected prechondrogenic cell cultures, we observed an increase in PNA positive cells at d2 and an increase in Alcian blue staining at d4 post infection, demonstrating that BMP-3 induces an early increase in cell adhesion followed by an increase in the accumulation of sulfated proteoglycans. Northern analysis of RNAs from BMP-3 infected cultures indicates BMP-3 may be delaying chondrocyte maturation as the levels of collagen type II and Ihh are elevated, while the level of collagen type X is decreased compared to untreated cells. These data support a model in which BMP-3, secreted by perichondrial cells, acts on prechondrogenic cells in the developing limb to control their maturation into hypertrophic chondrocytes, and modulates the responsiveness of these cells to osteogenic signals that direct bone formation.

Bone Formation Induced by a Novel Strategy of Plasmid DNA-Controlled Release from Biodegradable Scaffolds. G. Pelled*[1], J. Jang*[2], Y. Zilberman[1], L. D. Shea*[2], D. Gazit[1]. [1]Skeletal Biotechnology Laboratory, Hebrew University-Hadassah Medical Center, Jerusalem, Israel, [2]Department of Chemical Engineering, Northwestern University, Evanston, IL, USA.

Novel strategies for bone regeneration are being investigated for the treatment of massive bone defects. Most gene-based approaches for bone repair involve the use of viral vectors encoding for osteogenic genes. A huge effort is being conducted in order to develop a non-viral method for gene delivery. Current non-viral techniques are limited in efficiency of transduction, and temporal or spatial control of DNA release using these vectors is impossible. We hypothesized that in vivo bone tissue formation could be achieved by a temporal and spatial controlled release of DNA from biodegradable scaffolds. A gas foaming process has been utilized to fabricate poly (lactide-co-glycolide) (PLG) porous scaffolds from polymeric microspheres. The DNA release kinetics from the scaffolds was analyzed using the Hoechst dye-binding assay. The ability of DNA released from the polymer scaffolds to transfect cells in vitro was examined using NIH/3T3 cells grown on scaffolds containing the reporter genes luciferase, beta-galactosidase, and GFP. For the in vivo experiments, scaffolds containing 50 ugr of hBMP2 plasmid were prepared. In order to non-invasively and quantitatively detect osteogenic activity in vivo, we implanted the scaffolds in transgenic mice, which express Luciferase under human Osteocalcin promoter. Since Osteocalcin is a late osteogenic marker, the detection of Luciferase bioluminescence by a cooled charge coupled device (CCCD) system can be quantitatively correlated to an osteogenic process. The implants were harvested after 30 days and analyzed using uCT and immunohistochemistry. We were able to control the kinetics of plasmid DNA release from the scaffold by varying the molecular weight of the polymer or the size of microspheres. Intense bioluminescence was quantified in the site of implantation in the transgenic mice indicating osteogenic activity. The uCT 3-D analysis demonstrated the presence of active osteogenesis within the implantation site correlated with the collagen I positive matrix, as revealed by immunohistochemistry. We conclude that the controlled release of plasmid DNA from PLG scaffolds could serve as an effective therapeutic tool for bone regeneration.

BMP Antagonist—Noggin Enhances Regulated Bone Formation and Bone Healing Conferred by Self-activating Tet-on Retroviral Vector Expressing BMP4. H. Peng[1], A. Usas*[1], B. Gearhart*[2], B. Young*[1], J. Huard[1]. [1]Orthopaedic Surgery, University of Pittsburgh, Pittsburgh, PA, USA, [2]Growth and Development Laboratory, Orthopaedic Surgery, Children's Hospital of Pittsburgh, Pittsburgh, PA, USA.

Regulated therapeutic gene expression is needed for many gene therapy applications. To develop an optimal regulated gene expression system we tried to optimize a self-inactivating, tet-on retroviral vector system capable of doxycycline (Dox)-regulated therapeutic gene expression in stem cells. We have systematically studied the effects of different regulatory elements in the 3' LTR on gene expression. This analysis has revealed that an intact U3 region is essential for high level gene expression in transfected cells. The introduction of an SV40 poly-adenylation signal cannot compensate for the deteriorative effects upon gene expression that result from a spectrum of U3 deletions. Further analysis of gene expression in the transduced cells showed that optimal, inducible gene expression by a self-inactivating retroviral vector requires the preservation of the DR1 and the TATA box. These findings enabled us to identify the best way to design self-inactivating vectors through which high level expression of bone morphogenetic protein 4 (BMP4) can be turned on and off via the addition or withdrawal of Dox. Muscle-derived stem cells (MDSCs) transduced with this vector system elicited bone formation in normal animals only following administration of Dox. More importantly, these cells healed critical-sized skull defects following administration of Dox. However, histological analysis revealed that there was isolated bone nodular formation in the absence of Dox, and bone overgrowth following Dox induction. To overcome these problems, we added MDSCs transduced with retroviral vector expressing noggin into the implants, along with MDSCs transduced with retro-Tet-on-BMP4. This novel strategy completely blocked the background bone formation and prevented bone overgrowth, but still preserved the capability of Dox-regulated bone formation. Thus, the amount of bone formation is dependent on the duration of Dox induction. In conclusion, we have identified the optimal design for a self-inactivating, tet-on retroviral vector that can efficiently transduce MDSCs and promote bone formation and bone healing through controllable BMP4 gene expression. More importantly, we have develop a novel strategy to improve the outcome of regulated BMP4 expression through the use of its specific antagonist—noggin. We believe this vector system and the improved regulated gene expression based on co-delivery of specific antagonist can also be applied to other systems where regulated therapeutic gene expression is needed.

Identification of the Gli family of Zinc Finger Proteins as Powerful Regulators of BMP-2 Expression in Osteoblasts. M. Zhao[1], D. Chen[1], I. R. Garrett*[2], G. Rossini*[2], B. O. Oyajobi[1], H. Sasaki*[3], G. R. Mundy[1]. [1]Cellular and Structural Biology, University of Texas Health Science center at San Antonio, San Antonio, TX, USA, [2]Osteoscreen Inc., San Antonio, TX, USA, [3]Institute for Molecular and Cellular Biology, University of Osaka, Osaka, Japan.

BMP-2 is important in skeletal morphogenesis and postnatal bone formation, but the regulation of its transcription in osteoblasts is not well understood. Since hedgehog (Hh) signaling modulates BMP-2 transcription, and Hh proteins mediate their effects on bone development through the Gli family of transcriptional regulators, we investigated the effects of Gli proteins on BMP-2 transcription. In this study, we examined the functions of Gli2 and Gli3 on BMP-2 expression in osteoblasts. The constructs of full length Gli2 or Gli3 ($Gli2^{act}$, $Gli3^{act}$) and their C'-terminal truncated forms ($Gli2^{rep}$, $Gli3^{rep}$), were co-transfected with BMP-2 promoter reporter constructs (-2712/+165-Luc) in C2C12 cells, and reporter activity was assessed. We found that $Gli2^{act}$ markedly and dose-dependently stimulated BMP-2 transcription, while $Gli3^{act}$ had a weak stimulatory effect. In contrast, $Gli3^{rep}$ decreased promoter activity by 80%, and $Gli2^{rep}$ by 55%. Analysis of BMP-2 promoter deletion cassettes from –2712/+165 to –150/+165, suggested that the functional sequence which responds to both activator and repressor forms of Gli2 and Gli3 is located in the region from –150 to –310. Mutational analysis indicated that three putative Gli binding sites in this region are responsible for the regulation of BMP-2 transcription. Gli2-mediated regulation of transcriptional activity of BMP-2 promoter was further confirmed by measurement of BMP-2 mRNA. We found that these Gli proteins undergo proteolytic processing in osteoblasts. IBMX induced $Gli3^{190}$ degradation and production of a short form of Gli3 ($Gli3^{85}$) in C3H10T1/2 cells, which we found required the E3 ubiquitin ligase Slimb, and was blocked by treatment with proteasome inhibitors PSI and epoxomicin. PKA, a negative regulator of Hh signaling, significantly attenuated $Gli2^{act}$-mediated activation of BMP-2 promoter activity. These results suggest that the regulation by Gli2 and Gli3 of BMP-2 expression is cAMP-, ubiquitin- and proteasome-dependent. $Gli2^{act}$ increased osteoblast ALP level in C2C12 cells whereas $Gli2^{rep}$ decreased it. In mouse calvarial cultures, we found that $Gli3^{rep}$ transfection significantly inhibited the effects of proteasome inhibition to stimulate new bone formation. Taken together, these data suggest that Hh signaling transductors Gli2 and Gli3 play important roles as regulators of BMP-2 expression, which may account in part for their multiple effects on skeletogenesis.

Effect of Lepitn on Growth Plate and Chondrocyte Differentiation. Y. Kishida*, A. Myoui, N. Tamai*, A. Nampei*, M. Nishikawa*, M. Hirao*, T. Nakase, N. Shimizu*, H. Yoshikawa. Department of Orthopaedic Surgery, Osaka University Medical School, Suita, Japan.

Leptin is a 16-kDa protein encoded by the obese (ob) gene that hormonally regulates food intake and energy expenditure by negative feedback at the hypothalamic nuclei. It has been shown that leptin and its functional receptor (ObRb) are distributed widely and leptin mediates a variety of activities, including bone development. It was reported that femoral length in ob/ob mice, that had impaired leptin production, was shorter than in normal mice, which was rescued by locally administered leptin, suggesting that leptin has a direct effect on growth plate. Based on these observations, we first investigated the effect of leptin depletion on growth plate using ob/ob mice. Immunohistochemical analysis revealed that leptin was localized in prehypertrophic chondrocytes in normal mouse and Ob-Rb in hypertrophic chondrocytes both in normal and ob/ob mice. Although there was no difference in the microscopic appearance in growth plate and mRNA expression of type II, IX and X collagen by in situ hybridization, we found that the growth plates of ob/ob mice were more fragile than those of wild-type mice by mechanical test and easy to break at hypertrophic zone, suggesting that the matrix maturation is impaired in ob/ob mouse. To

obtain a better understanding of the role of leptin in enchondral ossification, we determined the effect of leptin on in vitro chondrocytic differentiation of murine ATDC5 cells that express Ob-Rb. We found that leptin, at a concentration of 1-10 ng/ml, which was an equivalent dose to normal serum concentration of leptin, abolished the matrix calcification in late stage of ATDC5 cell differentiation culture and profoundly inhibited and delayed cell apoptosis. Since parathyroid hormone-related protein (PTHrP) was reported to inhibit the terminal differentiation and apoptosis of chondrocytes as well as matrix mineralization, we next examined PTHrP mRNA expression by quantitative assay using a real-time polymerase chain reaction. In the presence of physiological concentration of leptin, PTH-rP expression by ATDC5 cells was gradually increased with time. On the other hand, without exogenous leptin, PTH-rP expression was decreased with time. Furthermore, the leptin effect on matrix mineralization was abolished by anti-PTH-rP neutralizing antibody. These findings suggest that leptin regulates matrix mineralization and apoptosis in ATDC5 cell differentiation culture via modulating the chronological expression pattern of PTH-rP. Taken together, our data suggests direct effect of leptin is essential in the normal chondrocyte differentiation and endochondral ossification.

Overexpression of Smad6 in Chondrocytes Distinctively Disturbs Terminal Differentiation of Chondrocytes and Causes Osteopenia in Transgenic Mice. M. Horiki*[1], N. Tsumaki*[1], A. Myoui[1], T. Imamura*[2], H. Yoshikawa[1]. [1]Orthopaedic Surgery, Osaka University Medical School, Suita, Japan, [2]Department of Biochemistry, The Cancer Institute, Tokyo, Japan.

Bone Morphogenetic Proteins (BMPs) are known to play an important role in promotion of cartilage proliferation and differentiation. There have been several reports showing that Smads mediate these BMP signals in chondrocytic cells *in vitro*. However, *in vivo* role of Smad proteins during endochondral bone formation has not been analyzed. In the present study, we tried to block Smad signaling in developing cartilage by overexpression of Smad6, an inhibitory Smad, in chondrocytes of transgenic mice.

Materials and Methods To prepare the Smad6 transgene construct, the complete Smad6 cDNA was linked to the promoter and enhancer sequences of theα2(XI) collagen chain gene. By microinjecting the transgene insert, transgenic mice were generated and analyzed.

Results and discussion Pleural lines of transgenic mice were established. Staining of skeleton showed that primordial cartilage of transgenic mice developed almost normally until birth. Calcification was slightly retarded in some skeletal components in transgenic mice. After birth, transgenic mice began to show dwarfism. At 3 weeks after birth, the average lengths of bony components were 30 % shorter in transgenic mice than in those of normal mice. Northern analysis revealed that the expression levels of Sox9 and type II collagen genes in transgenic mice were almost equal to those of normal mice, whereas expression of Type X collagen gene was reduced. Histological analysis showed that there was no marked difference in the zone of proliferating chondrocytes between normal and transgenic mice. Columnar alignment of hypertrophic chondrocytes in transgenic mice was slightly irregular when compared with that of normal mice. The primary spongiosa was significantly decreased in Smad6 transgenic mice than in normal mice, which was also confirmed by micro-CT analysis (Figure). Although transgene expression was detected in prolifertative and weakly hypertrophic chondrocytes, excess amount of Smad6 might interfere with signal transduction only at final stage of maturation process of cartilage. We speculate that impaired matrix of zone of hypertrophic chondrocytes might disturb proper replacement of cartilage by bone, leading to osteopenia.

BIG-3, a Novel WD-40 Protein, Accelerates Chondrocyte Differentiation in Vitro. F. Gori, M. B. Demay. Endocrine Unit, Massachusetts General Hospital/ Harvard Medical School, Boston, MA, USA.

Among the local signaling pathways that regulate the onset of chondrogenesis and the sequential steps of chondrocyte differentiation is the bone morphogenetic protein (BMP) signaling pathway. We recently identified a BMP-2 induced gene, named BIG-3 (BMP-2 Induced Gene 3kb) that is expressed in a prechondroblastic cell line, MLB13MYC clone 17. BIG-3 is also expressed in proliferating and hypertrophic chondrocytes *in vivo* in the developing growth plate. We, therefore, undertook studies to address the role of BIG-3 during chondrocyte differentiation *in vitro* using mouse clonal chondrogenic ATDC5 cells. When treated with insulin, transferrin and sodium selenite (ITS) these cells undergo differentiation, becoming hypertrophic chondrocytes that make mineralized matrix. Upon BMP-2 treatment (200 ng/ml) BIG-3 protein was dramatically induced in ATDC5 cells. To determine whether stable expression of BIG-3 could alter the program of chondrocytic differentiation, ATDC5 cells were stably transfected with the full-length coding region of BIG-3 (ATDC5-BIG-3) cloned downstream of the CMV promoter in pcDNA3.1 or with the empty vector (ATDC5-EV). BIG-3 overexpression accelerated matrix proteoglycan synthesis at 14 d, as assessed by Alcian Blue staining, compared to pooled ATDV5-EV clones, where faint Alcian Blue staining was seen at 21 d. While ATDC5-EV clones cultured without ITS failed to show specific Alcian Blue staining after 30 d in culture, untreated pooled ATDC5-BIG-3 clones synthesized considerable amounts of Alcian Blue staining proteoglycans. Alkaline phosphatase (AP) mRNA expression was higher by 21 d in ITS-treated ATDC5-EV and ATDC5-BIG-3 clones compared to untreated clones. By 30 d AP mRNA expression was dramatically higher in ITS-treated and untreated ATDC5-BIG-3 clones compared to ITS-treated and untreated ATDC5-EV clones. Osteopontin (OP) mRNA expression, a marker of late hypertrophic chondrocytes was higher by 30 d in ITS-treated ATDC5-BIG-3 clones compared to ITS-treated ATDC5-EV clones. Untreated ATDC5-BIG-3 clones expressed higher OP mRNA levels compared to the untreated ATDC5-EV clones. Overexpression of BIG-3 also accelerates mineralized matrix formation as assessed by Alizarin Red staining in both the presence and the absence of ITS. These findings, which demonstrate that BIG-3 accelerates chondrocyte differentiation *in vitro,* combined with the observation that BIG-3 is expressed in a cell maturation dependent fashion in the growth plate during embryonic development, suggest that this novel protein plays a regulatory role in the maturation of growth plate chondrocytes *in vivo.*

Alteration in Bone Density of Mice due to Heterozygous Inactivation of LRP6. Y. P. Kharode[1], P. D. Green*[1], J. T. Marzolf*[1], W. Zhao[1], R. Askew*[2], P. J. Yaworsky*[2], F. J. Bex[1]. [1]Women's Health Research Institute, Wyeth Reserach, Collegeville, PA, USA, [2]Genomics, Wyeth Reserach, Cambridge, MA, USA.

Mutations in LRP5 have been associated with a continuum of bone phenotypes. LRP6 is a closely related homologue of LRP5, and like LRP5 has been identified as a co-receptor in the Wnt signaling pathway. Embryos homozygous for an inactivating mutation in LRP6 die at birth and exhibit a variety of severe developmental abnormalities including truncation of the axial skeleton, limb defects, microophthalmia and malformation of the urogenital system. Unlike the LRP6 mutants, mice homozygous for LRP5 disruption are viable but develop a low bone mass phenotype and retain embryonic eye vascularization. Clinically, inactivating mutations of LRP5 result in a severe reduction in bone mass and ocular pathology but, interestingly, heterozygous carriers of these mutations can have an intermediate low bone mass phenotype. To investigate potential similar dosage effects of LRP6 on the mouse skeleton, we evaluated bone density of the femur of LRP6 +/- males and females at 9, 17 and 26 weeks of age. The distal femurs of female LRP6 +/- mice at all ages had 9.5% to 12% lower total bone mineral density (BMD) and 20 to 31% lower trabecular BMD than age matched wild-type (WT) mice. At 9, 17 and 26 weeks of age, total BMD values of the femur as measured by pQCT for female LRP6 +/- mice (475±12, 488±13, and 552±17 mg/cm^3, respectively) were significantly lower ($p<0.05$) than total BMD of femur for WT (539±16, 611±9, and 619±11 mg/cm^3, respectively). Trabecular BMD of the femur in female LRP6 +/- mice (113±7, 128±8, and 152±8 mg/cm^3) was significantly lower ($p<0.01$) than the trabecular BMD for the age matched WT groups (163±13, 175±6 and 191±7 mg/cm^3, respectively). MicroCT analysis of the distal femurs revealed that at all time points BV/TV, Connectivity density and trabecular number were significantly lower and trabecular separation was significantly higher in LRP6 +/- compared to the corresponding WT group. In male LRP 6 +/- mice, the values for total BMD and for trabecular density were 3.5 - 7% and 8 - 27% lower, respectively, than those for the corresponding age-matched WT groups. Total and trabecular BMD in male LRP6 +/- mice were lower than corresponding WT groups; however, statistically significant differences between LRP6 +/- and WT were observed only in trabecular BMD at 17 weeks (128±10 mg/cm3 vs.175±9, $p<0.05$) and at 26 weeks (162±8 vs. 220±18 mg/cm^3, $p<0.05$). We conclude that (1) mice heterozygous for LRP 6 gene have lower BMD than WT and (2) the magnitude of this difference is more pronounced in females than in males.

The Human LRP5 G171V Mutation in Mice Alters the Skeletal Response to Limb Unloading but Not to Ovariectomy. F. Bex[1], P. Green*[1], J. Marzolf*[1], P. Babij[2], P. Yaworsky*[2], Y. Kharode[1]. [1]Women's Health Research Institute, Wyeth Research, Collegeville, PA, USA, [2]Genomics Division, Wyeth Research, Cambridge, MA, USA.

We have demonstrated that transgenic mice expressing a G171V mutation in the low-density lipoprotein receptor related protein 5 (LRP 5) have a high bone mass phenotype strikingly similar to affected individuals in a kindred with this mutation. Previous studies have shown that these mice have an increased response to skeletal loading. To further characterize potential differences in mechanosensory regulation produced by the mutation, we have evaluated the skeletal response of these mice to unloading and have contrasted it with loading-independent effects of ovariectomy (ovx). Nine week old male transgenic (het) mice have significantly ($p<0.001$) higher total and trabecular bone mineral density (BMD) (570±7, 357±4 mg/cm^3, respectively) than their non-transgenic littermates (ntg) (360±13,147±4 mg/cm^3, respectively). To examine the effects of unloading, unilateral sciatic neurectomy was performed on the right limb of het and ntg male mice and femoral BMD measurements were taken after one and two weeks. At both time points, in both het and ntg mice, total and trabecular BMD were significantly decreased in the distal femur of the denervated limb compared to that for the contralateral intact limb. However, at both time points, the rate of bone loss due to unloading was greater for ntg than for het. After 2 weeks the denervation-induced decrease in total and trabecular density in ntg mice (16.3±1.6% and 19.7±2.2%, respectively) was significantly ($p<0.05$) greater than for the het mice (10.0±1.4% and 11.5±2.5%, respectively). To determine whether the mutation had any effect on ovx-induced osteopenia, het and ntg mice were ovx at 9 weeks of age and treated for 35 days with vehicle or 10 ug/kg/day 17β- estradiol (E2). Ovx resulted in significant bone loss in both het and ntg ovx groups compared to their respective sham- ovx controls and the rate of this bone loss was comparable for both groups. Ovx induced a 14.3% decrease in total BMD (696±6 to 597±7 mg/cm^3) and a 26.3% decrease in trabecular BMD (445±9 to 328±7 mg/cm^3) in the het group and a 14.9% decrease in total BMD (470±10 to 400±7 mg/cm^3) and 37.6% decrease in trabecular BMD (132±4 to 82±2 mg/cm^3) in the ntg group. Treatment with E2 completely prevented the ovx-induced bone loss in both het and ntg. In conclusion, the LRP5 G171V mutation does not substantially alter the rate of ovx-induced bone loss and responsiveness to E2 but it can attenuate bone loss due to unloading which would be in agreement with its suggested role in the response of bone to mechanical stress.

Histone Deacetylase (HDAC) 3 Interacts with the Amino Terminus of Runx2 and Represses Runx2-Dependent Transcription. T. M. Schroeder*[1], J. J. Westendorf[2]. [1]Graduate Program in Biochemistry, Molecular Biology and Biophysics, University of Minnesota, Minneapolis, MN, USA, [2]Orthopaedic Surgery and University of Minnesota Cancer Center, University of Minnesota, Minneapolis, MN, USA.

Runx2 (Cbfa1, AML-3), a member of the Runt Homology Domain protein family, is required for bone formation and osteoblast differentiation. As a transcription factor, Runx2 is capable of both activating and repressing osteoblast specific genes. Our lab is interested in defining the molecular mechanisms by which Runx2 represses transcription. As previously described, our studies indicate that Runx2 contains multiple autonomous repression domains, some of which are sensitive to histone deacetylase inhibitors. Histone deacetylases (HDACs) repress transcription by removing acetyl groups from lysine residues on histones and transcription factors, thereby facilitating chromatin condensation and altering protein function or stability. Co-immunoprecipitation and GST pulldown experiments revealed that HDAC3 interacts with the extreme amino terminus of Runx2, a region previously not defined as a repression domain. To study the effect of HDAC3 knockdown on osteoblast differentiation, RNA interference (RNAi) duplexes were designed against HDAC3. In a transient assay, one duplex significantly suppressed HDAC3 expression. This construct was used to in functional assays in which the effects of Runx2 and HDACs on the osteocalcin promoter were examined. As previously reported, Runx2 activates the bone-specific osteocalcin promoter three to five fold. HDAC3 did not affect the basal activity of the osteocalcin promoter but blocked Runx2-dependent activation of this promoter. Addition of the HDAC3 RNAi construct to the assay reversed HDAC3 repression of Runx2-mediated activation whereas a control RNAi construct had little effect. MC-3T3 cells stably expressing the HDAC3 RNAi duplexes are viable. The requirement of HDAC3 in osteoblast differentiation is being determined. Together, these data suggest that HDAC3 physically and functionally interacts with Runx2. Our model system will allow us to determine the role of HDAC3 in osteoblast differentiation and bone development.

Mechanisms Regulating Runx 1 and 2 Gene Expression During Mesenchymal Chondrogenesis. C. J. Lengner, C. Lepper*, A. J. van Wijnen, J. L. Stein*, J. B. Lian, G. S. Stein. Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA.

The Runx family of transcription factors are key regulators of cell fate determination. Runx1 and Runx2 are both highly expressed in condensing mesenchyme (CM). Runx1 is transcriptionally active in perichondrium, whereas Runx2 is expressed in osteogenic lineage cells. In vivo, CM receives BMP2 signals for formation of skeletal rudiments prior to overt chondrogenesis. The role of Runx factors in pre-chondrocytic mesenchyme is unclear. We therefore addressed the responses of the Runx genes to chondrogenic regulatory signals using in vitro models of undifferentiated mesenchyme [primary mouse embryonic fibroblasts (MEFs) and C3H10T$^{1/2}$ cells] and their induction towards chondrogenesis by BMP2. All three Runx genes were found to be expressed in these cells. Contrary to conventional expectation, we observe that Runx2 is suppressed by BMP2 during chondrogenesis induced by micromass conditions, while Runx1 is up-regulated under the same conditions. In further support of this regulation, we demonstrate transcriptional inhibition of Runx2 is mediated by the pro-chondrogenic transcriptional repressor NKX3.2 (Bagpipe). Suppression of Runx2 by NKX3.2 is limited to undifferentiated mesenchymal cells (NIH3T3, C3H10T1/2) and is abrogated in committed osteoblasts (MC3T3E-1, ROS 17/2.8). Furthermore, we find an inverse correlation between endogenous expression of Runx2 and NKX3.2 at the onset of BMP-2 induced chondrogenesis. In conclusion, these data indicate Runx1 may be involved in promoting chondrogenesis, and that inhibition of Runx2 by NKX3.2 may be required for the development of the chondrogenic phenotype in condensing mesenchyme. Our studies suggest that the presence of Runx2 in mesenchyme prior to chondrogenesis may reflect a function to support a progenitor population which will differentiate later in development.

Fibronectin Hep III Domain on Stromal Cells Is Required for Osteoclastogenesis at the Early Stage through an RGD-independent Manner. S. Arai*[1], Y. Azuma[2], A. Kudo[1]. [1]Department of Life Science, Tokyo Institute of Technology, Yokohama, Japan, [2]Teijin institute for Biomedical Reserch, Tokyo, Japan.

RANKL is expressed on various tissues and hematopoetic cells. However, osteoclastogenesis is regulated mainly on bone marrow stromal cells. We tried to isolate surface molecules regulating osteoclastogenesis on stromal cells. The mouse stromal cell line, TSB13, which can support osteoclastogenesis, was immunized into a rat, and a monoclonal antibody, A15-1, was chosen. A15-1 inhibited osteoclastogenesis dose-dependently at the early stage of osteoclastogensisis from osteoclast progenitors to mononuclear osteoclasts. However, inhibition was not observed in the stroma-free, sRANKL-induced osteoclastogenesis. We identified that the A15-1 antigen is fibronectin, a heterodimeric ECM glycoprotein and A15-1 binds its HepIII, which did not included domain. RGD sequence, an integrin-binding site. Antisense oligonucleotides against the mouse fibronectin mRNA were transfected into TSB13, resulting remarkable decrease of the ability of osteoclastogenesis. On the Hep III domain coated dish, osteoclastogenesis was stimulated. Moreover, the pro-B and pre-B cell lines that highly express RANKL on the surface were not able to support osteoclast differentiation, because the expression of the fibronectin is limited to mesenchymal lineage cells. Thus, the lack of fibronectin in other lineage cells implies the defect in osteoclastogenesis. In the in-vivo analyses, treatment with A15-1 significantly decreased both the number of mature osteoclasts and the area of erosion surface in PTH-induced hypercalcemia model mice. In this experiment, we firstly demonstrated the novel RGD-independent function of fibronectin on stromal cells in osteoclast differentiation. In adding to RANKL and M-CSF, fibronectin is necessary as the differentiation factor in osteoclastogenesis.

Promoter Region of Osteopontin that Directs Cell-specific and Developmental Regulation: An Analysis of Transgenic Mice. S. Nomura[1], Y. Higashibata*[1], T. Sakuma*[1], H. Kawahata*[1], S. Fujihara*[2], K. Moriyama[2]. [1]Pathology, Osaka university Medical School, Suita, Japan, [2]Orthodontics, School of Dentistry, University of Tokushima, Tokushima, Japan.

Osteopontin (OPN) is considered to plays important roles for controlling physiological and pathological calcification. OPN-expressing cell types in bone tissues are identified as osteoblasts, hypertrophic chondrocytes and osteoclasts. OPN expression is also detectable in a variety of cells such as epithelial cells in the developing and renal stone-forming kidney, granulated metrial gland cells (GMG cells) of maternal origin in placenta, glandular epithelial cells in mammary gland, macrophages in atherosclerotic plaques, and calcifying foci in breast cancer. Identification of the osteopontin promoter region controlling cell-specific expression in vivo provide us valuable information for the elucidation of the molecular mechanism in the calcification of the tissues. The transgenic mice carrying green fluorescent protein (GFP) gene under the control of 5.5-kb (Op5.5GFP), 3.1-kb (Op3.1GFP), 1.5kb Op1.5GFP) and 0.9-kb (Op0.9GFP) upstream region of mouse osteopontin gene were generated. Expression of GFP was investigated by means of Northern blotting, Western blotting, immunohistochemistry, in situ hybridization and by fluorescence. Localization of GFP-expressing cells was compared with those of OPN-expressing cells. GFP-expressing cell types in Op5.5GFP were identical to that of OPN-expressing ones. However, GFP expression was detected not only in hypertrophic chondrocytes but in proliferating and resting chondrocytes in Op3.1GFP, and fibroblastic cells expressed GFP in Op1.5GFP. No significant expression of GFP in bone tissue was detected in Op0.9GFP mice. Furthermore, the promoter region between 3.1kb and 1.5kb upstream was essential for the GFP expression in the kidney and placenta. The expression patterns obtained by the analysis of transgenic lines indicated the different promoter regions are involved in cell type specific expression of OPN gene. OPN-deficient mice carrying dominant negative OPN gene under the control of 5.5kb promoter showed significant abnormality in bone.

Role of Collagenase-3 (MMP-13) in Cartilage Resorption as Observed During the Development of the Secondary Ossification Center in the Tibia of Young Rats. I. Synthesis and Secretion of Procollagenase-3 at Sites of Cartilage Erosion. E. R. Lee[1], L. Lamplugh*[1], B. Kluczyk*[1], J. S. Mort*[2], G. Murphy*[3]. [1]Electron Microscopy Unit, Shriners Hospital for Children, Montreal, PQ, Canada, [2]Joint Diseases Laboratory, Shriners Hospital for Children, Montreal, PQ, Canada, [3]School of Biological Sciences, University of East Anglia, Norwich, United Kingdom.

The formation of a secondary ossification center in the cartilaginous epiphysis of long bones requires the excavation of canals and marrow space and, therefore, the resorption of cartilage. Earlier work from this laboratory has demonstrated with the assistance of anti-neoepitope antibodies, that the major cartilage component type II collagen is destroyed in this resorption by activated collagenase-3 cutting the fibrils (JBMR, vol17, S25, SA066, 2002). In the current study we have sought to identify the cell source of this collagenase-3 and to uncover details of its processing. Collagenase-3 is synthesized as a proenzyme bearing an inhibitory propeptide domain that is removed upon enzyme activation. We have reasoned that anti-peptide antibodies can be prepared against the propeptide and used to detect the proenzyme in the epiphysis by immunostaining, presumably at its cell source. Thus affinity purified antibodies have been prepared against the peptide HPVT-LAGILKKSTVTS corresponding to the amino acid residues 43 - 58 on the rat propeptide domain. With the aid of these antibodies we report here that the proenzyme is localized to newly developed sites of cartilage erosion precisely where the collagen is cleaved. Thus at 6 days of age, canals allowing the entry of capillaries are dug from the surface of the epiphysis (stage 1), while immunostaining indicative of the proenzyme appears at the blind end of each canal. By 8 days of age, the canal blind ends fuse to create a marrow space in the epiphysis (stage II), where the immunoreactivity occurs along the walls of the expanding marrow space (stage II). Highly reactive cells and matrix are found at the newly developed sites of cartilage erosion. The cells resemble septoclasts. They have a single nucleus, an abundance of rER and Golgi elements, contain dense bodies rich in cathepsin B and exhibit a deficiency of markers indicative of the macrophage-osteoclast lineage. The matrix in contrast, exhibits various stages of degradation and reveals reactivity indicative of the proenzyme along the surface of collagen fibrils. We conclude that a septoclast-like cell is involved in the synthesis and secretion of the collagenase-3 proenzyme at specified sites of cartilage resorption and that upon release, the proenzyme first associates with the fibril before becoming active and cleaving the collagen.

In Vivo Inhibition of Osteoblastic Metalloproteinases Leads to a Decreased Bone Turn-Over and an Increased Trabecular Bone Mass. V. Geoffroy*[1], C. Marty-Morieux*[1], N. Le Goupil*[1], P. Clement-Lacroix[2], C. Teraz*[3], M. Frain*[4], S. Roux[1], J. Rossert*[3], M. de Vernejoul[1]. [1]INSERM U349, Paris Cedex, France, [2]PROSKELIA, Romainville, France, [3]INSERM U489, Paris, France, [4]INSERM U368, Paris, France.

Although it has been suggested that matrix matalloproteinases (MMPs) may play a role in initiating the bone resorption process in vitro, there is to date no evidence that they play any role in in vivo bone maintenance. Mice specifically over-expressing TIMP-1 in osteoblasts have been generated to investigate the role of MMPs in bone in vivo.
We used an artificial promoter specifically driving cells of the osteoblastic lineage to overexpress the TIMP-1 (Tissue Inhibitor of MMPs) cDNA in mice. The level of expression of the transgene was about double that of the endogenous gene. Densitometric analysis, using DEXA and pQCT, and static and dynamic histomorphometry were used to evaluate the bone phenotype of mice from two independant transgenic lines. We showed that at 1 and 2.5 months of age only the female mice exhibited a bone phenotype. These mice displayed specific increases in the bone mineral density and volume of trabecular bone. This increase was accompanied by decreased trabecular separation, suggesting a decrease in bone resorption. Using an ex vivo resorption assay, we demonstrated that PTH-stimulated bone resorption was reduced in these mice. Evaluation of the bone histomorphometric dynamic parameters showed that the mineralizing surfaces and bone formation rate were both reduced. There was no change in the mineralization lag time or number of osteocyte lacunae. Using primary osteoblast culture and molecular analysis, we showed that the differentiation and function of osteoblasts from transgenic mice were normal, but that the ex vivo formation of mineralized nodules was delayed.
This model is the first to demonstrate that in vivo MMPs play a role in bone remodeling and bone balance. Moreover our data suggest that MMP activity could be involved in the hormonal regulation of the resorption by osteoblasts.

Axial but not Peripheral Fractures Are Increased in Monoclonal Gammopathy of Undetermined Significance (MGUS). L. J. Melton[1], S. V. Rajkumar*[2], S. Khosla[2], S. J. Achenbach*[1], A. L. Oberg*[1], R. A. Kyle*[2]. [1]Health Sciences Research, Mayo Clinic, Rochester, MN, USA, [2]Internal Medicine, Mayo Clinic, Rochester, MN, USA.

Fractures in multiple myeloma patients result from lytic bone lesions, generalized bone loss and elevated bone turnover due to excessive osteoclast recruitment/activation by autocrine and paracrine cytokine production. Myeloma is typically preceded by the premalignant condition, MGUS, which is over 20 times more common. Elevated bone turnover, but not excessive bone loss, has been seen in patients with MGUS, but the implications for fracture have never been assessed. To test the hypothesis (H_o) that the skeleton is unaffected in MGUS, we estimated fracture risk among the 488 Olmsted County, MN residents with MGUS first diagnosed in 1960-94 (52% men; mean age, 71.4 $\pm$ 12.8 yr), who were subsequently followed in a population-based retrospective cohort study for 3901 person-years. During this period of observation, 200 patients experienced 385 fractures that were ascertained by review of complete (inpatient and outpatient) community medical records; follow-up was censored at progression to myeloma. Compared to expected fracture rates in the community, statistically significant increases were seen for fractures at most axial skeletal sites, e.g. vertebrae (standardized incidence ratio [SIR], 6.3; 95% CI, 5.2-7.5). There was a slight increase in hip (SIR, 1.6; 95% CI, 1.2-2.2) but not distal forearm fractures (SIR, 0.8; 95% CI, 0.4-1.5) so the overall increase in osteoporotic fracture risk (moderate trauma fractures of hip, spine or wrist $\geq$ age 35 yr: SIR, 2.5; 95% CI, 2.1-2.9) was accounted for by the increase in vertebral fractures. The relative risk (SIR) of any axial fracture was 2.7 (95% CI, 2.3-3.1) compared to only 1.1 (95% CI, 0.9-1.4) for all limb fractures combined. In a multivariate analysis, the independent predictors of any subsequent fracture were age (hazard ratio [HR] per 10-year increase, 1.4; 95% CI, 1.3-1.6) and corticosteroid use (HR, 1.8; 95% CI, 1.2-2.6); greater weight at diagnosis of MGUS was protective (HR per 10 kg, 0.8; 95% CI, 0.8-0.94). Baseline M-protein level, an important determinant of myeloma progression, did not predict fracture risk even in the univariate analysis (HR per 1 g/dL, 1.1; 95% CI, 0.9-1.5). Age independently predicted vertebral fractures (HR, 1.4; 95% CI, 1.2-1.7), while greater body mass index was protective (HR, 0.9; 95% CI, 0.9-0.96). Thus, the risk of axial, but not peripheral, fractures is increased among MGUS patients even before progression to myeloma. Further assessment of the pathophysiologic basis for this observation is needed since elevated bone turnover, for example, might be treatable with antiresorptive agents.

IL-3 Enhances Bone Destruction and Tumor Cell Growth in Myeloma Bone Disease. J. W. Lee*[1], S. J. Choi[1], H. Y. Chung[1], G. D. Roodman[2]. [1]Medicine-Hematology/Oncology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Medicine-Hematology/Oncology, University of Pittsburgh and Department of Veterans Affairs Medical Center, Pittsburgh, PA, USA.

We previously reported that Macrophage Inflammatory Protein (MIP)-1α is produced by myeloma cell lines and by patients with Multiple Myeloma (MM). MIP-1α induces human OCL formation independently of Receptor Activator of NF-Kappa B Ligand (RANKL), MIP-1α levels correlate with bone destruction in myeloma patients, and patients with elevated levels of MIP-1α have an extremely poor prognosis. Blocking MIP-1α expression in an in vivo model of human MM profoundly decreases disease progression and bone destruction by inhibiting both myeloma cell homing to the marrow as well as tumor cell growth. We recently reported that the regulation of MIP-1α gene expression is abnormal in patients with MM due to increased expression of the transcription factor Acute Myeloid Leukemia-1A (AML-1A) compared to AML-1B. We hypothesized that the increased expression ratio of AML-1A to AML-1B in myeloma also induced abnormal expression of other hematopoietic and bone specific genes that contribute to the poor prognosis of MM. We identified Interleukin-3 (IL-3) as a gene dysregulated by imbalanced AML-1A and AML-1B expression in myeloma. IL-3 mRNA expressions levels were increased in 8 out of 11 unfractionated bone marrow samples and 5 out of 7 highly purified samples of CD138+ myeloma cells from patients with MM who had decreased AML-1B expression. IL-3 was not consistently increased in patients with a normal AML-1A/B ratio. IL-3 protein expression levels were significantly increased in freshly isolated bone marrow plasma from patients with MM (66.4 $\pm$ 12 versus 22.1 $\pm$ 8.2, p=0.038). Consistent with these observations, IL-3 mRNA levels decreased where AML-1B was overexpressed in transfected myeloma cells compared to cells transfected with AML-1A or empty vector. Further more IL-3 (100 pg/ml) in combination with 200 pg/ml of MIP-1α and/or 10ng/ml of RANKL enhanced human OCL formation compared to MIP-1α or RANKL alone. Interestingly, huge OCLs that contained more than 10 nuclei formed in human OCL marrow cultures treated with IL-3 and MIP-1α or RANKL. These OCL demonstrated enhanced bone resorption on dentine slices. Importantly, IL-3 stimulated the growth of IL-6 dependent myeloma cells in the absence of IL-6, even though IL-3 did not induce IL-6 expression by myeloma cells. These data suggest that increased IL-3 expression in the bone marrow microenvironment of patients with MM by imbalanced AML-1A and AML-1B expression increases bone destruction and tumor cell growth in myeloma.

Menin, the MEN1 Gene Product, Interacts Directly with the TGF-beta Signaling Molecule, Smad3. L. Canaff, G. N. Hendy. Calcium Research Laboratory, McGill University, Montreal, PQ, Canada.

Multiple endocrine neoplasia type 1 (MEN1) is an autosomal dominant disorder characterized by endocrine tumors of parathyroids, pancreas and pituitary. The tumor suppressor gene *MEN1* encodes a 610 amino acid nuclear protein called menin. Menin inactivation by antisense RNA antagonizes transforming growth factor type β (TGF-β) – mediated cell growth inhibition and menin co-immunoprecipitates with Smad3. Whether the interaction is direct and the sequence requirements for this are not known. To locate the Smad3 binding domain of menin, we generated truncated and deleted menin mutants and a panel of 12 naturally occurring menin missense mutants identified in MEN1 patients. Co-immunoprecipitation of transfected rat pituitary GH4C1 cells showed that menin Δ(1-40), menin Δ(1-100), menin Δ(277-477), menin Δ(195-610) and menin Δ(478-610) retained the ability to interact with Smad3 but the deletion of amino acids 1-195 from the N-terminus of menin abolished the interaction. Therefore, amino acids 101-195 are critical for menin-Smad3 interaction. All missense menin mutants retained the ability to co-immunoprecipitate with Smad3. To demonstrate direct interaction between menin and Smad3, we performed GST-

Smad3 pull-down reactions with *in vitro* translated ^{35}S-labeled full-length, deletion and missense mutants of menin. GST-Smad3 interacted with full-length menin, menin Δ(1-40), menin Δ(277-477), menin Δ(478-610) but not with menin Δ(40-277). All missense menin mutants interacted with Smad3. We previously showed that antisense menin suppressed, and co-expression of sense menin restored, TGF-β-induced transcriptional activity. Here, we investigated the ability of menin missense mutants to restore this activity. GH4C1 cells were transfected with a TGF-β responsive promoter reporter construct, antisense menin and wild-type or missense mutant menin constructs. Wild-type menin and missense mutants L22R, I86F, W126G, H139D, A242V, E255K, T344R, W423S, K502M and S555N were able to restore transcriptional activity. However, missense mutants A160P and A176P did not fully restore the activity. ^{35}S-labeled full-length Smad3, a Smad3 (EEVE) mutant that mimics the active phosphorylated molecule, and a Smad3ΔC mutant lacking aa 278-425 all interacted with GST-menin in pull-down assays. Therefore, the Smad3 MH2 domain and phosphorylation of the carboxyterminus are not essential for Smad3-menin interaction. These studies show that the interaction between menin and Smad3 is direct, the menin sequence 101-195 is critical for this, and identify amino acids within this region important for TGF-β stimulated transcriptional activity.

A Low-molecular-weight Heparin Markedly Reduced Osteolytic Bone Destruction in a Mouse Model of Breast Cancer Bone Metastases. S. M. Käkönen[1], K. S. Mohammad[2], R. S. Käkönen*[3], A. Marjamäki*[4], A. Wärri*[4], M. Salmivirta*[4], T. A. Guise[2]. [1]University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [2]University of Virginia, Charlottesville, VA, USA, [3]Pharmatest Services, Turku, Finland, [4]BioTie Therapies, Turku, Finland.

Heparin treatment effectively prevents venous thromboembolism, but may also prolong survival in patients with malignant disease. Experimental studies support the hypothesis that cancer progression can be influenced by heparin and heparin-related compounds. The possible mechanisms include control of tumor cell growth by heparin-binding growth factors, tumor cell invasion by heparin-inhibitable enzyme systems, tumor cell metastasis by heparin-binding cell surface selectins and tumor angiogenesis. The effects of heparin compounds on cancer-induced osteolysis in bone metastases have not been examined. An unfractionated heparin has been shown to promote bone resorption, suppress bone formation and induce osteoporosis, whereas low-molecular-weight (LMW) heparin compounds have less adverse effects on bone. We have evaluated the therapeutic potential of dalteparin, a LMW synthetic heparin to inhibit osteolytic bone destruction in an experimental model of tumor metastases to bone.

MDA-MB-231 breast cancer cells were inoculated into left cardiac ventricle of athymic nude mice, which were then administered with LMW heparin (5mg/kg/d) or vehicle subcutaneously once daily. Animals were weighed weekly and the development of osteolytic lesions was monitored by radiography. Hind and fore limbs and soft tissue were collected for histomorphometry to evaluate tumor burden, bone area and osteoclast number.

The body weight of LMW heparin-treated mice was significantly higher compared to the vehicle group at sacrifice. In addition, only 18% of LMW heparin-treated mice were cachectic compared to 86% of the vehicle mice. Osteolytic lesion area as measured by radiographs was significantly lower in the LMW heparin-treated group when compared to the control. Histomorphometric examination revealed a significant reduction in the tumor burden in bone in the LMW heparin-treated mice compared to the control group. There were no changes in the total bone area between the groups. In addition, there were no differences in soft tissue metastases between the groups.

Our data demonstrate that LMW heparin treatment can efficiently reduce osteolytic lesion area and tumor burden in bone. Furthermore, it had clear beneficial effects on body weight and tumor-related cachexia in tumor bearing mice. LMW heparin could be a potential therapy to reduce the occurrence of bone metastases in addition for being used as thromboprophylaxis in cancer patients.

Fc-OPG Inhibits Osteoclast Activity, while Tumor-derived OPG Enhances Tumor Growth. J. L. Fisher*[1], R. J. Thomas-Mudge*[1], J. Elliott*[1], D. K. Hards*[1], N. A. Sims[1], C. R. Dunstan[2], J. Slavin*[3], T. J. Martin[1], M. T. Gillespie[1]. [1]St. Vincent's Institute of Medical Research, Fitzroy, Australia, [2]Amgen Corporation, Thousand Oaks, CA, USA, [3]Pathology, St. Vincent's Hospital, Fitzroy, Australia.

Osteoprotegerin (OPG) as a recombinant protein (Fc-OPG) has been demonstrated to inhibit osteoclast formation and activation both in vitro and in vivo. Since the local production of OPG may also be a means to limit tumor expansion in bone by preventing osteoclastogenesis, we used MCF-7 and MCF-7 cells overexpressing OPG, PTHrP or both OPG+PTHrP (MCF-7+OPG, MCF-7+PTHrP and MCF-7+PTHrP+OPG) to assess the contribution of tumor-cell derived OPG in tumor behavior in bone. Each of these cell lines were injected into the proximal tibiae of athymic mice, and animals monitored for 2.5 weeks, after which they were sacrificed and their limbs were assessed by radiology and histology. The cell lines were also inoculated into the mammary fat pad (MFP) to examine the effect of OPG overexpression at the primary site.

No osteolysis was observed radiologically following inoculation of the MCF-7 or MCF-7+OPG cells, although small intramedullary tumors were evident histologically in the latter group. MCF-7+PTHrP+OPG developed larger tibial tumors than the MCF-7 cells overexpressing PTHrP alone (18.6 ± 3.1 % osteolysis as determined by radiology, compared with 9.0 ± 2.2 %, $p<0.05$). The enhanced tumor growth afforded by OPG expression by MCF-7 cells was also observed in MFP tumor growth (50 days) whereby OPG overexpressing tumors were 2- to 3-fold larger in size.

The increased tumor growth in both bone and MFP as a consequence of OPG overexpression was abrogated by treatment with Fc-OPG (2.5 mg/kg/day, subcutaneous). Notably for tumor growth in bone, Fc-OPG treatment dramatically reduced osteoclast numbers at the tumor-bone interface in mice with MCF-7+PTHrP tumors, but osteoclast numbers were unaltered by Fc-OPG treatment in mice with tumors produced by MCF-7+PTHrP+OPG cells. Fc-OPG treatment of mice injected with either cell type resulted in a change of osteoclast morphology, with a flattened appearance adjacent to bone and reminiscent of a quiescent osteoclast. The effects of Fc-OPG were restricted to in vivo growth, as it had no effect upon cell growth in vitro.

These results indicate that full-length native OPG exerts dramatically different actions on tumor behavior than Fc-OPG, and that Fc-OPG acts upon stromal cells in the breast and may principally affect osteoclast activity (rather than formation) in established tumors in bone.

Soluble RANK Diminishes Progression of Prostate Cancer in SCID-Hu Animal Model. J. Zhang[1], J. Dai[1], Y. Lu*[2], W. Dougall*[3], Z. Yao*[2], E. T. Keller[1]. [1]University of Michigan, Ann Arbor, MI, USA, [2]Tianjin Medical University, Tianjin, China, [3]Department of Molecular Biology and Immunology, Amgen Inc, Seattle, WA, USA.

Prostate cancer (CaP) develops metastatic bone lesions with a mixture of osteosclerosis and osteolysis. We have previously demonstrated that targeting RANKL with OPG inhibits CaP-induced osteoclast activity and prevents tumor establishment in bone. However, OPG blocks TRAIL-mediated apoptosis. Thus methods to block RANKL activity, other than OPG, may be important. Accordingly, we evaluated ability of soluble murine RANK-Fc (sRANK) to prevent progression of established CaP in bone. Forty SCID mice had human fetal bone implanted subcutaneously. Four weeks later, LuCaP 35 prostate cancer cells (3 x 10^5) were injected into the implanted bone and allowed to develop into tumors. Six weeks after tumor implant, mice were palpated for presence of tumors and serum PSA was measured (28/40 mice had palpable evidence of tumors and were positive for PSA). The mice with tumors were randomly divided into three groups (n=9/group) to be either immediately sacrificed (BASE) or receive either sRANK-Fc (200 μg/mouse) or saline vehicle (V) by intraperitoneal injection three times a week. Mice were sacrificed after 6 weeks of sRANK administration. Serum PSA levels were decreased by 40% in sRANK-treated mice compared to V-treated mice. Osteocalcin and bone-specific alkaline phosphatase (bone formation marker) were decreased by approximately 30% and 25%, respectively, in the sRANK-treated mice compared to the V-treated mice. Urinary Ntx (bone osteolysis maker) were reduced by 30% in the sRANK-treated animals. Radiographs revealed primarily osteosclerosis; however, it was not possible to accurately quantify differences between groups based on radiographs. Bone mineral density was increased by 12% and 4% in the V and sRANK groups, respectively, compared to the BASE group. The trabecular volume/total bone volume (represents total mineralized bone in the trabeculae) was increased by 30% and 5% in the V and sRANK groups, respectively, compared to the BASE group. Tumor area compared to bone area tested by histomorphometric measurement was increased by 60% and 25% in the V and sRANK groups, respectively, compared to the BASE group (this represents continued tumor growth). The osteoclast perimeter (# osteoclasts/mm trabecular bone) was decreased by 0% and 90% in the V and sRANK groups, respectively, compared to the BASE group. Taken together, these data demonstrate that sRANK-Fc can diminish progression of an established osteoblastic CaP cell line in human bone.

An Evaluation of the National Osteoporosis Society Position Statement on the use of Peripheral X-ray Absorptiometry. G. M. Blake, R. Patel, I. Fogelman. Osteoporosis Research Unit, Guy's, King's and St Thomas' School of Medicine, London, United Kingdom.

The recent United Kingdom National Osteoporosis Society (NOS) position statement on the use of pDXA devices proposes an algorithm that divides patients into 3 categories: (1) patients with a forearm T-score less than -2.5 who are recommended for treatment; (2) patients with a forearm T-score between -1 and -2.5 who are referred for spine and hip BMD measurements; (3) patients with a forearm T-score greater than -1.0 who are not treated. We have evaluated the clinical effectiveness of the NOS algorithm by comparing it with the alternative strategy of using forearm T-scores alone. The comparison was carried out using a mathematical model in which the population distribution of spine, hip and forearm BMD was described using a triaxial gaussian model. Correlation coefficients $r = 0.7$ were assumed between the different BMD measurements. Relative risks of fracture at each site were taken from the Marshall meta-analysis. The area under the curve (AUC) for the ROC curve showing the percentage of fracture cases plotted against the percentage of the whole population identified was calculated for the NOS algorithm and for forearm BMD alone. For identifying patients at risk of any type of fracture the AUC values were 0.62 and 0.59 respectively. For patients at risk of hip fracture they were 0.71 and 0.66, and for spine fracture 0.69 and 0.65. The small difference between the AUC values suggests that use of forearm BMD alone with an adjusted T-score threshold can reproduce the clinical outcome of the NOS algorithm. Detailed results of the model for discrimination of patients at risk of hip fracture are shown in the Table. For example, at age 65 20% of patients are treated on the basis of their forearm BMD, 55% are referred for spine and hip BMD, after which a

total of 33% of patients are treated. The forearm BMD measurements identify 30% of future hip fracture cases compared with 63% using the NOS algorithm. However, use of forearm BMD with a modified threshold of T = -2.1 would identify 56% of hip fracture cases while still treating 33% of the population. We conclude that use of forearm BMD alone with a modified T-score threshold of –2.1 would save the need for spine and hip scans and identify only slightly fewer fracture cases for treatment.

	% General Population Treated				% Hip Fracture Population Treated		
Age	Forearm T < -2.5	Referred for spine and hip	NOS algorithm	Adjusted T-Score	Forearm T < -2.5	NOS algorithm	Forearm $T < T_{adjust}$
55	7	45	14	-2.1	13	38	31
60	13	51	22	-2.1	21	50	43
65	20	55	33	-2.1	30	63	56
70	33	53	50	-2.1	46	78	72

Parameters of Hip Geometry and Bone Mineral Density Measured by Dual Energy X Ray Absorptiometry as Predictors of Hip Fracture Risk in Elderly Women from EPIDOS Cohort. F. Duboeuf*, P. Szulc, A. M. Schott*, P. Meunier, P. D. Delmas. U 403, INSERM, Lyon, France.

Bone architecture is an important determinant of bone strength . Cross sectional studies suggest that structural parameters of hip geometry derived from hip dual Energy X ray absorptiometry (DXA) may provide a simple method to assess the risk of hip fracture. The aim of our study was to test this hypothesis prospectively. We measured femoral neck bone mineral density (BMD) on a Lunar DPX at baseline and parameters of neck geometry in 65 elderly women who subsequently had a hip fracture and in 167 age matched controls, as part of the EPIDOS prospective cohort. We calculated the Estimated Cross Sectional Area (ECSA), the Estimated Endosteal Diameter (EED), the Estimated Cortical Thickness (EACT), and the Estimated Trabecular Volume Fraction (ETVF) according to the equations given by T Beck et al (1). Femoral neck diameter (ND) was measured with the Lunar DPX Software. Buckling ratio was derived from the following equation : (ND/2)/EACT. Results (see Table) shows that several parameters of hip structure (ECSA, EACT, and ETVF) predict the risk of hip fracture as well as hip BMD. Hip fracture risk seems related to a lower bone mineral content (ECSA) but not to a smaller bone size (neck width). On a morphological basis, low ECSA in hip fracture patients is associated with a decreased cortical thickness (EACT) which results in a decreased bending strength (lower section modulus) and an increased bone instability (higher buckling ratio). However, when these parameters were adjusted for hip BMD, none of the Odds ratio remained significant
Age, Weight and Height adjusted Odds Ratios (per 1 SD) for prediction of hip fracture

	All fractures (65)	Cervical fractures (42)	Trochanteric fractures (23)
Neck Diameter	NS	NS	NS
ECSA	2.0 (1.4-2.9)	1.6 (1.1-2.5)	2.9 (1.6-5.5)
EED	NS	NS	NS
EACT*	2.5 (1.7-3.7)	1.9 (1.2-3.0)	4.4 (2.1-9.2)
ETVF*	2.4 (1.6-3.6)	1.8 (1.2-2.9)	4.3 (1.9-9.6)
Sec Modulus	1.7 (1.2-2.4)	NS	2.3 (1.3-4.0)
Buckling Ratio	0.5 (0.3-0.7)	0.6 (0.4-0.8)	0.3 (0.2-0.6)
BMD*	2.5 (1.6-3.7)	1.9 (1.2-2.9)	4.3 (2.0-8.8)

*NS, Non significant, * Significantly different between cervical and trochanteric fracture*
We conclude that parameters of hip geometry derived from BMD measurements by DXA predict the risk of hip fracture in elderly women, but that this prediction is highly related to the BMD value. More reliable techniques to assess hip architecture, such as high resolution quantitative computerized tomography, might be necessary to explore the contribution of bone architecture to hip fragility, independently of bone mass.

The Effect of 3D-XA Derived Geometric Parameters on Proximal Femur Failure Load Prediction. A. Le Bras*[1], S. Kolta[2], C. Roux[2], J. Fechtenbaum[2], W. Skalli*[1], D. Mitton*[1]. [1]LBM-ENSAM-CNRS, Paris, France, [2]Rheumatology, Cochin Hospital, Paris, France.

Bone mineral density (BMD g/cm²) measured by Dual energy X-ray Absorptiometry (DXA) has proven to be an important risk factor for hip fracture. Other structural factors such as bone micro and macro-architecture independently affect bone resistance. Bone macro-architecture has already been evaluated using 2 dimensional images, either on X-ray films or on DXA scans. Several geometric parameters have been evaluated as hip axis length (HAL), femoral neck axis length (FNAL), femoral neck diameter, neck-shaft angle, cortical wall thickness,… Many of these parameters predict fracture and some independently of BMD results. However, these 2D parameters greatly depend on patient positioning and inter individual anatomical differences. Therefore, their 3D evaluation would be more precise. A method of 3 Dimensional X-ray Absorptiometry (3D-XA) allowing 3D reconstruction of human proximal femurs using 2 orthogonal DXA scans was described (1). The aim of this study was to calculate whether adding the geometric parameters calculated on the 3D reconstruction of proximal femurs to areal BMD improve failure load prediction . 24 human proximal femurs were included 5 Males and 19 Females, aged 84±13 y. Two perpendicular DXA scans were acquired on a Delphi-W (Hologic) device. Areal density was measured as usual (g/cm²) and 3D reconstruction was done using both scans as previously described (1). On the 3D reconstruction we defined some geometrical parameters as the femoral neck axis length, the neck shaft angle, the femoral neck minimal cross sectional area and the femoral head diameter. Stance phase was selected for mechanical testing. Femoral shaft was maintained at an angle of 25° to the vertical. A vertical load was applied on femoral head at 12.7 mm/min. The vertical displacement and the compression strength were measured during the test. All the fractures were subcapital. Failure load was best correlated to femoral neck areal BMD ($r^2 = 0.62$, $p<0.0001$). Adding the 3D geometrical parameters in a linear multivariate regression model significantly improves failure load estimation ($r^2 = 0.73$, $p =0.0001$). This is the first study combining areal BMD and real 3D geometric parameters calculated from DXA images. It demonstrates that the measurement of geometric parameters using the 3D-XA method is possible and that adding these parameters to areal BMD allows better estimation of failure load for sucapital fracture in human femurs.
This work was supported by Biospace Instruments, France.

Interpretation of Peripheral Densitometry Devices in Clinical Practice: A Triage Approach to Diagnose Osteoporosis. J. A. Clowes, R. Eastell, N. F. A. Peel. Clinical Sciences (North), University of Sheffield, Sheffield, United Kingdom.

It is unclear how we might use peripheral densitometry in clinical practice. If we were to consider the T-score of the total hip as the 'gold standard' for the diagnosis of osteoporosis, then we could establish thresholds for each peripheral device above which the probability of osteoporosis is very low (<5%) or below which the probability of normal or osteopenic BMD is very low (<5%). We propose to use such a triage approach to identify individuals who require 1) additional central densitometry measurements (those between thresholds) or based on a peripheral measurement alone can be 2) recommended treatment (below lower threshold) or 3) appropriately reassured (above upper threshold).
We recruited 500 postmenopausal women (age 55-80 years) from the general population (population study) and 279 women with osteoporotic hip, vertebral, forearm and humeral fractures (fracture study). All subjects had measurements of spine, total hip (QDR4500A) and forearm DXA (DTX 200), forearm pQCT (XCT 2000) and QUS of the heel (Achilles+, DTU One, QUS 2, UBIS 5000), forearm (Omnisense) or phalanges (DBM Sonic).
In a population-based cohort (prevalence osteoporosis 9.8%) this triage approach correctly identified between 31% (DTU One SOS) and 73% (DTX 200, XCT 2000) of subjects in whom a treatment decision could be made without additional central DXA. The best performing QUS devices (QUS 2 BUA, UBIS 5000 BUA) identified 57% of subjects. In a fracture cohort (prevalence osteoporosis 36%) between 20% (DBM Sonic) and 41% (DTX 200, XCT 2000) of subjects did not require central DXA. The best performing QUS devices (UBIS 5000 BUA) identified 38% of subjects. The table shows thresholds for 9 measurements in the population study. Thresholds in the fracture population were slightly lower.
We conclude that a triage approach to interpreting peripheral densitometry results enables a treatment decision to be made in a substantial percentage of the population, but only with some devices.

Metacarpal BMD and Cortical Index are Significant Predictors of Hip Fracture. S. Vasireddy, S. Bal, L. Reaney*, C. McGurk*, J. Kanis, E. McCloskey. University of Sheffield, Sheffield, United Kingdom.

The combination of assessments of skeletal strength and extra-skeletal risk factors optimises the identification of patients at high risk of future fracture. While hip BMD remains the reference standard, other more widely applicable skeletal measurements may be of value. In this study we have compared the ability of metacarpal BMD (mBMD) and cortical index (MCI) to that of hip BMD to predict incident hip fractures using a prospective case-control design.

The study cohort comprised 5212 women aged 75 years or older (mean 80 years, range 75-100) enrolled to a double-blind placebo-controlled study of the bisphosphonate, clodronate (Bonefos®). Baseline BMD at the total hip and distal forearm were measured by DXA (Hologic QDR4500 and Osteometer DTX200 respectively). Bilateral hand radiographs obtained at baseline were analysed using digital x-ray radiogrammetry (Sectra, Denmark) to produce automated measures of metacarpal BMD and MCI in 153 women who sustained incident hip fractures and in 532 randomly selected controls who remained free of hip fracture during a median follow-up of 4 years.

Cases with hip fracture had significantly lower hip BMD, forearm BMD, mBMD and MCI than controls. In univariate logistic regression analysis, the odds ratios (OR) for hip fracture per 1SD decrease in mBMD and MCI of 1.8 (95%CI 1.5-2.2, P<0.0001) and 1.7 (95%CI, 1.4-2.1, P<0.0001) respectively were similar to that of forearm BMD (1.9, 95%1.6-2.4, P<0.0001) while similar decreases in hip BMD demonstrated a larger gradient of risk (OR 2.4, 95%CI 1.9-3.0, P<0.0001). Adjusting for treatment with clodronate did not influence results. Metacarpal BMD and MCI remained significant predictors of hip fracture following adjustment for clinical predictors including age, height and body weight (OR 1.5, 95%CI 1.2-1.9, P=0.001 and 1.4, 1.1-1.7, P=0.002 respectively) but were not independent of forearm BMD or hip BMD. Following adjustment for the clinical variables, the ORs for the metacarpal indices remained comparable to that of forearm BMD (1.5, 95%CI 1.2-1.9) but was lower than that for hip BMD (2.0, 95%CI 1.6-2.6).

We conclude that metacarpal BMD and MCI are significant predictors of hip fracture independently of other extra-skeletal clinical risk factors. In the absence of access to hip BMD, mBMD or MCI may prove useful skeletal measures of fracture risk to include in the risk assessment of individuals.

Bone Mineral Density (BMD) and Radiographic Texture Analysis (RTA) of Densitometer Generated Calcaneus Images in Patients with and without Osteoporotic Fractures. T. J. Vokes[1], M. L. Giger*[2], M. R. Chinander*[2], M. J. Favus[1], V. Jaros*[1], D. Singh*[1]. [1]Medicine/Endocrinology, University of Chicago, Chicago, IL, USA, [2]Radiology, University of Chicago, Chicago, IL, USA.

Bone fragility is determined by bone mass, measured as BMD, and by bone structure, which cannot be easily assessed using currently available methods. RTA is an experimental method for evaluating bone structure. We have previously shown that radiographic texture analysis of densitometer-obtained heel images can differentiate subjects with and without vertebral fractures.

The purpose of this study was to determine whether RTA of densitometer-generated calcaneal images also differentiates subjects with and without any osteoporotic fractures (vertebral or peripheral). BMD of the lumbar spine, femoral neck and calcaneus was measured and RTA performed in 195 subjects referred for routine BMD testing (79 with and 116 without fractures). RTA yielded RMS (root mean square - a measure of the magnitude of variation in the trabecular pattern), FMP (first moment of the power spectrum – a measure of the coarseness of the trabecular pattern), and a fractal dimension, estimated using Minkowski dimension analysis. Fracture group had lower femoral neck (but not lumbar spine or calcaneus) BMD (p=0.001), and higher texture features fractal (p=0.001) and FMP (p=0.04), all by t-test. The same variables were significant predictors of presence of fractures in univariate analysis. In multivariate analysis, the presence of fractures was best predicted by a combination of femoral neck BMD (p<0.001) and fractal (p<0.001), and by the combination of fractal (p<0.001) and calcaneus BMD (p=0.001). In a subgroup of 93 women with untreated postmenopausal osteoporosis, texture features but not BMD measurements differed between 36 subjects with and 57 without fractures. In this subgroup, the highest area under the ROC curve Az=0.814 was achieved by a combination of calcaneus BMD, fractal, and FMP (figure).

We conclude that RTA differentiates subjects with and without fractures as well as BMD measurements. In postmenopausal women, a combination of calcaneal BMD and RTA, both obtained using a peripheral densitometer, provides a better assessment of fragility than the standard central BMD measurement.

Determinants of Proximal Femoral Strength in Elderly Women. T. F. Lang[1], J. H. Keyak*[2], A. Yu*[1], Y. Lu[1], L. Do*[1], J. Li*[1]. [1]Radiology, University of California, San Francisco, San Francisco, CA, USA, [2]Orthopaedic Surgery, University of California, Irvine, San Francisco, CA, USA.

DXA BMD estimates hip fracture risk by acting as a surrogate for bone strength. But this hybrid measure of bone density and size provides little information about how these factors individually determine hip strength. To address this, we used quantitative computed tomography (QCT) based finite element (FE) models, which encompass the full spatial distribution of material properties in the hip, to estimate failure load (FL) in 51 women (mean age 74.3±4.5 years). We related FL to integral and compartmental bone density and geometry quantified from the QCT scans.

Subjects underwent QCT imaging of the hip (GE 9800Q, 3mm slices). FE models of the left hip were built from the QCT scans, and were loaded in conditions simulating single-limb stance (producing subcapital fractures) and a fall backwards and to the side (trochanteric fractures). The FE procedure produced stance (FL_s) and fall (Fl_{fall}) failure load estimates in kN. To compare abilities of volumetric and areal BMD to predict hip strength we linearly regressed FL_s and Fl_{fall} against integral volumetric (viBMD) and integral areal BMD (aBMD). We built multivariate models relating FL_s and FL_{fall} to age, height and weight and to cortical BMD (cBMD), trabecular BMD (tBMD) and minimum femoral neck cross-sectional area (mincsa). The contribution of each parameter was given as standardized beta. Results are tabulated below.

aBMD and viBMD were roughly equivalent predictors of FL_s and FL_{fall} (r=0.7-0.8, $RMS_{error}FL_s$=1.7-2.0 kN, $RMS_{error}FL_{fall}$=0.43-0.44 kN). After height and weight correction, FL_{fall} declined with age (3%/yr, p=0.01) but not Fl_{stance}. Multivariate models including compartmental BMD and size parameters tended to predict FL better than aBMD or viBMD. In these models, tBMD, cBMD and mincsa independently predicted FL_s, but only tBMD and mincsa predicted FL_{fall}.

We observed different risk factors for hip fractures during single-limb stance and falls. These results agree with epidemiologic findings of different risk factors for cervical and trochanteric fractures.

FL type (kN) (mean± SD)	R (RMS_{error} kN)	tBMD β_{std} (p)	cBMD β_{std} (p)	mincsa β_{std} (p)
FL_s (11.5±3.03)	0.9 (1.53)	0.45 (<0.0001)	0.40 (0.02)	0.27 (0.007)
FL_{fall} (1.8±0.73)	0.9 (0.39)	0.60 (<0.0001)	0.27 (0.12)	0.30 (0.004)

Geometric Characteristics of the Developing Tibia in Early Pubertal Girls: A Quantitative MRI Study. H. M. Macdonald*[1], A. Heinonen*[2], K. M. Khan*[3], K. J. MacKelvie*[4], H. Sievanen*[5], K. P. Whittall*[6], B. B. Forster*[6], H. A. McKay[7]. [1]Human Kinetics, University of British Columbia, Vancouver, BC, Canada, [2]UKK Institute, Tampere, Finland, [3]Family Practice, University of British Columbia, Vancouver, BC, Canada, [4]Endocrinology, University of British Columbia, Vancouver, BC, Canada, [5]Department of Health Sciences, University of Jyvaskyla, Tampere, Finland, [6]Radiology, University of British Columbia, Vancouver, BC, Canada, [7]Orthopaedics, University of British Columbia, Vancouver, BC, Canada.

INTRODUCTION: During puberty girls reach a peak bone mineral accrual velocity of approximately 325 g/yr. As bone mass, geometry and structure are all determinants of bone

strength it is essential that all parameters be characterized in the growing skeleton. Currently there is very little prospective data on bone geometry in growing girls.
AIM: Therefore, we studied change in tibial cross-sectional cortical area (CoA), total area (ToA), cortical to total area ratio (CoA/ToA) and cross-sectional moment of inertia (CSMI) in sixteen 10-11 yr old girls across two years of growth.
METHODS: We measured height and weight by standard methods and maturity by Tanner breast staging. We used a 1.5T MR system (GE Medical Systems) with a quadrature head coil to measure CoA, ToA and CSMI of slices located proximal to the distal tibia end plate at 10% (distal site), 15%, 20%, 30%, 50%, 60% (shaft sites) and 80% (proximal site) of the total tibial length. The sequence was T1-weighted, spin echo in the aforementioned seven transverse (tibial) planes, 3.0 mm sections with no gap.
RESULTS: After 2 years, the increase in ToA along the tibial length ranged from 17% to 23%. The CoA increased significantly more (19% to 24%) at the shaft sites compared with the distal site (9%). The CoA/ToA ratio increased significantly more at the shaft compared with both proximal and distal sites where it decreased by 4% and 8% respectively. Changes in CSMI are presented (Figure).
CONCLUSION: These MRI outcomes quantify the region specific change in bone parameters along the tibial length during growth in girls. Distally, changes in periosteal dimensions accounted for greater increases in bone strength whereas strength increases at the tibial shaft are explained by cortical enlargement. This reflects the axial compressive and bending moments, respectively, experienced at these two sites.

The Value of Bone Turnover Markers in the Prediction of Vertebral Fracture in Patients Using Oral Glucocorticoids. T. P. van Staa[1], R. Eastell[2], I. P. Barton*[1], R. Rizzoli[3], M. K. Javaid[4], C. Cooper[4]. [1]Procter&Gamble Pharmaceuticals, Egham, United Kingdom, [2]University of Sheffield, Sheffield, United Kingdom, [3]Hopitaux Universitaires, Geneva, Switzerland, [4]Medical Research Council, Southampton, United Kingdom.

Several bone turnover markers (BTM) predict fracture risk in postmenopausal osteoporosis, but their value in patients using oral glucocorticoids (GC) is unknown. The objective of the study was to evaluate whether BTMs, vitamin D and intact parathyroid hormone (PTH) predict fracture in GC users.
Data were obtained from two randomized clinical trials (risedronate prevention and treatment studies) with similar methods but different inclusion criteria with respect to prior CS exposure. The study population comprised of 306 patients with one-year vertebral fracture assessment (111 placebo and 195 risedronate patients) and included 30 patients with an incident fracture. The following bone turnover markers were measured at baseline and after 6 months: bone specific alkaline phosphatase (Bone ALP), osteocalcin (OC), deoxypyridinoline/creatinine (DPD/Cr), pyridinoline/creatinine (PYD/Cr)), and N-telopeptide of type I collagen (NTX). PTH and serum 25-hydroxy-vitamin D_3 [$25(OH)D_3$] were also measured at baseline. Cox regression analysis was used to determine whether these variables predicted incident vertebral fracture after 12 months.
In the placebo group, the age- and sex-adjusted relative rate (RR) of fracture in relation to baseline BTMs for 1 unit (standard deviation) increase were as follows: DPD/Cr 1.72 (95% confidence interval 0.99-2.99), NTX 1.76 (1.01-3.06), PYD/Cr 1.65 (1.03-2.64), Bone ALP 1.18 (0.71-1.96), OC 0.89 (0.49-1.63). PTH predicted fracture [age-sex-adjusted RR 1.80 (1.03-3.15), which became 4.62 (1.33-16.05) after BMD adjustment]. Vitamin D was not predictive [age-sex-adjusted RR 0.72 (0.38-1.37)]. In the risedronate group, both baseline BTMs and changes after 6 months of treatment did not predict fracture. The reduction in fracture risk in the risedronate group (relative to placebo) was similar across levels of baseline bone markers and vitamin D [e.g., the RR in patients with NTX ≤51 nmol BCE/mmol (median) was 0.31 (0.09-1.06), and > 51 was 0.37 (0.11-1.25)]. For baseline PTH, the RR in the patients with PTH ≤ 25 ng/mL was 0.98 (0.26-3.65), and 0.09 (0.02-0.34) for PTH > 25 (test for interaction P > 0.05).
In conclusion, markers of bone resorption predicted fracture better than markers of bone formation in the placebo group. BTM did not predict fracture in the risedronate group. Higher PTH levels were also predictive of fracture and appeared to be associated with a larger treatment effect of risedronate.

Disclosures: ***T.P. van Staa****, None.*

Markers of Bone Turnover and History of Prior Fractures as Predictors of Long Term Fracture Risk in Postmenopausal Women Without Osteoporosis : The OFELY Study. E. Sornay-Rendu*, F. Munoz*, P. Garnero, F. Duboeuf*, P. D. Delmas. Unit 403, INSERM, Lyon, France.

Although a low bone mineral density (BMD) is the most important risk factor for fracture in postmenopausal women, about half of patients with incident fractures have baseline BMD above the WHO diagnostic threshold of osteoporosis (T score ≤ -2.5). Several studies have shown that bone turnover markers (BTM) and history of prior fracture are BMD independent risk factors for fractures. The aim of this study was to investigate whether the assessment of BTM and history of fracture could be used to identify, within women with a non osteoporotic BMD level, those at risk of fracture that may need a therapeutic intervention. We measured at baseline BMD by DXA at the spine and total hip and BTM in 668 postmenopausal women (mean age : 62 yr). Women were categorized in 3 groups according to their baseline BMD values : normal (T score at the spine and hip>-1), osteopenic (T score at the spine or hip between -2.5 and -1) and osteoporotic (T score at the spine and/or hip ≤-2.5). During a median 9.1 yr (IQ :2.9) of follow-up, 158 incident fractures including 50 vertebral and 108 non-vertebral fractures were recorded in 115 women : 10% in normal, 47% in osteopenic and 43% in osteoporotic women based on BMD.
In the whole population, baseline values of bone ALP in the highest quartile and history of prior fracture were associated with increased fracture risk with age adjusted hazard ratios [HR(95%CI)] of 1.5(0.98-2.2) and 2.4(1.5-3.7) respectively. The table shows the age adjusted HR, sensitivity and specificity of bone alkaline phosphatase, history of prior fracture and their combination for predicting fracture risk in women with BMD values in the osteopenic range. Similar results were obtained with serum osteocalcin and CTX. Thus, in women with osteopenia 59% of them with incident fractures could be identified with history of fractures and a single BTM measurement.

Predictors	HR (95% CI), p value	Sensitivity	Specificity
Bone ALP	2.2 (1.3-3.7), p<0.006	43	75
History of prior fracture	2.7 (1.4-5.0), p<0.002	29	89
Bone ALP and / or prior fracture	2.7 (1.5-4.6), p<0.0006	59	66

We conclude that in postmenopausal women with BMD values in the osteopenic range, a marker of bone turnover and history of prior fracture predict the risk of fracture up to 10 years later. Their assessment may play an important role in identifying women at high risk of fracture who could not be adequately detected by BMD measurement alone, and who may benefit from a therapeutic intervention.

Role of the Promoter –1997 G/T and -1663indelT Polymorphic Sites on the Transcription Regulation of the COL1A1 Gene. S. Balcells*[1], N. Garcia-Giralt*[1], A. Enjuanes*[2], X. Nogues[3], L. Mellibovsky*[3], A. Diez[3], D. Grinberg*[1]. [1]Genetics, University of Barcelona, Barcelona, Spain, [2]Urfoa, Institut Municipal d'Investigació Mèdica, Barcelona, Spain, [3]Hospital del Mar Universitat Autònoma de Barcelona, Barcelona, Spain.

We identified two new polymorphisms in the upstream regulatory region of COL1A1 which were associated to BMD in postmenopausal women: one is a DIP (deletion/insertion polymorphism) at –1663 with two alleles containing 7 or 8 Ts, and the second, a SNP at –1997, with G or T alleles. We also showed that the sites containing these polymorphisms (PCOL1 and PCOL2) were binding sites for osteoblastic nuclear proteins, and that there were affinity differences between the two alleles of each polymorphism (JBMR 17:384-93, 2002). Here we present functional analyses of these regulatory regions using a luciferase reporter gene assay in MG63 cells. In order to compare the four different haplotypic combinations for the two polymorphisms (G/8T, G/7T, T/8T, T/7T), we prepared constructions of the full promoter (-2483 +40) or shorter ones in which a region from –1284 to –254, known to harbour a strong negative regulatory element (IR), was deleted. Preliminary results indicate that the two haplotypes bearing T at –1997(T/8T and T/7T) were the ones associated to a lower level of transcription, particularly haplotype T/8T in the absence of the IR. We have also tested constructions in which only one of the polymorphic sites was present, to compare the two alleles at each site. Transcription associated with the -1997T seemed to be lower than that associated with -1997G. Differences for the -1663 alleles were only observed in the absence of the IR: the 7T allele showed higher luciferase activity than the 8T allele. Finally, we have analysed different constructions bearing combinations of three different parts of the COL1A1 promoter in basal conditions or under different treatments (vitamin D, dexamethasone, TNFalpha, IL-1beta, estrogen, testosterone and PTH) to identify regions containing responsive elements. The main results were that vitamin D stimulated transcription only in the absence of the IR region, dexamethasone stimulated in all cases but has a greater effect if the polymorphisms were present, while TNFalpha and IL-1beta always decreased luciferase levels. In conclusion, variants –1997 T/G and -1663 indelT play a role in the transcription regulation of the COL1A1 gene, compatible with the BMD differences found among women bearing different genotypes at these sites.

An X-Chromosome Locus Modulates Lumbar BMD in Postmenopausal Women, and Age-Dependent Decline of Spinal BMD in Mice. H. Mroczkowski*[1], C. A. Parsons*[2], O. M. E. Albagha*[2], D. M. Reid*[2], S. C. Manolagas[3], S. H. Ralston[2], R. J. Shmookler Reis[4]. [1]Biochem./Molec. Biol., Univ. of Arkansas for Medical Sciences and CAVHS, Little Rock, AR, USA, [2]Medicine & Therapeutics, Univ. of Aberdeen, Aberdeen, United Kingdom, [3]Medicine, Univ. of Arkansas for Medical Sciences and CAVHS, Little Rock, AR, USA, [4]Geriatrics, and Biochem./Molec. Biol., Univ. of Arkansas for Medical Sciences and CAVHS, Little Rock, AR, USA.

We recently identified several quantitative trait loci (QTL) for post-maturity change in spinal BMD of mice, by interval mapping in an interstrain-cross F2 population. From a significant mouse QTL on the X chromosome, we located the corresponding (conserved-synteny) region of the human X chromosome by reference to the working-draft human genome sequence. DNA sequencing and single base extension techniques, using protocols modified from those of the ABI SNaPshot and Molecular Dynamics SNuPe systems, were developed to genotype at single nucleotide polymorphisms (SNPs) across this human genomic interval. We then investigated the allele proportions for each SNP in a population of postmenopausal women from northeastern Scotland (n=3653). Subjects were ordered by lumbar-spine BMD values adjusted for age, height and weight, to identify individuals in the highest and lowest bone density deciles of the normalized population distribution. We performed initial genotyping in quadruplicate on replicate pools of DNA samples, created by combining equal amounts of DNA from each individual in a decile group. Analysis of the SNP allele peak height ratios implied a significant difference between the high and low DNA pooled samples at one SNP ($p<0.0002$), and this apparent difference was confirmed by testing the individual DNA samples comprising each pool ($p<0.004$). Reanalysis of pooled data, by a procedure that includes sampling and assay variance to calculate significance, gave 3 adjacent SNPs with p values <0.003 (Figure). Fine-scale mapping has thus narrowed the candidate region to <75 kilobase pairs and two possible genes. This study demonstrates the feasibility and benefit of transferring QTL information between the mouse and human genomes, at a stage well in advance of gene identification, relying on association mapping in large human populations to narrow the implicated interval.

Completion of a Whole-Genome Scan for Linkage to Bone Mineral Density in Forty-two Caucasian Families. K. Sol-Church*[1], L. D. Spotila[2], H. Li*[1], G. N. Picerno*[1], D. L. Stabley*[1], K. Wang*[1], J. Korkko*[3], R. Kosich*[4], D. Prockop*[3], A. Tenenhouse*[5], C. McKay[6], M. Devoto*[1]. [1]Biomedical Research, Alfred I duPont Hospital for Children, Wilmington, DE, USA, [2]Drexel University, Philadelphia, PA, USA, [3]Tulane University, New Orleans, LA, USA, [4]Mcp, Hahnemann University, Philadelphia, PA, USA, [5]McGill Bone Centre, McGill University, Montreal, PQ, Canada, [6]Nephrology, Alfred I duPont Hospital for Children, Wilmington, DE, USA.

Osteoporosis of the femoral neck and lumbar spine is caused, in part, by low bone mineral density (BMD). In an attempt to identify the specific genes that might influence BMD, and thus osteoporosis, we and others have performed whole genome scans for linkage. The results of these studies are notable for the diversity of chromosomal loci with positive support for linkage. Included in this list are loci on chromosomes 1p, 1q, 2p, 4, 5q, 6p, 10, 11p, 11q, 12. Our initial study (EJHG (1998) 6:151) identified three loci in seven families recruited through a proband with low BMD. One of the loci, 1p36, was investigated further in a total of 42 families (HMG (2001) 10:2447) demonstrating further support for linkage of the hip BMD trait to 1p36.2-36.3. Here we report results of completion of a whole genome scan on the expanded sample of 42 families.

The families were recruited from the Metabolic Bone Centre of Montreal General Hospital, and were composed of from one to 12 nuclear families. Linkage mapping marker set v2.5 (Applied Biosystems) was used to genotype the available individuals, and data were compiled using Genotyper 2.1. Mendelian errors were detected by means of the Pedmanager software. Linkage was analyzed using the SOLAR package (AJHG (1998) 62:1198) that implemented a variance components approach. Data for chromosomes with lod-scores greater than 1 were also analyzed by means of the transmission disequilibrium test using the QTDT software (AJHG (2000) 66:279).

Heritability of BMD was 0.51 +/- 0.13 (femoral neck) and 0.79 +/- 0.1 (lumbar spine). Significant covariates included in the linkage and the QTDT analyses were age, sex, and BMI. In addition to lod = 2.85 at 1p36, two sites had lod scores greater than 1.5 for the femoral neck trait. These loci were 2p (34 cM from pter, lod = 1.76) and 22p (0 cM, lod = 1.94). The 2p locus also gave a lod score greater than 1 for the lumbar spine (35 cM, 1.30). Of these loci, none was significant in the QTDT analysis.

On the basis of our current data analysis, we conclude that there is some statistical support for loci on chromosomes 2p and 22p. The completion of this genome scan on this expanded set of families has served to place the observation of linkage at 1p36 in the context of a whole-genome scan.

A QTL with Pleiotropic Effects on Serum Levels of Osteocalcin and Bone Alkaline Phosphatase in Baboons Maps to a Region Corresponding to Human Chromosome 6p21.1-21.3. L. M. Havill, M. C. Mahaney, J. Rogers. Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX, USA.

We conducted a bivariate statistical genetic analysis of serum concentrations of bone specific alkaline phosphatase (Bone ALP), a highly specific marker of osteoblast function, and osteocalcin (OC), another osteoblast product and a marker of bone turnover, to search for genes with pleiotropic effects on these phenotypes. Using commercially available enzyme immunoassay kits, Bone ALP and OC were assayed in frozen serum samples obtained from 611 pedigreed baboons (*Papio hamadryas*) (437 females, 174 males) aged 5.5-30.0 years. We used a maximum likelihood variance decomposition approach to estimate the following parameters simultaneously for both traits: population (male) mean; mean effects of age, age^2, age-by-sex, age^2-by-sex, height, weight, and osteophytosis score; the proportion of the residual phenotypic variance due to the additive effects of genes (heritability (h^2)); unmeasured environmental factors (e^2), and the correlations between both traits due to shared genetic effects (ρ_G) and shared unmeasured environmental factors (ρ_E). Variation in serum Bone ALP and OC levels showed residual heritabilities of 0.17 (p=0.0005) and 0.25 (p=0.0006), respectively. A significant positive genetic correlation between the two phenotypes (ρ_G=0.42, p=0.003) provides strong evidence that 18% of the additive genetic variance in the two traits is attributable to the same gene(s). Initial univariate linkage screens localized possible QTLs for genes influencing variation in Bone ALP (LOD=2.80) and OC (LOD=2.71), to opposite ends of a 30 cM region of baboon chromosome 4 (homologous to human chromosome 6). Maximization of a multivariate multipoint linkage model, parameterized according to the bivariate model (above) and allowing for an additive genetic correlation due to the QTL, improved evidence for linkage (LOD=3.28) in this same region, localizing a single QTL intermediate to human microsatellite markers D6S422 and D6S259. This region of baboon chromosome 4 corresponds to human chromosome 6p21.1-21.3. Likelihood ratio tests reject the hypothesis of coincident linkage (p=<0.00001) supporting the pleiotropic effect of a single QTL on two markers of bone formation and turnover in the baboon. Given the close genetic and physiological similarity of this animal to humans, these results should be highly informative in our search for genes affecting skeletal maintenance and repair in humans.

Testing Association and Linkage of 8 Candidate Genes with BMD in 405 Caucasian Families Using Multiple SNP Markers and Haplotypes. L. J. Zhao*[1], J. R. Long*[2], H. Shen*[1], P. Y. Liu*[2], Y. Y. Zhang*[2], P. Xiao[1], D. H. Xiong[1], L. Elze*[2], R. R. Recker[2], H. W. Deng[1]. [1]Biomedical Sciences, Osteoporosis Research Center, Omaha, NE, USA, [2]Osteoporosis Research Center, Omaha, NE, USA.

With robust design and analyses, a large family sample, multiple SNPs (single nucleotide polymorphism) and haplotypes, this study is to test thoroughly 8 prominent candidate genes for BMD: vitamin D receptor (VDR), estrogen receptor α (ER-α), apolipoprotein E (APOE), type I collagen α 1 (COL1A1), transforming growth factor β 1 (TGF-β1), parathyroid hormone receptor type 1 (PTHR1), interleukin-6 (IL6) and tumor necrosis factor receptor 2 (TNFR2). Previous studies using a limited few markers, relatively small samples, and/or unreliable designs have yielded largely inconsistent results. 405 families with 1,874 Caucasians were recruited, phenotyped and genotyped. The program QTDT (quantitative transmission disequilibrium test) was used to test 28 SNPs in these genes (4 SNPs for the VDR gene, 6 for ER-α , 4 for APOE, 4 for PTHR1, 3 for COL1A1, 3 for TGF-β1, 2 for IL6 and 2 for TNFR2). Strong linkage disequilibrium was generally detected for SNPs within these genes. For the VDR gene, significant linkage with the ultra-distal BMD (UD BMD) was detected for all the four individual SNPs (p<0.005). Analyses of the haplotypes of the VDR confer further evidence for linkage of the VDR with the UD BMD (p<0.0001). Linkage was also detected for all the 4 SNPs of VDR with total body BMD (p<0.01), and for SNP rs2228570 with radius BMD (P<0.01). The haplotype ATAC of the VDR was associated with low BMD at intertrochanter (p<0.003), hip (p=0.005) and for the whole body (p<0.01). For the ER-α gene, SNP rs932477 was associated with wrist BMD variation (p=0.005). Association was also found for the ER-α haplotype CGCGAA with high body BMD (p<0.005), and haplotype CACGGG with low hip BMD (p<0.008) respectively. For the APOE gene, both individual SNPs and haplotype analyses suggested its linkage to whole body BMD (p<0.008). For the PTHR1 gene, the haplotype GATG was associated with high BMD at hip (p<0.002), femoral neck (p<0.0001), trochanter (p<0.01), intertrochanter (p<0.005), and whole body (p<0.003). Subjects carrying the haplotype GATG had femoral neck BMD 6.04% higher than none-carriers. Haplotype AACA of the PTHR1 gene was associated with high BMD at hip (p<0.006) and intertrochanter (p<0.005). In summary, our work supports that the VDR and APOE genes are linked to BMD variation and the ER-α and PTHR1 genes are associated with BMD variation in our Caucasian sample.

Association of Apolipoprotein E Genotypes with Bone Mineral Density and Bone Loss in Early Postmenopausal Scottish Women. H. M. Macdonald[1], F. M. McGuigan*[1], P. N. Tasker*[1], A. Bassiti*[1], S. C. Main*[1], S. A. New[2], D. M. Reid[1], S. H. Ralston[1]. [1]Medicine and Therapeutics, University of Aberdeen, Aberdeen, United Kingdom, [2]School of Biological Sciences, University of Surrey, Guildford, United Kingdom.

The Apolipoprotein E4 (APOE 4) allele has been associated with reduced bone mineral density (BMD) in postmenopausal women from Japan and the Netherlands, and with rates of bone loss in peri- and postmenopausal American women. In this study we investigated whether APOE genotype influences BMD or bone loss using subjects from the Aberdeen Prospective Osteoporosis Screening Study (APOSS). A total of 3883 women underwent bone densitometry in 1990-3 (mean ± SD age: 48.5 ± 2.4 y) and again in 1997-2000 (mean ± SD duration of follow up: 6.3 ± 0.9 y). So far, 1755 of these women have been genotyped for APOE by DNA sequencing using the fluorescence-based MegaBACE™ system. Allele frequencies were: E3 78.2%; E4 14.0%; E2 7.8%. Genotypes in Hardy Weinberg equilibrium were as follows: E3/E3 1075 (61.3%), E3/E4 386 (22.0%), E2/E3 207 (11.8%), E2/E4 46 (2.6%), E4/E4 30 (1.7%), E2/E2 11 (0.6%). There was no association between APOE genotype and baseline BMD at either lumbar spine or femoral neck (FN), excluding an effect on peak bone mass. However FN bone loss was greatest in carriers of the E4 allele and least in carriers of E2 (Table). Reflecting this fact, FN BMD at follow-up was lowest in carriers of E4 and highest in carriers of E2. The differences remained significant after adjustment for age, weight, height, smoking, socio-economic status, physical activity and menopausal status/HRT use. There was no significant relationship between APOE genotype and bone loss at the lumbar spine (data not shown).

Table. Effect of APOE genotype on FN BMD

Mean BMD ± SD	APOE 2 (2/2 and 2/3)	APOE (3/3)	APOE 4 (4/4 and 3/4)	P
N	218	1075	416	
Baseline FN BMD (g/cm^2)	0.892 ± 0.14	0.886 ± 0.12	0.877 ± 0.12	0.250
Follow up FN BMD (g/cm^2)	0.855 ± 0.13	0.838 ± 0.12	0.827 ± 0.12	0.025
FN BMD change (%/y)	-0.60 ± 1.11	-0.83 ± 1.06	0.84 ± 0.91	0.007

The association between APOE 4 genotype, reduced BMD and increased early postmenopausal bone loss is confirmed in this large population based cohort of early postmenopausal women from Scotland. Further work is required to establish whether this effect is mediated through vitamin K transport, interaction with dietary fat/ cholesterol or an independent effect. Dietary information collected at follow-up for 3239 women from APOSS will allow us to investigate any interaction between dietary vitamin K, dietary fat and APOE genotype on BMD.

Disclosures: ***H.M. Macdonald****, None.*

Relationship of ColIA1 Sp1 Polymorphism, BMD and Fracture Risk in Older Women: The Study of Osteoporotic Fractures. D. R. Greene*[1], L. Lui[2], K. L. Stone[3], P. Morin*[4], T. A. Hiller*[5], J. Li*[1], S. R. Cummings[6]. [1]Human Genetics, Roche Molecular Systems, Alameda, CA, USA, [2]University Of California, San Francisco, San Francisco, CA, USA, [3]University of California, San Francisco, San Francisco, CA, USA, [4]National Marine Fisheries Service, San Diego, CA, USA, [5]Kaiser Permanente Center for Health Research, Portland, OR, USA, [6]California Pacific Medical Center, San Francisco, CA, USA.

Osteoporosis accounts for significant mortality and morbidity and will continue to increase with projected increases in the elderly population. There are several treatment regimens for osteoporosis, some approved for prevention. However, the use of these agents has been limited to the prevention of initial or additional fractures after osteoporosis has developed. Better diagnostics for identifying osteoporosis would help to target individuals at high risk. There are several genetic polymorphisms associated with osteoporosis. One of the most closely studied is a polymorphism in the Sp1 binding region of the Collagen IA1 gene. We assessed the relationship of the ColIA1 polymorphism with bone density and fracture risk in 4428 older women participating in the multi-center Study of Osteoporotic Fractures. Blood samples collected in 1988-9 were genotyped for the polymorphism in the Sp1 binding site of Col1A1 using either a Taqman assay or real-time allele specific PCR. Bone mineral density of the hip and spine were assessed by DXA (Hologic, Inc.) Incident hip fractures were ascertained by tri-annual postcard follow-up, and subsequent confirmation based on review of radiology reports. Incident spine fractures were determined based on vertebral morphometry, using paired spine radiographs collected at the baseline exam (1986-88) and an average of 3.7 years later. Of the 4428 women included in this study, 266 hip fractures occurred during a mean follow-up of 11.3 years. After controlling for age, weight, use of estrogen and total hip BMD, we found that women who were homozygous for the minor allele of the ColIA1 polymorphism had an approximate 70% increase is risk of hip fracture compared to those homozygous for the major allele (RR=1.70; 95% CI 0.91 - 3.18 p=.09). Although a similar trend was observed for vertebral fracture, it was not close to statistical significance. Similarly, there was no observed association between the ColIA1 polymorphism and BMD. In conclusion, we found a borderline significant increased risk of hip fracture among women homozygous for the minor allele of the polymorphism in the Sp1 binding region of ColIA1. This result is comparable to the results from a meta-analysis of the literature on ColIA1, and illustrates the necessity of multiple studies and large cohorts to assess modest genetic effects.

Genetic Variation in LDL Receptor-Related Protein 5 (LRP5) is a Major Risk Factor for Male Osteoporosis: Results from Cross-Sectional, Longitudinal and Case-Control Studies. U. Choudhury*[1], M. C. de Vernejoul[2], S. Deutsch*[1], T. Chevalley[3], J. P. Bonjour[3], S. E. Antonarakis*[1], R. Rizzoli[3], S. L. Ferrari[3]. [1]Division of Medical Genetics, Geneva University Medical School, Geneva, Switzerland, [2]INSERM U349, Hôpital Lariboisière, Paris, France, [3]Division of Bone Diseases, Department of Geriatrics and Internal Medicine, Geneva University Hospital, Geneva, Switzerland.

Mutations in the LDL receptor-related protein 5 gene (LRP5) cause osteoporosis-pseudoglioma (OPPG) and bone dysplasias with "high bone mass". The contribution of LRP5 polymorphisms to the population-based variation in bone mass and osteoporosis risk is unknown.

We investigated 5 LRP5 SNPs that were not in complete linkage disequilibrium and had a frequency above 2% in relation to areal bone mineral density (aBMD), bone mineral content (BMC) and bone area at the lumbar spine in 877 healthy Caucasian males and females aged 6 to 69 years. This sample included 332 growing children with longitudinal bone measurements for two years. An independent case-control study was performed in 86 men with early idiopathic osteoporosis, including 60 fractures, and 84 age-matched controls (mean age ±SD, 51 ± 13 yrs).

In the population-based study, two LRP5 missense substitutions (exon9 c.1999G>A and exon 18 c.3989 C>T) were associated with aBMD (P=0.01 and p=0.041, respectively), BMC (P=0.001 and P=0.028) and bone area (P=0.003 and P=0.043), as well as with stature (P=0.002 and P=0.072) (all analyses adjusted and standardized for age, gender and weight, Z-scores). LRP5 haplotypes were also significantly associated with all 3 skeletal measurements (P=0.012-0.002), with Z-scores differences between haplotypes greater than 2 Z-scores in men. In children, exon 18 genotypes were associated with two-years gain in BMC (P=0.042), vertebral area and height (P=0.005 and P=0.0013, respectively), and in stature (P=0.025). In adult males, LRP5 polymorphisms accounted for up to 15% of the population variance in these traits. In turn, exon18 T allele was associated with an increased multivariate relative risk (odds ratio 2.53, 95% CI [1.23-5.19], p=0.011, adjusted for age, weight and height) whereas LRP5 haplotype 1 was associated with a decreased risk (odds ratio 0.40, 95% CI [0.19-0.86], p=0.018) of osteoporosis in men.

In summary, LRP5 genetic variation contributes substantially to the determination of vertebral bone mass and stature, likely by influencing bone size during growth. We conclude that LRP5 genetic variation plays a major role in the determination of peak bone mass in Caucasians and represents an important susceptibility gene for osteoporosis in men.

Transcriptional Induction of the Gene Encoding α3 Chain of Type IX Collagen (*COL9A3*) by SOX9 Contributes to the Susceptibility of Knee Osteoarthritis. T. Ikeda*[1], A. Mabuchi*[1], A. Fukuda[2], S. Kamekura*[2], I. Kou*[1], H. Hiraoka*[2], A. Kawakami*[2], S. Yamamoto*[2], U. Chung[2], Y. Takatori*[2], M. Takigawa[3], H. Sakai*[4], A. Sudo*[5], A. Uchida*[5], K. Nakamura[2], H. Kawaguchi[2], S. Ikegawa*[1]. [1]Riken SNP Research Ctr., Tokyo, Japan, [2]Univ. of Tokyo, Tokyo, Japan, [3]Univ. of Okayama, Okayama, Japan, [4]Dokkyo Univ., Mibu, Japan, [5]Univ. of Mie, Tsu, Japan.

Although osteoarthritis (OA) is a common and serious skeletal disorder, its genetic and molecular backgrounds are little understood. Because mutations in type IX collagen genes (*COL9A1, COL9A2, COL9A3*) cause chondrodysplasia with early-onset OA phenotypes in humans and mice, we performed an association analysis on knee OA patients using single nucleotide polymorphisms (SNPs), and found a significant association of a marker SNP in *COL9A3* (1740C>T). Immunohistochemical analyses revealed focal induction of type IX collagen early in the repair stage of the OA articular cartilage of humans and mouse models, suggesting that *COL9A3* impedes OA progression. We further performed dense mapping of polymorphisms in the entire *COL9A3* gene and its 3-kb upstream sequences, and identified 62 polymorphisms. Association studies of these polymorphisms using 499 knee OA patients and 385 controls determined that a VNTR (variable number of tandem repeat)-like polymorphism in intron 25, located close to the marker SNP, showed the strongest association (p=0.001). Of this polymorphism, the one-repeat allele (1R) conferred high risk (p=0.004, OR=1.35) and the two-repeat allele (2R) low risk (p=0.001, OR=0.78) for OA. Since the repeat sequence had SOX9-binding motifs, we examined the transcriptional regulation of *COL9A3* by SOX9. SOX9 overexpression in human carcinoma cell lines induced *COL9A3* mRNA as well as *COL9A1*, *COL9A2* and *COL2A1* mRNA. Electrophoretic mobility shift assays with *in vitro*-translated SOX9 and luciferase-reporter assays in the SOX9-overexpressing cells transfected with the polymorphic repeat of *COL9A3* showed that this repeat strongly bound and responded to SOX9, both of which were abrogated by mutations in the SOX9-binding motifs. The reporter activity was dependent on the repeat number: it was stronger in cells transfected with 2R than those with 1R. In addition, overexpression of SOX9 in cultured dermal fibroblasts derived from individuals with different genotypes for the allele showed more rapid induction of *COL9A3* mRNA in cells with 2R than those with 1R. These findings strongly suggest that the SOX9-binding polymorphic enhancer in *COL9A3* affects type IX collagen transcription and thus contributes to the susceptibility of knee OA. SOX9 and its related molecules could therefore be targets of novel treatments of OA and cartilage regenerative medicine.

Contribution of the Vitamin D Receptor and Collagen I Alpha 1 Genes to Hip Fracture Risk. T. V. Nguyen, L. M. Esteban*, C. P. White, S. F. Grant, E. M. Gardiner, J. R. Center, J. A. Eisman. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia.

The risk of hip fracture risk is partly determined by genetic factors. Polymorphisms of the vitamin D receptor (VDR) and collagen 1α1 (COLIA1) genes have been associated with bone mineral density (BMD), and with fracture risk. It is not clear whether the two genes have additive effects on hip fracture risk. This study examines the contribution of VDR and COLIA1 genotypes to the liability to hip fracture in postmenopausal women.
Genotypes of the VDR (*TT, Tt, tt*) and COLIA1 (*SS, Ss, ss*) genes were determined in 677 (69 hip fracture and 608 non-fracture) women of Caucasian background, aged 70 ± 7 (mean ± SD), who were participants in the Dubbo Osteoporosis Epidemiology Study, Australia. Women with the *tt* genotype was significantly higher in the hip fracture group (26%) compared to those in the non-hip fracture group (14.4%; p = 0.03). Moreover, women with the *ss* genotype were over-represented in the hip fracture (10%) compared to those in the non-fracture group (4.4%; p = 0.04). After adjusted for age and femoral neck BMD in a multiple logistic regression model, women with *tt* genotype had a 2.6-fold (95% CI: 1.2 to 5.3), and women with *ss* genotype were associated with a 3.8-fold (95% CI: 1.3 to 10.8) increase risk of hip fracture. Approximately 33% of the liability to hip fracture was attributable to the presence of the *tt* genotype of the VDR gene and *ss* genotype of the COLIA1 gene.
Caucasian women with VDR *tt* genotype and COLIA1 *ss* genotype were associated with increased hip fracture risk, and the association was independent of BMD and age.

Endocannabinoid Regulation of Bone Remodeling. O. Ofek*[1], M. Fogel*[1], M. Attar-Namdar*[1], Y. Tam*[1], R. Müller[2], R. Mechoulam*[3], E. Shohami*[3], I. Bab[1]. [1]Bone Laboratory, Hebrew University of Jerusalem, Jerusalem, Israel, [2]Institute for Biomedical Engineering, Swiss Federal Institute of Technology (ETH) & University of Zürich, Zürich, Switzerland, [3]School of Pharmacy, Hebrew University of Jerusalem, Jerusalem, Israel.

Endocannabinoids, the endogenous ligands of cannabinoid receptors, are involved in complex central and peripheral physiologic systems. The role of endocannabinoids in the control of body weight and reproduction and the leptin negative regulation of both endocannabinoid levels and osteoblastic activity lead us to hypothesize that endocannabinoid signaling is involved in the regulation of bone remodeling. Indeed, micro-computed tomography of the distal femoral metaphysis of male and female knockout mice lacking the predominantly central CB1 cannabinoid receptor (*Cnr*) demonstrated a skeletal phenotype with a markedly reduced trabecular bone volume, number and connectivity. Normal mice given nine daily injections of the endocannabinoid 2-arachidonoyl glycerol (2AG) showed a dose (1-20 mg/Kg/day) dependent increase in trabecular bone formation rate consequent to increased mineralization perimeter, but not mineral appositional rate, suggesting 2AG stimulation of osteoblast number with no effect on osteoblast activity. To assess the occurrence of direct endocannabonoid signaling in bone, we measured the *Cnr* mRNA levels in the murine ST2 and MC3T3 E1 stromal cell lines and primary bone marrow derived stromal cell cultures. No expression could be detected in undifferentiated cells. However, progressive expression, specifically of the peripheral CB2 *Cnr* was clearly evident in cells grown in an osteogenic medium for 10-30 days. The cannabinoid radioligand [^{3}H]HU-243 bound competitively to the differentiated cells. An exceptionally high level of CB2 mRNA was found in bone marrow derived murine osteoclasts developing in the presence of M-CSF and RANKL and in their monocyte progenitors. Both the osteoblastic and osteoclastic cells also express the endocannabinoid degrading enzyme fatty acid amide hydrolase. Collectively, these data suggest potent endocannabinoid regulation of bone remodeling by direct signaling in bone cells as well as via central, yet unidentified pathway(s). The endocannabinoids appear to discriminate osteoblasts from other stromal cells, including osteoblast precursors, as portrayed by the restriction of cannabinoid receptor expression to differentiated osteogenic cells. The discovery of the bone endocannabinoid regulatory system will hopefully facilitate the development of a new generation of bone anabolic/antiresorptive strategies to gain a higher peak bone mass, prevent and rescue bone loss and accelerate bone wound healing.

Cytokines Suppress Adipogenesis and Induce Osteoblastgenesis through the TAK1/TAB1/NIK Cascade. I. Takada*[1], M. Suzawa*[2], S. Kato[1]. [1]Institute of Molecular and Cellular Bioscience, University of Tokyo, Tokyo, Japan, [2]Department of Physiology, University of California San Francisco, Usa, CA, USA.

Pluripotent mesenchymal stem cells in bone marrow differentiate into adipocytes, osteoblasts and other cells. Balanced cytodifferentiation of stem cells is essential for the formation and maintenance of bone marrow but the mechanism of these control is largely unknown. We found that ST2 cells, a bone marrow derived mesenchymal stem cells differentiate into adipocyte with PPAR-gamma ligand (Troglitazone) but differentiate into osteoblasts expressing alkaline phosphatase when treated with both troglitazone and cytokines such as interleukin-1 (IL-1) and tumour-necrosis factor-alpha (TNF-alpha). The inhibitory effect of cytokines on adipogenesis in ST2 cells suggested that the ligand-induced transcriptional activity of PPAR-gamma might be suppressed by these cytokines.
To investigate this, we examined the transcriptional activity of PPAR-gamma in ST2 cells using a transiently expressed reporter assay and found that the ligand-induced transcriptional activity of PPAR-gamma was supressed by IL-1 and TNF-alpha, and that this suppression is mediated through NF-kappaB activated by the TAK1/TAB1/NF-kappaB-inducing kinase (NIK) cascade, a downstream cascade associated with IL-1 and TNF-alpha signalling.
In a co-immunoprecipitation assay treated with cytokines and troglitazone in ST2 cells, we detected an association between endogenous NFkappaB complex and endogenous PPAR-gamma. However, other nuclear receptors such as GR did not show this cytokine-induced association with NFkappaB in ST2 cells. Then we examined this association further with GST pull down assay and found that the DNA-binding C domain of PPAR-gamma was identified as a p65-interacting region. And unlike suppression of the PPAR-gamma transcriptional activity by MAP kinase-induced growth factor signalling through phosphorylation of the A/B domain, NF-kappaB blocked PPAR-gamma binding to DNA. Finally, we studied the molecular mechanism of the recruitment of NFkappaB to PPAR-gamma by examining potential PPAR-gamma coactivators and corepressors and found that PGC-2, a PPARgamma AF-1 specific coactivator associated with PPAR-gamma and NFkappaB complex.
These results indicate that the expression of IL-1 and TNF-alpha in bone marrow may alter the fate of pluripotent mesenchymal stem cells, directing cellular differentiation towards osteoblasts rather than adipocytes by suppressing PPAR-gamma function through TAK1/TAB1/NIK-NFkappaB cascade.

Specific Cytoplasmic Tyrosine Residues in c-Fms Regulate ERK Activation during Osteoclastogenesis. S. Takeshita, R. Faccio, S. L. Teitelbaum, F. P. Ross. Pathology, Washington University School of Medicine, St. Louis, MO, USA.

ERK signaling is pivotal for the proliferation and differentiation of many cell types. Recent reports reveal that ERK inhibition suppresses osteoclast (OC) formation from M-CSF-dependent bone marrow macrophages (MDBMs). Expanding on this information, we found that ERK activation is required only during the early stages of MDBM proliferation/differentiation. Given these observations and the fact that M-CSF is the strongest inducer of ERK activation in MDBMs, we analyzed the signaling pathways by which c-Fms activates this MAPK. To this end, we retrovirally transduced MDBMs with c-Fms chimeric receptors containing seven tyrosine (Y) residues (559, 697, 706, 721, 807, 921 and 974) mutated to phenylalanine (F), singly or in combination. Initial studies revealed that Y559F and Y807F decreased MDBM proliferation while Y559F, but not Y807F, reduced ERK phosphorylation. Interestingly, the Y559F/Y807F double mutation completely abolished proliferation, while continuing to stimulate ERK. These data led to experiments aimed at identifying the Y residue(s) responsible for initiating ERK activation. Using additional mutants we identified Y559 and Y697, which are c-Src and Grb2 binding sites, respectively, as critical residues for activation of the ERK pathway. The Y559F/Y697F double mutation blocked both cell division and ERK activation. While Y559F reduced ERK activity as described above, Y697F exhibited only minor effects. Surprisingly, chimeric receptors containing only Y559 or Y697, with all remaining Y mutated to F, stimulated ERK, but not MDBM division, establishing that the ERK pathway alone is insufficient to induce OC precursor proliferation. We next examined other signaling cascades downstream of M-CSF that may mediate these events. Since the kinases c-Src and PI3K regulate macrophage growth, we performed studies using the specific inhibitors PP2 (c-Src) and LY294002 (PI3K). Both compounds separately blocked ERK activation and MDBM proliferation. When combined, the two inhibitors synergistically suppress MDBM proliferation. Consistent with the known stimulatory effect of ERKs on OC differentiation, we found that PP2 also decreased this process. Lastly, the same Y to F mutants that suppress proliferation inhibit OC differentiation independently. In conclusion, we propose that OC precursor proliferation/differentiation requires (1) c-Fms signaling from the residues Y559 and Y807 or the combinations Y559/Y807 and Y559/Y697 and (2) activation of the c-Src and PI3K pathways. Finally, the ERK pathway, while necessary, is not sufficient for proliferation and differentiation of OC precursors.

RAS Association Domain Family Protein, RASSF1C, Is a Binding Partner and a Potential Intracellular Mediator of the Actions of IGF Binding Protein-5 (IGFBP-5) in Human Osteoblasts. Y. Amaar, S. Bala*, D. J. Baylink, S. Mohan. Musculoskeletal Disease Center, J.L. Pettis VAMC, Loma Linda, CA, USA.

Previous studies have shown that IGFBP-5 is a multifunctional protein that acts not only as a traditional binding protein but also functions as a growth factor independent of IGFs to stimulate bone formation. The intrinsic growth factor action of IGFBP-5 has been predicted to involve binding of IGFBP-5 to a putative receptor to induce downstream signaling pathways and/or nuclear translocation of IGFBP-5 to influence transcription of genes involved in osteoblast cell proliferation/differentiation. To identify the molecular pathway by which IGFBP-5 exerts its intrinsic biological activity in osteoblasts, we undertook studies to identify proteins that bound to IGFBP-5 using IGFBP-5 as bait in yeast two hybrid screen of U2 human osteosarcoma cell cDNA library. One of the clones that interacted strongly with the bait under high stringency conditions corresponded to the isoform C of the RAS association family 1 gene (RASSF1C) which encodes 270 amino acids. The interaction between RASSF1C and IGFBP-5 is confirmed by *in vitro* co-immunoprecipitation studies, using rIGFBP-5, IGFBP-5 polyclonal antibody, and cell lysates overexpressing RASSF1C. Northern blot and RT-PCR analysis showed that the RASSF1C is expressed in both untransformed normal human osteoblasts (derived from calvaria and rib) and in

osteosarcoma cell lines (TE85, SaOS-2 and U2), which are known to produce IGFBP-5. In order to determine if RASSF1C is an intracellular mediator of IGFBP-5 actions, we evaluated the effect of blockage of RASSF1C production on osteoblast proliferation. Addition of synthetic RASSF1C specific small interfering (si) RNA duplex caused a dose-dependent decrease in cell number (38% at 200 nM of siRNA, P<0.01) in human osteoblasts which produce abundant IGFBP-5.This effect was specific since a control siRNA duplex did not produce a similar effect. Conclusions: 1) Our study provides the first evidence that osteoblasts produce RASSF1C, a splice variant of RASSF1 that interacts with IGFBP-5 and regulates osteoblast proliferation. 2) Based on our findings and the recent findings that IGFBP-5 stimulates growth in human interstinal smooth muscle by RAS-dependent activation of p38 MAP kinase and Erk1/2 pathways, we predict that RASSF1C is an important intracellular mediator of the actions of IGFBP-5 and perhaps other growth factors in osteoblasts.

Insulin-Like Growth Factor-I Is Essential for Normal Bone Development. Y. Wang*, T. Sakata, B. P. Halloran, H. Z. ElAlieh*, S. J. Munson*, D. D. Bikle. Endocrine Unit, VA Medical Center , University of California, San Francisco, San Francisco, CA, USA.

Although insulin-like growth factor-I (IGF-I) has been identified clearly as an important growth factor for the skeleton, the role of IGF-I on embryonic bone development has not been evaluated in detail. To assess the role of IGF-I in modulating fetal skeletal development, we analyzed fetal bone tissue of mice homozygous for targeted ablation of the gene encoding IGF-I (IGF-I-/-) with respect to skeletal phenotype, and markers of chondrocyte proliferation and differentiation. In IGF-I -/- mice, skeletal malformations including short-limbed dwarfism were evident from E 14.5 to E18.5. Abnormal structures of spinal ossification centers, characterized by smaller hypertrophic chondrocyte size and number, were identified by H&E; staining on E18.5. A delay of mineralization in the spinal column, sternum and fore paws was identified by alizarin red-alcian blue staining in whole mount of skeletons on E14.5 to 18.5 and by von Kossa staining in bone sections of the spine on E18.5. The mRNA level of bone differentiation marker osteocalcin in the spine of IGF-I-/- mice was decreased to 16% of that of their wild type littermates (IGF-I +/+), however, no reduction was observed in mineralization of the long bones of IGF-I -/- mice. Although the extent of the proliferative zone in the growth plates of long bones and spinal ossification centers was normal in the IGF-I -/- mice, chondrocyte proliferation was reduced as assessed by PCNA staining. In the spinal ossification center, expression of collagen II was lower in IGF-I -/- mice, but not in the growth plates of long bones. No difference was observed in the expression of collagen X between IGF-I -/- and wildtype mice. Expression of Indian hedgehog (Ihh), which plays an important role in regulation chondrocyte differentiation, was reduced in IGF-I -/- mice in growth plates of long bones and the spinal ossification center, whereas expression of parathyroid hormone-related peptide (PTHrP), in a negative feedback loop with Ihh in regulating chondrocyte differentiation, was increased. Our results indicate that IGF-I is essential for normal embryonic bone development. IGF-I promotes chondrocyte proliferation, differentiation, and endochondral bone formation. Ihh and PTHrP are involved in regulating these effects of IGF-I on bone development. The effects of IGF-I on bone development are site specific in that lack of IGF-I leads to a greater delay in differentiation and mineralization of the spine than that of the long bones.

Jab1 Enhances SCF E3 Ligase-Mediated Smad4 Degradation. M. Wan, Y. Tang*, C. Lu*, X. Cao. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

TGF-β/BMPs exert a wide variety of biological activities, in particular, the regulation of skeletal development and bone remodeling. Smad4 is the critical common mediator shared in both TGF-β and BMP signaling pathways. Thus, the regulation of Smad4 protein steady state level is an important means of modulating TGF-β/BMP function. Protein degradation by the ubiquitin-proteasome pathway plays a vital role in regulating functional activity of signaling molecules, and substrate ubiquitination by a specific E3 ligase is a critical step in this pathway. Here we identified a specific SCF E3 ligase for Smad4 protein degradation. The SCF E3 ligase complex we identified contains four subunits: Skp1, Cul1, Roc1 and a substrate recognition subunit, β-TrCP. First, we examined the interaction between Smad4 and β-TrCP in yeast two-hybrid assays. Results of β-gal activity indicated that Smad4 specifically interacts with β-TrCP. We then confirmed the interaction between Smad4 and β-TrCP1 by immunoprecipitation assays in mammalian cells. The effects of SCF complex or its individual component on Smad4 steady-state level in cells were assessed by transient transfection and Western blotting. Our results indicate that Smad4 expression was almost abolished in the presence of three E3 ligase components (Cul1, Roc1 and β-TrCP). Roc1 with Cul1 or Cul1 with β-TrCP1 significantly down regulates Smad4, whereas, the individual components of SCF complex did not affect Smad4 expression level. To examine whether enhanced Smad4 turnover by SCF is due to its ability to promote ubiquitination of Smad4, *in vivo* ubiquitination assays were performed. Ubiquitin-conjugated Smad4 products were observed when both SCF components and ubiquitin were ectopically expressed. Thus, $SCF^{\beta\text{-}TrCP}$ is the specific E3 ligase that mediates Smad4 degradation. Jab1 (Jun activation domain binding protein 1) was reported to interact with Smad4 and induce its ubiquitination for degradation. To determine the molecular mechanism through which Jab1 exerts its Smad4 degradation activity, we first examined whether Jab1 has any effect on the Smad4-β-TrCP interaction by immunoprecipitation assay. As we expected, Jab1 enhances the interaction of endogenous Smad4 with β-TrCP in cells. In addition, overexpression of Jab1 in cells significantly enhances the degradation of Smad4 induced by SCF E3 ligase. Importantly, overexpression of the E3 ligase or Jab1 inhibits TGF-β- or BMP-induced gene transcription. Taken together, our data suggest that SCF is the E3 ligase mediating Smad4 degradation and Jab1 enhances its activity. Therefore, Jab1 and SCF may play critical roles in regulating cell proliferation and differentiation in response to TGF-β and BMP through a degradation pathway.

Inhibin A Prevents Orchidectomy-Induced Bone Loss in Mice. D. Gaddy[1], D. S. Perrien[1], N. S. Akel*[1], D. C. Montague[1], R. A. Skinner*[2], F. L. Swain*[2], L. J. Suva[2]. [1]Physiology and Biophysics, University of Arkansas for Medical Sciences, Little Rock, AR, USA, [2]Orthopaedic Surgery, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

We have previously demonstrated that Inhibin-A suppresses and Activin-A stimulates osteoblast and osteoclast differentiation in primary Swiss-Webster murine bone marrow cultures, as well as osteoblastogenesis in cultures of primary human bone marrow cells. These data led to our hypothesis that Inhibins act to suppress bone turnover and maintain bone mass through direct inhibitory effects on osteoblast and osteoclast development. To test this hypothesis in vivo in male mice, we utilized the GeneSwitch system which uses transgenic transactivator mice with liver-specific expression of a mifepristone-activated chimeric nuclear receptor (GLVP), crossed with transgenic target mice containing a GVLP-responsive promoter upstream of polio-virus IRES (internal ribosome entry site)-linked sequences coding for the alpha- and beta-subunits of inhibin A. This intercross produced "bigenic" mice capable of regulable expression of inhibin A from the liver, which when induced was associated with suppressed levels of FSH (Mol Endo, 2000 Jul;14(7):1075-85). We determined that both the GLVP only (monogenic) and the bigenic crossed mouse strains obtained peak bone mass at 5-6 months of age, as determined by bone densitometry using the Piximus (Lunar). At peak bone mass, baseline BMD measurements were performed prior to sham or orchidectomy (ORCH) of male mice, and the subcutaneous placement of mefipristone or vehicle-containing pellets (Innovative Research). Animals were followed for 4 weeks prior to obtaining femoral bone marrow for osteogenic culture, and tibial analyses of bone volume by microCT. Marrow cultures were initiated from both monogenic and bigenic mice, and cultured in the presence of ascorbic acid and betaglycerolphosphate, and in the presence or absence of Inhibin A, noggin or BMP2. As we previously reported (Endocrinology 2002 Jan;143(1):74-83), both Inhibin A and noggin suppressed recruitment of cells into the osteoblastic lineage (number of AP+ CFU-F), as well as mineralization (number of CFU-OB, and alizarin red normalized to protein). Induction of monogenic mice with mefipristone had no effect on either intact or ORCH bone volume or architecture in the proximal tibia. However, inhibin expression induced by mefipristone in bigenic mice protected against ORCH-induced volumetric bone loss (BV/TV) ($p<0.05$), which appeared to be due to a decrease in trabecular number. Together, these data provide direct in vivo evidence that Inhibin A regulates bone turnover and bone mass through bone marrow cell differentiation.

The Anti-apoptotic Effects of Mechanical Stimulation in Osteoblasts/Osteocytes Are Transduced by the Estrogen Receptor (ER): A Novel Ligand-Independent Function of the ER. J. I. Aguirre[1], L. I. Plotkin[1], B. Strotman*[1], L. K. McCauley[2], I. Gubrig[1], S. Kousteni[1], S. C. Manolagas[1], T. Bellido[1]. [1]Endocrinology, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. Arkansas for Med. Sci., Little Rock, AR, USA, [2]School of Dentistry, University of Michigan, Ann Arbor, MI, USA.

Like estrogens, mechanical stimulation of osteocytic cells promotes their survival; and this effect is mediated via activation of the extracellular signal regulated kinases (ERKs), shown elsewhere in this meeting. Based on this and evidence that mice lacking the estrogen receptor (ER)α exhibit a poor response to mechanical loading, we examined here whether ER participates in mechanotransduction. MLO-Y4 osteocytic cells, which express ERα and ERβ, but not the androgen receptor (AR), were subjected to biaxial stretching (5% elongation for 10 min at 3 cycles/min) using a BioFlex loading station. Stretching increased ERK phosphorylation, as assessed by Western blot analysis, and also caused translocation and nuclear accumulation of ERK2, demonstrated by using a green fluorescent protein (GFP)-ERK2 fusion protein. Consistent with an ER-mediated action, pretreatment of the cells with the ER antagonist ICI182,780 for 20 min abolished stretching-induced ERK phosphorylation. Moreover, nuclear accumulation of GFP-ERK2 in response to stretching was abolished by silencing both the endogenous ERα and ERβ in MLO-Y4 cells by introducing small interference (si) RNAs. Introduction of siRNA for the non-essential protein lamin A/C, used here as a negative control, had no effect. Consistent with these findings, stretching increased ERK phosphorylation in osteoblastic cells derived from wild type mice, and ICI182,780 abolished this response. On the other hand, osteoblastic cells derived from mice lacking both ERα and ERβ (DERKO), but expressing normal levels of AR, did not exhibit stretching-induced ERK phosphorylation or nuclear accumulation of GFP-ERK2. Lastly, the anti-apoptotic effects of E_2 and stretching on MLO-Y4 cell apoptosis were additive, as a suboptimal concentration of E_2 (10^{-9}M) in combination with suboptimal stretching (only 1 min) increased nuclear GFP-ERK2 accumulation to a greater extent than the individual treatments. More importantly, whereas the suboptimal individual treatments did not prevent etoposide-induced apoptosis, their combination did. Taken together, these results indicate that the ligand-naïve ER, but not the AR, transduces mechanical signals; and that ligand-dependent as well as ligand-independent actions of the ER are involved in the regulation of the survival of osteocytes and osteoblasts.

Correlation of Osteocyte-like Cell Deformation due to *in-vitro* Fluid Flow Shear Stress with Attachment, Dendrite Extension, and PGE_2 Production. D. P. Nicolella[1], A. J. Siller-Jackson*[2], P. P. Cherian[2], D. Shin*[1], J. X. Jiang[2], E. Sprague*[2], J. Lankford*[1], L. F. Bonewald[3]. [1]Southwest Research Institute, San Antonio, TX, USA, [2]University of Texas Health Science Center at San Antonio, San Antonio, TX, USA, [3]University of Missouri at Kansas City, Kansas City, MO, USA.

In-vitro, osteocytes are highly responsive to fluid flow shear stresses suggesting that fluid flow within the bone matrix controls bone mechanotransduction. However, neither fluid flow rates nor shear stresses acting on cells and the resulting cell deformations have been quantified *in-vivo*. Thus, the relationship between *in-vivo* mechanical signals and *in-vitro* mechanical stimulation is not well known. We hypothesize that it is neither fluid flow nor matrix deformation per se, but rather the resulting cell deformation that causes the biological response. The purpose of this study was to quantify cell deformation due to *in-vitro* fluid flow mechanical stimulation. MLO-Y4 osteocyte-like cells were subjected to steady fluid flow generated shear stress using a parallel plate flow chamber at 0.2 Pa, 0.8 Pa, and 1.6 Pa. The cells were imaged with a digital camera attached to an optical microscope prior to the onset of flow and then again within 30 sec after the onset of flow (initial cell deformation). The cells were subjected to a total of 10 minutes of flow after which the flow was stopped, the cells were imaged, the flow re-started, and the cells were imaged again (cell deformation after 10 minutes). Using a digital image correlation technique, cell deformation was measured by comparing images captured prior to flow to images taken directly after the onset of flow at the beginning and at the end of the 10 min. of flow. Cell deformation increased as a function of fluid shear stress from 0.27% at 0.2 Pa to 4.9% at 1.6 Pa. This increase in cell deformation also correlates to an increase in biological responses, such as PGE_2 production. After ten minutes of flow, however, cell deformation was significantly reduced from 4.9% to 2.6% at 1.6 Pa. In addition, at the end of 10 min. of flow, cell branching was increased and dendritic processes were extended, in most cases making contact with neighboring cells. *In-vivo* fluid flow shear stresses in bone have been analytically estimated to be on the order of 0.2 to 3.0 Pa. When applied *in-vitro*, this level of fluid shear stress results in significant cell deformation, on the order of measured bone matrix deformation due to microdamage. In summary, the cells adapted to their *in-vitro* mechanical environment by reducing their compliance resulting in significantly lower cell deformation and by increasing the length of their dendritic processes to establish cell contacts in order to facilitate cell to cell communication.

Transcriptional Induction of FosB/DeltafosB Gene by Mechanical Stress in Osteoblasts. D. Inoue, S. Kido, S. Kato*, T. Matsumoto. Department of Medicine and Bioregulatory Sciences, University of Tokushima, Tokushima, Japan.

DeltafosB, a short splicing isoform of fosB, has been shown to increase bone mass by stimulating bone formation when over-expressed in transgenic mice. We have shown that deltafosB mRNA and protein expression is induced in osteoblast lineage cells both by fluid shear stress (FSS) in vitro and by mechanical loading in vivo. Therefore, deltafosB may play a role in mechanical stress-induced bone formation. In the present study, we further explored the mechanism of deltafosB induction. We found that fosB/deltafosB mRNA induction by FSS was inhibited by gadlinium (Gd), EGTA and BAPTA, but not by nifedipine, suggesting an involvement of calicium influx through Gd-sensitive cation channel. Moreover, we found that FSS activated ERK, which was mimicked by Ca ionophore and inhibited by EGTA and BAPTA, and that fosB induction was blocked by ERK inhibitors such as U0126. Thus, induction of fosB gene expression was dependent on Ca and ERK. To analyze transcriptional effects, we cloned the mouse fosB gene promoter region, subcloned into a luciferase reporter vector, and transfected into primary osteoblasts and MC3T3-E1 cells. We found that the (-1000-+307) and (-603-+307) but not the (-327-+307) fragments responded to FSS with more than two-fold stimulation, indicating that the sequences from –603 to –327 conferred the FSS effects. This region corresponds to the c-fos promoter region which has recently been suggested to confer shear stress response and contains similar DNA elements to the counterpart in the c-fos promoter: upstream CRE-like (CRE1: -469 to -462), SRE-like (-419 to -410), and downstream CRE-like sequences (CRE2: -404 to –397). Further transcriptional analyses with luciferase reporter gene assays using tandem oligonucleotides corresponding to each element suggested a major contribution of the CRE2 sequences. DNA precipitation assay revealed that FSS induced CREB1/ATF1 phosphorylation and subsequent binding of phosphorylated CREB to the CRE2 element in an ERK-dependent manner. Interestingly, although c-fos-derived consensus SRE responded to FSS, fosB SRE did not, suggesting that fosB gene transcription is subject to a different mode of regulation from that of c-fos gene. In conclusion, we have demonstrated for the first time that FSS induces fosB/deltafosB gene expression at the transcriptional level in osteoblasts through a Ca/ERK/CREB pathway in a manner distinct from c-fos gene. Thus induced deltafosB expression may contribute to mechanical stress-induced bone formation.

Deficiency of CIZ, a Nucleocytoplasmic Shuttling Protein, Prevents Unloading-induced Bone Loss through the Enhancement of Osteoblastic Bone Formation in vivo. K. Hino*[1], T. Nakamoto*[2], M. Morinobu[3], K. Tsuji[1], A. Nifuji[1], H. Yamamoto*[3], H. Hirai*[2], M. Noda[1]. [1]Dept of Molecular Pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]University of Tokyo, Tokyo, Japan, [3]Ehime University, Matsuyama, Japan.

Unloading results in bone loss which leads to disuse osteoporosis, one of the major medical issues in our ageing society. However, the mechanisms underlying this phenomenon has not been fully elucidated. Mechanical stress could affect cells through their adhesion machinery and subsequently regulate gene expression. CIZ (Cas interacting zinc finger protein) is a nucleocytoplasmic protein, which localizes at cell adhesion plaques, associates with p130 Cas and recognizes specific DNA elements to regulate transcription of the genes encoding collagen and the MMP. CIZ also regulates BMP signaling. Thus, CIZ could be one of the possible candidate molecules to modulate bone metabolism under unloading and/or loading condition. To test the hypothesis that CIZ may be involved in the mechanical stress regulation of bone metabolism *in vivo*, we examined the effects of CIZ-deficiency on unloading-induced bone loss using tail suspension model. Two dimensional μCT analysis indicated that tail suspension reduced the levels of cancellous bone volume (BV/TV) in the distal end of the femur within the area of 800 ×350μm in wild type mice. In contrast, reduction in cancellous bone volume due to tail suspension was suppressed in CIZ KO mice. To address whether CIZ-deficiency suppression of the unloading-induced bone loss could be due to alterations in osteoblastic activities, bone marrow cells were cultured in the presence of ascorbate and beta-glycerophosphate after tail suspension. In wild type mice, tail suspension reduced the formation of alizarin red positive nodules. In contrast, CIZ-deficiency suppressed such reduction in the levels of nodule formation after tail suspension. Bone marrow cell cultures were also conducted in the presence of vitD and dexamethasone and TRAP positive cells were counted .TRAP positive cell numbers were not altered by the tail suspension regardless of the genotype. We also examined the effect of the CIZ deficiency on the cortical bone. μCT analysis of the cross section of the femur at the levels one forth from its distal end indicated that tail suspension suppressed cortical bone area in wild type mice. In contrast, CIZ deficiency suppressed such reduction in the cortical bone area in the femur after tail suspension. These data indicated that CIZ deficiency suppressed tail suspension-induced bone loss in cortical and cancellous bone possibly through CIZ actions on the cells in osteoblastic lineage to modulate bone response to unloading.

Pubertal Effects on the Muscle-Bone Mechanostat on Differentially Loaded Bones. N. J. Crabtree[1], N. Loveridge[2], M. S. Kibirige*[3], J. N. Fordham[3], N. J. Shaw[4]. [1]Queen Elizabeth Hospital, Birmingham, United Kingdom, [2]Cambridge University, Bone Research Group(MRC), Cambridge, United Kingdom, [3]South Cleveland Hospital, Middlesbrough, United Kingdom, [4]Birmingham Children's Hospital, Birmingham, United Kingdom.

The skeleton is a mechanically optimised organ such that its strength is regulated by loads routinely applied to it. According to the muscle-bone mechanostat theory, these loads mainly arise from muscle forces rather than gravitational weight. However, it is possible that other factors play an important role in this basic relationship. The aim of this study was to examine the possible effects of puberty and gender on the muscle-bone relationship on differentially loaded regions of the body.

637 healthy white children aged 5-18 years, had whole body & lumbar spine DXA. The ratio of bone mineral content to lean tissue mass was calculated for arms (ARMratio), legs (LEGratio) and the lumbar spine (LSratio). The data was analysed using MANOVA, including gender, puberty, lean body mass (LBM), fat body mass (FBM), age & height in the model.

There were no significant differences in the muscle-bone ratio in the prepubertal children. However, after adjustment for body size, significant gender and pubertal differences could be detected for both LSratio and ARMratio, with girls having more bone mineral per unit LBM in both regions. A similar trend was observed in the legs, although this did not reach significance even by late puberty. For the LEGratio the greatest variation explained by the model, was FBM closely followed by height. For the ARMratio the largest variation was explained by height and the least by FBM, however both were significant ($p<0.05$).

	Girls			Boys		
	Pre	Early	Late	Pre	Early	Late
LSratio	*0.90 (0.01)	‡*0.96 (0.02)	‡*1.07 (0.02)	0.85 (0.01)	‡0.79 (0.02)	‡0.83 (0.03)
LEGratio	5.4 (0.05)	5.5 (0.06)	5.5 (0.7)	5.3 (0.05)	5.4 (0.07)	5.3 (0.11)
ARMratio	5.9 (0.07)	‡6.0 (0.08)	‡6.0 (0.09)	5.7 (0.07)	‡5.1 (0.1)	‡5.2 (0.15)

$P<0.05$ diff. between *pre-, early- & post- puberty, ‡genders

Increases seen in the ratios with increasing height would suggest that the long bones are mechanically optimised for both the physical load and the local bending forces to which they are subjected. The differential effects of puberty on the muscle-bone relationship could in part be explained by the dramatic increase in circulatory estrogen observed in girls as they progress through puberty. However, this estrogenic effect appears to be modulated by the influence of gravitational load.

Rest-Inserted Loading and IGF-1 Synergistically Initiate Bone Formation in the Senescent Skeleton. S. Srinivasan, S. C. Agans*, K. A. King*, T. S. Gross. Orthopaedics, University of Washington, Seattle, WA, USA.

While counteracting age-related bone loss via general physical activities of daily living has attractive benefits, mild types of activity are ineffective in influencing bone cell dynamics. Interestingly, we recently observed that inserting 10-s of rest between low-magnitude loading cycles was sufficient to initiate significant bone formation in the aged skeleton. However, we were unable to further augment the response of aged bone (despite doubling of load magnitudes *and* 4-fold increases in loading cycles), which suggests an inherent age-related blunting of the osteogenic response. This result indicates that age-related deficits in osteoblastic cells may need to be explicitly counteracted to overcome this blunting, and importantly, to augment bone mass in the aged skeleton. We hypothesized that supplementing rest-inserted loading with an agent such as insulin-like growth factor-1 (IGF-1) capable of modulating osteoblast function would synergistically enhance bone formation induced in the aged skeleton. We examined this proposal using two groups of senescent female C57BL/6 mice (n=3/grp, 26 mo) that received 0.5 or 1 mg/Kg of rhIGF-1 (s.c.) 5 days/wk for 2-wk. Utilizing the non-invasive murine tibia loading device, the right tibiae of all animals were subject to a 50 cycle/d, low-magnitude loading protocol with a 10-s rest inserted between each cycle. The left tibiae served as internal controls for the effects of systemically administered IGF-1 while the right tibiae provided data regarding the interaction of IGF-1 with low-magnitude rest-inserted loading. Animals received calcein labels on days 3 and 12 for determination of dynamic histomorphometry parameters at the periosteal surface of the tibia mid-shaft. The minimal bone formation rates induced in control (left) bones in animals receiving 0.5 mg/Kg and 1.0 mg/Kg of IGF-1 were similar (0.038 ± 0.01and 0.042 ± 0.04 $\mu m^3/\mu m^2/d$, respectively). Rest-inserted loading supplemented with 0.5 mg/Kg IGF-1 only minimally increased bone formation (0.074 ± 0.07 $\mu m^3/\mu m^2/d$, only one of three animals responded). In contrast, rest-inserted loading supplemented with 1.0 mg/Kg IGF-1 resulted in a substantial increase in bone formation (0.135 ± 0.03 $\mu m^3/\mu m^2/d$, all three mice responded, range: 0.09 to 0.19 $\mu m^3/\mu m^2/d$). These results support our hypothesis and suggest that low-magnitude rest-inserted loading when supplemented with low-dose IGF-1, synergistically enhances bone formation in senescent animals. While preliminary, our observation of synergy holds promise as a means to initiate, enhance and sustain bone formation responses sufficiently to significantly influence bone mass and strength in the senescent skeleton.

A School Curriculum Based Exercise Program Is Associated with Increased Bone Mineral Accrual and Bone Size in Girls During Early Growth – a 2 Years Prospective Controlled Intervention Study in 126 Girls. C. Lindén*, P. Gardsell, O. Johnell, M. K. Karlsson. Dept of Orthopaedics, Inst of Orthopaedics, Malmo, Sweden.

There are three previous published prospective exercise intervention studies in prepubertal girls, spanning 7 - 12 months where all but one evaluate girls with interest in exercised as they volunteered to participate in the exercise study. The purpose of this study was to evaluate an exercise intervention program within the school curriculum during the first school years, as to catch also girls not specific interested in exercise, and to extend previous observation to a 2 years prospective study, previously never published.

A population based cohort including 62 healthy Caucasian girls (92% participation rate) aged 7.6 (0.6) from four classes within the two first grades in one school were included in a school curriculum with 40 minutes physical activity every school day. The curriculum included general physical activity, ball games, running and jumps. A controls served 64 healthy age and gender matched girls within three schools in the same area subjected to the general Swedish curriculum of physical activity in these grades, 60 minutes per week. Bone mineral density (BMD; g/cm2) and bone size were measured with dual X ray absorbtiometry (DXA) at total body (TB), lumbar spine (LS), third lumbar vertebra (L3), femoral neck (FN) and leg before initiation of the intervention and after 2 years. Data is presented as mean (SD).

There were no differences in height, weight, total lean body mass, total fat content, BMD or bone size at baseline when comparing the groups. The annual gain in BMD was greater in the intervention group in comparison with the controls during the 2 year follow-up (annual gain in g/cm2 in TB BMD 0.03 (0.011) versus 0.02 (0.009), LS BMD 0.04 (0.031) versus 0.03 (0.016) and leg BMD 0.06 (0.019) versus 0.05 (0.015), all $p < 0.05$ respectively). Also bone size increased more within the intervention group (annual gain in cm2 in FN area 0.29 (0.243) versus 0.17 (0.267) and L3 area 0.75 (0.383) versus 0.46 (0.330), both $p < 0.05$ respectively). The discrepancies remained also after adjusting for differences in weight gain during the study period.

A school based exercise program within the general curriculum during the first school years seems to in girls be associaed with a greater increase in BMD and bone size.

Rest Alleviates Tissue Saturation Due to Repetitive Mechanical Loading. S. L. Poliachik, S. C. Agans*, K. A. King*, T. S. Gross, S. Srinivasan. Department of Orthopaedics and Sports Medicine, University of Washington, Seattle, WA, USA.

The response of bone to repetitive mechanical loading demonstrates both threshold and saturation behavior as the number of applied cycles increases. We hypothesized that rest-inserted loading can overcome the saturation normally observed in response to a high number of repetitive load cycles. To investigate the bone formation response to an increasing number of load cycles, we contrasted repetitive and rest-inserted loading using from 5 to 500 cycles at a single load magnitude. The right tibiae of 53 C57Bl/6J mice (female, 16wk) were externally loaded every other day (3 d/wk) for 3 weeks using a non-invasive murine tibia loading device. Calcein was administered on days 10 and 19, and animals were sacrificed on day 22. The animals were randomly assigned to one of 7 protocols, all generating a mean peak normal strain of 1200μ at the mid-diaphysis: repetitive loading of 5, 100, 250 or 500 cycles, or 10, 50 or 250 cycles with a 10s rest inserted between each cycle. Peak strains were determined using strain gage measurements and finite element analysis. Standard dynamic histomorphometry measures were used to determine bone responses at the mid-shaft of the right (loaded) and left (intact contralateral) tibiae. Periosteal bone formation in animals loaded with rest-inserted protocols exceeded the response of repetitive loading as the number of cycles increased (Figure). In repetitive loading protocols, 100 cycles were required to increase BFR above control levels, with the response saturating at 250 cycles (1.5-fold increase in number of cycles). In contrast, BFR induced by rest-inserted loading increased above control levels with only 10 load cycles, and the augmented response appeared to continue even after a 25-fold increase in applied cycles (10 to 250 cycles). We conclude that rest-inserted loading promotes a greater osteogenic response with an increase in the number of applied load cycles as compared to repetitive loading. In contrast, repetitive loading requires a greater number of cycles to exceed control values and the response saturates quickly, as others have noted. Although the mechanism is unclear at present, rest-inserted loading appears to alleviate the tissue saturation that normally limits the osteogenic response to repetitive cyclic loading.

Bcl-2 is a Pivotal Mediator of the Anti-apoptotic Effect of PTH on Osteoblasts: Evidence from RNA Silencing and Bcl-2-deficient Mice. A. A. Ali, L. I. Plotkin, I. P. Foote*, R. A. Wynne*, T. Bellido, C. A. O.Brien, S. C. Manolagas, R. L. Jilka. Div. Endo&Metab, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. of Arkansas for Medical Sciences, Little Rock, AR, USA.

Published evidence, as well as work presented elsewhere in this meeting, indicate that the anabolic effect of intermittent PTH administration is due at least in part to attenuation of osteoblast apoptosis; and that PTH exerts this effect via a Runx2-mediated increase in the transcription of anti-apoptosis genes like Bcl-2. To establish the pivotal role of Bcl-2 in the anti-apoptotic effect of PTH, we have decreased Bcl-2 expression in OB-6 osteoblastic cells using RNA silencing. We report that introduction of Bcl-2 silencing RNA (siRNA) caused a 70-80% reduction in the level of Bcl-2 protein as measured by Western blot analysis, compared to controls comprising mock-transfected cells or cells transfected with siRNA to lamin A/C. The transfection efficiency was >95% as indicated by fluorescence microscopy of cells co-transfected with FITC-labeled luciferase siRNA. Unlike the control cells, PTH failed to inhibit etoposide-induced apoptosis of cells transfected with Bcl-2 siRNA, as determined by enumeration of cells staining for active caspase-3. In full agreement with these findings, PTH failed to inhibit etoposide-, dexamethasone-, or anoikis-induced death of osteoblastic cells cultured from neonatal calvaria of Bcl-$2^{-/-}$mice (progeny of breeders from Jackson Labs), as determined by trypan blue staining or caspase-3 activity; whereas PTH did inhibit apoptosis of cells from wild type littermates. Consistent with a gene dose-response, calvaria cells from Bcl-2 heterozygotes (Bcl-$2^{+/-}$) exhibited a 40-50% reduction in the level of Bcl-2 protein, and attenuation of the anti-apoptotic effect of PTH by 50%. These results indicate that the absolute level of Bcl-2 is a critical determinant of the pro-survival effect of PTH on osteoblastic cells. Based on this and evidence that the anti-apoptotic effect of PTH also requires phosphorylation and thereby inactivation of the pro-apoptotic protein Bad, which normally binds to and neutralizes Bcl-2 during programmed cell death, we hypothesize that the pro-survival property of PTH is due at least in part to increased synthesis of Bcl-2 and reduced availability of Bad. The combined effect increases the total amount of free Bcl-2 available to sequester proteins like Bak and Bax that participate in the initial stages of the death program.

Transgenic Expression of Human Bcl-2 in Osteoblasts in Mice Prevents Glucocorticoid-Induced Apoptosis. G. Gronowicz, W. Zhang*, M. Y. Nahounou*, M. B. McCarthy*, A. C. Lichtler, A. G. Pantschenko*. Orthopaedics, University of Connecticut Health Center, Farmington, CT, USA.

High dose glucocorticoids leads to bone loss primarily by decreasing bone formation and increasing osteoblast apoptosis. Glucocorticoids have been shown to produce apoptosis by down-regulating bcl-2. To elucidate the role of apoptosis in bone, a transgenic mouse (Col2.3bcl-2) was developed with a 2.3 kb Col1a1 promoter fragment driving the the 1.7 kb region of the human bcl-2 in mature osteoblasts. Three founder lines were established. They appeared healthy and bred normally, however body weight, body length and femur length of Col2.3bcl-2 mice were smaller than their non-transgenic littermates (+/+) at 2 months, which had been similar at 1 month. IHC of human bcl-2 expression in femurs of 2-month heterozygote Col2.3bcl-2 mice (Tg/+) revealed transgene protein expression in osteoblasts at the growth plate, the endosteal surface and areas of active bone formation on the periosteal surface of the cortical bone. Human bcl-2 expression was also found in the calvarial osteoblasts. Static histomorphometric analysis of the calvaria demonstrated that calvaria width was reduced in Col2.3bcl-2 (103.4 ± 9.2 um vs. 130.7 ± 5.6 um, $p < 0.02$) compared to their +/+ littermates. Osteoclast number per bone surface and % osteoclast surface was reduced in the Col2.3bcl-2 mice compared to +/+ littermates (1.6 ± 0.5 % vs. 5.5 ± 1.2 %, $p<0.01$, and 4.7 ± 1.7 % vs. 15.5 ± 4.3%, $p < 0.04$, respectively). The decreased calvaria width in the transgenic mice suggest decreased bone resorption and formation. Administration of varying concentrations of dexamethasone (0.1, 0.3 and 1 mg/kg body weight) produce a dose-dependent increase in apoptotic osteoblasts in calvaria of +/+ mice visualized by TdT-mediated dUTP nick end labeling (TUNEL). 2-month-old Tg/+ and +/+ mice were treated with 1 mg/kg BW of dexamethasone or saline vehicle each day for 7 days and then sacrificed. Paraffin-embedded calvaria were evaluated for apoptotic osteoblasts (Ob) and osteocytes (Os). Few apoptotic cells were seen in the periosteum or sutures. No significant differences were found in the baseline apoptosis in either group treated with saline. Glucocorticoids were shown to increase osteoblast and osteocyte apoptosis in nontransgenic mice but this effect was significantly blunted in the transgenic mice, which express human bcl-2.

% TUNEL Positive Cells *p<0.05

	Dex +/+	Dex Tg/+	Veh +/+	Veh Tg/+
%Ob	39.8 ± 2.3	11.0 ± 3.1*	3.3 ± 1.6	3.7 ± 2.3

Phenotypic Characterization of Col2.3bcl-2 Transgenic Mice with Bone-Directed Expression of Bcl-2. A. G. Pantschenko*, W. Zhang*, M. Y. Nahounou*, F. Ledgard*, M. B. McCarthy*, A. C. Lichtler, G. Gronowicz. Orthopaedics, University of Connecticut Health Center, Farmington, CT, USA.

Bcl-2 plays an important role in preventing apoptosis in osteoblasts and is regulated by numerous growth factors and hormones that affect bone mass. To explore the role of bcl-2 in bone remodeling and development, we have established and characterized a CD-1 transgenic mouse that expresses human bcl-2 in mature osteoblasts. The Col2.3bcl-2 mouse was created with a 2.3 kb Col1a1 promoter fragment driving the 1.7 kb region of human bcl-2 cDNA. Three Col2.3bcl-2 founder lines were established which appeared healthy and bred normally. Body weight, body length and femur length were similar at 1 month of age. In general, the Col2.3bcl-2 heterozygote mice (tg/+) were significantly smaller than the corresponding nontransgenic littermates (+/+) at 2 and 6 months of age with the greatest difference observed at 2 months of age. To confirm transgene protein expression, human specific anti-bcl-2 antibody was used for immunohistochemistry. Human bcl-2 was expressed in osteoblasts at the growth plate, regions of the endosteal surface and areas of active bone formation on the periosteal surface of cortical bone. Non-transgenic littermates were negative for human bcl-2 expression. Static histomorphometric analysis of calvaria from 2 month-old mice showed a significant decrease in calvaria width in the tg/+ mice (103.4 ± 9.2 µm vs. 130.7 ± 5.6 µm) ($p < 0.02$), and a significant decrease in % osteoclast bone surface (4.7 ± 1.7 % vs. 15.5 ± 4.3 %) ($p < 0.04$) and osteoclast number per mm2 bone surface, (1.6 ± 1.2 vs. 5.4 ± 0.5) ($p < 0.01$). Therefore, Col2.3bcl-2 mice had thinner calvaria with fewer osteoclasts than +/+. In femurs, no significant differences were found between tg/+ and +/+ littermates. However, a comparison of sex differences in femurs of wild-type mice revealed that males had significantly more % trabecular bone (BV/TV, 13.1 ± 1.3 % vs. 8.5 ± 0.6 %) ($p < 0.002$), and decreased % osteoclast surface (15.3 ± 2.2 % vs. 21.0 ± 1.3 %) ($p < 0.03$) and % osteoblast surface (15.1 ± 0.8 % vs. 29.4 ± 1.7%) ($p < 0.001$) than +/+ females. However, transgenic Col2.3bcl-2 mice did not have any significant differences between males and females, as was observed for the +/+. Preliminary observations of the Col2.3bcl-2 mouse suggests that; 1) bone resorption is affected by bcl-2 expression in osteoblasts, 2) bcl-2 expression affects bone remodeling later in development (i.e. 2 months) rather than earlier, and 3) bcl-2 appears to abrogate the sex differences observed in the wild-type mice. Thus, the Col2.3bcl-2 mouse is a useful model for studying the role of apoptosis in bone development and remodeling.

Transgenic Overexpression of ICER Affects cAMP-Inducible Gene Expression in Osteoblasts. F. Liu*, Y. Huang, B. E. Kream. Medicine, University of Connecticut Health Center, Farmington, CT, USA.

ICER, inducible cAMP early repressor, is a member of the CREM family of transcription factors that modulate cAMP-inducible gene expression. Four isoforms of ICER (I, Iγ, II, IIγ) arise by alternative splicing of a primary transcript that is initiated from the intronic P2 promoter of CREM. ICER acts as a dominant negative transcription factor since it contains almost exclusively the basic leucine zipper domain that specifies dimerization and DNA binding. We previously demonstrated that parathyroid hormone (PTH) induces the expression of all ICER isoforms in osteoblasts mainly through the cAMP-protein kinase A pathway. To study the role of ICER in cAMP-inducible gene expression in osteoblasts, we generated transgenic mice with ICER I and ICER II expression under control of 3.6 kb of the rat Col1a1 promoter and 1.6 kb of the rat Col1a1 first intron. The ICER I and II transgenes were engineered with the FLAG epitope tag to facilitate protein detection. Primary calvarial osteoblatic cells were prepared from 6-8 days old wild type (WT) and ICER transgenic (TG) mice. Immunostaining with an anti-FLAG antibody showed that transgenic ICER was expressed strongly in the nuclei of most TG cells. After 7 days of culture, cells were treated with 10 µM forskolin (FSK) for 0, 0.5, 1, 2 and 4 h. The expression of 3 cAMP-inducible genes, c-Fos, IL-6 and Cox-2, were examined by Northern blot analysis. All signals were normalized to actin expression. In TG cells, FSK induction of c-Fos and IL-6 was decreased by 20-30% at 1 h and by 30-40% at 2 h compared to WT cells. By contrast, FSK induction of Cox-2 was increased at all time points in TG cells: by 40% at 0.5 h, 70% at 1 h, 92% at 2 h and 110% at 4h. Similar results were seen in cells treated with 10 nM PTH. In summary, our results show that primary osteoblasts prepared from ICER TG mice had a lower magnitude of induction of c-Fos and IL-6 in response to FSK than WT cells. However, the response of Cox-2 to FSK and PTH was enhanced in TG cells. We hypothesize that ICER may interfere with a transcriptional inhibitor(s) in the Cox-2 promoter while antagonizing positive transactivating factors in the c-Fos and IL-6 promoters.

Epigenetic Regulation of Mouse RANKL Gene Expression. S. Kitazawa, A. Darwanto*, R. Kitazawa. Division of Molecular Pathology, Kobe University Graduate School of Medicine, Kobe, Japan.

Receptor activator of NF-kappaB ligand (RANKL) is a membrane-bound signal transducer requisite for differentiation and maintenance of osteoclasts. Except for some subpopulations of lymphocytic cells, RANKL expression is limited among stromal/osteoblasic cells which actively support osteoclast formation. To address the issue of what epigenetic mechanism gives the specificity of RANKL gene expression to stromal/osteoblastic cells in response to bone resorptional stimuli, we characterized the mouse RANKL gene promoter that contains three Runx2-binding sites, one CRE shared by the vitamin D response element (VDRE) and two CpG clustering regions (one around the transcription start site, and the other downstream of the VDRE). Using purified DNA from various normal mouse non-RANKL expressing tissues, we analyzed the CpG methylation status by Southern blotting after methylation sensitive (Hpa II) and resistant (Msp I) restriction enzymatic digestion, and by sodium bisulfite mapping. We found that DNA from most of the normal non-RANKL expressing tissues showed a methylation pattern in the 5'-flanking region of the RANKL gene by Southern blotting. Mirroring Southern blot analysis, sodium bisulfite mapping showed methylated cytosine heterogeneously scattered in both CpG loci in these tissues. Furthermore, in later passaged-ST2 stromal/osteoblastic cell lines that ceased to express RANKL gene in response to vitamin D3, a higher methylation rate was observed around Runx2-binding sites and the transcription start site than in early-passaged-ST2 cells. Since transcriptional induction of bone specific gene expression by Runx2 is achieved by recruiting histone acetylase, and since transcription repression by methylated-cytosine is achieved by recruiting histone deacetylase by metyl-CpG binding proteins, these results suggest that the histone acetylation status defined by the balance between bone-specific transcription factors like Runx2 and metyl-CpG binding proteins is an important epigenetic event defining bone tissue-specificity and vitamin D-dependency as well as the heterogeneity and diversity of the stromal/osteoblastic cells in RANKL gene expression.

A Homeobox Gene Msx2 Stimulates the Osteoblastic Differentiation of Mesenchymal Cells in the Absence of Cbfa1/Runx2. F. Ichida*[1], K. Hata*[1], F. Ikeda[1], K. Yamashita*[1], T. Matsubara*[1], K. Hisada*[1], H. Yatani*[1], A. Yamaguchi[2], R. Nishimura[1], T. Yoneda[1]. [1]Osaka Univ, Suita, Japan, [2]Nagasaki Univ, Nagasaki, Japan.

Recent studies have revealed the importance of a homoeobox gene Msx2 in skeletogenesis. Mice deficient in Msx2 manifested persistent calvarial foramen with a defect in cortical and cancellous ossification in skull and a decrease in osteoblast number. Moreover, it is found that heterozygous mutations of Msx2 cause enlarged parietal foramina (PFM) characterized by oval defects in parietal bones in human. However, the molecular mechanism by which Msx2 regulates osteogenesis is still poorly understood. To understand the role of Msx2 in the regulation of osteogenesis, we studied the actions of Msx2 in an in vitro model in which the multipotent mesenchymal cell lines including C3H10T1/2 and C2C12 showed osteoblastic differentiation with increased alkaline phosphatase activity (ALP) upon treatment with BMP2. Msx2 expression was induced in C3H10T1/2 cells by the treatment with BMP2 in parallel with osteoblastic differentiation. Of note, introduction of Msx2 using adenovirus system promoted the osteoblastic differentiation of C3H10T1/2 and C2C12

cells. The effects of Msx2 were enhanced in the presence of BMP2 or co-introduction of Cbfa1. To determine whether Cbfa1 is essential for Msx2 to promote osteoblastic differentiation, we examined the effects of Msx2 on osteoblastic differentiation in the Cbfa1-deficient mesenchymal cell line named C2 that was established from Cbfa1 knock out mouse calvariae. BMP2 induced Msx2 expression and increased ALP activity in C2 cells. Furthermore, introduction of Msx2 alone also elevated ALP activity in C2 cells. These results suggest that Cbfa1 is not essential for the induction of Msx2 expression by BMP2 and that Msx2 leads the differentiation of mesenchymal cells toward osteoblastic direction in a Cbfa1-independent fashion. We next examined the effects of Msx2 overexpression on the mineralization of the primary neonatal mouse calvarial osteoblasts. Alizarin red staining demonstrated that overexpression of Msx2 increased the mineralization of primary calvarial osteoblasts in the presence of BMP2. On the other hand, overexpression of mutant Msx2, which is associated with PFM in human, inhibited BMP2-induced mineralization. In conclusion, our data suggest that Msx2 stimulates the osteoblastic differentiation of mesenchymal cells in the absence of Cbfa1 and also regulates the mineralization of osteoblasts. Msx2 may be an alternative molecule to Cbfa1 that is involved in the regulation of the differentiation of mesenchymal cells and osteoblast mineralization.

The Effects of BIG-3 on Osteoblast Differentiation Are not Dependent upon Endogenously Produced BMPs. F. Gori, M. B. Demay. Endocrine Unit, Massachusetts General Hospital/Harvard Medical School, Boston, MA, USA.

Skeletal development *in vivo* occurs via two major processes, intramembranous and endochondral ossification. Among the local signaling pathways that play a role in these processes is the bone morphogenetic protein (BMP) signaling pathway. We recently identified a BMP-2 induced gene, named BIG-3 (BMP-2 Induced Gene 3kb) that encodes a novel protein belonging to the WD-40 repeat family of proteins. We have demonstrated that BIG-3 dramatically accelerates the program of osteoblastic differentiation when stably expressed in MC3T3-E1 cells. In addition, BIG-3 is developmentally expressed in cartilage and osteoblasts, suggesting that this protein plays a developmental role in both endochondral and intramembranous bone formation. Since BIG-3 is upregulated by BMP-2, we examined the potential interactions between BIG-3 and the BMP-2 signaling pathway during osteoblastic differentiation. To evaluate whether endogenous BMPs were required for the effects of BIG-3 on osteoblast differentiation, we treated MC3T3-E1 cells, stably transfected with the full-length coding region of BIG-3 (MC3T3E1-BIG-3) cloned downstream of a CMV promoter in pcDNA3.1, or MC3T3E1-cells transfected with the empty vector (MC3T3E1-EV), with noggin, a protein that blocks the actions of BMP-2, BMP-4 and BMP-7. Noggin treatment of pooled MC3T3E1-EV clones inhibited alkaline phosphatase (AP) activity by 57% fold compared to untreated pooled MC3T3E1-EV clones at 21 days in culture. Conversely, noggin treatment of pooled MC3T3E1-BIG-3 clones did not affect AP activity even at doses as high as 1 mg/ml. Noggin treatment also decreased the expression of Cbfa1 and type I collagen mRNAs by 1.9 and 2,3 fold, respectively, in pooled MC3T3E1-EV clones by 14 days but not in pooled MC3T3E1-BIG-3 clones. Addition of noggin to pooled MC3T3E1-EV clones significantly decreased mineralized matrix formation, reflected by a 5.5 fold decrease in Alizarin Red staining at 21 days compared to untreated clones. The effects of noggin on mineralized matrix formation persisted in pooled MC3T3E1-EV clones at 30 and 35 days (4.5 and 4.9 fold, respectively), whereas no effect was observed in pooled MC3T3E1-BIG-3 clones at any time point.
The observation that noggin treatment does not block the acceleration in differentiation seen in MC3T3-E1 cells stably expressing BIG-3, suggests that the actions of this novel WD-40 protein in accelerating osteoblastic differentiation are not dependent upon endogenously produced BMPs.

Dlx5 Function As a Key Switch Between BMP-2-Induced Osteoblast Differentiation and TGF-b1- Derived Antagonism. M. Lee, H. Park*, H. Kim*, H. Ryoo. Dept. of Biochemistry, School of Dentistry, Kyungpook National University, Daegu, Republic of Korea.

BMP-2 not only blocks myogenic differentiation but also induces osteoblast differentiation in myogenic C2C12 cells. In contrast, TGF-b1 cannot support osteoblast differentiation and it even dramatically inhibits BMP-mediated osteoblast differentiation although Runx2 expression is induced by both BMP-2 and TGF-b1. Therefore the induction of Runx2 is not sufficient to explain the BMP-induced osteoblast differentiation and TGF-b1-derived antagonism. Our previous reports suggested that Dlx5 is a direct and specific target of BMP-signaling and the proximal target in turn, stimulated the downstream transcription factor Runx2, and consequently resulted in the bone marker gene expression in BMP-induced osteogenic transdifferentiation. In this study, we investigated whether the inhibitory role of osteoblast differentiation by TGF-b1 was also mediated by BMP-specific target, Dlx5. The induction of Dlx5 gene expression by constitutively active BMPR-IA or IB was completely or partially blocked by TGF-b1 treatment. Cycloheximide experiment showed that the inhibition of Dlx5 expression by TGF-b1 is dependent on new protein synthesis. Since Dlx5 induction by BMP-2 is observed as early as 1hr after stimulation and the new protein synthesized by TGF-b1 suppresses Dlx5 expression before being induced by BMP-2, we assumed that an immediate early gene product might be involved in the Dlx5 suppression by TGF-b1 and then we checked the involvement of AP-1 on Dlx5 suppression by blocking AP-1. A dominant negative c-fos (A-fos) that inhibits Jun-dependent transactivation was used for this AP-1 blocking. Interestingly, the exogenous A-fos significantly antagonized the Dlx5 suppression by TGF-b1. Moreover, one of AP-1 components, c-Jun protein level increased 1 hr after TGF-b1 treatment but not by BMP-2 in C2C12 and MC3T3-E1 cells. Finally we confirmed that c-Jun overexpression alone could suppress BMP-induced Dlx5 even in the absence of TGF-b1. Taken together, these results indicate that Dlx5 is the primary target where the opposing action of TGF-b1 on BMP-2-induced osteoblastic differentiation occurs and the c-Jun protein newly synthesized by TGF-b1 involves in the suppression of Dlx5.

PKIγ Knock Down Inhibits Termination of Immediate-Early Gene Expression Induced by PTH. X. Chen, J. C. Dai, S. A. Orellana*, E. M. Greenfield. Case Western Reserve University, Cleveland, OH, USA.

Immediate-early genes, such as IL-6 and c-fos, mediate both the catabolic and anabolic effects of PTH. We have shown that the primary mechanism responsible for termination of PKA activity, CREB phosphorylation, and immediate-early gene expression following stimulation by PTH acts downstream of receptor desensitization, adenylyl cyclase activation, and cAMP degradation (Am J Physiol Cell Physiol 283:1432-40, 2002). We therefore hypothesized that inhibition of PKA activity by the protein kinase inhibitor (PKI) family is responsible for termination of transcription factor phosphorylation and gene expression. We found that PKIγ mRNA and protein are strongly expressed in ROS17/2.8 and MC3T3-E1 osteoblastic cells, while little or no PKIα or PKIβ mRNAs are expressed. We also cloned and sequenced rat PKIγ from ROS17/2.8 cells (GenBank #AY150308). To test the role of PKIγ in termination of immediate-early gene expression, in vitro transcribed siRNA duplexes directed against the PKIγ coding region were transfected into ROS17/2.8 cells. Virtually complete knock down of PKIγ mRNA and protein was observed after 24 hours. This knock down increased the level of IL-6 and c-fos mRNAs induced at early time periods (≤1 hour) by PTH and extended the length of time that the mRNAs are induced (≥4 hours vs. 2 hours in mock-transfected cells). The effects of PKIγ knock down were confirmed using ROS17/2.8 clones stably transfected with PKIγ antisense constructs in the Tet-Off expression system. After 24 hours of tetracycline withdrawal, two independent antisense clones exhibited a similar temporal pattern of effects to that observed with siRNA except of somewhat reduced magnitude. Controls included antisense clones with tetracycline as well as sense and irrelevant clones ± tetracycline. The smaller effect on gene expression in these antisense transfection experiments is most likely due to partial knock down of PKIγ (~50% at both the mRNA and protein levels). To study the mechanism of action of PKIγ, PKA translocation was assessed by immunofluorescence and by western blotting of nuclear extracts. All 3 PKA catalytic domain isoforms were found to translocate into and out of the nucleus with maximal levels 15-30 minutes after exposure to PTH in ROS17/2.8 cells. These kinetics are consistent with PKIγ binding to nuclear PKA and transporting it back to the cytoplasm. Taken together, our results demonstrate that inhibition of PKA activity by endogenous PKIγ is a major mechanism responsible for termination of immediate-early gene regulation induced by PTH. These findings are the first in any cell type showing that endogenous levels of PKI are sufficient to regulate PKA signaling.

Negative Regulation of Runx2/Cbfa1 Activity by Src Signaling in Osteoblasts. S. K. Zaidi, A. J. Sullivan*, A. J. van Wijnen, J. L. Stein*, G. S. Stein, J. B. Lian. Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA.

Although Src tyrosine kinase signaling has an established role in osteoclast maturation, bone-forming osteoblasts isolated from Src deficient mice exhibit accelerated differentiation, with upregulation of several bone differentiation markers including osteocalcin. Here we have explored the mechanisms involving regulation of osteoblast differentiation by Src tyrosine kinase. Consistent with the upregulation of osteocalcin in Src null osteoblasts, we show that inhibition of Src tyrosine kinases in ROS 17/2.8 osseous cells by a chemical inhibitor or by a dominant negative inhibitor of Src tyrosine kinase (DN) results in the induction of endogenous osteocalcin transcript. We find that this inhibition of Src tyrosine kinase abrogates interaction of the bone related Runx2/Cbfa1 transcription factor with Yes-associated protein (YAP), a co-regulatory protein downstream of Src/Yes/Crk tyrosine kinases. Furthermore, the chromatin immunoprecipitation (ChIP) assay shows that Runx2 is required for the recruitment of YAP to the endogenous osteocalcin gene promoter. To further explore the potential role of YAP-Runx2 interaction in upregulation of the osteocalcin upon Src inhibition, we used a rat osteocalcin promoter (rOC) that contains three Runx binding elements and is upregulated in response to Runx2. We show that over-expression of YAP suppresses Runx2 mediated increase in rOC promoter activity in a dose dependent manner. To further examine the role of Src-YAP signaling cascade in regulation of Runx2 activity, a point mutation was introduced in YAP interacting domain of Runx2 (Runx2 Y433A). We find that the Runx2 Y433A mutant does not interact with YAP and does not respond to co-expression of YAP, but exhibits a higher transcriptional activation potential on the rOC promoter. This indicates that the endogenous YAP contributes to repression which is relieved in the Runx2 Y433A mutant. We then examined the possible role of endogenous YAP in maintaining Runx2 activity using a dominant negative inhibitor of YAP (YAP 1-301). This mutant, which resides in the cytoplasm, also relieves suppression of the rOC promoter activity thus demonstrating that the endogenous YAP plays a key regulatory role the maintenance of Runx2 activity. Taken together, our results provide molecular insights into the mechanism(s) underlying the induction of osteoblast differentiation markers in the absence of Src signaling.

A Glucocorticoid-Induced Transcription Factor Inhibits Adipocyte Differentiation and Stimulates Alkaline Phosphatase Activity in Mesenchymal Cells. X. Shi, W. Shi, Q. Li, B. Song*, M. Wan, S. Bai, L. Yang*, X. Cao. Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

Gluocorticoids (GCs) are effective anti-inflammatory and immunosuppressive agents. However, long term GC usage causes fat accumulation in the bone marrow and accelerates trabecular bone loss, resulting in osteoporosis. Here we report that a GC-induced leucine zipper protein (GILZ) feedback inhibits GC effects on adipocyte differentiation and stimulates alkaline phosphatase (ALP) activity in mesenchymal cells. To investigate the mechanisms of GC-induced osteoporosis, we identified GILZ as a GC-induced antagonist. Gel shift assay showed that GILZ binds to a 40-bp DNA fragment containing a tandem repeats of the C/EBP binding site in the promoter region of PPARγ2 gene. Northern and Western analyses showed that the expression of GILZ mRNA and protein were rapidly and transiently induced by synthetic glucocorticoid dexamethasone. Upon its induction, GILZ binds to PPARγ2 promoter and represses PPARγ2 gene transcription. Importantly, the adipocyte differentiation was blocked when GILZ was overexpressed in C3H10T1/2 mesenchymal and 3T3-L1 preadipocytes. In accordance with the inhibition of adipogenesis, the expression of PPARγ2, C/EBPα, as well as adipocyte differentiation marker genes including adipsin and lipoprotein lipase were all inhibited in GILZ-expressing stable cells as measured by quantitative real-time RT-PCR. Interestingly, however, the ALP activity was significantly increased in GILZ-expressing C3H10T1/2 stable cell. The increase of ALP activity was even dramatic when these stable cells were treated with osteogenic supplements lacking dexamethasone. These data demonstrated that GILZ is a novel GC-induced antagonist that upon its induction, it blocks GC-induced adipogenesis of bone marrow stem cells and stimulates osteoblast differentiation, and therefore, GILZ is a prominent candidate for the development of new therapeutic agents to eliminate the side-effects of GCs on bone metabolism.

Functional Antagonism of Msx2 Repression by C/EBP for Regulation of OC Gene Transcription During Osteoblast Differentiation. M. Q. Hassan*, J. Liu*, G. S. Stein, J. L. Stein*, A. J. van Wijnen, J. B. Lian. Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA.

The CAAT enhancer binding proteins C/EBPβ and C/EBPα are upregulated during osteoblast differentiation and are transcriptional activators of bone-related genes including osteocalcin. Formation of a Runx2-C/EBP complex in mature osteoblasts results in a 30 fold synergistic enhancement of OC transcription. The proximal (-208) OC promoter contains a Runx2/Cbfa1 site (-165/-159), and the C/EBP site (-105/-99) which is contiguous to the OC Box homeodomain (HD) element (-99/-76), a suppressor domain. The HD protein Msx2 represses OC transcription through sequence specific DNA binding, but can interact with other transcription factors including Runx2/Cbfa1. Therefore, we have addressed the interrelationships among these regulatory proteins during osteoblast differentiation by functional assays with WT and element specific mutations in -208 OC-CAT, and by chromatin immunoprecipitation (ChIP) assays at stages of primary calvarial cell differentiation. We confirmed by co-immunoprecipitation studies that Msx2 and Runx2 form a complex and that Msx2 is most associated with the OC promoter in proliferating osteoblasts by ChIP assays. The WT, mRunx2 and mRunx2-mC/EBP transgenes all exhibit a 2-fold repression in response to Msx2, indicative of the repressor activity at the HD site. However, a 2-fold repression is also observed when only the HD site is mutated, suggesting Msx2 is mediating repression through another element. Indeed, when both the Runx2 and the HD elements are mutated, repression by Msx2 is lost, indicating that both sites contribute to down regulation of OC. Thus, HD repression occurs through two different mechanisms: through homeodomain protein-DNA and protein-protein interactions. This finding is further supported by 4-fold repression observed in response to Msx2 when only the C/EBP element is mutated, suggesting that C/EBP can counteract HD mediated repression directly and through Runx2. During osteoblast differentiation, we find increasing C/EBPβ and δ factors associated with the OC promoter, and decreased Msx2 protein levels. Thus, our studies indicate that OC gene transcription is tightly regulated in early stage osteoblasts by HD protein repression through direct and indirect interactions. At later stages of osteoblast differentiation, C/EBP-Runx2 interactions predominate to upregulate OC transcription.

Genomic Regulatory Network for Early BMP2 Response Genes in Osteoblasts and Role of Dlx 5 and Related Family Members Using Retroviral Vectors. D. Guo*[1], M. A. Harris[1], A. Kishnaswamy[1], A. C. Lichtler[2], S. E. Harris[1]. [1]Oral Biology, U. of Missouri at Kansas City, Kansas city, MO, USA, [2]U. of Connecticut Health Center, Farmington, CT, USA.

A single short treatment of BMP2 to osteoblasts is capable of initiating a cascade of growth, cell migration, matrix rearrangement, and differentiation to a mineralizing matrix. Some of the earliest transcription factors induced in preosteoblasts by BMP signaling belong to the distalless related or Dlx family of transcription factors. Overexpression and knock-out experiments in mice have demonstrated a critical role for Dlx 5 and Dlx 6 in osteoblast growth and differentiation. We want to identify some of the genes directly regulated by Dlx5 and related family members. This will allow us to begin building a genomic regulatory network of early BMP action in osteoblasts. Previous studies have showed that Dlx5 and Dlx2 are two of the earliest genes induced by BMP2 in primary rat osteoblast and the mouse 2T3 osteoblast-like cells. To explore the gene regulatory network involved in BMP2 response, the homeodomain of Dlx5 was fused with Engrailed, a strong transcription repressor. This gene construct will in principle, inhibit genes regulated by Dlx5 and related family members. The ENG-Dlx5HD (DNA binding homeodomain only) construct, as well as a control empty vector were first packaged into a retrovirus, and infected into 2T3 cells. 90% of the cells were infected as determined by GFP fluorescence from a 3' IRES-GFP cassette in the virus. The infected control and ENG-Dlx5HD 2T3 cells were then exposed to 100ng/ml of BMP2 from 1 to 4 hours, followed by mRNA extraction, and micro-array assay of 5000 probes. A subset of 136 genes that were induced more than 1.6 to 20 folds by BMP2 in the control group at 1hr time point were first chosen for further analysis. Of this set of 136 genes, over 60 genes showed no or little response (lower than 50%) to BMP2 in the ENG-Dlx5HD group, while the remaining genes showed a BMP2 response in the presence of the ENG-Dlx5HD virus. This indicates that the 60 gene set is most likely dependent on Dlx transcription factors for some part of their regulation, while the remaining set are regulated by BMP2 by other sets of transcription factors and signals. Northern blottings of several genes was used to confirm several aspects of our genomic network model. By using mouse and human genomic comparisons of the these 136 genes (10kb of 5' flanking, the transcription unit, and 10kb of 3' flanking DNA) to search the Dlx/Msx, Smad 1, and Cbfa1 binding sites, we have demonstrated a significant increase in the number of clusters of Dlx/Msx sites in the gene set that is directly regulated by Dlx family members.

Abnormalities of Osteoblast Lineage Differentiation in Presenilin Heterozygous Knockout Mice. P. Liu, X. Jiang*, L. Wang*, D. Rowe. University of Connecticut, Farmington, CT, USA.

During embryogenesis, the osteoprogenitor lineage is required to produce a critical number of mature osteoblasts for normal limb development. Knock out mice with a phenotype of abnormal limb formation have revealed a number of genes and associated molecular pathways likely to be important to lineage differentiation. The presenilin KO (PSKO) has severe axioskeletal and brain abnormalities. This gene is a crucial member of the Notch signaling pathway which is known to influence lineage specification and differentiation, proliferation and programmed cell death. Because the osteoprogenitor lineage utilizes the same molecular pathways to maintain bone remodeling in adult tissues, we questioned whether mice with a hypomorphed PS gene could have a bone phenotype. Mice heterozygous for the PSKO mutation (PSKO/+) have normal size and no obvious loss of vertebral trabecular bone by μCT. To assess the ability of the osteoprogenitor lineage to generate mature osteoblasts, pOBCol3.6GFP and pOBCol2.3GFP transgenes were introduced producing PSKO/+ and +/+ littermates carrying these visual trangenes. Previously we have shown that the 3.6 transgene activates with a low intensity in preosteoblasts and brightens during early osteoblast differentiation. The 2.3 transgene activates in mature mineralizing osteoblasts.
CryoJane frozen sections of decalcified femur showed decreased numbers of 2.3GFP+ cells in the PSKO/+ mice relative to +/+ mice. The number of 3.6GFP+ cells was increased in PSKO/+ mice along the endosteal and trabecular bone surface and there was enhanced activity in the fibroblast-like cells of the periosteum. The number of BrdU positive cells lining the bone surfaces was also increased in the PSKO/+. Marrow stromal fibroblasts cultures were established from the PSKO/+ and +/+ mice. The number of cells expressing the 2.3 transgene in the PSKO/+ was significantly less than +/+, while the number of cells expressing the 3.6 transgene was remarkably increased in the PSKO/+ cultures. Mature cultures from the PSKO/+ carrying either transgene showed reduced mineralization and OC expression, while Col1a1 and BSP were enhanced. We interpret these results to indicate that the PSKO/+ mouse maintains a relatively normal bone mass in part by increasing the production of precursor cells sufficient to overcome an impaired conversion of early to mature osteoblasts. This inherent inefficiency in mature osteoblast production may act as an osteoporosis risk gene which, when combined with other factors affecting lineage progression (age or estrogen deficiency), will result in an osteoporosis phenotype. The use of the GFP marker gene may be a useful tool for identifying other genes important to lineage progression.

Murine Frizzled-1 is Upregulated by BMP-2 and Antagonises Wnt/β-Catenin Signalling in Murine Pluripotent Mesenchymal Cells. S. Roman Roman[1], D. Shi*[2], V. Stiot*[1], B. Vayssière*[1], T. Garcia[1], R. Baron[1], G. Rawadi*[1]. [1]Proskelia Pharmaceutical, Romainville, France, [2]CNRS, Paris, France.

Wnts are a family of secreted glycoproteins that play important roles in development by regulating cell growth and polarity. Wnts bind to receptor complex composed of Frizzled (Fz) and lipoprotein receptor-related protein (LRP) family members. Wnt signaling has been recently demonstrated to play a crucial role in osteoblast differentiation and bone formation. Mice and humans lacking LRP5 display a decreased bone mass and bone formation, whereas other mutations in the same gene lead to a high bone mass phenotype. We have previously shown that BMP2 induces the secretion of Wnt proteins in osteoblasts, suggesting that some of the bone anabolic properties of BMPs are exerted via a Wnt autocrine pathway. Genome-wide expression analysis of genes involved in the Wnt signaling cascade in response to BMP2 in mesenchymal pluripotent cell lines show that BMP-2, but not TGF-β1, induces the expression of murine frizzled-1 (mFz1) in C3H10T1/2 and C2C12 cell lines. Overexpression of mFz1 in the same cells represses BMP-2-mediated and Wnt-dependent alkaline phosphatase (ALP) induction. Accordingly, mFz1 overexpression significantly reduces Wnt3a-mediated ALP induction. To investigate the mechanism by which mFz1 inhibits ALP induction we examined the effect of mFz1 on the canonical β-catenin signaling cascade. Overexpression of mFz1 in mesenchymal cells significantly represses Wnt3a-mediated TCF-1 activation. Furthermore, microinjection of mFz1 tran-

scripts in *Xenopus* embryo inhibits the ability of Wnt1 to induce the expression of the Wnt/ß-catenin target gene *Siamois* in animal cap assay, and secondary axis formation in whole embryo. Using chimeric constructs in which N- and C-terminal segments of mFz1 were replaced by the corresponding parts of XFz3 (which is linked to the β-catenin pathway) we demonstrate that: i) the C-terminal cytoplasmic tail of mFz1 is sufficient to activate signaling through β-catenin and ii) the antagonistic activity of this receptor resides in the N-terminal part, within the cysteine-rich domain. Thus, a member of the frizzled receptor family, mFz1 is capable of antagonizing Wnt/β-catenin signaling. Our findings demonstrate that some members of the Frizzled family of receptors can negatively modulate Wnt signaling, while others are necessary for the activation of this signaling cascade. The fact that mFz1 is induced during BMP2-stimulated osteoblast commitment and differentiation therefore suggests the existence of a negative feed-back mechanism to down-regulate BMP-2-induced Wnt signaling, possibly playing an important role in the control of osteoblast differentiation.

Pleiotropic Functions of N-Cadherin in Osteoblasts. C. Lai-Huang, S. Cheng, R. Civitelli. Bone and Mineral Diseases, Washington University, St. Louis, MO, USA.

We have previously shown that expression of a truncated mutant of N-cadherin (Ncad) with dominant negative action globally inhibits osteoblast cadherins resulting in delayed acquisition of peak bone mass in mice and retarded osteoblast differentiation. To gain insights on the specific role of Ncad in bone, we used mice harboring a null mutation of the Ncad gene. Calvarial cells of heterozygous $Ncad^{+/-}$ mice (homozygous loss of Ncad is embryonically lethal) express lower abundance of Ncad protein relative to $Ncad^{+/+}$ cells. Whole body bone mineral density (BMD) by DEXA was only marginally (<4%; n.s.) lower in $Ncad^{+/-}$ mice relative to wild type littermate up to 6 months of age, implying that a single allele of Ncad is sufficient to maintain bone mass. The abundance of cadherin-11 and R-cadherin was not increased by single allele Ncad deletion, thus excluding compensatory changes of the other major osteoblast cadherins. Surprisingly, development of calcified nodules was faster and more intense in calvarial cells isolated from $Ncad^{+/-}$ mice relative to $Ncad^{+/+}$ cells, in the presence of ascorbic acid and β-glycerophosphate. Likewise, bone marrow stromal cells from heterozygous mice developed ~40% more alizarin red positive colony forming units than wild type cells, although the difference disappeared after 4 weeks of culture. In 2-week calvarial cultures, alkaline phosphatase (ALP) activity was 5-fold higher in $Ncad^{+/-}$ relative to $Ncad^{+/+}$ cells, whereas Cbfa1 mRNA abundance was not different. These in vitro data seem to suggest that Ncad may inhibit full osteoblast differentiation, keeping cells in a less differentiated state. Consistent with this view, Ncad mRNA expression, determined by real time RT-PCR, was progressively down regulated with time in differentiating $Ncad^{+/+}$ calvarial cells, while cadherin-11 mRNA remained unchanged. Interestingly, the mineralization time lag between heterozygous and wild type calvarial cells was not observed in the presence of BMP-2 (150ng/ml). Finally, phosphorylation of p38 MAP kinase by BMP-2 (a critical step in the action of BMP-2 in osteoblasts) was stronger in wild type than in $Ncad^{+/-}$ cells, as was up-regulation of alkaline phosphatase activity, while the effect on p-ERK was similar, suggesting that osteogenic stimulators may offset an inhibitory action of Ncad. In conclusion, Ncad has pleiotropic and complex functions in bone forming cells. While it is critically important in the early stages of osteoblast differentiation, Ncad may function as an inhibitor of late differentiation, perhaps contributing to modulate the timing of bone mineralization. In vivo, the positive effects of Ncad on osteogenic differentiation seem to prevail.

PTH Promotes Osteoblastic Differentiation/Commitment but not Proliferation in GFP-Marked Primary Osteoblast Culture. Y. Wang, Y. Liu*, S. Lee*, D. W. Rowe. University of Connecticut Health Center, Farmington, CT, USA.

Primary calvarial cell cultures derived from mice transgenic for pOBCol2.3GFP and pOBCol3.6GFP respond to PTH administered for the first 7 days of a 21-day culture period with an increase in both fluorescent markers of osteoblast differentiation. Either an expansion in the number of precursor cells capable of subsequent osteoblast differentiation or an enhancement in the proportion of precursors that become osteoblasts are the two contrasting possibilities that are addressed in the present study. The pOBCol3.6GFP transgene activates in early preosteoblastic cells and intensifies its activity as the early osteoblasts differentiate within the bone nodule. Using a computer controlled inverted microscope, serial digital images covering approximately 63% of the culture well recorded the progress of the developing bone nodules under identical photographic conditions. Individual images from multiple time points of culture were thresholded for intensity of GFP expression. The analysis revealed two distinct peaks of GFP expression that clearly separated differentiated bone nodules from surrounding preosteoblasts. Cultures exposed to PTH for 7 days showed a decrease in the area covered with low intensity GFP signal and a corresponding increase in the area with strong GFP expression. This result suggests that the preosteoblast population is not expanded by PTH but rather a greater proportion of precursor cells differentiate into osteoblasts. To validate this impression, parallel cultures were dispersed with trypsin/collagenase and aliquots were assessed for their DNA content or subjected to FACS analysis. Data showed that PTH treatment did not increase the DNA content of the culture and FACS analysis did not show a significant change in the proportion of GFP positive or negative cells. This result confirms that the 7-day PTH exposure does not increase the number of cell within the culture or change the proportion of GFP positive or negative cell. When cultures that had been exposed to PTH for 7 days were subjected to FACS sorting and replated for a 21-day culture period, both the GFP positive and negative population showed increased osteoblast differentiation relative to control FACS sorted cells. Similarly, untreated FACS sorted and replated GFP positive and negative cell population responded to a 7-day PTH exposure with a higher proportion of osteoblastic nodules relative to untreated control by day 21 of culture. The present study strongly suggests that the 7-day PTH treatment enhances the proportion of cells committed to enter osteoblastic differentiation whether they are at the preosteoblast (GFP positive) or pluripotential (GFP negative) level of differentiation.

Calcyclin, a Ca^{2+}ion Binding Protein, Plays a Role for Anabolic Effects of Statin on Bone. R. Hwang*, E. Lee*, S. Li*, Y. Jin*, Y. Rhee*, S. Lee*, Y. Kim*, S. Chung*, S. Lim*. Division of Endocrinology, Department of Internal Medicine, College of Medicine, Brain Korea 21 Project for Medical Sciences, Yonsei University, Seoul, Republic of Korea.

The simvastatin is a pro-drug of a potent 3-hydroxy- 3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor and inhibits cholesterol synthesis in humans and animals. In the previous studies, in vitro treatment of pharmacological dose of statins stimulated bone formation. To identify the mediators of the anabolic effect of simvastatin on osteoblasts, we tried to identify and characterize simvastatin-induced proteins by using proteomic analysis. Calvarial cells dissected from mice aged P1(postnatal 1) were treated with simvastatin in various doses(10^{-9}~10^{-6}M). For the proliferation assay, simvastatin was treated intermittently, 6 hour per 2 days, for 8 days totally because statins exert a number of effects 1) stabilizing cells 2) inhibition of cell proliferation, particularly lipophilic statins by multifaceted mechanisms. The proliferation of statin-induced OB cell was increased dose-dependently compared to the control without statin. The activation of osteoblast genetic markers such as alkaline phosphatase (ALP), type I collagen and osteoclacin in the presence of simsvastatin was remarkable in dose-dependant manner. The mouse calvarial cells with or without statin treatment were subjected to protein purification and subsequent two-dimensional(2D) electrophoresis. Two-dimensional protein patterns were analyzed by PDQuest (Bio-Rad) software and determined by mass-assisted laser desorption/ionization time-of-flight (MALDI TOF) analysis. Calcyclin was up-regulated more than 10 times. Up-regulated calcyclin mRNA after simvastatin treatment was validated by reverse transcription in mouse calvarial cell. In confocal microscope experiment, GFP-Calcyclin fusion protein was visualized in cytoplasm of MC3T3-E1 and was quickly shifted to nucleus 20 min. after the simvastatin treatment. Calcyclin cDNA were subcloned into pcDNA 3.0 to see whether this protein plays a role in osteoblastogenesis apart from statin. The expression of ALP mRNA was increased without treatment of simvastatin in MC3T3-E1 cells transfected with sense calcyclin DNA. It was also noticed that the proliferation was enhanced significantly in the presence of sense calcyclin gene. In conclusion, simvastatin stimulates the proliferation and early differentiation of osteoblast. Calcyclin is one of the candidate proteins playing a role in osteoblstogenesis in response to simvastatin, although the precise functions of calcyclin in osteoblast remain unknown.

Potentiation of Wnt Signaling by Activation of the Nongenotropic Function of the Estrogen Receptor in Osteoblastic Cells. M. Almeida, J. Chen, L. Han, A. M. Vertino, H. Peng*, S. Kousteni, S. C. Manolagas. Div Endo/Metab, Center for Osteoporosis and Metabolic Bone Diseases, CA Veterans Healthcare System, Univ of Arkansas for Med Sciences, Little Rock, AR, USA.

Mutations in LRP-5 and secreted Frizzled-related protein-1 revealed an important role of the Wnt signaling pathway in the regulation of bone mass. Estrogens regulate components of the Wnt signaling pathway, but it is unknown whether such regulation results from genotropic or nongenotropic mode of estrogen receptor (ER) action. We employed 4-estren-3α,17β-diol (estren), a compound that reproduces the nongenotropic effects of sex steroids without affecting classical transcription and exhibits bone anabolic properties and investigated its effects on Wnt signaling. In HeLa cells permanently transfected with either the wild type ERα or the ligand binding domain of the ERα fused to a membrane-localization sequence, estren, at 10-8M, upregulated the expression of Wnt-2 by 8-fold and Frizzled 10 (Frz10), a soluble Wnt receptor, by 3.5-fold , as determined by real time PCR. At the same concentration 17β-estradiol (E2) had a considerably weaker effect on Wnt-2 and Frz10 (1.5- and 2- fold stimulation respectively). In line with its effects on HeLa cells, estren upregulated Wnt-1, by 9-fold and in addition downregulated the Wnt antagonist Dickkopf (Dkk-1), by 2-fold, in MC3T3-E1 osteoblastic cells. Further, estren suppressed c-jun expression in MC3T3-E1 cells (2-fold) and c-jun phosphorylation in OB-6 osteoblastic cells. Moreover, it suppressed c-jun activity in murine vertebrae following short term administration to OVX mice (48 hours). The suppressive effect of estren on both c-jun and Dkk-1 expression in MC3T3-E1 cells was detectable within 1 hr, preceding an exponential upregulation of Wnt-1 at 14 and 24 hrs. E2 also had an early suppressive effect on c-jun and Dkk-1 at 1hr, but unlike estren, it did not upregulate Wnt-1 at 14 or 24 hrs. In agreement with the upregulating effect of estren on the expression of Wnt-1 and its suppressive effect on Dkk-1, it stimulated Wnt/β-catenin-mediated transcription by the T-cell factor (TCF) in MC3T3-E1 cells carrying a TCF reporter construct. This latter effect was at least 4-fold greater than the effect of E2 and it could be blocked by overexpression of Dkk-1. It is reported elsewhere in this meeting that estren induces osteoblast lineage commitment and differentiation and that this effect is prevented by Dkk-1. Based on this and evidence that c-jun downregulates Dkk-1, the results reported herein indicate that a c-jun-mediated decrease of Dkk-1 along with an increase of Wnt-1 and Wnt-2 and/or their receptor Frz10 by a nongenotropic action of the ER may account in part for the bone anabolic properties of ANGELS.

Hyaluronan Increases RANKL Expression in Mouse Primary Osteoblasts Through CD44: A Potential Role in Age-related Bone Loss. J. Cao*[1], P. Singleton*[1], S. Majumdar*[2], A. Burghardt*[2], L. Y. W. Bourguignon*[1], B. P. Halloran[1]. [1]Endocrine Unit, Department of Medicine, University of California, San Francisco, San Francisco, CA, USA, [2]Magnetic Resonance Science Center, Department of Radiology, University of California, San Francisco, San Francisco, CA, USA.

Hyaluronan (HA), the major non-protein glycosaminoglycan component of the extracellular matrix in mammalian bone marrow, functions in part through its receptor, CD44, to stimulate a series of intracellular signaling events that lead to cell migration, adhesion, and activation. With aging, HA concentration and RANKL expression increase and OPG expression decreases. To determine whether HA activation of CD44 influences the receptor activator of nuclear factor κB ligand (RANKL) and osteoprotegerin (OPG) expression, we measured the expression of RANKL and OPG in osteoblast-like cells from animals of different ages and from young CD44-/- mice treated with HA and anti-CD44 antibody. We also studied bone structure of wildtype and CD44-/- mice using micro CT.

Addition of HA dose-dependently increased RANKL mRNA (3.6-fold) and protein (3-fold) levels in osteoblast-like cells from young donors. Stimulation of RANKL could be blocked with anti-CD44 antibody. Treatment of cells with HA or anti-CD44 antibody had no significant effect on OPG mRNA levels. Compared to control mice, tibial mass, proximal tibial cancellous bone volume and structure (μCT) of CD44-/- mice are normal but the tibia was shorter, cortical bone was thicker, and medullary area was smaller. CD44-/- animals also expressed less RANKL in whole bone (-30%) and in osteoblast-like cells (-50%). Cells from CD44 knockout animals failed to respond to either HA or CD44 antibody treatment. With aging, the responsiveness of osteoblast-like cells to HA treatment were decreased. Cells from old mice showed no response to HA and CD44 antibody treatment.

In conclusion, HA can increase RANKL expression in osteoblasts through CD44, and the absence of CD44 in the CD44-/- mouse results in a bone phenotype consistent with decreased endocortical resorption. The interaction between HA and CD44 may play a role in age-related bone loss.

The bHLH Transcription Factor P8 Enhances Bone Formation by Promoting Osteoblast Cell Proliferation and Inhibiting Osteocalcin Expression. Y. Abe*[1], W. Chen[1], R. Isoda*[1], S. Yang*[1], M. Nishino*[2], Y. P. Li[1]. [1]The Forsyth Institute, Harvard School of Dental Medicine, Boston, MA, USA, [2]Department of Pediatric Dentistry, The University of Tokushima School of Dentistry, Tokushima, Japan.

There is clear clinical evidence that genetic modulated osteoporosis results from functional defects of the osteoblast. However, the genes underlying these genetic syndromes of osteoporosis remain largely unknown. The purpose of this study was to characterize osteoblast transcription factors that regulate bone formation. Subtractive-differential screening was used to clone the transcription factors selectively expressed in osteoblasts. We identified a bHLH transcription factor, P8 that is predominantly expressed in mature osteoblasts. We confirmed that P8 exhibits similar up-regulated expression as osteocalcin during osteoblast differentiation by Northern Blot and *In Situ* Hybridization. To study the function of P8 in bone formation *in vitro* model, we generated a rat pre-osteoblast cell line ROBC10 derived from day 19 fetal rat calvaria. ROBC10 cells are able to differentiate to mature osteoblast that produce matrix proteins and form mineralized nodules in differentiation medium *in vitro.* Forced expression of P8 in ROBC10 cells resulted in 2.5 fold increases of mineralized nodules. In contrast, cells transfected with vectors containing P8 in antisense orientations resulted in 80% decreased mineralized nodules relative to cells transfected with vector alone. To evaluate the molecular basis of P8 bone formation function, we studied the effects of P8 on osteoblast cell proliferation, apoptosis and gene regulation. Our results showed that forced expression of P8 in ROBC10 cells resulted in the cells growing significantly more rapidly. The number of cells was about 2.5 fold when compared with that in the control group. ROBC10 cells transfected with vectors containing P8 in antisense orientations resulted in 40% decreased cell proliferation relative to cells transfected with vector alone. No apoptosis change was observed in the ROBC10 cells transfected either with vectors containing P8 in sense or antisense orientations. Cotranfection studies demonstrated that osteocalcin promoter activity was reduced to 20% of that of the control group without P8 expression. Previous studies in other laboratories indicated that osteocalcin is an inhibitor of bone formation. Our results suggested that P8 is a key regulator of bone formation. P8 enhances bone formation *in vitro* by promoting osteoblast cell proliferation and regulating osteoblast gene expression.

Recruitment of Bone-Forming Cells from Remote Bone Marrow Sites During Fracture Healing. D. S. L. Shirley*, D. Marsh*, G. Jordan, G. Li. Department of Trauma and Orthopaedic Surgery, Queen's University of Belfast, Belfast, United Kingdom.

Osteoblast precursors reside in the marrow and periosteum and small numbers circulate in the blood. We have previously found an increase in circulating fibroblastic cells after fracture in humans, suggesting a systemic response following skeletal injury. This study tests the hypothesis that some of the osteoblasts integral to fracture healing, are recruited from remote bone marrow sites, via the peripheral circulation.

34 New Zealand White rabbits had tibial bone marrow harvested, 3 weeks prior to the creation of an ulnar fracture. The marrow stromal cells were isolated and cultured for 3 weeks. These autologous cells were fluorescently labelled, (PHK 26, Sigma, UK,) 1 day prior to re-implantation. The labelled cells were either re-introduced into the fracture gap (Group I, n = 9), into a vein (Group II, n = 12), or into a remote bone marrow cavity (Group III, n = 6). The control, (group IV, n = 7) did not receive any labelled cells. The fracture was established 48 hours prior to cell return. Animals were culled at either 3 or 12 weeks post-fracture. In group II, 3 animals were also sacrificed at 1 day and 1 week. Representative callus, lung, liver, spleen, blood, marrow and kidney tissues were harvested, from all animals. Solid tissues were cryo-sectioned and examined with a confocal microscope. The labelled cells were expressed as the average in 5 high power fields. Cytospins were made from the blood and marrow samples and the labelled cells expressed as a percentage of the total cells.

No labelled cells were identified in the group IV callus. Labelled cells were found in all group I callus, (mean 28.4 per high power field), all group II callus, (mean 10) and in all group III animals, (mean 23.5). There was no statistical difference in the number of cells found in the callus of groups I, or III. The labelled cells appeared on trabecular surfaces in all sections, and they were often surrounded by osteoid. A small number of labelled cells were found in the blood, marrow, lung, liver and spleen of all animals in groups I-III. No labelled cells were identified in the kidney tissue.

This study is a "proof of concept", demonstrating that bone-forming cells can be recruited from remote bone marrow sites and are integral in fracture healing. The presence of labelled cells in callus following venous delivery, supports their recruitment via the blood. The mechanisms of how these bone marrow cells are recruited to the site of injury needs further investigation. Understanding this phenomenon could provide new treatment alternatives for non-union and other bone pathology.

Autoregulation of BMP Expression Mediates Osteogenic Differentiation of Murine Marrow Stromal Cells in Culture. C. M. Edgar, V. Chakravarthy*, G. L. Barnes, S. Kakar*, L. C. Gerstenfeld, T. A. Einhorn. Boston University School of Medicine, Boston, MA, USA.

The role of bone morphogenetic protein expression in the autoregulation of osteogenic differentiation of adherent murine marrow stromal cells (MSCs) in vitro was assessed. When grown in full osteogenic media (beta-glycerolphosphate, ascorbic acid, and 10^{-8} dexamethosome (Dex)), over 21 days these cells showed a temporal progression of osteogenic differentiation characterized by the development of mineralizing nodules, an increase in APase activity, increased expression of Dlx5 and Runx2, and a commensurate decreases in the expression of measured AP1 transcription factor family members. These changes were accompanied by sequential temporal increases in Col1α1, OPN, BSP and OC expression. As differentiation progressed, these cultures uniquely upregulated the expression of BMPs 2, 3B, 4, 6, 7, and 8A. Noggin treatment inhibited the nodule counts by 50%-70%; this was accompanied by reduced expression of osteoinductive transcription factors and phenotypic markers during MSC differentiation. In contrast, the addition of BMP-7 (OP-1) or BMP-2 increased nodule counts by 30%-50% and the expression of osteogenic markers and transcription factors from two to greater than ten fold depending on the specific mRNA(s) assayed. Interestingly, the addition of BMP -7 inhibited the expression of all of the endogenously expressed BMPs with the exception of BMP-2 while BMP-2 inhibited the expression of all of the endogenously expressed BMPs with the exception of BMP-7. A comparison of the effects of two common osteogenic culture additives (beta-glycerolphosphate and ascorbic acid (Asc+GP) or both Asc+GP and 10^{-8} Dexamethasome) demonstrated that each additive separately enhanced differentiation by ~20% and 50% respectively, as compared to 10% FBS only, based on both nodule counts and the expression of osteogenic mRNA. Interestingly, Dex led to a proportionate increase in the expression of multiple endogenously produced BMPs. A time course study of BMP expression over 1, 3, 6, 12, and 24 hours after a single treatment with Dex demonstrated that BMPs 8A and 3B were selectively upregulated two to four fold, while BMPs 2, 4, and 6 remained unchanged suggesting that BMPs 3B and 8A are selectively responsive to corticosteroid regulation. In summary, these data show that the osteogenic differentiation of MSCs is predominantly driven by the endogenous production of their own BMPs. Furthermore, the data demonstrate that the addition of exogenous BMPs downregulate endogenous BMP expression. Finally, these data suggest that corticosteroid induction of osteogenic differentiation may be mediated through the selective induction of BMPs 3B and 8A.

Thrombospondin-2 Inhibits Marrow Stromal Cell Adipogenesis. W. Luow*[1], C. N. Bennett*[2], O. A. MacDougald*[2], J. D. Miller*[1], K. D. Hankenson[1]. [1]Orthopaedic Surgery, University of Michigan, Ann Arbor, MI, USA, [2]Molecular and Integrative Physiology, University of Michigan, Ann Arbor, MI, USA.

Marrow stromal cells (MSC) are mesenchymal progenitors that differentiate to become endosteal osteoblasts and marrow adipocytes. A shift in the differentiation of MSC to adipocytes rather than osteoblasts is thought to contribute to the development of osteoporosis. Previous work has shown that recombinant thrombospondin-2 (TSP2), a secreted matricellular protein produced by MSC, promotes osteogenic differentiation, but inhibits adipogenic differentiation.

The purpose of this study was to further explore the significance of TSP2 in regulating MSC adipogenic differentiation. We utilized three different progenitor cell types, immortalized TSP2-null MSC (obtained from TSP2 knockout mice crossed with transgenic mice carrying a temperature sensitive SV40 large T antigen), immortalized WT MSC, and the preadipocyte line 3T3L1. Two different adipogenic induction protocols were utilized, MDI (isobutylmethylxanthine, dexamethasone, insulin), or MDIT (MDI + the PPARgamma agonist, troglitazone) a more potent adipocyte inducer than MDI alone. WT MSC showed

a 50% reduction in adipocyte formation relative to TSP2-null in the presence of MDI, but when induced with MDIT there was no difference between WT and TSP2-null. As well, the addition of 50 nM recombinant TSP2 inhibited TSP2-null MSC adipogenic differentiation 50% secondary to MDI, but not MDIT. Interestingly, recombinant TSP2 was not effective at reducing adipogenesis of potently preadipocytic 3T3L1 cells in MDI. The production of TSP2 by WT MSC secondary to adipogenic induction was studied using both real-time, reverse-transcriptase PCR and western blotting. WT MSC showed a reduction in TSP2 protein (75% less) and RNA (50% less) levels 24 hours following MDI treatment. This decrease continued until the cessation of the experiment at day 12. Rather surprisingly we found that TSP2 is a late-stage adipogenic inhibitor. TSP2 could be removed from the media as late as day 9 of a 12 day assay and the TSP2-null MSC retained normal adipogenic potential. Likewise, addition of TSP2 at day 9, during the maturation phase of lipid containing vesicles, inhibited differentiation. The treatment of TSP2-null MSC with truncated recombinant fragments of TSP2 shows that the type I repeats of the molecule are required for the inhibition of adipogenic differentiation. We hypothesize that the type I repeats of TSP2 interfere with late stages in adipogenic differentiation, either decreasing fatty acid synthesis or fatty acid uptake from the media, and that its effectiveness as an inhibitor is abrogated secondary to more potent adipogenic conditions.

PKCalpha is Downstream of Alphavbeta3 Integrin and Contributes to Adhesion-Induced ERK1/2 Activation in Osteoclasts. N. Rucci[1], L. Orrù*[1], C. DiGiacinto*[1], S. Migliaccio*[1], M. Longo*[1], A. Taranta*[1], R. Baron[2], A. Teti[1]. [1]Department of Experimental Medicine, University of L'Aquila, L'Aquila, Italy, [2]Department of Cell Biology and Orthopaedics, Yale University School of Medicine, New Haven, CT, USA.

Osteoclast alphaVbeta3 integrin engagement leads to cytoskeleton reorganization and activates a signalling cascade critical for bone resorption and cell survival. Several downstream pathways are presently known to transduce alphaVbeta3 signalling, but the potential role of serine-threonine protein kinases C (PKCs) has not yet been elucidated. Mouse primary bone marrow osteoclast-like cells (OCs) attached to immobilized LM609, a monoclonal antibody recognizing native alphaVbeta3, showed selective translocation of PKCalpha to the membrane and cytoskeletal compartments. Other PKC isoforms, representative of all classes of this family, did not appeared to be associated with alphaVbeta3 signalling. PKCalpha re-distribution was dependent on alphaVbeta3 since it occurred in alphaVbeta3 – stably transfected CHO cells, but not in parental cells which failed to attach to LM609. Immunoprecipitation revealed the presence of PKCalpha in a complex with the alphaVbeta3 integrin upon adhesion to LM609. This complex associated with the tyrosine kinases FAK in CHO cells and PYK2 in OCs. Adhesion to LM609 triggered ERK1/2 phosphorylation in the cytosolic as well as in the membrane and the cytoskeletal compartments. ERK1/2 activation did not appear to involve the Shc pathway as this adapter protein was not recruited by the alphaVbeta3 integrin, nor was it phosphorylated upon adhesion to LM609. The alphaVbeta3/PKCalpha immunocomplex was disrupted by chelation of intracellular calcium by BAPTA, which also inhibited PKCalpha translocation to the membrane/cytoskeletal compartments and subsequent ERK1/2 phosphorylation. In contrast, chelation of extracellular calcium had no effect. Neither PLCgamma nor PI3-K were implicated in PKCalpha translocation/recruitment by alphaVbeta3 and ERK1/2 phosphorylation. In contrast, inhibition of PKCalpha by the selective inhibitor Go6976 or by long-term treatment with phorbol 12-myristil 13-acetate significantly blunted ERK1/2 phosphorylation. Interestingly, these treatments failed to affect cell adhesion to LM609, suggesting a role of this PKC in events downstream of attachment to substrate. In conclusion, this study demonstrates the selective involvement of a PKCalpha cascade in the ERK1/2 phosphorylation pathway triggered by the alphaVbeta3 integrin. This cascade does not affect the ability of OCs to interact with the substrate but appears mandatory for ERK1/2-mediated pathways, which affect the differentiation and survival of OCs.

OPG Tightly Regulates Levels of a Soluble form of RANKL In Vivo and In Vitro. Y. Nakamichi*[1], N. Udagawa[2], M. Mogi*[3], A. Togari*[3], M. Nakamura*[4], N. Sato*[3], Y. Kobayashi[1], N. Takahashi[1]. [1]Institute for Oral Science, Matsumoto Dental Univ., Shiojiri, Japan, [2]Biochemistry, Matsumoto Dental Univ., Shiojiri, Japan, [3]School of Dentistry, Aichi gakuin Univ., Nagoya, Japan, [4]Pediatric Dentistry, Matsumoto Dental Univ., Shiojiri, Japan.

Osteoprotegerin (OPG) knockout (-/-) mice exhibit aberrant bone metabolism characterized by accelerated bone resorption and formation. Recently, it was reported that the serum level of RANKL was markedly elevated in a patient of OPG-deficient juvenile Paget's disease (N Engl J Med 347:210, 2002). We examined how OPG regulates serum levels of RANKL using OPG (-/-), OPG (-/+) and wild type (WT) mice. The serum concentration of OPG in OPG (-/+) mice was significantly lower than that in WT mice [OPG (-/+) mice, 0.64±0.06 ng/ml; WT mice, 1.68 ±0.30 ng/ml], suggesting that the serum levels of OPG reflects the gene dosage. The serum concentrations of RANKL in OPG (-/-), OPG (-/+) and WT mice were 2.38±0.08 ng/ml, 0.37±0.01 ng/ml and 0.08±0.02 ng/ml, respectively. Thus, the serum level of RANKL was strikingly elevated in OPG (-/-) mice. When $1,25(OH)_2D_3$ ($1,25D_3$) was administered into OPG (-/-) and WT mice, serum RANKL concentrations were markedly increased in OPG (-/-) mice [11.6±5.09 ng/ml], but slightly in WT mice [0.13±0.02 ng/ml]. There was a possibility that OPG interfered with the interaction between anti-RAKL antibody and RANKL in the ELISA, when OPG formed a complex with RANKL in serum. Then, we established an ELISA for the complex of RANKL and OPG using anti-RANKL antibody-coated plates and peroxidase-linked anti-OPG antibody. The complex was detected only in serum of OPG (-/+) mice [0.32±0.04 ng/ml] but not of WT mice. Primary osteoblasts prepared from OPG (-/-), OPG (-/+) and WT mice were cultured in the presence or absence of 10^{-8} M $1,25D_3$. Concentrations of OPG, RANKL and the complex of OPG-RANKL in the conditioned medium showed the tendency similar to those in serum observed in vivo experiments. RANKL mRNA expression was similarly induced in response to $1,25D_3$ in osteoblasts from mice with three different genotypes. These results suggest that serum concentrations of RANKL is tightly regulated by circulating OPG at the post- translational level. OPG is proposed to be a potent inhibitor for the release of RANKL from RANKL expressing cells.

Decreased Bone Resorption and Increased Trabecular Bone Mass in Female Mice Lacking Placental Growth Factor. E. Daci*[1], P. Carmeliet*[2], S. Torrekens*[1], K. Moermans*[1], R. Van Looveren*[1], R. Bouillon[1], G. Carmeliet[1]. [1]Laboratory of Experimental Medicine and Endocrinology, Katholieke Universiteit Leuven, Leuven, Belgium, [2]Center for Transgene Technology and Gene Therapy, Katholieke Universiteit Leuven, Leuven, Belgium.

VEGF plays an important role in bone metabolism, whereas the role of its homologue, placental growth factor (PlGF) in this process is unknown. We investigated bone growth and remodeling in female mice lacking PlGF compared with wild type (WT) mice. PlGF deficiency resulted in decreased vascularization in the distal femoral metaphysis of newborn mice. Surprisingly, this was associated with an increase in trabecular bone volume (+ 18%) measured in the proximal tibia, an increase which became more pronounced in 12 weeks and 16 weeks-old PlGF-deficient mice (+ 43% and + 38%, respectively). These histomorphometry data were confirmed by pQCT analysis, showing that the trabecular bone mineral density was elevated in the knockout mice at 12 weeks (+ 30%) and 16 weeks (+ 40%), whereas cortical bone parameters were only minimally affected. However, serum osteocalcin levels measured in PlGF-deficient mice of different ages were 20% to 45% lower compared with WT mice. In agreement, mineral apposition rate and bone formation rate were 47% and 61% lower in the knockout bones, suggesting a low bone turnover in PlGF-deficient mice. Supporting a decrease in bone resorption, the urinary excretion of collagen cross-links was reduced by 29% and 43% in 12 and 16 weeks-old knockout mice, respectively. Bone demineralization, assessed by measuring calcium release in embryonic metatarsal cultures, was significantly decreased in PlGF-deficient explants, indicating that PlGF is required for osteoclastic bone resorption. Osteoclast formation in vitro was significantly decreased in PlGF-deficient cultures, and neutralizing antibodies against PlGF or its receptor Flt-1 partially inhibited osteoclast formation in WT cultures. Moreover, the size of osteoclasts and the number of nuclei/cell were considerably lower in PlGF-deficient cultures. On the other hand, PlGF deficiency did not affect the migration of mature osteoclasts, their survival or dentine-resorbing activity. Finally, in vivo administration of antiFlt-1, protected trabecular bone mass in ApoE-deficient mice from the high bone turnover and bone loss.
In conclusion, deficiency of PlGF in female mice results in decreased osteoclast formation, low bone turnover, and increased trabecular bone mass, indicating that PlGF is critical for the maintenance of normal bone mass through regulation of osteoclastic bone resorption.

Small GTP-binding Protein Rac1 Is Involved in the Cytoskeletal Organization and Activation of Osteoclasts. A. Fukuda[1], T. Akiyama[1], A. Hikita*[1], Y. Kadono[1], T. Miyazaki[1], M. Matsuda*[2], H. Oda*[1], K. Nakamura*[1], S. Tanaka[1]. [1]Department of Orthopaedic Surgery, Faculty of Medicine, The University of Tokyo, Tokyo, Japan, [2]Department of Tumor Virology, Research Institute for Microbial Diseases, Osaka University, Osaka, Japan.

Osteoclasts are terminally differentiated cells with a short life span, and in the absence of trophic factors, such as M-CSF or RANKL, they undergo rapid apoptosis. Various types of bisphosphonates, nonhydrolyzable analogs of pyrophosphate currently widely used in treating osteoporosis, have been reported to stimulate osteoclast apoptosis. Although the exact mechanism of action of bisphosphonates still remains elusive, recent studies have revealed that nitrogen-containing bisphosphonates inhibit posttranslational prenylation of small GTP-binding proteins (G-proteins), which may cause osteoclast apoptosis. We previously reported that Rac1, one of the Rho family members of small G-protein, is implicated in the M-CSF-induced pro-survival signaling in osteoclasts, and required for the activation of Akt in response to M-CSF. In the present study, we examined the role of Rac1 in the cytoskeletal organization and the bone-resorbing activity of osteoclasts using adenovirus vector expression system. We constructed adenovirus vector carrying cDNA of fusion protein of EGFP and dominant negative Rac1 ($Rac1^{DN}$) gene, and osteoclast-like cells (OCLs) generated in mouse co-culture system were infected with this virus as well as the control virus (EGFP virus). Clear induction of these molecules in OCLs was demonstrated by green fluorescence and Western blot analysis. We examined the effects of $Rac1^{DN}$ expression on the cytoskeletal organization of OCLs using time-lapse video microscopy. M-CSF treatment caused rapid and prominent membrane ruffling and subsequent cytoplasmic spreading in OCLs, which was inhibited by $Rac1^{DN}$ overexpression to 70% of the control levels as quantified with image analysis softwares. On the other hand, actin ring formation in $Rac1^{DN}$-overexpressing cells as examined by rhodamine-labelled phalloidin staining was comparable to that in the control OCLs. OCLs expressing $Rac1^{DN}$ underwent apoptotic cell death even in the presence of M-CSF. We next examined bone-resorbing activity of these cells, and found that $Rac1^{DN}$ overexpression dose-dependently suppressed pit formation of OCLs on dentine slices. These data suggest that not only does Rac1 mediate survival signaling downstream of M-CSF in osteoclasts, but also plays an important role in the bone-resorbing activity of the cells by regulating membrane dynamics.

HSP70 Secreted during Osteoclast Differentiation Is Related to Cell Death of Osteoclast Precursor. E. Lee*, R. Hwang*, S. Li*, Y. Jin*, Y. Rhee*, S. Lim*. Division of Endocrinology, Department of Internal Medicine, College of Medicine, Brain Korea 21 Project for Medical Sciences, Yonsei University, Seoul, Republic of Korea.

Osteoclasts are highly specified multinucleated bone resorbing cells known as part of the mononuclear phagocyte system. RANKL is a type II membrane protein of the TNF family and plays a critical role in the regulation of osteoclastogenesis. Our aim was to identify and characterize the proteins induced by RANKL that are structurally and functionally undefined. In this study, we attempted to investigate the difference, using proteomics technique, of expression pattern between RANKL-induced cells and those not induced. Briefly, the cells were isolated from bone marrow of mouse femur and tibiae, and then were cultured in complete α-MEM media overnight. Next day, the non-adherent cells were removed, and only the adherent cells were further cultured in the presence of M-CSF. After 24 hr, the cells were treated with RANKL for 3 days. And the obtained cells were subjected to protein purification and subsequent two-dimensional electrophoresis. After visualization of protein spots, digital gel images obtained by scanner were analyzed by PDQuest software (Bio-rad, USA). Interest protein spots determined using peptide mass spectrometry method by matrix-assisted laser desorption/ionization time-of-flight mass spectrometry (MALDI-TOF MS). Among many spots induced by M-CSF or/and RANKL, the expressions of HSP60 and HSP70 were significantly upregulated in the differentiated osteoclasts. HSP60 and HSP70 proteins have been shown to be involved in diverse cellular responses of various cell types. Western blotting analyses also showed a remarkable increase in HSP70 during osteoclast formation in mouse bone marrow cell cultures in the presence of M-CSF and RANKL. HSP60 revealed increased, but not significant, during osteoclast differentiation. Surprisingly, HSP60 and HSP70 are secreted proteins during osteoclast differentiation. Secretions of HSP60 and HSP70 were increased in osteoclast precursor cells more than in mature osteoclast cells. To investigate the function of secreted HSP70 during osteoclastogenesis, the TRAP staining pattern of the cells treated with only M-CSF or/and RANKL was compared with those treated together with HSP70. The precursors of osteoclasts were all dead in the group treated with inducible HSP70. In conclusion, HSP70 might be one of natural self regulators of osteoclastogenesis. Our findings indicate that HSP60 and HSP70 have a role in regulation of osteoclast formation and function potentially by participating in osteoclastogenesis by M-CSF and RANKL.

Interactions between MITF and PU.1 Required for Osteoclast Differentiation. K. C. Mansky, R. Hu*, M. C. Ostrowski*. Molecular Genetics, Ohio State University, Columbus, OH, USA.

The microphthalmia associated transcription factor MITF is a basic helix-loop-helix zipper (bHLHzip) that is a critical regulator of terminal differentiation in osteoclasts. The severe osteopetrotic phenotype in mice harboring the MITF-mi allele is the result of a defect in the terminal differentiation of osteoclasts. Immature mononuclear osteoclasts are present in the mi/mi mice, but these do not fuse or form ruffled borders, or express genes necessary for osteoclast function such as TRAP and cathepsin K. Unlike MITF-mi mice, mice that are null for MITF expression (MITF-vga) do not exhibit a severe osteopetrotic phenotype. PU.1 is a hematopoietic transcription factor that is also necessary for osteoclast formation. Our lab has previously shown that mice that are heterozygote for both the mi mutation and for a PU.1 knockout allele (Pu.1+/-) have an age resolving osteopetrotic phenotype, suggesting that these factors collaborate during osteoclast formation. To better understand the role of MITF and PU.1 in osteoclast differentiation, we are analyzing the bone phenotype of the PU.1 (+/-), and the mi and vga mutations. We have determined that mice with genotype PU.1 (+/-);MITF-mi/MITF-vga have a severe osteopetrotic phenotype that does not resolve by 30 days of age. In addition, to genetic interactions, we have also demonstrated that MITF and PU.1 proteins physically and functionally interact. We have recently created mutations within the MITF HLH region that no longer interact with PU.1, and further characterization of these mutations is ongoing.

Because MTIF and PU.1 interactions are necessary for differentiation of osteoclasts, we are interested in understanding extracellular signals that regulate the activity of these transcription factors. The receptor activator of NF-kB ligand (RANKL) is a member of the tumor necrosis factor family and provides an essential signal to osteoclast progenitors for their differentiation into osteoclasts. We have previously demonstrated that MITF is a target of RANKL/p38 MAPK pathway required for osteoclast differentiation. Our preliminary evidence indicates that PU.1 is also a target of the RANKL/p38 MAPK pathway in osteoclasts. We have mapped two potential p38 MAPK sites in the PEST region of PU.1. Currently we are studying the role of these phosphorylation sites in regulating PU.1 activity. Our results indicate that interactions between MITF and PU.1 are critical for osteoclast differentiation and that RANKL/p38 MAP kinase activity may modulate the activity of the MITF/PU.1 complex.

Reconstitution of DAP12 Expression Restores Osteoclast Multinucleation In Vitro. M. B. Humphrey[1], S. Spusta*[1], K. Ogasawara*[2], L. Lanier*[2], M. C. Nakamura[1]. [1]Dept. of Medicine, VA Medical Center and University of California, San Francisco, CA, USA, [2]Dept. of Microbiology and Immunology, University of California, San Francisco, CA, USA.

Deficiency of the signaling adapter protein DAP12 is associated with bony abnormalities in mice and humans. We and others have recently demonstrated that DAP12 deficient mice have increased bone mass and show abnormal osteoclast development in vitro. Under in vitro stimulation with M-CSF and RANK Ligand, DAP12 deficient osteoclast precursors form only mononuclear TRAP+ osteoclasts (OCs) able to resorb bone on dentine slices. Quantitative assessment of resorption on calcium phosphate discs shows that OCs derived in vitro from DAP12-/- mice resorb 3 fold less than those derived from C57BL/6 wild type mice.

To verify that lack of formation of in vitro multinucleated osteoclasts derived from DAP12 deficient mice is due to the absence of the DAP12 gene, we used retroviral transduction to express DAP12 in DAP12-/- osteoclast precursors. Retrovirus was generated using a PMX-pie vector cotransfected into 293T cells with a PCL-Ecotropic packaging plasmid. FLAG-tagged DAP12 cDNA was inserted in PMX-pie upstream of GFP cDNA located 3'of an IRES. Retroviral containing supernatants harvested at 48 hrs were used to spinoculate bone marrow macrophages cultured 24 hr in 20 ng/ml M-CSF. Retrovirus encoding FLAG-DAP12 and GFP or GFP alone (control) was used to transduce bone marrow macrophages isolated from DAP12 deficient mice. Following transduction, cells were treated with 10ng/ml M-CSF and 75ng/ml RANKL for 7-10 days. Efficiency of transduction by expression of GFP showed 30-50% transduction of cells at 7-10 days. DAP12-/- bone marrow macrophages transduced with control virus did not develop TRAP+ multinucleated osteoclasts following incubation with M-CSF and RANKL, instead developing only TRAP+ mononuclear OCs. Infection of DAP12-/- osteoclast precursors with DAP12 retrovirus led to formation of 17 +/- 2.4 multinucleated osteoclasts per well ($p<0.0001$). Thus expression of DAP12 in DAP12-/- osteoclast precursors restored formation of multinucleated osteoclasts.

Interestingly, DAP12-/- osteoclast precursors treated with extremely high amounts of M-CSF (100ng/ml) in combination with RANKL (100ng/ml) also formed multinucleated osteoclasts in vitro. Stimulation with extremely high levels of M-CSF was recently observed to rescue development of beta3 integrin -/- osteoclasts in vitro.

These findings verify a role for DAP12 in osteoclast multinucleation in vitro and suggest that DAP12 and M-CSF signal transduction pathways likely intersect and play overlapping roles during osteoclast formation.

Small GTP-binding Rab3D Modulates Intracellular Trafficking of a Subset of Post-TGN Vesicles Necessary for Osteoclastic Bone Resorption. M. H. Zheng[1], N. J. Pavlos*[1], J. Xu*[1], S. L. Teitelbaum[2], P. Rigby*[3], J. M. Papadimitriou*[4], F. P. Ross[2]. [1]Dept of Surgery and Pathology (Orthopaedics), University of Western Australia, Nedlands, Australia, [2]Department of Pathology, Washington University School of Medicine, St Louis, MO, USA, [3]Dept of Pharmacology, University of Western Australia, Nedlands, Australia, [4]Dept of Surgery and Pathology (Pathology), University of Western Australia, Nedlands, Australia.

Osteoclastic bone resorption is a highly dynamic process that requires the tight ordering of intracellular trafficking events in order to maintain the structural and functional polarization of the ruffled border and basolateral domains. Here we have identified the small Rab GTP-binding protein Rab3D as a putative regulator of secretory vesicle transport by a degenerative PCR-based approach. Using a combination of confocal immunofluorescence and time-lapse microscopy, Rab3D was found to localize and direct post-TGN vesicular transport and fusion events. Site direct mutagensis showed Rab3DQ81L mutant RAW264.7 precursor cells and derived osteoclasts displayed the enlargement and aggregation of Rab3D compartments in cytoplasm, where as Rab3DN135I mutant showed restricted Rab3D trafficking at the TGN and Rab3DΔCSC mutant displayed diffusely distribution of EYFP-signal in cytoplasm. Rab3DN135I mutant osteoclasts exhibited a typical defect of bone resorption capacity *in vitro*. Finally, we have shown that Rab3D knock out mice exhibit characteristics of osteosclerosis. The metaphyseal region in mice lacking Rab3D displays dense and irregular shaped trabecular bone. Histomorphometric analysis revealed that all of structure parameters of trabecular mass (BV/TV; Tb.N; Tb.Sp, ES) were significantly compromised in the Rab3D -/- mice. The volume of trabecular bone in Rab3D-/- mice was dramatically increased as compared to the wild type. In short, our results implicate a functional role for Rab3D in the early stages of post-TGN secretory vesicle transport in osteoclasts during bone resorption.

Regulation of Cytochrome c Oxidase Activity by c-Src in Osteoclasts. T. Miyazaki[1], L. Neff[2], S. Tanaka[1], W. C. Horne[2], R. Baron[2]. [1]Department of Orthopaedic Surgery, The University of Tokyo, Tokyo, Japan, [2]Department of Cell Biology and Orthopaedics, Yale University, New Haven, CT, USA.

The non-receptor tyrosine kinase c-Src, which is highly conserved throughout evolution and widely expressed, is a member of a family of nine protein-tyrosine kinases that associate with the cytoplasmic surface of cellular membranes. It is generally thought that Src's regulation of cell adhesion, movement and proliferation involves its activity as a plasma membrane-associated molecular switch that links a variety of extracellular cues to specific intracellular signaling pathways. c-Src has also been reported to be present on late endosomes in fibroblasts, synaptic vesicles in PC12 cells, secretory vesicles in chromaffin cells, vesicular structures in osteoclasts and the Golgi apparatus in CHO cells. However, the functions of c-Src on intracellular membranes still remain to be determined. Recently, Lyn, another Src family kinase, was found in rat brain mitochondria. To examine whether or not c-Src is also located in mitochondria, we performed immunoelectron microscopy. c-Src was located within mitochondria where it appeared to be associated with the inner membrane. In addition, we found that c-Src phosphorylated cytochrome c oxidase (Cox) using blue native 2D gel analysis. To examine the functional consequences of the tyrosine phosphorylation of

Cox by Src, we investigated whether or not Src kinase activity affected Cox activity. Cox activity was reduced in Src family tyrosine kinase-deficient fibroblasts and Cox activity was restored by c-Src reintroduction, suggesting that c-Src regulates Cox activity. To examine the physiological significance of the up-regulation of Cox by c-Src, we selected osteoclasts as a model system. Down-regulation of Src kinase activity by kinase-dead Src or wild type Csk overexpression inhibited Cox activity in osteoclasts, while up-regulation of Src kinase activity by kinase-dead Csk expression induced higher Cox activity. Furthermore, bone-resorbing activity of osteoclasts is impaired by down-regulating Cox activity by Cox subunit IV (CoxIV) antisense, as well as by c-Src deficiency. Increasing Src kinase activity by expressing kinase-dead Csk does not reverse the inhibitory effect of CoxIV antisense on bone resorption, suggeting that Cox is a downsteam effector of c-Src. These results place c-Src's function in a new context and suggest a novel link between c-Src and Cox.

Chk Controls Actin Organization and Bone Resorption through Regulating c-Src Activity in Osteoclasts. T. Matsubara*[1], F. Ikeda[1], K. Hata*[1], D. Tamura*[1], S. Tanaka[2], S. V. Reddy[3], G. Roodman[3], B. F. Boyce[4], G. R. Mundy[5], R. Nishimura[1], T. Yoneda[1]. [1]Osaka Univ, Osaka, Japan, [2]Facult Med, Univ Tokyo, Tokyo, Japan, [3]Cancer Inst, Univ Pittsburgh, Pittsburgh, PA, USA, [4]Univ Rochester Med Ctr, Rochester, NY, USA, [5]Univ TX Hlth Sci Ctr San Antonio, San Antonio, TX, USA.

Csk is a tyrosine kinase that selectively suppresses c-Src activity through phosphorylation of a tyrosine527 in the c-terminal portion of c-Src. Since Csk expression is ubiquitous but not osteoclast-specific and the phenotype of c-src-deficient mice indicates a specific role of c-src in osteoclast function, we hypothesized that osteoclasts had a unique Csk-like tyrosine kinase specifically regulating c-src activity and bone resorption in osteoclasts. Based on this hypothesis, we screened a cDNA library of human osteoclast-like cells and isolated a Csk homologue tyrosine kinase Chk. Western analysis demonstrated that Chk was restrictedly expressed in osteoclasts and brain, whereas Csk expression was observed in all tissues examined. Immunohistochemical examination showed that Chk was preferentially expressed in the ruffled borders in bone-resorbing osteoclasts in human bones. Biochemical studies showed that Chk phosphorylated tyrosine527 of c-Src and inhibited c-Src kinase activity. To further explore the interactions between Chk and c-Src in osteoclasts, we determined the subcellular localization of Chk and c-Src in TRAP-positive osteoclast-like cells that formed in spleen cells of wild-type (WT) or c-Src-deficient (src-/-) mice. In WT osteoclasts, Chk and c-Src were co-localized in the actin rings. In contrast, src-/- osteoclasts exhibited disrupted actin ring formation and diffuse Chk expression in the cytoplasm. Introduction of c-Src into src-/- osteoclasts using adenovirus system restored the actin ring formation and bone resorbing activity, indicating the importanceof c-Src in the regulation of actin organization and bone resorption. To investigate the role of Chk in the regulation of c-Src activity, actin organization and bone resorption, Chk was overexpressed in osteoclasts formed following the treatment with M-CSF and soluble RANKL in mouse spleen cells. We found that Chk overexpression profoundly disrupted actin ring formation and reduced c-Src activity. Moreover, an actin-binding protein vinculin that is normally localized in the actin ring dispersed in the cytoplasm following Chk overexpression. Most importantly, these cells demonstrated reduced bone resorption in the pit assays. In conclusion, our results suggest that Chk is a tyrosine kinase that is preferentially expressed in osteoclasts and inhibits the actin organization and bone resorption through negative-regulation of c-Src.

Regulation of Arp2/3 –WASp Complex Formation by Phosphoinositides in Osteoclasts. M. A. Chellaiah, R. S. Biswas. Department of OCBS, Dental School, University of Maryland, Baltimore, MD, USA.

Gelsolin is a critical protein in osteoclast podosome assembly. Transduction of mouse osteoclasts (OCs) with HIV-TAT peptides containing either full length gelsolin (FL-GSN) or phosphoinositide binding domains (PBDs) produced a dominant negative effect on actin ring organization, podosome assembly, and bone resorption of OCs. These OCs exhibited numerous podosome clusters in which each F-actin rich dot-like structure is larger than those observed in typical podosome structures. Translocation of podosome clusters to normal reorganization of podosomes at the clear zone area and formation of actin-ring was affected in these OCs. Also, the association of phosphoinositides (PIs) with the transduced gelsolin peptides containing PBDs affecting the function of PBDs in the endogenous gelsolin. Failure to form actin ring in these OCs may be due to decreased F-actin turnover, and increased PIs binding with the transduced peptides. Previously, we demonstrated transformation of podosome clusters to individual podosomes and translocation of these podosomes to the periphery in a time-dependent manner in OCs transduced with constitutively active, TAT-Rho^{Val14} (Chellaiah et al., 2000 JBC 275, 11993).

As an additional step to understand the molecular mechanisms on actin ring formation, we analyzed the effects of osteopontin (OPN) on PIs and Wiskott-Aldrich syndrome (WASp) protein distribution in mouse oseoclasts. WASp protein controls podosomes and dynamic actin-containing adhesion structures of primary human macrophages and actin ring formation in yeast cells. In osteoclasts, our observations have demonstrated colocalization of WASp with actin and PtdIns P2 (not PtdIns P3) in the actin ring structures of resorbing osteoclasts. Osteoclasts plated on glass coverslips exhibited colocalization of actin and WASp in podosomes as well as in the ring-like structure at the periphery. OPN stimulated PtdIns P2 and Arp3 association with WASp. Transduction of constitutively active Rho^{Val14} into OCs increases interactions of Arp2 or 3 protein and PtdIns P2 with WASp. The potent Rho inhibitor, C3 transferase decreased the OPN or Rho- induced cellular levels of PtdIns P2 as well as the Arp2/3-WASp complex formation, indicating that Rho regulates the synthesis of PtdIns P2. Moreover, transduction of OCs with TAT-PBDs of gelsolin decreased the association of PtdIns P2 with WASp as well as Arp2/3 interaction with WASp. Taken together, these results demonstrate that PIs and Rho GTPase are required for the WASp-Arp2/3 complex formation. Also, these observations identify the potential role of Arp2/3 and WASp complex in the signaling pathway that leads to OC actin ring formation.

p62 ^{ZIP} - A New Member of RANKL Signaling Pathway in Osteoclasts (OCL) Formation and a Novel Target for Treating Bone Metastasis. N. Kurihara[1], S. V. Reddy[1], L. A. Ehrlich*[1], N. Kawanabe[1], M. T. Daiz-Meco*[2], J. Moscat*[2], G. D. Roodman[1]. [1]University of Pittsburgh, Pittsburgh, PA, USA, [2]University Complutense, Madrid, Spain.

Osteolytic bone destruction is extremely common in multiple myeloma and breast cancer, and occurs in up to 60 to 80% of patients and plays a critical role in promoting tumor growth. In particular, the cytokine RANK ligand (RANKL) is upregulated in the bone microenvironment in response to tumor products (IL-1, IL-11, prostaglandin, PTHrP). Adhesive interactions between tumor cells and marrow stromal cells result in production of IL-6, and TNF-α by marrow stromal cells, which further enhance tumor cell growth and survival, chemoresistance, and bone destruction. Therefore, agents that inhibit OCL formation and block the effects of tumor-stromal cell interactions should have a major impact on both tumor growth and osteolytic bone destruction.

Recently, a new member of the RANKL signaling pathway, sequestasome-1 (also known as p62 or ZIP for ζPKC interacting protein), was identified and implicated in NF-κB activation by RANKL. p62^{ZIP} plays a critical role in NF-κB activation induced by TNF-α, CD40 and IL-1 through its interactions with the atypical protein kinases, ζPKC or λPKC. Thus p62^{ZIP} is involved in multiple signaling pathways that result in enhanced tumor cell survival and bone destruction. It is our hypothesis that inhibiting p62^{ZIP} expression or that of the atypical PKC's will profoundly diminish osteolytic bone destruction and tumor growth in patients with bone metastases by blocking the effects of RANKL and IL-6 produced in the tumor-bone microenvironment in response to TNF-α.

To test this hypothesis, we have examined the role of p62^{ZIP} in RANKL and TNF-α induced human OCL formation. A retroviral construct containing the p62^{ZIP} gene or empty vector was transfected into human OCL precursors and the effects of overexpressing p62^{ZIP} on OCL formation were examined. Western blot analysis confirmed overexpression of p62^{ZIP} in these cells**.** OCL formation was significantly increased in cultures of OCL precursors overexpressing p62^{ZIP} and treated with RANKL or TNF-α compared to cultures of empty vector transduced cells. Furthermore, OCL precursors overexpressing p62^{ZIP} formed OCL at very low concentrations of RANK (1ng/ml) or TNF-α (10pg/ml) which did not induce normal OCL. The OCL formed by precursors transfected with p62^{ZIP} were larger than normal OCL. Importantly, RANKL induced OCL formation was blocked by transduction of normal OCL precursors with a p62^{ZIP} antisense construct. These results show that p62 plays an important role in OCL formation and suggest that blocking p62 signaling should have a profound effect on OCL formation induced by tumors.

NFATc1 Is a Critical Trancription Factor for RANKL-induced Differentiation of Osteoclasts. S. Kim*[1], H. Takayanagi[2], T. Koga*[2], T. Taniguchi*[1]. [1]Department of Immunology, Graduate School of Medicine, University of Tokyo, Tokyo, Japan, [2]Department of Immunology, Graduate School of Medicine, University of Tokyo. PRESTO, Japan Science and Technology Corporation, Tokyo, Japan.

Receptor activator of NF-kB ligand (RANKL) is a key cytokine to induce the differentiation of osteoclast precursors into osteoclasts. The binding of RANKL to its receptor RANK induces the activation of various downstream molecules such as NF-kB and AP-1. Although other cytokines such as interleukin-1 (IL-1) also activate similar signal cascades, RANKL specifically induces the osteoclast differentiation.

We performed a genome-wide screening of RANKL-inducible genes using gene chip analysis. Nuclear factor of activated T cells c1 (NFATc1) was the most strongly induced transcription factor by RANKL. We confirmed the induction of mRNA and protein of NFATc1 by RANKL with northern blot analysis and immunofluorescence staining, respectively. We also examined the localization of NFATc1 protein in vivo and showed that it colocalized with osteoclasts stained for TRAP or cathepsin K. The activation and induction mechanism of NFATc1 has been well studied in T lymphocytes: Calcium signal induces the activation of calcineurin and calcineurin induces the dephosphorylation of NFATc1, resulting in its nuclear localization. Interestingly, we found out that the RANKL signal, but not the IL-1 signal, induces calcium influx in osteoclast precursors and the addition of BAPTA-AM, calcium specific chelator, strongly inhibits the induction of NFATc1 in mRNA level and blocks osteoclast differentiation. The osteoclast differentiation was also blocked by calcineurin inhibitors such as cyclosporinA and FK506. By using TRAF6- or Fos-deficient mice, we examined the induction mechanism of NFATc1. RANKL-induced NFATc1 expression was impaired in both mutant mice, suggesting that TRAF6 and c-Fos are involved in the induction of NFATc1. We also examined the activation of TRAP promoter by NFATc1. Using a reporter assay, we identified TRAP and calcitonin receptor genes as direct transcriptional targets of NFATc1, and revealed that c-Fos is one of the functional partners of NFATc1. Because NFATc1-deficient mice are embryonic lethal, we established an osteoclast formation system of embryonic stem cells (ES cells). NFATc1-deficient ES cells could not differentiate into osteoclasts while wild type cells differentiated into osteoclasts. Furthermore, overexpression of NFATc1 in the osteoclast precursors induced osteoclast differentiation without addition of RANKL. These results strongly suggest that NFATc1 is an essential transcription factor that integrates RANKL signaling for terminal differentiation of osteoclasts.

The Enzymatic Activity of a Unique Osteoclastic Protein-Tyrosine Phosphatase (PTP-oc) Is Essential for Activation of Osteoclast-Like Cells: Evidence for Activation via the c-src/NFκB Pathway. K. H. W. Lau[1], M. Amoui*[1], S. M. Suhr[2], D. J. Baylink[1]. [1]Musculoskeletal Disease Center, Jerry L. Pettis Mem VAMC, Loma Linda, CA, USA, [2]Biochemistry, Yonsei University, Seoul, Republic of Korea.

Our previous antisense studies have indicated that a structurally unique osteoclastic PTP, PTP-oc, has an essential role in osteoclast activity. This study investigated if the enzymatic activity of PTP-oc is required for osteoclast activation by determining the effects of overexpression of wild type (wt) and the inactive, dominant negative (dn) PTP-oc on bone resorption activity of osteoclast-like cells derived from two cell lines of osteoclast lineage (RAW264.7 and U937 cells). Several RAW264.7 and U937 stable clones overexpressing wt or dn PTP-oc were produced with our newly developed transposon-based pPC gene transfer vector. Each of the clones showed 4- to 6-fold overexpression of either wt or dn PTP-oc. The bone resorption activity of "osteoclast-like" cells derived from RAW264.7 clones overexpressing wt PTP-oc was significantly ($p<0.01$) greater by 2- to 3-fold, while that of "osteoclast-like" cells from RAW264.7 clones overexpressing dn PTP-oc was lower (by >50%, $p<0.05$) than that of "osteoclast-like" cells derived from control clones. Similar results were obtained with U937 clones. These findings are consistent with the interpretation that the enzymatic activity of PTP-oc is essential for osteoclast resorption. To determine the mechanism whereby PTP-oc activates osteoclast resorption, we determined the c-src activation [assessed by the decrease in tyr-527 phosphorylation level (PY-527)] and NFκB activation (monitored by IκBα degradation and NFκB nuclear translocation) in each clone, since activation of c-src and NFκB are each essential for osteoclast activation. RAW264.7 and U937 cell clones overexpressing wt PTP-oc each showed greater c-src activation (75% decrease in PY-527, $p<0.01$) and NFκB activation (70% decrease in cellular IκBα level and 2- to 3-fold increase in nuclear NFκB level, $p<0.01$ for each), whereas cells stably overexpressing dn PTP-oc had lower c-src activation (30% increase in PY-527, $p<0.05$) and NFκB activation (25% increase in cellular IκBα level and 75% decrease in nuclear NFκB level, $p<0.05$ for each) compared with corresponding control cells. The c-src activation ($r = -0.998$, $p<0.001$) and NFκB activation ($r = 0.989$, $p<0.05$) each correlated with the bone resorption activity of the "osteoclast-like" cells derived from these cell clones. In conclusion, we demonstrated for the first time that, 1) the PTP-oc enzymatic activity is essential for osteoclast activity, and 2) the PTP-oc-mediated osteoclast activation is mediated in part by activation of c-src and/or NFκB.

An Animal Model for the Isolation of Mammalian Osteocytes using a Membrane-Bound Enzyme, which in Bone Is Specifically Expressed in Osteocytes. K. E. de Rooij[1], E. de Wilt*[1], M. M. L. Deckers*[1], M. C. de Ruiter*[2], I. Que*[1], S. E. Papapoulos[1], C. W. G. Lowik[1]. [1]Endocrinology, Leiden University Medical Center, Leiden, Netherlands, [2]Anatomy, Leiden University Medical Center, Leiden, Netherlands.

Osteocytes are the most abundant cells in bone, which implies an important role for osteocytes in bone homeostasis. It has been generally accepted that osteocytes act as sensors of mechanical loading of the bone and convey these signals to the osteoblasts and osteoclasts to remodel the bone. At present, it is not known how osteocytes fulfil their mechanosensing function or which other functions they may perform in bone homeostasis. This is mainly due to the fact that osteocytes are very difficult to isolate from their surrounding matrix. In addition, little is known about the differentiation of osteocytes from osteoblasts.

In this study, we describe the identification of a membrane-bound protein that, within bone, is exclusively expressed in osteocytes. This protein is an enzyme involved in cell-cell interactions and belongs to a large family of receptor-like proteins. We have obtained transgenic mice in which one exon of this protein is replaced by the ß-galactosidase (LacZ) gene. Deficiency of the protein does not result in an aberrant phenotype in these mice. Long bones and calvariae of these transgenic mice were isolated and analyzed for ß-galactosidase activity by staining with X-gal. Histologic analysis showed that only osteocytes exhibit ß-galactosidase activity. The blue staining was present throughout the cells and the cellular processes could easily be distinguished.

To investigate the possibility of generating osteocytes *in vitro*, bone marrow cells of the transgenic mice were cultured under osteogenic conditions. After 21-28 days, blue stained cells could be observed associated with nodules and the number of LacZ positive cells could be increased by the addition of BMPs to the culture medium. Histologic analysis revealed that all positive cells were surrounded by extracellular matrix and cellular processes could be observed.

In conclusion, these mice represent an excellent model for the investigation of osteocyte biology. The formation of osteocytes *in vitro*, and the effect of different compounds on this process, can easily be monitored by analysis of LacZ activity by either staining with X-gal or enzymatic assays. Since the protein is present on the membrane, antibodies raised against this protein could provide the first tool for the isolation of mammalian osteocytes, allowing us to study differences in gene expression between osteocytes and osteoblasts. This will generate information on the specific properties of osteocytes and improve our knowledge about their function(s).

The Accuracy of Historical Height Loss for Detection of Prevalent Vertebral Fractures. K. Siminoski[1], K. Lee*[2], H. Jen*[2], R. Warshawski*[2]. [1]Radiology and Internal Medicine, University of Alberta, Edmonton, AB, Canada, [2]Radiology, University of Alberta, Edmonton, AB, Canada.

We have evaluated the accuracy of using historical height loss (HHL) to detect the presence of vertebral fractures. Subjects were women referred for specialist assessment of osteoporosis (n = 480; average age 56 yrs; range: 18 - 92 years). HHL was determined as the difference between the tallest recalled height and current height as measured using a stadiometer. Vertebral morphometry was performed from T4 to L4. Prevalent vertebral fracture was defined as a vertebral height ratio <0.80. One or more fractures were present in 34.3%; the average number of fractures among those with fractures was 2.3

Historical height loss was correlated with the number of vertebral fractures ($r = 0.53$; $p<0.001$). Height decreased by 1.2 cm per fracture; after adjustment for age and tallest recalled height, height loss per fracture was 1.0 cm ($r = 0.647$, $p < 0.0001$). In a multivariable model, adjusted height loss (adjusted for age and tallest recalled height) was 0.82 cm per thoracic fracture and 1.32 cm per lumbar fracture ($r = 0.66$, $p<0.0001$) .

The area under the receiver operating characteristic curve for the ability of HHL to detect vertebral fractures was 0.69 (95% confidence interval, 0.64-0.74; $p<0.001$). The risk of fracture increased substantially only when HHL >6 cm while the risk of fracture was reduced when HHL <2 cm. The odds ratio (shown in the first table) rose from 1 for HHL = none (likelihood ratio 0.5) to 20.7 when HHL >6 cm (likelihood ratio 10.5). Accuracy results are shown in the second table.

The following applications can be made from this data: HHL <2 cm rules out the presence of vertebral fracture with moderate accuracy. HHL >6 cm rules in the presence of vertebral fracture with moderate accuracy. This approach will correctly classify 54% of subjects; incorrectly classify 21% (mostly single low-grade fractures that are false negatives); and leave 25% unclassified.

Likelihood and Odds Ratios

Height Loss (cm)	Likelihood Ratio	Odds Ratio
None	0.5	1.0
0-2	0.5	1.0
2-4	1.5	3.0
4-6	1.1	2.2
6-8	4.8	9.4
>8	10.5	20.7

Historical Height Loss (HHL) Accuracy

Height Loss (cm)	Sensitivity	Specificity	PPV	NPV
None	100	0	34	INF
>0	87	25	38	79
>2	65	68	51	79
>4	37	86	58	72
>6	26	96	78	71
>8	13	99	85	69

Postmenopausal Bilateral Oophorectomy and Hip Fractures in Older Women. D. M. Antoniucci*[1], D. E. Sellmeyer*[1], J. A. Cauley[2], K. E. Ensrud[3], J. L. Schneider*[1], S. R. Cummings[4], L. J. Melton[5]. [1]University of California, San Francisco, CA, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]University of Minnesota, Minneapolis, MN, USA, [4]Coordinating Center and California Pacific Research Institute, San Francisco, CA, USA, [5]Mayo Clinic, Rochester, MN, USA.

Bilateral oophorectomy after natural menopause has been associated with an increased risk of osteoporotic fractures, raising questions about the advisability of incidental oophorectomy in older women. It has been postulated that the increased fracture risk is explained by a decline in serum estradiol and testosterone levels following the oophorectomy. We tested this hypothesis in a prospective study of a community-based cohort of 9704 Caucasian women aged 65 years or older (Study of Osteoporotic Fractures): we randomly selected 89 cases of hip fracture, 138 cases of new morphometric vertebral fracture and 247 controls. Serum samples collected at baseline were assayed for estradiol and free testosterone. There were no significant differences at baseline in age (72.8±5.6 vs. 72.9±5.5 years, p=0.9) or weight (64.2±10.8 vs. 65.8±13.2 kgs, p=0.40) between the women who underwent postmenopausal oophorectomy (n=51) and those who did not (n=423). Excluding the women on estrogen, total estradiol levels did not differ significantly in the two groups (0.59±0.3 vs. 0.66±0.3 pg/ml, p=0.23), but free testosterone levels were lower in the women who underwent oophorectomy than in those who did not (1.48±1.4 vs. 2.12±1.6 pg/ml, $p<0.001$). All analyses were adjusted for age and weight, and women on estrogen therapy were excluded. In a Cox-proportional hazards analysis that took account of the case cohort design, a history of postmenopausal oophorectomy was associated with an increased risk of hip fracture (HR=2.6; 95% CI=1.3–5.1), but not vertebral fracture (HR=1.1; 95% CI=0.3–5.1). The relationship between oophorectomy and hip fracture was not altered by adding serum estradiol level (HR=2.5; 95% CI=1.2–4.9), serum

free testosterone level (HR=2.7; 95% CI=1.3–5.4), or both (HR=2.6; 95% CI=1.3-5.3) to the model. These data confirm that postmenopausal oophorectomy is associated with an increased risk of hip fracture. In fact, postmenopausal oophorectomy had a larger effect in this cohort than surgical menopause prior to age 48 (HR=1.6; 95%CI=0.6-4.5). Importantly, the increased risk of hip fracture is not explained by decreases in estradiol or testosterone levels. Even though the mechanism by which oophorectomy after menopause increases the risk of hip fracture has not yet been fully elucidated, these findings suggest that incidental oophorectomy after menopause may not be innocuous, and should be considered carefully in each potential patient.

Disclosures: ***D.M. Antoniucci****, None.*

F288

One-Third of Osteoporotic Women Without Fractures will Experience Vertebral Fractures after Five Years if Untreated. R. Lindsay[1], S. Pack*[2], Z. Li*[3]. [1]Helen Hayes Hospital, West Haverstraw, NY, USA, [2]Procter & Gamble Pharmaceuticals, Egham, United Kingdom, [3]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

Vertebral fractures are a risk factor for further vertebral and nonvertebral fractures and 1–in–5 women will experience further vertebral fractures in the year following a vertebral fracture. Our objective was to complement this analysis by investigating longitudinal changes in a population of osteoporotic women who are initially fracture–free, modelling the fracture prevalence over time.

We estimate the 1–year risks of patients having increased numbers of vertebral fractures. We do this separately for different numbers of existing fractures to generate a matrix of risk estimates. Women were selected from the placebo arms of the risedronate fracture trials (VERT–MN, VERT–NA, HIP) with lumbar spine or femoral neck BMD T–score <-2.5 or prevalent vertebral fractures. A total of 2326 women met these criteria with a mean age of 73 years and 70% vertebral fracture prevalence. Mean lumbar spine and femoral neck T–scores were –2.7 and –2.6 respectively. Women received calcium and vitamin–D for up to 3 years. Using the 1–year risk estimates, we use a simple Markov model to model over time a hypothetical population of osteoporotic women, initially without vertebral fractures. Repeated application of the yearly risks simulates how the prevalence of fractures increases annually. Confidence intervals for the 5– and 10–year prevalence estimates were obtained using bootstrap computations.

If left untreated (only calcium and vitamin–D), after 1 year 8% (CI:6,10) of a population meeting the selection criteria would be expected to have one or more vertebral fractures, i.e. a 1–in–13 risk. After 5 years 33% (CI:25,41) will have vertebral fractures and 11% (CI:8,16) will have two or more. After 10 years the prevalence estimates are 55% (CI:44,65) and 29% (CI:22,37) respectively. Sensitivity analysis shows that the first fracture risk is highly influential and each 1% reduction in absolute risk translates to approximately a 4% reduction in 5–year prevalence. Correspondingly, a therapeutic agent reducing the 1–year relative risk by 75% would cut the 5–year prevalence estimate to 10%.Fracture, and multiple fracture, prevalence rapidly increases over time if an osteoporotic population is untreated. Treating to prevent the first fracture significantly reduces the future burden of the disease.

Effectiveness of Vertebral Morphometry Using DXA to Detect Prevalent Osteoporotic Vertebral Fracture. R. D. Chapurlat, F. Duboeuf*, O. H. Marion-Audibert*, P. D. Delmas. INSERM U403, Lyon, France.

Vertebral morphometry, which can be performed along with the BMD measurement using newest DXA machines, might save the time and cost of making radiographs to detect vertebral deformities. Diagnostic effectiveness of DXA morphometry compared to simple radiographs, however, has not been established so far.

We have performed vertebral morphometry using a Hologic Delphi machine (Instant Vertebral Assessment [IVA]) in 56 patients (30 ambulatory patients with a T score < -2.5 and 26 inpatients admitted for osteoporotic vertebral fracture) to detect prevalent vertebral deformities. Spine xrays were also made, as the gold standard for diagnosis of vertebral fracture. Both IVAs and xrays were read by 2 experts, without knowledge of results of the other technique, using the Genant semi-quantitative method. Discrepancies between readers were solved by consensus. First, we examined precision of vertebral deformity evaluation by calculating the agreement (kappa scores) between the 2 readers for reading of IVAs and xrays, and second, sensitivity and specificity of IVA for the diagnosis of vertebral deformity.

We identified 60 vertebral deformities by xrays in those 56 patients. Discrepancies between readers were greater with xrays for vertebrae T11 and above, whereas with IVA, frequency of discrepancies increased for T8 and above. With IVA, kappas varied from vertebra to vertebra, ranging from 1.00 to 0.41 for lumbar vertebrae, and from 0.84 to 0.31 for thoracic vertebrae. With xrays, kappas also varied with vertebrae, ranging from 1.00 to 0.85 for lumbar vertebrae, and from 0.76 to 0.31 for thoracic vertebrae. The agreement between the 2 techniques was good from L4 to T12 (kappas ranging from 0.79 to 0.65), whereas it was moderate or poor for other vertebrae (kappa ranging from 0.85 to 0.18 for T11 to T4). The mean sensitivity of the IVA assessment to detect vertebral deformities established using xray reading was 71% for lumbar vertebrae, 66% for thoracic vertebrae from T12 to T8 and 77% from T9 to 5. Specificity of the IVA reading to detect vertebral deformities was excellent, ranging from 97% for lumbar vertebrae to 96% for thoracic vertebrae from T12 to T8, and 93% for thoracic vertebrae from T7 to T5.

We conclude that when diagnostic accuracy of vertebral deformities is poor using xrays (for higher thoracic vertebrae), accuracy and precision of IVA parallel. Compared to xray assessment of vertebral deformities, IVA allows few false positives and a sizeable proportion of false negatives.

Bone Mineral Density and Fracture Risk in Subjects with Type 2 Diabetes Mellitus: the Rotterdam Study. I. I. de Liefde*[1], M. van der Klift*[1], C. E. D. de Laet*[2], P. L. A. van Daele*[1], A. Hofman*[2], H. A. P. Pols[1]. [1]Department of Internal Medicine, Erasmus MC, Rotterdam, Netherlands, [2]Department of Epidemiology & Biostatistics, Erasmus MC, Rotterdam, Netherlands.

Previous studies show conflicting results concerning the association between type 2 diabetes mellitus, bone mineral density (BMD) and fracture risk. Therefore, we looked into this association in participants of the Rotterdam Study, a large prospective population-based cohort study of 7983 men and women aged 55 years or older.

At baseline, between 1990 and 1993, blood samples were drawn both before and after a non-fasting glucose tolerance test. Subjects were classified as diabetics if they used anti-diabetic medication or when the pre- or post load serum glucose level was 11.1 mmol/L or more. Subjects reporting onset of diabetes at or before age 30 years (type 1 diabetes mellitus) were excluded from the analyses. BMD was measured using DEXA at both the femoral neck and lumbar spine. Follow-up of non-vertebral fractures occurred through an automated record system involving GP's and local hospitals. Two trained research physicians independently verified all reported fractures.

Complete baseline and follow-up data were available for 6650 individuals, including 792 subjects with diabetes. During follow-up (6.5 years on average), 771 subjects suffered at least one non-vertebral fracture. Adjusting for age, diabetics had a significantly higher BMD, both at the femoral neck and the lumbar spine, compared to non-diabetics (0.86 vs. 0.83 g/cm^2 and 1.12 vs. 1.09 g/cm^2, respectively). This remained unchanged after additional adjustment for other confounders. However, diabetics had an increased risk of non-vertebral fractures, both crude and after adjustment for age, gender, BMI, smoking, falling, visual site, renal function, lower limb disability, use of diuretics, and femoral neck BMD (HR 1.4 (95% CI 1.0-1.8)). For hip and wrist fractures, a similar but non-significant trend was observed. We repeated the analysis separately for diabetics treated with anti-diabetic medication before baseline and for newly diagnosed diabetics. The increased fracture risk was restricted to treated diabetics, with a significantly increased risk for non-vertebral and wrist fractures (HR 1.7 (1.2-2.5) and 2.1 (1.1-4.2) respectively), independent of potential confounders and BMD.

The results of this study show that subjects with type 2 diabetes mellitus have a higher BMD. However, especially those subjects with anti-diabetic medication, have an increased fracture risk compared to non-diabetics, suggesting that, independently of BMD, other factors such as polyneuropathy and general co-morbidity play an important role in the increased fracture risk.

Biochemical Markers of Bone Turnover Predict both Non-vertebral and Vertebral Fractures. J. Finigan, D. M. Greenfield*, A. Blumsohn, R. A. Hannon, R. Eastell. Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom.

Biochemical markers of bone turnover have been shown, although not consistently, to have predictive value for fractures. We carried out a 10-year prospective study of a population-based group of women who were ages 50 to 85 years. At baseline we measured hip and spine bone mineral density (BMD) and markers of bone turnover: pyridinoline (PYD), deoxypyridinoline (DPD), N- and C-telopeptides of type I collagen (NTX, CTX), bone alkaline phosphatase (BAP, iBAP) and procollagen type I C-terminal propeptide (PICP), with urine markers corrected for creatinine. Incident vertebral fractures were determined by visual reading by a single radiologist of spinal radiographs at 0, 2, 5, 7 and 10 years, and non-vertebral fractures were confirmed by radiologist reports. The table shows the relative risks (RR) of fracture per standard deviation (log transformed) using a Cox Regression Model, based on time to first fracture.

Marker of bone turnover	Non-vertebral fracture (n=70) RR (95% CI)	Vertebral fracture (n=29) RR (95% CI)
PYD / Cr	1.47 (1.16, 1.86) ***	1.65 (1.16, 2.35) **
CTX	1.31 (0.98, 1.74) ^	1.88 (1.11, 3.18) **
DPD / Cr	1.30 (1.01, 1.67) *	NS
BAP	1.26 (1.01, 1.59) *	NS
iBAP	1.34 (1.04, 1.73) *	NS
PICP	NS	1.38 (0.95, 2.00) *
NTX / Cr	NS	1.70 (1.10, 2.60) *

* p<0.05, ** p<0.01, *** p<0.001, ^ p=0.052

PYD/Cr remained significant for both types of fracture when entered into multivariate analyses with BMD or age, while CTX remained significant for vertebral fractures only. With age only, DPD/Cr still predicted non-vertebral, and NTX/Cr predicted vertebral fractures.

The relative risks of extremity fractures (hands, feet and skull) for each of the markers are shown below.

Marker of bone turnover	Extremity fracture (n=22) RR (95% CI)
PYD / Cr	1.91 (1.26, 2.89) ***
DPD / Cr	1.61 (1.04, 2.50) *
BAP	1.59 (1.06, 2.38) **
iBAP	1.95 (1.24, 3.06) ***

Only PYD/Cr consistently predicts all types of fracture, independently of age and BMD. Some markers predict fractures of the hands, feet and skull at least as strongly as they predict non-vertebral fractures as a whole.

Disclosures: ***J. Finigan****, None.*

F295

Frailty, Debility and Poor Health Predict Vertebral Fractures but Not Non-vertebral Fractures. J. Finigan, D. M. Greenfield*, A. Blumsohn, R. A. Hannon, N. F. A. Peel*, R. Eastell. Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom.

Many risk factors predict fractures overall, but it is less clear whether certain factors are specific to vertebral fractures. We carried out a 10-year prospective study of a population-based group of women who were ages 50 to 85 years. At baseline we measured bone mineral density (BMD) by dual-energy x-ray absorptiometry and collected fasting blood samples and 24-hour urine for biochemical measurements including serum calcium, alkaline phosphatase, parathyroid hormone, creatinine, phosphate, albumin and thyroid hormones, and urine calcium and creatinine. Medical and lifestyle data were obtained by standardized questionnaire. Incident vertebral fractures were determined by visual reading by a single radiologist of spinal radiographs at 0, 2, 5, 7 and 10 years, and non-vertebral fractures were confirmed by radiologist reports.

Risk factors that predicted both types of fracture included age, BMD at the lumbar spine, hip or total body, years of estrogen exposure and prevalent vertebral fracture. Relative risks (RR) that predicted vertebral fracture only, using a Cox Regression Model and survival time to first fracture, are shown in the table.

Risk factor	RR (95% CI) of Vertebral Fracture (n=29)
Height **	1.73 (1.20, 2.51) per SD reduction
Weight *	1.60 (1.02, 2.50) per SD reduction
Body fat (g) *	1.56 (1.02, 1.39) per SD reduction
Heavy smoking ^	2.30 (0.97, 5.41) upper quartile of pack-years v non-smokers
S calcium *	1.71 (1.12, 2.60) per SD reduction
S albumin ***	2.04 (1.33, 3.13) per SD reduction
S total T3 ***	1.88 (1.34, 2.64) per SD reduction
Grip strength **	2.78 (1.31, 5.92) lower quartile v the rest
Limited ability to:	
Carry a suitcase **	1.89 (1.22, 2.92) per difficulty level 1 - 3
Stand in a queue *	1.76 (1.07, 2.90) per level
Run for a bus **	2.46 (1.36, 4.45) per level

* p<0.05, ** p<0.01, ***p<0.001, ^ p=0.057

Serum albumin and T3, and self-reported ability to run for a bus, remained significant when entered into multivariate analyses with either lumbar spine or hip BMD or with age. When combined with age only, both heavy smoking and body fat were still at or close to significance.

Low levels of T3 and of albumin are each associated with sickness and chronic poor health. We conclude that overall frailty, which may comprise general poor health, small or thin body size and lack of strength and physical capability, predicts vertebral fractures but does not predict non-vertebral fractures.

F296

Relative Importance of BMD, Markers of Bone Turnover, Height and Body Weight as Predictors of Hip Fracture – A Prospective Case-Control Study. E. McCloskey[1], T. Jalava*[2], S. Vasireddy*[1], S. Bal[1], M. Beneton*[1], D. Charlesworth*[1], J. Kanis[1], A. Blumsohn[1]. [1]University of Sheffield, Sheffield, United Kingdom, [2]Schering Oy, Helsinki, Finland.

While it is accepted that combinations of risk factors are useful to identify patients at high risk of fracture, the role of biochemical markers alone or combined with BMD remains undefined. The aim of this study was to compare the ability of total hip BMD and biochemical markers to predict incident hip fracture in a large prospective case control study.

The study cohort comprised 5212 women aged 75 years or older (mean 80 years, range 75-100) enrolled to a double-blind placebo-controlled study of the bisphosphonate, clodronate (Bonefos®). Baseline BMD at the total hip was measured by DXA (Hologic QDR4500). Fasting serum was collected at entry between 9am and 1130am and was stored at -40C until analysis. In a case control analysis, baseline values of hip BMD, serum bone-specific alkaline phosphatase (Bone ALP, Beckman Ostase) and serum C-telopeptide of type I collagen (sβCTX, Roche Elecsys) were evaluated in 157 women who sustained incident hip fractures and in 544 randomly selected controls who remained free of hip fracture during a median follow-up of 4 years.

Cases with hip fracture had significantly lower hip BMD and higher sβCTX than controls, whereas serum BsALP was similar in the two groups. In univariate logistic regression analysis, the odds for hip fracture per 1SD increase in sβCTX was 1.3 (95%CI 1.1-1.5, P=0.01) while a decrease in hip BMD of 1SD demonstrated a larger gradient of risk (OR 2.5, CI 2.0-3.1, P<0.0001). Body weight alone was predictive of fracture (OR 1.85 per 1SD decrease, CI 1.48-2.32; P<0.001). Adjusting for treatment with clodronate did not influence results. Total hip BMD remained a significant predictor of hip fracture following adjustment for clinical predictors including age, height and body weight (OR 2.1, CI 1.6-2.6, P<0.0001). However, prediction of hip fracture by sβCTX was not independent of these clinical predictors (OR 1.1, CI 0.9-1.4, P=0.31) and was reduced still further following adjustment for hip BMD (OR 1.0, CI 0.8-1.2, P=0.63).

We conclude that these markers of bone turnover have limited incremental utility for prediction of hip fractures in an elderly female population. βCTX is predictive of fracture, but is not independent of age, body weight or hip BMD. Reduced body weight is an important predictor of hip fracture.

The Incidence of Hip and Colles' Fractures Correspond to Seasonal Changes in Serum Vitamin D and Parathyroid Hormone. J. A. Pasco*[1], M. J. Henry*[1], M. A. Kotowicz[1], K. M. Sanders*[1], E. Seeman[2], H. G. Schneider[3], G. C. Nicholson[1]. [1]Clinical & Biomedical Sciences: Barwon Health, The University of Melbourne, Geelong, Australia, [2]Medicine, The University of Melbourne, Melbourne, Australia, [3]Biochemistry, The Alfred Hospital, Melbourne, Australia.

Vitamin D insufficiency and secondary hyperparathyroidism are risk factors for fractures in institutionalized elderly populations. The aim of this study was to determine whether vitamin D insufficiency contributes to the population burden of fractures. Annual periodicities of fractures, circulating 25-hydroxyvitamin D (25OHD), parathyroid hormone (PTH), bone resorption markers (C-terminal telopeptide, CTx) and UV radiation were measured as part of the Geelong Osteoporosis Study, a population-based study set in south-eastern Australia (latitude 38-39S). Fractures were ascertained prospectively during three years using radiographs from the two radiological practices servicing a community of 27,203 women aged 55 years and over.

Cyclic variations in serum 25OHD lagged one month behind variations in UV radiation, with a peak following mid-summer and nadir following mid-winter (p<0.001). Periodicity of serum PTH was the inverse of serum 25OHD, with a phase shift of +1 month (p=0.058). The peak in serum CTx followed 1-2 months after the peak in serum PTH. Seasonal periodicity amongst 439 hip fractures and 307 Colles' fractures followed a simple harmonic model (p=0.078, 0.002, respectively) with the peak frequency occurring 0.5-2 months after peak serum PTH and about 1.5-3 months after the nadir in serum 25OHD. Periodicity of Colles' fractures and CTx were coincident.

The fall in serum vitamin D during winter is accompanied by secondary hyperparathyroidism, an increase in bone resorption markers and an increased frequency of hip and Colles' fractures. Whether vitamin D supplementation during winter will reduce the population burden of fractures requires investigation.

Circulating Levels of Cytokine Soluble Receptors Predict Incident Fractures in Older Men and Women: The Health Aging and Body Composition Study (HABC). J. A. Cauley[1], J. M. Zmuda[1], A. B. Newman*[1], M. Pahor*[2], F. Tylavsky*[3], S. R. Cummings[4], T. Harris*[5]. [1]U of Pitt, Pittsburgh, PA, USA, [2]Wake Forest U, Winston Salem, NC, USA, [3]U of Tenn, Memphis, TN, USA, [4]UCSF, San Francisco, CA, USA, [5]NIA, Bethesda, MD, USA.

Cytokines play major roles in regulating bone remodeling in the bone microenvironment. Nevertheless, the relationship of circulating levels to fracture is uncertain. In the current analysis, we tested the hypothesis that greater concentrations of interleukin-6 (IL-6), tumor necrosis factor (TNF-α) IL-2-soluble receptor (sR), IL-6-sR, TNF sR1 and TNF sR2 are related to an increased risk of fracture. The study population included 2,971 well-functioning white and black women and men (42%, black; 51%, women) age 70-79 enrolled in HABC. Cytokines were measured in frozen plasma samples using standard protocols. Cytokine soluble receptors were measured in a subset (n=1430). Total hip BMD was measured at baseline and 4 years later with DXA (Hologic 4500A). During 3.9 years of 97% complete follow-up, we validated 156 non-traumatic fractures. We compared the top quartile of cytokine vs. the lower 3. Analyses were adjusted for race, gender, age, BMI, smoking, NSAIDS use, baseline BMD, health status and comorbidity. The Relative Risk (RR) of fracture was about 60-70% increased in subjects with the greatest cytokine soluble receptor levels compared to subjects with lower levels (Table). There was no association with IL-6 or TNF-α.

Table: RR of Fracture: Top Quartile of Cytokine vs. the lower 3.

Cytokine (pg/ml)	**RR**	**(95% CI)**
IL-6 (>2.78)	1.27	(0.68, 1.88)
()TNF-α >4.11)	1.20	(0.83, 1.74)
TNF sR1 (>1792)	1.64	(1.00, 2.67)
TNF sR2 (>4021)	1.76	(1.09, 2.85)
IL-6sR (>41,989)	1.66	(1.02, 2.70)
IL-2sR (>1,648)	1.79	(1.12, 2.85)

Of interest, the average annual percent loss in total hip BMD was greater among subjects with the highest IL-2sR levels (-0.48 %/yr) compared to lower levels (-0.30 %/yr) (p=0.0009). Similar results were observed for the other cytokine soluble receptors.

In conclusion, higher cytokine soluble receptors levels may identify subjects with an increased rate of bone loss and increased risk of fracture. The underlying mechanism is unknown but could reflect influences on bone turnover.

Ten Year Fracture Prediction using QUS and Axial BMD Measurements in Peri-Menopausal Women: BUA Predicts Wrist Fractures Independently of BMD. A. Stewart*, D. M. Reid. Osteoporosis Research Unit, University of Aberdeen, Aberdeen, United Kingdom.

Quantitative ultrasound (QUS) has been shown to be predictive of fracture in the elderly, but few studies have measured women around the time of the menopause. The Aberdeen Prospective Osteoporosis Screening Study (APOSS) is a longitudinal study of bone mass studied throughout the peri-menopausal years. Initially over 5000 women aged 45 to 54 years were scanned using spine and hip DXA (Norland XR-26 scanner) and in a cohort of 1000 also by QUS (Walker Sonix 575, measuring broadband ultrasound attenuation (BUA) only). These women have now been followed up for over 10 years (mean = 10.9 yrs, SD 0.3 yrs) and incident fractures identified and validated. In the QUS cohort (n=1000) we have fracture data on 636 women. Of these 61 have had a validated fracture, while 23 indicated a fracture but these have not been been confirmed as yet. The remaining 552 women did not indicate an incident fracture. The fractures were mostly of the wrist (n = 14) and ankle (n = 15), with other fracture sites including rib (n = 3), foot/toes (n = 7), hands/fingers (n = 9) and miscellaneous (n = 13). Cox Regression Model was used to calculate relative risks (RR) with time to fracture/follow-up being the time dependent variable. All variables used were baseline measurements. Using BUA measurements the unadjusted RR is 1.37 (95%CI 1.06-1.76) for 1 SD change in BUA. When adjusted for age, height, weight and menopausal status the RR is 1.39 (1.08-1.79). However when also adjusting for neck BMD the RR is no longer significant (RR = 1.32, 95% CI 0.99-1.76). To compare with DXA measurements the RR (adjusted for age, height, weight and menopausal status) in this cohort for 1 SD is 1.64 (95%CI 1.22-2.21) for spine BMD and 1.38 (95%CI 1.03-1.84) for neck. BMD. If we just look at the wrist fractures (i.e. osteoporotic site) the unadjusted RR is 2.91 (95%CI 1.69-5.01) and adjusted for age, height, weight and menopausal status this remains highly significant (RR = 3.25 (95%CI 1.76-6.02)). After adjustment for the neck BMD in the wrist facture cohort the RR remained highly significant (RR = 3.20 (95%CI 1.67-6.12)) indicating BUA is an independent predictor of wrist fractures. To compare with DXA measurements the RR (adj. for age, height, weight and menopausal status) for 1 SD change is 2.07 (95%CI 1.12-3.86) for spine BMD and 2.23 (95%CI 1.17-4.25) for neck. BMD. In conclusion BUA is a predictor of fractures in early postmenopausal women. This is especially true of fractures at the wrist where BUA is independent of BMD measurement and a better predictor than BMD measurements. Therefore BUA may be a method of measuring future fracture risk at the time of the menopause to assist in decision making regarding prophylactic treatment.

F303

Prevalent Wrist Fracture After Age 50 is a Risk Factor for Incident Hip and Incident Morphometric Vertebral Fracture Independent of Bone Mineral Density (BMD). J. T. Schousboe[1], H. A. Fink[2], B. C. Taylor[2], K. L. Stone[3], T. A. Hillier[4], M. C. Nevitt[3], K. E. Ensrud[2]. [1]Park Nicollet Clinic, Mpls, MN, USA, [2]U of MN, Mpls, MN, USA, [3]UCSF, SF, CA, USA, [4]NW Kaiser Permanente, Portland, OR, USA.

Wrist fracture (WF) has been reported to be a risk factor for subsequent hip (HF) and vertebral fractures, but prior studies have not controlled for BMD.

We examined these associations with data from the Study of Osteoporotic Fractures (SOF), a prospective cohort study examining predictors and outcomes of osteoporosis in 9704 women aged ≥65 yrs. At SOF visit 1, 1100 women self-reported prior WF since age 50. 120 additional women reported WF occurring between visits 1 and 2 that were confirmed by review of radiographic reports. Calcaneal BMD was measured at visit 1and total Hip BMD was measured at visit 2. Incident morphometric vertebral fractures (MVF) were determined by comparison of digitalized lateral spine radiographs from visit 3 with those obtained at visit 1 (mean interval 3.8 years). Incident HF occurring after visit 2 were confirmed by review of radiographic reports.

Logistic regression was used to assess the age, age and calcaneal BMD, and multivariate adjusted odds ratios (OR) for incident MVF occurring after visit 1 in women with versus those without WF prior to visit 1.

Proportional hazards regression was used to assess the age, age and total hip BMD , and multivariate adjusted hazard ratios (HR) for incident HF occurring after visit 2 in women with versus those without WF prior to visit 2. As approximately half of HF occurred within the first 7 years of follow-up after visit 2, we also examined the HR for incident HF for the follow-up period from 0 to 7 years after visit 2, and separately during the follow-up period that began 7 years after visit 2.

Odds of Incident Morphometric Vertebral Fracture Associated with Prevalent Wrist Fracture

	Age adjusted OR (95%CI)	Age & BMD Adjusted OR (95%CI)	Multivariate Adjusted OR (95%CI)
All MVF	1.70 (1.28, 2.25)	1.38 (1.04, 1.83)	1.36 (1.02, 1.81)

Rate of Incident Hip Fracture Associated with Prevalent Wrist Fracture

	HR (95%CI)	HR (95%CI)	HR (95%CI)
All HF	1.41 (1.15, 1.73)	1.11 (0.90, 1.36)	1.10 (0.90, 1.36)
0-7 yrs follow-up period	1.83 (1.39, 1.44)	1.43 (1.09, (1.87)	1.45 (1.10, 1.91)
>7 yrs follow-up period	1.05 (0.76, 1.44)	0.83 (0.60, 1.15)	0.82 (0.59, 1.12)

Prior wrist fracture is a risk factor for morphometric vertebral fracture independent of age and BMD. Prior wrist fracture is also a risk factor for incident hip fracture; this association is largely explained by lower hip BMD among those with prior wrist fracture and wanes with increasing length of follow-up.

Disclosures: ***J.T. Schousboe****, None.*

High Peak Bone Mass Associated with Physical Activity may Result in Fewer Fragility Fractures in Elderly Men. A. H. Gustavsson*[1], F. Nyquist*[2], C. Karlsson*[2], T. Olsson*[3], P. Nordström[1], M. K. Karlsson[2]. [1]Department of Surgical and Perioperative Sciences, Sports Medicine Unit, Umeå, Sweden, [2]Department of Orthopaedics, Malmö, Sweden, [3]Department of Public Health and Clinical Medicine, Umeå, Sweden.

Background: It has been suggested that increasing bone mass by intense physical activity during childhood and adolescence may decrease the risk of osteoporosis and subsequently the risk of fracture later in life. This implies that the gain in bone mass is not lost when physical activity is decreased.

Methods: In the longitudinal part of this study, 97 athletes (mean age 21.0±4.5 years) and 49 control subjects (mean age 22.4±6.3 years) were studied at baseline and after a mean period of 5 years. The groups did not differ in weight or height at baseline. Bone mineral density (BMD; g/cm2) was measured for total body, femoral neck, spine and arms using dual-energy X-ray absorptiometry. In a second cohort consisting of 400 former soccer and ice hockey players aged 60 years or more (mean age 71.0±6.0 years), and double age matched controls (mean age 71.0±5.9 years), the prevalence of fractures was evaluated using a questionnaire.

Results: At baseline, the athletes and controls differed significantly in bone density at all sites (P<0.001), but there were no other significant differences between the two groups considering anthropometric data. Between baseline and the follow up, 55 athletes stopped their active sports career. These men were found to have lost significantly more BMD at the femoral neck (0.09 vs. 0.02 g/cm2, P=0.002), and gained less total body BMD (0.02 vs. 0.05 g/cm2, P=0.02) than the 42 athletes that remained active throughout the study, but not compared to the controls. At follow up the former athletes still had higher BMD of the total body (1.33 vs. 1.27 g/cm2, P=0.001), neck (1.20 vs. 1.11 g/cm2, P=0.02), and arms (1.07 vs. 1.00 g/cm2, P<0.001) compared to the controls. In the second cohort the proportion of individuals with fragility fractures sustained after age 50 was reduced in the former athletes (2.0 % versus 4.2 %, P=0.02) and there was also a significant difference in wrist fractures alone (0.75 % versus 2.5 %, P=0.04).

Conclusion: In summary, the results of the present study suggest a sustained high BMD from previous physical activity may result in fewer fragility fractures in the elderly.

Predictors Of Osteoporosis In Men: Data from the Canadian Multicentre Osteoporosis Study (CaMos). N. Diaz-Granados*[1], G. Tomlinson*[1], N. Kreiger*[1], T. M. Murray[1], W. P. Olszynski[2], A. M. Cheung[1], and the Camos Research Group*[3]. [1]University Of Toronto, Toronto, ON, Canada, [2]University Of Saskatchewan, Saskatoon, SK, Canada, [3]McGill University, Montreal, PQ, Canada.

In order to reduce the burden of illness associated with osteoporosis and its related fractures in men, we need to identify men who are at higher risk for osteoporosis. Baseline data from the Canadian Multicentre Osteoporosis Study (CaMos), a population-based prospective cohort study, were used to identify predictors of osteoporosis in men. Out of the 2884 men recruited into CaMos, we identified 1768 (61%) Caucasian men, aged 50 or older who had not taken oral steroids for more than 3 months and for whom we had measured femoral neck bone mineral density (FN BMD). T-scores were derived using the young male CaMos reference population and the WHO definition for Osteoporosis (T-score < -2.5) was the threshold used to dichotomize the outcome. Predictors were ranked *a priori* in order of importance by two clinical experts, an epidemiologist and a graduate student in epidemiology. Only the variables ranked in the top 50% were considered in these analyses and these included: age, education, height, weight, medical history, family medical history, reproductive history, smoking, physical activity, sunlight exposure, dietary habits (including calcium and caffeine intake). The mean age of men in this study was 65 years (range 50 to 96) and 5% (n = 89) had osteoporosis. Backwards stepwise logistic regression analysis using Akaike's Information Criterion (AIC) as the variable selection criterion demonstrated that lower weight (75 to 90 kgs: odds ratio (OR) = 0.2, 95% CI = 0.1 – 0.3, and > 90 kgs OR = 0.1, 95% CI =0.1 – 0.3, compared to < 75 kgs); current smoking (OR = 2.2, 95% CI =1.3 - 3.8); older age (OR = 1.8, 95% CI =1.4 – 2.4); a history of a minimal trauma fracture since age 50 (OR = 2.4, 95% CI =1.3 – 4.4); and a family history of osteoporosis (OR = 2.2, 95% CI =1.1 – 4.4) were all predictive of osteoporosis (the area under the Receiver Operating Characteristic curve for this model was 0.82, standard error = 0.02). The risk factors identified in this study are similar to those found for women and may be useful in identifying men who are at higher risk for osteoporosis and, by inference, osteoporotic fractures.

F309

ER-α Genotype Modulates the Relationship Between Bioavailable Estradiol Levels and Bone Loss and BMD in Elderly Men. S. Khosla[1], B. L. Riggs[1], E. J. Atkinson*[2], C. Mavilia*[3], F. Del Monte*[3], L. J. Melton[4], M. L. Brandi[3]. [1]Endocrinology, Mayo Clinic, Rochester, MN, USA, [2]Biostatistics, Mayo Clinic, Rochester, MN, USA, [3]Department of Clinical Physiopathology, University of Florence, Florence, Italy, [4]Health Sciences Research, Mayo Clinic, Rochester, MN, USA.

Bioavailable estradiol (bio E_2) levels are important determinants of BMD and of rates of bone loss in elderly men, and bio E_2 levels < 11 pg/ml may represent the threshold for skeletal estrogen (E) deficiency. Moreover, in women, E-deficiency or sufficiency has much less impact on rates of bone loss or fracture risk in subjects with the Pvu II pp genotype of the E receptor (ER)-α gene versus those with the P allele (PP or Pp) (JBMR 15:2479, 2000). To evaluate the interaction between E levels and ER-α genotype in men, we measured BMD and rates of bone loss (over 4 yrs) and related these to bio E_2 levels and the ER-α Xba I and Pvu II genotypes in 114 men age 60-90 yrs. The X/P and x/p alleles were in strong linkage dysequilibrium. As previously reported, in the overall group of subjects, the rate of bone loss at the mid-radius was related to bio E_2 levels for bio E_2 < 11 pg/ml (R = -0.36, P = 0.004), whereas there was no correlation between bio E_2 and the rate of bone loss for bio E_2 > 11 pg/ml (R = -0.09, P = NS). This relationship was, however, driven entirely by men carrying the X or P alleles; in men with the xx or pp genotypes, there was no correlation between bio E_2 and rate of bone loss, regardless of the bio E_2 level (Table). This was confirmed by statistical analysis testing for an interaction between bio E_2 (for values < 11 pg/ml) and genotype (P = 0.02 and 0.05 for the X and P alleles, respectively).

Bio E_2, pg/ml	Spearman correlation coefficient of bio E_2 to rate of mid-radius bone loss			
	+X (XX or Xx)	+P (PP or Pp)	-X (xx)	-P (pp)
< 11	-0.42*	-0.42*	-0.07	-0.15
> 11	-0.13	-0.17	-0.07	-0.15

*P < 0.005

In addition to longitudinal rates of bone loss, we also noted similar, statistically significant interactions between bio E_2 and Xba I and Pvu II genotypes for cross-sectional BMD at the radius and femur neck: BMD at these sites was higher (by 21-24%) in men with bio E_2 levels > 11 pg/ml versus those with bio E_2 < 11 pg/ml only if they were also carriers of the P or X alleles; BMD at these sites was not different in men with the pp or xx genotypes and high vs low bio E_2 levels. We conclude that the ER-α genotype modulates the relationship between bio E_2 levels and both bone loss and BMD in elderly men; as in women, men with the P or X alleles have rates of bone loss and BMD that depend much more on circulating E levels than those with the pp or xx genotypes.

Older Men with Weight Loss Have Increased Rates of Hip Bone Loss, Irrespective of Adiposity or Intention to Lose Weight. K. Ensrud[1], R. Fullman*[2], M. Stefanick*[3], H. Fink[1], E. Barrett-Connor[4], C. Lewis[5], P. Bowman*[1], E. Orwoll[6], J. Cauley[7]. [1]VAMC & U of MN, Minneapolis, MN, USA, [2]UCSF, San Francisco, CA, USA, [3]Stanford U, Palo Alto, CA, USA, [4]UCSD, San Deigo, CA, USA, [5]U of AL, Birmingham, AL, USA, [6]OHSU, Portland, OR, USA, [7]U of Pittsburgh, Pittsburgh, PA, USA.

Older men with weight loss have higher rates of bone loss, but the effects of adiposity and intention to lose weight on this association are uncertain. To test the hypothesis that elderly men with recent weight loss have higher rates of hip bone loss irrespective of adiposity or intention to lose weight, we measured body mass index (BMI), body composition, and total hip bone mineral density (THBMD) at a baseline and subsequent exam (average 2.2 yrs between exams) in a cohort of 323 men aged ≥65 yrs at baseline. During this period, 15% of participants lost ≥5% of their baseline weight (weight loss), while the remaining 85% (stable weight or weight gain) had a <5% change from their baseline weight (76%) or gained ≥5% or more of their baseline weight (9%). The mean annual percent change in THBMD was calculated by category of weight change. The average age-adjusted rate of decline in THBMD increased from -0.26% /yr in men with stable weight or weight gain to -0.97%/yr in men with weight loss (p <0.0001). Further adjustment for baseline health status, body mass index, THBMD did not alter these results. Among both heavier and thinner men, higher rates of hip bone loss were observed in men with weight loss (p >0.09 for interaction between weight change and BMI). Our findings were unchanged when lean mass or fat mass was substituted for BMI in the analyses. In addition, higher rates of hip bone loss were observed in men with weight loss, irrespective of intention to lose weight (p > 0.39 for interaction).

	Mean Annual % Change in THBMD (95% CI)	
	Weight Loss	Stable Weight or Weight Gain
Overall Cohort	-0.97 (-1.28,-0.66)	-0.26 (-0.39,-0.13)
BMI ≥ 26.6*	-1.18 (-1.70,-0.66)	-0.14 (-0.31,0.04)
BMI < 26.6*	-0.85 (-1.24,-0.47)	-0.40 (-0.60,-0.21)
Trying to Lose Weight	-0.94 (-1.33,-0.55)	-0.18 (-0.38,0.02)
Not Trying to Lose Weight	-1.08 (-1.55,-0.61)	-0.28 (-0.48,-0.08)

*Median BMI=26.6 kg/m^2

Older men with weight loss in later years have increased rates of hip bone loss, even among overweight men and those trying to lose weight. Measurement of weight change should be included in the clinical assessment for osteoporosis risk in older men.

Disclosures: ***K. Ensrud****, Merck 2; Eli Lilly 2; Pfizer 2; Berlex 2.*

F313

How Many Fractures in Men Are Attributable to Low Bone Density? T. V. Nguyen, J. R. Center, J. A. Eisman. Bone and Mineral Research Program, Garvan Institute of Medical Research, Sydney, Australia.

In the elderly population, approximately one third of osteoporotic fractures occur in men. Among many risk factors for fracture, low bone mineral density (BMD) is considered an important determinant. However, it is not known how many fractures are attributable to low BMD. This study was designed to estimate the proportion of fractures attributable to low BMD in a sample of 821 men (average age: 70 yr, range: 60 to 92 yr) who have been participating in the Dubbo Osteoporosis Epidemiology Study since mid-1989.

Approximately 11% and 21% of the men had femoral neck BMD T-scores<-2.5 and T-scores<-2.0, respectively. During the 13-year follow-up period, 118 men sustained a symptomatic low trauma fracture, including femoral neck (n=26), vertebrae (n=43), and distal radius and humerus (n=12). Approximately 23% and 34% of those with fracture had femoral neck BMD T-scores<-2.5 and T-scores<-2.0, respectively. The risk of fracture increased 3-fold (95% confidence interval [CI]: 1.8 - 5.0) among those with T-scores<-2.5, and 2.2-fold (95% CI: 1.4 - 3.4) among those with T-scores<-2.0. Between 18% and 20% of all fractures in elderly men were attributable to low BMD. The BMD-attributable risk was 38% for hip fractures, 41% for symptomatic vertebral fractures, and 34% for distal radius and humerus fractures.

In these older men, low BMD was a strong predictor of fracture risk, but still accounted for only a modest proportion of fractures. The majority of fractures occurred in men with BMD T-scores>-2.5. The data imply that current cut-off values of BMD for the diagnosis of osteoporosis in men are ina ppropriate.

Impaired Sleep Increases the Risk of Falls in Older Women: A Prospective Study with Objective Measurements of Sleep. K. L. Stone[1], J. L. Schneider*[1], T. Blackwell*[1], J. A. Cauley[2], K. E. Ensrud[3], T. A. Hillier[4], S. Ancoli-Israel*[5], D. Claman*[1], S. R. Cummings[6]. [1]University of California, San Francisco, San Francisco, CA, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]University of Minnesota, Minneapolis, MN, USA, [4]Kaiser Permanente Center for Health Research, Portland, OR, USA, [5]University of California, San Diego, San Diego, CA, USA, [6]San Francisco Coordinating Center, San Francisco, CA, USA.

Sleep deprivation is associated with decreased cognitive and functional performance, both risk factors for falls. No study has used objective measurements of sleep to determine whether poor sleep increases the risk of falls, and perhaps fractures.

We assessed sleep patterns in 2,131 women aged 80 and older using the Sleep-Watch-O™ actigraph (Ambulatory Monitoring, Inc.), which utilizes a piezoelectric sensor to detect fine movements. An algorithm is applied to movement patterns to determine sleep-wake states. The actigraph was worn on the non-dominant wrist for a minimum of 72 hours. Incident falls were ascertained by postcard follow-up every 4 months. 'Fallers' were defined as those who experienced ≥ 1 fall per interval (on average) subsequent to the sleep assessment (mean follow-up 0.6 years).

240 women were classified as fallers. After controlling for age, body mass index, race, and use of sleep medications, women who self-reported excessive daytime sleepiness (score of ≥ 16 on the Epworth Sleepiness Scale) experienced 2.6-fold increased risk of being a faller (RR=2.6; 95% CI=1.3 – 5.4) compared to others. We found that objective measures of sleep were significantly associated with increased risk of falling. Relative risks (RR) and 95% confidence intervals (CI) are shown below (table).

Sleep Efficiency* (%)		# Long Wake Episodes**		Total Sleep Time (hours)	
Category	RR (95% CI)	Category	RR (95% CI)	Category	RR (95% CI)
< 60%	1.5 (1.1, 2.2)	< 5	1.0 (ref)	< 4	1.8 (1.2, 2.6)
60-<70%	1.8 (1.2, 2.7)	5 - <8	1.1 (0.8, 1.5)	4 - <6	1.3 (0.9, 1.7)
70-<80%	1.1 (0.7, 1.6)	≥ 8	1.5 (1.1, 2.2)	6 - <8	1.0 (ref)
≥ 80%	1.0 (ref)			≥ 8	1.2 (0.7, 2.1)

* % of time-in-bed scored as sleep ** wake episodes > 30 min

Further analysis suggests that these associations are only partly mediated by excessive daytime sleepiness. Other factors, such as decreased cognitive or physical function, may contribute to increased risk of falling among poor sleepers.

We conclude that sleep disruption and excessive daytime sleepiness significantly increase risk of falls. Improving sleep in older patients may significantly reduce risk of falls and fractures.

21 To 45 Year Old Premenopausal Women Suffering from Major Depression Are at Increased Risk for Osteoporosis. G. Cizza, F. Eskandari*, P. Martinez*, S. Torvik*, C. Kotila*, S. Mistry*, N. Sebring*, B. Drinkard*, D. Ronsaville*, J. Reynolds*, P. W. Gold*. National Institutes of Health, Bethesda, MD, USA.

Osteoporosis is a common and silent condition characterized by bone fragility and increased risk of fractures. Thus, the identification of unrecognized risk factors for osteoporosis is of scientific and clinical importance. Major depressive disorder (MDD) is also common, affecting 5-9% of women of all ages. Subjects with MDD often exhibit

hypercortisolism, increased levels of IL-6 and other endocrine changes that may predispose them to osteoporosis. To determine whether MDD is an unrecognized risk factor for low bone mass in premenopausal women, we assessed the proportion of subjects with osteopenia or osteoporosis (respectively defined as -1 and –2.5 SD below peak bone mass) by DEXA measurements, in 81 women with MDD (age=35.3±6.8) and in 44 healthy controls (age=34.7±6.9) matched for race.

Prevalence of osteopenia or osteoporosis at any skeletal site in women with MDD and matched controls.

Skeletal site	Osteopenia		Osteoporosis	
	MDD (n=81)	Controls (n=44)	MDD (n=81)	Controls (n=44)
AP Lumbar Spine	14%	16%	7%	0%
Femoral Neck	15	5	5	0
Trochanter	18	5	1	0
Total Femur	16	2	0	0

Women with MDD had a significantly greater prevalence of osteopenia or osteoporosis than controls at all hip sites (all p<.02, as assessed by Wilcoxon's rank sum test for ordinal data). The majority of these premenopausal subjects were unaware of having osteoporosis. Two of the 9 women with osteoporosis were younger than 30. Total calcium intake (dietary and supplements) was similar for women with osteopenia/osteoporosis (1085±814 mg/day), and women with normal BMD (above -1 SD) whether depressed (1357±657) or controls (1491±549). Reported caffeine and alcohol intake and level of physical conditioning (12 min Cooper test) were also similar in depressed and control subjects. However, mean 24 hr plasma cortisol levels (collected hourly) tended to be higher (p< .09) in subjects with osteoporosis than in women with normal BMD. In regression analysis there was a negative relationship between 24h mean plasma cortisol and spine BMD even after correcting for BMI (p<.003; r^2 .11). In conclusion, low bone mineral density is significantly more common in women with MDD than in matched controls, suggesting that MDD may be an unrecognized risk factor for osteopenia or osteoporosis. The prospective evaluation of these subjects being conducted in this study will help to establish whether there is a causal relationship between MDD and osteoporosis in premenopausal women.

High Protein Diets Acutely Increase Intestinal Calcium Absorption but Not Kinetic Measures of Bone Resorption. J. E. Kerstetter[1], R. H. Raphael*[1], K. O. O'Brien*[2], D. M. Caseria*[3], D. E. Wall*[4], K. L. Insogna[3]. [1]School of Allied Health, University of Connecticut, Storrs, CT, USA, [2]Bloomberg School of Public Health, Johns Hopkins University, Baltimore, MD, USA, [3]School of Medicine, Yale University, New Haven, CT, USA, [4]School of Medicine, Yale University, New Haven, CT, USA.

High protein diets induce hypercalciuria in humans, but the source of the additional urinary calcium is unknown. It has been suggested that high protein diets increase bone resorption because the high endogenous acid production engendered by protein requires buffering, in part, from the skeleton. Whether this phenomenon explains the increase in urine calcium is unclear. Therefore, dual stable calcium isotopic methodology was used to evaluate the acute effect of a high protein diet on calcium kinetics in women. The study consisted of 2 weeks of a lead-in, well-balanced diet containing moderate calcium, sodium and protein followed by 10 days of an experimental diet. The experimental diet was controlled in calcium (20 mmol) and sodium (100 mmol) and contained one of two levels of protein (1.0 g/kg and 2.1 g/kg). Thirteen healthy women (10 young and 3 postmenopausal) received both levels of dietary protein in random order. On the morning of experimental day 5, subjects received an oral dose of ^{44}Ca followed by an IV dose of ^{42}Ca. Following isotope dosing, 8 serial blood collections, 36 hours of timed urine collections, and 5 days of spot urine samples were analyzed for calcium isotopes. By day 4, urinary calcium in every subject increased during the high protein in comparison to the moderate protein diet (3.57 ± 0.35 versus 5.23 ± 0.37 mmol/d, p < 0.0001, paired t-test). Intestinal calcium absorption increased from 18.5 ± 1.6 % during the moderate protein diet to 26.2 ± 1.9 % during the high diet (p < 0.0001, paired t-test). The increase in calcium absorption accounted for 90 % of the increase in urinary calcium. There were no differences in kinetic measures of bone formation (Vo+), bone resorption (Vo-) or bone balance between levels of dietary protein. All subjects were in negative bone balance regardless of the level of protein, suggesting 20 mmol of dietary calcium is insufficient to maintain bone health. These data directly demonstrate that the acute rise in urinary calcium in response to a high protein diet is explained, not by changes in bone homeostasis, but by an increase in intestinal calcium absorption.

Chronic High-Dose Glucocorticoids in Children Induce Obesity with Minimal Bone Loss. M. B. Leonard[1], B. S. Zemel[1], V. A. Stallings*[1], H. I. Feldman*[2]. [1]Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, USA, [2]Medicine, University of Pennsylvania, Philadelphia, PA, USA.

Steroid sensitive nephrotic syndrome (SSNS) is an excellent model of glucocorticoid (GC)-induced osteopenia in children. During treatment with GC, the underlying disease is inactive and does not recur as long as the GC therapy is continued. SSNS is frequently complicated by GC-induced obesity. The objective of this study was to assess bone density and bone dimensions in children with SSNS, relative to body size. Whole body and paired anterioposterior (AP) / lateral spine DXA (Hologic QDR 2000) measures of bone area, bone mineral content (BMC) and areal-bone mineral density (BMD, gm/cm^2) were obtained in the array mode in 188 healthy controls and 61 children with SSNS, ages 4 to 21 yrs. All SSNS subjects were in remission and 80% were on GC at evaluation. The paired spine scans were used to estimate vertebral volume assuming vertebrae approximate an elliptical cylinder; volumetric BMD was calculated using BMC from the lateral spine scan. The SSNS subjects had received a cumulative lifetime GC dose of (mean ± SD) 870 ± 760 mg/kg over a median interval of 18 mo (range 4 to 83). The average daily GC dose was 1.1±0.7 mg/kg/day. The SSNS subjects had significantly decreased height z-scores (Ht-Z) (-0.1±1.0 vs. 0.3±1.0, p < 0.01) and increased BMI z-scores (BMI-Z) (1.3±1.0 vs. 0.3±1.1; p < 0.0001) compared with controls, consistent with GC effects. Ht-Z was associated with cumulative GC exposure, p<0.001; BMI-Z was not. Bone measures were log transformed and multivariate regressions used to generate ratios (95% CI) for bone measures in SSNS compared with controls, adjusted for maturation, race and gender. All vertebral measures (AP and lateral area, BMC, areal-BMD and volumetric BMD for age, and AP and lateral BMC for bone area) were not different in SSNS compared with controls. However, when adjusted for BMI-Z, volumetric BMD (ratio 0.94 [95% CI 0.90-0.99]) and AP spine BMC for area (0.96 [0.92-0.99]) were marginally decreased in SSNS compared with controls; p < 0.05. Whole body bone area for height was increased in males with SSNS compared with controls (1.07 [1.02-1.12]), p=0.01; however, when adjusted for BMI-Z, the SSNS and controls were not different. Whole body BMC for age and for height were not different in SSNS, compared with controls. We have previously reported that obesity results in significantly increased vertebral volumetric density and increased whole body area and BMC for height. The GC-induced obesity in SSNS may protect the spine and whole body from bone loss relative to age and height. In conclusion, children with severe SSNS do not have significant bone deficits for age or height despite high-dose chronic GC exposure.

Estrogen Receptor-Beta Plays a Regulatory Role in Cortical Bone but not in Trabecular Bone in Aged Male Mice. H. Z. Ke, H. Qi, D. T. Crawford*, H. A. Simmons, G. Xu*, T. A. Brown, D. D. Thompson. Cardiovascular and Metabolic Diseases, Pfizer Global Research and Development, Groton, CT, USA.

It has been reported that lacking estrogen receptor-beta (ER-b) increases cortical bone and partially prevents age-related trabecular bone loss in female mice. However, the role of ER-b in skeletal growth, development and maintenance in males is not clearly understood. It has also been reported that ER-b does not play a role in bone growth and remodeling in males based on the data generated from ER-b knockout (KO) young male mice. The purpose of this study was to evaluate the effects of ER-b KO in male mice in older ages to determine whether ER-b plays a role in trabecular and cortical bone in males. Groups of KO male mice and wild-type (WT) littermates were autopsied at 6, 13 and 21 months of age. Body weight, seminal vesicle weight and femoral length did not differ at all age groups between KO and WT. Trabecular density by pQCT, trabecular bone volume and connectivity by micro-CT, and trabecular bone formation and resorption indices by histomorphometry at distal femoral metaphysis (DFM) did not differ significantly between KO and WT at all age groups, indicating that ER-b does not play a role in regulating trabecular bone. Trabecular density and trabecular bone volume gradually decreased with age between 6 and 21 months of age in both KO and WT, indicating the ER-b plays no role in age-related trabecular bone loss in males. At 6 months of age, KO mice did not differ from WT in total bone mineral content and density at DFM and femoral shaft (FS), illustrating that ER-b play minimal or no role in cortical bone during growth phase. Between 6 and 13 months of age, cortical bone area, cortical content and periosteal circumference of FS increased significantly with age in both KO and WT. However, all increments were significantly larger in KO than in WT. Therefore, these cortical bone parameters were significantly higher (+11% to +23%) in KO compared with WT at 13 months of age. At this age, KO male mice also had a larger marrow cavity, indicating a higher endocortical bone resorption compared with WT. Between 13 and 21 months of age, all cortical bone parameters of FS increased slightly with age in KO while did not change with age in WT. These data demonstrate that ER-b does not play a role in either trabecular or cortical bone during growth phase (prior to 6 months of age), and plays an inhibitory role in cortical bone formation and endocortical bone resorption but not in trabecular bone remodeling during the adult and aged phases (between 6 to 21 months of age) in male mice.

Sex Hormone Binding Globulin, Bioavailable Estradiol and Testosterone and Vertebral Fractures in Men. E. R. Legrand, D. Chappard, C. Gibert*, P. Insalaco*, V. Simon*, M. Baslé*, M. Audran. Service de rhumatologie, CHU, Inserm, EMI 0335, Angers, France.

Background: The exact mechanism of bone loss remains unknown in primary osteoporosis in men. We have shown that serum concentration of Sex Hormone Binding Globulin (SHBG) was increased in men with osteoporosis and was correlated with bone markers and hip Bone Mineral Density *(Legrand, Bone 2001, 29: 90-95).*

Aim: To evaluate the relationships between SHBG, bioavailable testosterone and estradiol and vertebral fractures in men with low BMD.

Methods: 346 men (mean age 57.3 years) with a spine or hip low BMD (T-score < -1) were included in a cross sectionnal but prospective study. Age, BMI, clinical risk factors and BMD were checked. Fasting serum samples were assayed for total and free testosterone, total and bioavailable estradiol and SHBG. Spinal X-ray films were analyzed independently by two trained investigators who were unaware of the patient status. Vertebral fracture was defined as a reduction of at least 20 percent in the anterior, middle or posterior vertebral height.

Results: The 194 men (56%) with at least one vertebral fracture were older (62.0 vs 51.5 years, *p< 0.01*) and had a lower hip BMD (0.81 vs 0.89 gr/cm2, *p< 0.01*). After ajusting

for age and BMI, these men had a higher SHBG serum level (45.2 vs 30.7 nmol/l, *p< 0.01*), a lower serum free testosterone (11.6 vs 14.2 ng/l, *p< 0.01*), a lower serum bioavailable testosterone (12.1 vs 18.0 %, *p< 0.01*), a lower serum bioavailable estradiol (61.2 vs 89.5 %, *p<0.01*).
Logistic regression analysis showed that age (10 years increased : Odds Ratio=1.9, *CI 1.5-2.3*), hip BMD (1 SD decrease: O R=1.9, *CI 1.5-2.7*) were associated with the presence of at least one vertebral fracture. After adjusting for age and BMD, SHBG serum level (1 SD increase: OR= 1.8, *CI 1.2-2.6*), serum bioavailable testosterone(1 SD decrease: OR= 1.5, *CI 1.1-2.1*), serum bioavailable estradiol (1 SD increase: OR= 1.5, *CI 1.2-2.2*) were also strongly associated with the presence of vertebral fracture. The analysis was repeated for the presence of multiple fractures (at least 2 vertebral fractures) and the Odds Ratios were quite similar.
Conclusions: These results strongly suggest that serum SHBG and bioavailable sex steroids play a key role in pathogenesis of bone loss and vertebral fractures in men. Furthermore, these biological markers might be useful to evaluate the vertebral fracture risk in men, in addition to age and BMD.

Acute Androgen Deprivation Causes Early, Sustained Bone Loss: A Longitudinal Study. P. S. Coates[1], J. M. Wagner[1], M. E. Shoup*[1], J. L. Ryan[1], S. M. Sereika*[1], J. B. Nelson*[1], D. L. Trump*[2], S. L. Greenspan[1]. [1]Univ. of Pittsburgh, Pittsburgh, PA, USA, [2]Roswell Cancer Center, Buffalo, NY, USA.

Androgen deprivation therapy (ADT) is a common, effective therapy for men with prostate cancer. However, the resultant hypogonadism is a risk factor for osteoporosis. To examine the relationship between the onset of therapy and bone loss, we studied 114 men prospectively over 12 months and assessed bone mineral density (BMD) and markers of bone turnover. We compared healthy age-matched controls (n=39) to men with stable prostate cancer and no metastatic disease who were: 1) not on ADT (n=26), 2) initiating ADT (<6 months, mean 3±1 months±SD, n=22), and 3) chronically on ADT (>6 months, mean 32±34 months, n=27). At baseline, there were no statistically significant differences in age, height, weight, BMI, PTH, or vitamin D. Table results are mean±SD, *p<0.05 across 4 groups.

BMD, Body Fat, and Markers at 12 Months

	No ADT	Acute ADT	Chronic ADT	Controls
Spine BMD (%/yr)	0.9±2.6	-2.1±2.7	0.1±5.9	-0.0±2.3
Total hip BMD (%/yr)	0.4±2.1	-2.6±2.5*	0.9±2.2	0.0±1.9
Total radius BMD (%/yr)	0.0±3.2	-2.6±2.8*	-1.8±3.1	-0.8±1.9
Total body BMD (%/yr)	0.1±2.5	-2.6±2.2*	-0.8±1.9	-0.2±1.3
Percent body fat (%/yr)	2.1±7.7	10.0±6.5*	1.2±6.2	1.0±5.6
NTx (nMBCE/nMCr)	28.8±19.7	64.0±36.4*	29.8±21.8	38.3±15.4
Osteocalcin (ng/mL)	4.3±1.1	7.8±2.1*	5.6±2.4	5.1±1.7

At 12 months, BMD at the total hip, radius, and total body were significantly reduced, percent body fat increased, and absolute urinary NTx and serum osteocalcin were significantly elevated in men on ADT compared to those in the other groups. At 6 months, absolute levels of urine NTx were inversely related to bone loss at the spine (r=-0.46, p<0.000), total hip (r=-0.34, p<0.01), total radius (r=-0.53, p<0.001), and total body (r=-0.34, p<0.01) at 12 months. Similarly, absolute levels of osteocalcin at 6 months were inversely related to bone loss at the spine (r=-0.36, p<0.01), total radius (r=-0.39, p<0.001), and total body (r=-0.35, p<0.01) at 12 months.
We conclude that initiation of acute ADT in men with prostate cancer results in significant decreases in BMD over 12 months, which can be predicted by early changes in biochemical markers. By approximately 3 years, the rate of bone loss slowed despite continued ADT. Further studies are needed to assess the long-term consequences of this early increase in bone turnover and bone loss in men with prostate cancer on ADT.

Disclosures: ***P.S. Coates****, None.*

The Relative Roles of the Sex Steroids in Idiopathic Osteoporosis in Men. E. S. Kurland[1], S. Khosla[2], T. L. Colvin*[1], S. L. Heller*[1], J. Powell*[1], B. Seltzer*[1], D. McMahon*[1], J. P. Bilezikian[3]. [1]Medicine, Columbia University, College of Physicians and Surgeons, New York, NY, USA, [2]Endocrinology, Mayo Clinic, Rochester, MN, USA, [3]Medicine and Pharmacology, Columbia University, College of Physicians and Surgeons, New York, NY, USA.

The important role of estrogen in establishing peak bone mass in men has been established through observations in 1 ER-α and several aromatase deficient subjects. Direct studies in adult men have further confirmed an important role for estrogen in maintaining bone mass and controlling bone turnover. Little is known about the relative role sex steroids play in idiopathic osteoporosis (IOP) in young to middle aged men in whom all known secondary causes of osteoporosis including hypogonadism are ruled out and could not account for aberrations in estrogen physiology if present. To clarify a potential role of estrogen in IOP, we recruited 44 men with Z-scores of <-2.0 at the lumbar spine (LS), total hip and/or 1/3 radius, as well as 44 healthy non-osteoporotic men as controls with Z-scores >-1.0 at all sites. The 2 groups were matched for age, BMI, and ethnicity. Sex steroid measurements were made on both groups with results as follows:

Variable	Patients (n =44)	Controls (n =44)	Unadjusted p-value	Adjusted p-value *
BMI kg/m^2	24.1 ± 0.6	25.4 ± 0.3	0.06	---
Testosterone ng/dL	644.4 ± 24.4	722.9 ± 31.5	0.07	0.02
Estradiol, E_2 pg/mL	20.8 ± 0.9	25.2 ±0.9	0.0003	0.0006
Estrone pg/mL	35.9 ± 1.2	41.9 ± 1.9	NS	NS
Bioavailable T ng/mL	121.1 ± 7.8	154.5 ± 8.3	NS	0.007
Bioavailable E_2 pg/mL	9.7 ± 0.6	13.0 ± 0.7	0.0003	0.0006
SHBG nmol/L	41.0 ± 1.9	37.4 ± 2.1	NS	NS

* Adjusted for Age and BMI, all values ± SEM
To further clarify which of these indices best distinguished cases from controls, a step-wise discriminant analysis was performed. In order of importance, E_2, BMI, total T, and SHBG best explained differences between cases and controls accounting together for 30% of the variance between groups; E_2 accounted for 17% of the variance. Correlations between sex steroids and bone density (BMD) at all sites further demonstrated that in patients with IOP, E_2 was significantly correlated with BMD of the LS (r =0.3; p =0.05) with a trend for significance at the 1/3 radius for E_2 and total T. There was no correlation between sex steroids and BMD in controls (E_2 at LS, r= 0.03, p= 0.8). The results are consistent with a potentially important role for estrogen deficiency in the pathogenesis of IOP in men.

Cytokines and Bone Loss in Pre-menopausal Women with Celiac Disease. M. L. Bianchi[1], M. T. Bardella*[2], S. Saraifogher*[1], E. Galbiati*[1], O. Borghi*[3], A. Dubini*[3]. [1]Bone Metabolic Unit, Istituto Auxologico Italiano IRCCS, Milano, Italy, [2]Cattedra di Gastroenterologia, Istituto di Scienze Mediche IRCCS, University of Milano, Milano, Italy, [3]Istituto Auxologico Italiano IRCCS, Milano, Italy.

Low bone mass and osteoporosis are frequently encountered in patients, especially post-menopausal women, affected by celiac disease (CD) and intestinal malabsorption.
We studied 64 women affected by CD (aged 35.3±4 yrs). All were pre-menopausal to avoid the influence of menopause on bone metabolism and bone mass. They were divided in two groups: (1) the GFD group, including patients in a stable condition, on a gluten-free diet (GFD) for at least 2 years, with no active signs of disease and no anti-gliadin and anti-endomisium antibodies; (2) the no-GFD group, including newly diagnosed patients evaluated before starting GFD.
All patients had regular menses, and had no other diseases besides CD, nor used drugs influencing calcium metabolism. The two groups were similar for age and clinical history.
A group of healthy women of similar age was also evaluated.
We measured calcium, phosphate, magnesium, calciotropic hormones, bone turnover markers, intestinal calcium absorption (calculating the area under the curve, AUC), lumbar spine BMD, cytokines IL-6, IL-1beta, TNFalpha, TNFbeta, IL-12, IL-18, RANKL, osteoprotegerin (OPG).
The main results were:
-- GFD group: moderate osteopenia (Z-score -1.4±.5), NTx slightly increased (53±3 nMBCE/mMcrea), intestinal calcium absorption decreased (AUC FAD% 4140±130 vs 5134±230 in controls, p<.02);
-- no-GFD group: osteopenia (Z-score -1.9±.5), NTx markedly increased (121±14 nMBCE/mMcrea, p<.03), PTH increased (51±8 pg/ml, p<.03), 25-OH D decreased (15.3±3.5 ng/ml, p<.03), intestinal calcium absorption decreased (AUC FAD% 3120±110, p<.01).
There was a slight increase in IL-6 only in the no-GFD group (1.3±.3 vs .6±.2 pg/ml in controls), while in both groups IL-12 and IL-18 were decreased (p<.05 vs controls), and RANKL and OPG were increased (RANKL: + 65% in the GFD group, + 418% in the no-GFD group, p<.02 vs controls; OPG: +53% and +121% respectively, p<.02).
It seems that also in pre-menopausal women, CD can cause derangement of bone metabolism and low bone mass, even if long-term gluten-free diet can induce some improvement. Reduced intestinal calcium absorption seems not to be the only mechanism affecting the calcium metabolism and the loss of bone mass. Various regulating cytokines appear to have a role in the bone loss in celiac patients, even during gluten free diet.

Ibandronate is Highly Efficacious in Postmenopausal Women with High Baseline Bone Turnover Rates. C. H. Chesnut[1], P. D. Delmas[2], C. Christiansen[3], P. Mahoney*[4], R. C. Schimmer[4]. [1]University of Washington, Seattle, WA, USA, [2]Claude Bernard University and INSERM Research Unit 403, Lyon, France, [3]Center for Clinical and Basic Research, Ballerup, Denmark, [4]F. Hoffmann-La Roche Ltd, Basel, Switzerland.

Although there is still much discussion concerning the clinical utility of biochemical markers of bone turnover in postmenopausal osteoporosis (PMO), studies suggest that high levels of bone turnover are associated with faster, and possibly greater, bone mineral density (BMD) losses and increases in fracture risk. The efficacy of antiresorptive therapies in patients with high bone turnover at baseline remains to be fully established. Ibandronate is a highly potent, nitrogen-containing bisphosphonate that has recently demonstrated signif-

icant and substantial antifracture efficacy in postmenopausal women with osteoporosis.[1] In the overall population, oral daily (2.5mg; n=977) and intermittent (20mg every other day for 12 doses every 3 months; n=977) ibandronate regimens reduced vertebral fracture risk by 62% (p=0.0001) and 50% (p=0.0006), respectively, relative to placebo (n=975) after 3 years. Interestingly, a subgroup of patients who had high baseline levels of biochemical markers of bone resorption (CTX/creatinine or NTX/creatinine levels of more than 2 standard errors above the mean study values) achieved even greater relative fracture risk reduction than the overall population. After 3 years, the lifetable vertebral fracture rate in patients with high baseline bone turnover was 11.85% in the placebo arm (n=99) versus 3.87% and 2.78% in those taking daily (n=105) and intermittent (n=116) oral ibandronate, respectively, corresponding to relative risk reductions of 74% (p=0.0430) and 85% (p=0.0149), respectively. Thus, in patients with high baseline bone turnover, ibandronate demonstrates a substantial antifracture benefit, whether administered daily or with a between-dose interval of >2 months. These results confirm the robust and consistent antifracture effect with ibandronate.

Relationship of Early Changes in Bone Turnover to the Reduction in Vertebral Fracture Risk with Risedronate – The HIP Study. A. Blumsohn[1], I. P. Barton*[2], A. Chines[3], R. Eastell[1]. [1]University of Sheffield, Sheffield, United Kingdom, [2]Procter & Gamble Pharmaceuticals, Egham, United Kingdom, [3]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

Anti-fracture efficacy of antiresorptive therapies is only partially explained by increases in bone mineral density (BMD). Early decreases in bone turnover may also play a role. We tested this hypothesis by measuring 2 bone turnover markers, the N-telopeptide of type I collagen (NTX) and procollagen type I N-propeptide (PINP), in osteoporotic patients in the risedronate HIP fracture trial. We studied 938 women with a femoral neck BMD T-score less than -3 (mean age, 74 years, SD 3) who received calcium (and vitamin D if required) and placebo or risedronate 2.5 or 5 mg daily for 3 years. The reductions in urinary NTX (median, 47 and 57%) and PINP (39 and 53%) at 3 to 6 months of risedronate 2.5 and 5 mg, respectively, were significantly associated (P<0.05) with the reduction in vertebral fracture risk (48% over 3 years). The changes in both NTX and PINP accounted for approximately one third (NTX, 33%, p<0.05; PINP, 30%, p<0.05) of risedronate's effect in reducing the risk of vertebral fractures over 3 years, compared with placebo. In keeping with our previous findings with the VERT study, the relationship between vertebral fracture risk and change from baseline in NTX was not linear (p<0.05 in the 5 mg group). There was little further improvement in fracture benefit below a decrease of 30 to 35% for NTX. In conclusion, the decrease in bone turnover in patients taking risedronate accounts for some of the reduction in vertebral fracture risk. There may be a level of bone resorption reduction below which there is no further fracture benefit.

Intra-Venous Pamidronate Infusion Prevents Bone Loss and Renal Stone Formation During 90-Day Bed Rest Study. H. Ohshima*[1], Y. Watanabe*[2], C. Sekiguchi*[1], M. Fukunaga[3], A. Okada*[3], K. Kohri*[3], H. Ohta[3], Y. Seino[3], K. Takaoka[3], T. Esashi*[3], T. Matsumoto[3], T. Nakamura[3]. [1]Medical Research and Operations Office, National Space Development Agency of Japan, Tsukuba, Japan, [2]Advanced Engineering Services, Tsukuba, Japan, [3]Bone Loss Countermeasure Advisory Working Group, Tsukuba, Japan.

Introduction We have developed a bone loss countermeasure program for Japanese astronauts to reduce the risk of bone loss and renal stone formation for long-duration space flight. To validate the preventive pharmacological countermeasure in a ground-based study, NASDA participated in a 90-day bed rest study at the Space Clinic in Toulouse, sponsored by European, French and Japanese space agencies.

Methods Twenty-five male volunteers were split into three groups: control (CON; 9 subjects), pamidronate (PMD; 7), and exercise groups (EX; 9). PMD (60 mg in 500ml saline solution) was infused intravenously 14 days before the bed rest. BMD by DXA, urinary Ca excretion, and bone markers were measured before, during, and up to one year after bed rest. Abdominal radiograms were taken before and after bed rest.

Results DXA results showed the BMD of the total proximal femur decreased by 6.2 % in the CON group and 3.6 % in the EX group, while the PMD group exhibited no change after the three-month bed rest period. Urinary Ca excretion significantly increased in CON and EX groups during bed rest. In the PMD group, urinary Ca excretion decreased immediately after infusion, stayed low for one month, and gradually recovered to the baseline level towards the end of bed rest. Moreover, renal calcification was detected on the plain radiogram after bed rest, in two from the CON group and four from the EX group, but none from the PMD group. CTX, NTX and DPD increased in CON and EX groups, but were suppressed in the PMD group.

Conclusion PMD infusion effectively maintains the BMD of proximal femur under 90-day microgravity simulation by inhibiting bone resorption. It also reduces the incidence of renal calcification by inhibiting urinary Ca excretion.

Once-weekly Oral Ibandronate Prevents Bone Loss in Postmenopausal Women. L. B. Tankó[1], B. J. Riis[1], D. Felsenberg[2], E. Czerwinski*[3], A. Burdeska*[4], I. Jonkanski*[5], C. Hughes*[6], C. Christiansen[1]. [1]CCBR A/S, Ballerup, Denmark, [2]Radiology Department, University Hospital Benjamin Franklin, Berlin, Germany, [3]Polish Foundation of Osteoporosis, Krakow, Poland, [4]Hoffmann-La Roche Ltd, Basel, Switzerland, [5]Hoffman-La Roche Ltd, Basel, Switzerland, [6]Hoffman-La Roche Ltd, Welwyn, United Kingdom.

The aim of the present study was to investigate the efficacy, safety, and dose-response of once-weekly oral ibandronate in the prevention of postmenopausal bone loss. Six hundred and thirty women were randomized into four strata according to time since menopause (TSM, 1-3 years vs. >3 years) and baseline bone mineral density (BMD; normal: T-score > -1 vs. osteopenic: -2.5 ≤ T-score ≤ -1) of the lumbar spine. Within each stratum women were further randomized to receive once-weekly ibandronate (5, 10, or 20 mg/week) or placebo for 24 months. Efficacy parameters were the relative changes from baseline in spine (L1-4) and hip BMD, and biochemical markers of bone turnover (serum and urinary C-telopeptide of collagen type I (CTX), osteocalcin, and alkaline phospatase) measured by dual energy X-ray absorptiometry and ELISA, respectively. Once-weekly treatment with ibandronate induced dose-dependent increases in spine and hip BMD. At Month 24, differences between the relative changes in spine and hip BMD induced by 20 mg ibandronate and placebo was 4.0% and 2.7%, respectively. Similar or more pronounced differences were seen in osteopenic women of TSM 1-3 years (5.3% and 3.5%) and of TSM >3 years (3.5% and 2.9%), respectively. A dose-dependent suppression of all biochemical markers of bone turnover was observed with significant decreases in the 20 mg dose groups of all strata at Month 24. The overall safety results indicated that once-weekly oral ibandronate was well-tolerated at all three doses. Once-weekly oral treatment with 20 mg ibandronate provides an effective and safe therapy for the prevention of postmenopausal bone loss. This study provides further evidence of the effectiveness of ibandronate when administered, in a prevention setting, as a non-daily dosing regimen.

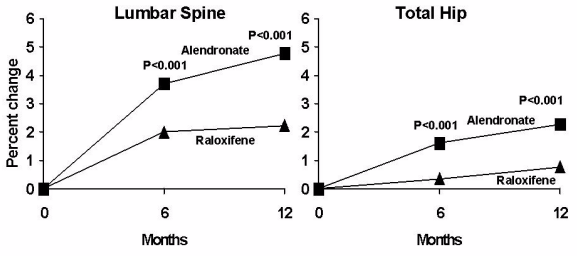
Greater Increases in BMD with Alendronate Compared to Raloxifene: Results from EFFECT-International. P. Sambrook[1], P. Geusens[2], J. Ferrer-Barriendos*[3], C. Ribot[4], J. Angulo Solimano*[5], N. Verbruggen*[6], K. Gaines*[6], M. E. Melton[6]. [1]University of Sydney, Sydney, Australia, [2]Biomedical Research Institute-LUC, Diepenbeek, Belgium, [3]H-Central De Asthrias, Oviedo, Spain, [4]Hôpital Paule de Viguier, Toulouse, France, [5]Instituto Medico Miraflores, Lima, Peru, [6]Merck & Co., Inc., Whitehouse Station, NJ, USA.

This 12 month, multicenter, international, double-blind trial was designed to evaluate the effect on BMD of alendronate (ALN) as compared to raloxifene (RLX) when used to treat postmenopausal women with osteoporosis.

Patients with osteoporosis (T-score ≤-2.0 at either lumbar spine or total hip) were enrolled at 50 centers in 16 countries. The patients were randomized to treatment with either active ALN 70 mg once weekly + RLX placebo daily or active RLX 60 mg daily + ALN placebo once weekly. Treatment within the past year with estrogen, estrogen analogs, or bisphosphonates was an exclusion. Measurements included spine and hip BMD, markers of bone turnover (BSAP and urinary NTx), and adverse experience reporting for assessment of tolerability.

A total of 487 women were enrolled; mean age 62 years; 79% Caucasian. Alendronate produced a greater increase in BMD than did raloxifene at 12 months at the lumbar spine, total hip, hip trochanter, and femoral neck (P≤0.001). The increase in BMD with alendronate compared to raloxifene was also greater at 6 months at the spine and hip.



Greater reduction in bone turnover was seen with alendronate compared to raloxifene: NTx decreased by 68% with alendronate compared to 28% with raloxifene at 12 months (P<0.001); BSAP decreased by 51% with alendronate compared to 12% with raloxifene at 12 months (P<0.001). The difference between agents in reduction for both BSAP and NTx was noted at the earliest time point measured (6 months, P<0.001). Overall tolerability was similar for the 2 agents. Percentage of patients reporting upper GI AEs was similar between groups (15% ALN, 22% RLX). Reporting of vasomotor symptoms was greater with RLX (4% ALN, 10% RLX, P=0.01).

This study demonstrates that alendronate provides greater increases in BMD at both hip and spine sites than does raloxifene, and that alendronate has greater antiresorptive activity than does raloxifene. Although overall reporting of adverse events and upper GI events were similar, more patients reported vasomotor symptoms with raloxifene.

Sustained Anti-Fracture Efficacy of Risedronate Treatment Over 7 Years in Postmenopausal Women. S. Goemaere*[1], O. H. Sorensen[2], T. D. Johnson*[3], A. Chines[3], C. Roux[4]. [1]Ghent University Hospital, Ghent, Belgium, [2]Hvidovre University Hospital, Hvidovre, Denmark, [3]Procter & Gamble Pharmaceuticals, Mason, OH, USA, [4]Hospital Cochin, Paris, France.

Risedronate (RIS) has been shown to significantly reduce vertebral and nonvertebral fracture incidence in randomized, placebo-controlled clinical trials.

In a 2-year extension of the multinational study (VERT-MN), RIS demonstrated a sustained antifracture effect. At the end of the 5 years, 220 women completed the study of which 164 participated in a further 2-year extension in which all patients were given RIS 5 mg daily. We now report the results for those women who either continued another 2 years on RIS (RIS group, n=83) or initiated RIS (PLBO/RIS group, n=81). Throughout the 7-year study, all patients received 1000 mg/d calcium and if baseline levels were low, up to 500 IU/day of vitamin D. The 2 groups had similar baseline characteristics in terms of age, BMD and prevalent vertebral fractures that were also similar to the original cohort.

Over 7 years, lumbar spine (LS) BMD increased from baseline by 11.5% in the RIS group and 6.1% in the PLBO/RIS group. The increase in LS BMD from year 5 to year 7 was 5.2% and 1.7%. for the PLBO/RIS and RIS groups, respectively.

Annualized incidence (%) of radiographic new vertebral fractures and clinical non-vertebral fractures is shown below

	Vertebral Fractures		Non-vertebral Fractures	
	PLBO / RIS	RIS	PLBO / RIS	RIS
Years 0-3	7.6	4.7	3.3	2.0
Years 4-5	12.3	5.2	4.3	3.0
Years 6-7	3.8	3.8	3.7	3.0

McNemar's analysis was performed to determine whether the vertebral fracture incidence in the RIS group has changed during years 6-7 as compared to years 4-5 . No significant change was observed suggesting a sustained antifracture effect of RIS. Similar analyses for the PLBO/RIS group showed a significant change, which is consistent with fracture risk reduction.

The cumulative incidence of clinical osteoporosis-related nonvertebral fractures over 7 years was 25.9% and 15.7% in the PLBO/RIS and RIS groups, respectively. Bone resorption marker urinary NTX decreased by 54% (median) at 3 months and remained decreased thereafter (range, 54-63%). In conclusion, the results of this study are supportive of a sustained antiresorptive effect of risedronate accompanied by a protective antifracture effect.

The Fracture Intervention Trial Long Term Extension (FLEX): 3 Year Interim Results. K. Ensrud[1], A. Santora[2], A. Schwartz[3], S. Suryawanshi*[2], E. Barrett-Connor[4], A. Feldstein*[5], W. Haskell*[6], M. Hochberg[7], J. Torner*[8], D. Black[3]. [1]VAMC & U of MN, Minneapolis, MN, USA, [2]Merck, Rahway, NJ, USA, [3]UCSF, San Francisco, CA, USA, [4]UCSD, San Deigo, CA, USA, [5]Kaiser Center for Health Research, Portland, OR, USA, [6]Stanford U, Stanford, CA, USA, [7]U of MD, Baltimore, MD, USA, [8]U of IA, Iowa City, IA, USA.

Prior trials including the Fracture Intervention Trial (FIT) have shown that therapy with alendronate (ALN) increases bone mineral density (BMD) and decreases fracture risk for at least 4 yrs. However, it is unknown if continued therapy with ALN will result in preservation or further gains in BMD. To determine whether further therapy with ALN increases BMD relative to placebo (PBO), FLEX enrolled 1099 women aged 60-86 yrs who were assigned to ALN in FIT and received 3-6 yrs of ALN (mean 5 yrs) and re-randomized them to ALN 10 mg/d (30%), ALN 5 mg/d (30%), or PBO (40%) for 5 additional years. All women receive calcium/ vit D supplements. Primary endpoint is change in total hip BMD. We report here results from a pre-planned interim analysis after 3 yrs.

Among these women who had prior ALN therapy in FIT, further therapy with ALN (5 & 10 mg groups pooled) for 3 yrs maintained or increased mean BMD compared with PBO at the total hip (2.0% difference) and lumbar spine (2.6%) (Table). Cumulative increases in total hip BMD from FIT baseline were higher for pooled ALN groups (3.0%) compared with PBO (0.9%) (Table). Compared with the 5 mg group, maintenance of hip BMD during FLEX was slightly greater in the 10 mg group, though gains in spine BMD did not significantly differ. Evaluation of change in bone turnover markers showed partial resolution of prior treatment effect in the PBO group (mean 25% increase in urinary N-telopeptide/Cr and 17% increase in bone alkaline phosphatase from FLEX baseline) compared with relatively stable levels in the pooled ALN groups (p<0.001 for both comparisons). Safety and tolerability profile of ALN was similar to that of PBO, including the incidence of upper GI adverse events (30% for pooled ALN groups & 36% for PBO). In conclusion, compared with women who stop therapy after an average of 5 yrs, those who continue ALN maintain a higher BMD.

Table. Mean % Change (SE) in BMD from FLEX Baseline to FLEX Month 36 & from FIT Baseline to FLEX Month 36 (note: all patients received 3-6 yrs of ALN use prior to FLEX)

Site	% Change from FLEX Baseline to FLEX Month 36 (mean 2.9 yrs) Mean (SE)		% Change from FIT Baseline to FLEX Month 36 (mean 8.6 yrs) Mean (SE)	
	PBO	ALN	ALN / PBO	ALN / ALN
Total Hip	-2.39* (0.18)	-0.42*† (0.15)	0.85* (0.27)	3.00*† (0.23)
Lumbar Spine	0.94* (0.24)	3.49*† (0.20)	10.41* (0.42)	12.93*† (0.35)

* p < .01 within-treatment test of mean = 0

† p < .001 for comparison between ALN vs. PBO

Consistency of Response to 6-Year Treatment with Alendronate among Subgroups. D. J. Hosking[1], C. Christiansen[2], R. D. Wasnich[3], M. Wu*[4], P. D. Ross[4], A. Mantz*[4], C. Sisk*[4], A. Santora[4]. [1]Mineral Metabolism, Nottingham City Hospital, Nottingham, United Kingdom, [2]Center for Clinical and Basic Research, Ballerup, Denmark, [3]Hawaii Osteoporosis Center, Honolulu, HI, USA, [4]Merck & Co., Inc., Rahway, NJ, USA.

The bisphosphonate alendronate is effective for both the treatment and prevention of osteoporosis. The purpose of the present investigation was to evaluate changes in lumbar (L1-L4) spine bone mineral density (BMD) after 6 years of treatment with alendronate in healthy postmenopausal women as a function of age, years since menopause, baseline BMD, or body mass index (BMI). A separate analysis was conducted for each variable using tertile subgroups. In the Early Postmenopausal Intervention Cohort (EPIC) study, 1609 healthy postmenopausal women were randomized to placebo, alendronate 2.5 mg, alendronate 5 mg, or open-label estrogen/progestin. BMD was measured annually using a Hologic QDR 2000 densitometer. Relative to placebo, there was a consistent, dose-related benefit of alendronate treatment on lumbar spine BMD for all subgroups, although the magnitude of BMD changes varied among certain subgroups. Percent changes in BMD at Year 6 are presented for the placebo and 5 mg groups in the following table:

AGE (yr)	**≤52**		**53 to 55**		**>55**	
Treatment	**N**	**Mean (SD)**	**N**	**Mean (SD)**	**N**	**Mean (SD)**
Placebo	95	-4.38 (4.44)	56	-3.55 (4.49)	79	-0.86 (3.92)
Alendronate 5 mg	67	2.55 (4.69)	38	2.60 (4.66)	44	6.16 (4.65)

YSM	**≤2**		**3 to 7**		**>7**	
Treatment	**N**	**Mean (SD)**	**N**	**Mean (SD)**	**N**	**Mean (SD)**
Placebo	85	-5.53 (4.24)	83	-2.09 (4.03)	62	-0.64 (3.87)
Alendronate 5 mg	44	2.41 (5.49)	53	4.67 (4.08)	51	3.68 (5.06)

BASELINE SPINE BMD	**T≤-1.5**		**T= -1.4 to -0.6**		**T>-0.6**	
Treatment	**N**	**Mean (SD)**	**N**	**Mean (SD)**	**N**	**Mean (SD)**
Placebo	73	-2.24 (5.08)	83	-3.01 (3.94)	74	-3.64 (4.55)
Alendronate 5 mg	39	3.48 (4.47)	51	4.21 (5.20)	59	3.22 (5.00)

BMI (kg/m²)	**≤23.41**		**23.42 to 26.82**		**>26.82**	
Treatment	**N**	**Mean (SD)**	**N**	**Mean (SD)**	**N**	**Mean (SD)**
Placebo	78	-4.48 (4.43)	84	-2.86 (4.48)	68	-1.37 (4.21)
Alendronate 5 mg	63	2.59 (4.10)	44	3.99 (4.61)	42	4.81 (6.04)

Women in the placebo group who were younger, were less than 7 years postmenopausal, had higher baseline spine BMD, or had lower BMI values had greater BMD declines compared with other women, but alendronate treatment exhibited a positive benefit in every situation. Statistical tests for interaction did not detect any significant treatment-by-subgroup interactions. In conclusion, postmenopausal women treated with placebo for 6 years experienced significant progressive declines in BMD. Conversely, treatment with alendronate for 6 years produced dose-dependent increases in bone mass irrespective of years since menopause, baseline lumbar spine BMD, and body mass index (BMI).

Oral Daily Ibandronate Rapidly Reduces the Risk of New Mild, Moderate and Severe Vertebral Fractures after 1, 2 and 3 Years. D. Felsenberg[1], P. D. Miller[2], R. C. Schimmer[3], S. E. Papapoulos[4]. [1]Universitätsklinikum Benjamin Franklin, Berlin, Germany, [2]CCBR, Lakewood, CO, USA, [3]F. Hoffmann-La Roche Ltd, Basel, Switzerland, [4]Leiden University Medical Center, Leiden, Netherlands.

Ibandronate, a potent, nitrogen-containing bisphosphonate, is the subject of an extensive clinical development program. A recent multicenter, randomized, placebo-controlled phase III study in postmenopausal women with osteoporosis (oral iBandronate Osteoporosis vertebral fracture trial in North America and Europe: BONE) demonstrated that oral daily (2.5mg) ibandronate significantly and substantially reduces the risk of new morphometric vertebral fractures (VFs) by 62% (p=0.0001) versus placebo after 3 years.[1] In addition, daily ibandronate normalized the rate of bone turnover and significantly increased spinal and hip BMD. To investigate the ability of oral daily ibandronate to prevent new incident VFs of varying degrees of severity, a retrospective exploratory analysis was conducted using established criteria.[2] Definitions used to diagnose mild, moderate and severe incident VFs were as follows: relative height reduction in a vertebral body (anterior, middle or posterior heights) of >20%–25% for mild fracture, >25%–40% for moderate fracture and >40% for severe fracture. Oral daily ibandronate consistently and significantly reduced risk of combined new mild, moderate and severe VFs after 1 (50%; p=0.03), 2 (52%; p=0.001) and 3 (49%; p=0.0002) years of treatment. For the combined analysis of VFs of a higher degree of severity (moderate and severe), an even more pronounced effect was seen: daily ibandronate significantly and consistently reduced the risk of debilitating moderate and severe VFs by 59% after 1, 2 and 3 years (see figure). These findings corroborate the

results from the analysis of new morphometric VFs. In summary, oral daily ibandronate significantly reduces risk of new mild, moderate and severe VFs within 1 year of treatment. This magnitude of risk reduction is sustained throughout 2 and 3 years of therapy. The proven oral daily ibandronate (2.5mg) regimen is the active comparator in ongoing studies to evaluate two novel treatment approaches: once monthly oral and intermittent i.v. injections.

F354

A Multinational Study Demonstrating Significant Reduction in the Incidence of New Vertebral Fractures with Oral Daily and Intermittent Ibandronate. R. Wasnich[1], D. Felsenberg[2], R. Lorenc[3], C. Hughes*[4], R. C. Schimmer[4]. [1]Radiant Research, Honolulu, HI, USA, [2]Universitätsklinikum Benjamin Franklin, Berlin, Germany, [3]Osteoporotic Center, The Children's Memorial Health Institute, Warsaw, Poland, [4]F. Hoffmann-La Roche Ltd, Basel, Switzerland.

Less frequent bisphosphonate dosing is predicted to enhance patient management in postmenopausal osteoporosis. Ibandronate is a potent, nitrogen-containing bisphosphonate that can be given with extended between-dose intervals. The fracture efficacy of oral daily (2.5mg) and intermittent (20mg every other day for 12 doses every 3 months) ibandronate was recently demonstrated in a multinational, placebo-controlled, double-blind, randomized study (oral iBandronate Osteoporosis vertebral fracture study in North America and Europe: BONE), involving 2,946 women in North America and Europe.[1] After 3 years, daily and intermittent ibandronate significantly reduced the risk of new incident vertebral fractures in the overall population by 62% [p=0.0001] and 50% [p=0.0006], respectively, relative to placebo. Substantial increases in lumbar spine and hip BMD and decreases in biochemical markers of bone turnover were also observed. Both regimens were well tolerated, with a safety profile similar to placebo. The frequency of patients with new incident vertebral fractures, and the corresponding reduction in the relative risk, was also analyzed by continent. A significant reduction in the incidence of new vertebral fractures was observed in both European and North American patient subgroups. In the North American subgroup (n=995), the incidence of new vertebral fractures was significantly lower in the daily (3.2%; 95% CI, 1.0–5.4; p=0.0242; n=331) and intermittent (3.7%; 95% CI, 1.3–6.1; p=0.0372; n=333) arms compared with the placebo arm (8.0%; 95% CI, 4.6–11.3; n=331) after 3 years. At this time point, the relative-risk reductions compared with placebo were 75% and 54%, respectively. A similar finding was observed in the European subgroup (n=1,933). After 3 years, the incidence of new vertebral fractures was significantly lower in the daily (5.4%; 95% CI, 3.5–7.3; p=0.0028; n=646) and intermittent (5.5%; 95% CI, 3.6–7.4; p=0.0051; n=644) arms compared with the placebo arm (10.3%; 95% CI, 7.7–13.0; n=643). At this time point, the relative-risk reductions compared with placebo were 57% and 48%, respectively. This sub-analysis confirms the robust and consistent fracture efficacy of oral daily and intermittent ibandronate in postmenopausal osteoporosis. Ongoing studies are evaluating the efficacy and safety of oral monthly ibandronate regimens in postmenopausal osteoporosis.

F356

The Effect of Hormone Replacement Therapy, Alendronate, or the Combination of Both on Hip Structural Geometry: A 3-Year, Randomized, Double-Blind, Placebo-Controlled, NIH-Funded Clinical Trial. S. L. Greenspan[1], R. Bhattacharya*[1], T. J. Beck[2], N. M. Resnick*[1], R. A. Parker*[3]. [1]Univ. of Pittsburgh, Pittsburgh, PA, USA, [2]Johns Hopkins School of Medicine, Baltimore, MD, USA, [3]Harvard School of Public Health, Boston, MA, USA.

Fracture reduction by hormone replacement therapy (HRT) and alendronate (ALN) is only partially explained by increased bone mineral density (BMD). These agents may improve bone strength by alterations in structural geometry, which are not depicted by BMD. To examine bone structural geometry following treatment with HRT, ALN, and combination therapy (HRT+ALN) vs. placebo, we examined femoral neck geometric parameters at the narrow neck (NN) and intertrochanter (IT) during a 3-year, blinded, prospective clinical trial. Cross-sectional moments of inertia (CSMI), bone cross-sectional area (CSA), section modulus (SM, a measure of bending strength), cortical thickness (CT), and buckling ratio (BR, an index of cortical stability) were assessed from Hologic BMD DXA data using "Hip Structure Analysis" by Beck. We randomized 373 community-dwelling postmenopausal women to ALN 10 mg/d, HRT (conjugated estrogen 0.625 mg/d ± progesterone), ALN+HRT, or placebo.

NN BR*	12.1#	8.0#	5.9#	5.9#

Table Legends: *p<0.05 across 4 groups, #p<0.05 from baseline, ^p<0.05 HRT vs. HRT+ALN, **p<0.05 HRT vs. ALN

All BMD and structural parameters improved on active treatment. Only one structural parameter improved more on ALN than HRT, but nearly all IT parameters improved more on combination therapy than with HRT alone. Because of less precision for structural parameters than BMD, we cannot determine whether combination therapy is superior to ALN alone, although the trends all support this conclusion.

The Efficacy of Clodronate (Bonefos®) to Reduce the Incidence of Osteoporotic Fractures in Elderly Women Is Independent of the Underlying BMD. E. McCloskey[1], T. Jalava*[2], A. Oden*[3], H. Johansson*[3], K. Kayan*[1], M. Beneton*[1], J. Brazier*[1], J. Nicholl*[1], A. Richards*[1], J. Cliffe*[1], L. Reaney*[1], J. Nevalainen*[2], J. Kanis[1]. [1]University of Sheffield, Sheffield, United Kingdom, [2]Schering Oy, Helsinki, Finland, [3]University of Stockholm, Stockholm, Sweden.

Bisphosphonates significantly reduce the incidence of fractures in women with low BMD, but their efficacy in women with normal or osteopaenic BMD is less well studied. The aim of this study was to quantify the effect of oral clodronate on the incidence of osteoporotic fractures in an elderly cohort of women unselected for osteoporosis.

We studied 5592 women aged 75 years and older, randomly selected from the local population, in a 3 year double-blind, placebo controlled study of clodronate 800mg daily. Women were randomised regardless of the presence or absence of risk factors such as low BMD or prior fracture. At baseline, the two treatment groups were well-matched for the prevalence of risk factors except for a small but statistically significant higher prevalence of prior non-vertebral fractures in the clodronate group (24.4 vs. 21.1%, p=0.004). The efficacy of clodronate was determined using Cox regression analysis and the interaction between BMD and other factors on the effect of clodronate to reduce fracture risk was examined using a Poisson model.

At entry to the study, only 19.3% of women had osteoporosis defined as a total hip BMD<0.64g/cm^2 (Hologic QDR4500). Treatment with clodronate was associated with a significant decrease in the incidence of any clinical fracture (HR 0.80, 95%CI 0.68-0.94, p=0.005) or any osteoporotic fracture during the 3 years of treatment (HR 0.77, 95%CI 0.64-0.93) though the incidence of hip fractures was similar in the two groups (2.0 vs. 2.1%, p=0.92). The reduction in risk remained unchanged in models adjusting for age, BMI, total hip BMD and prior fracture. There was no significant interaction between the reduction in risk and total hip BMD at entry to the study when examined as a continuous variable (p=0.22) or as a categorical variable (osteoporosis, osteopenia or normal, p=0.71). The number needed to treat to prevent an osteoporotic fracture varied from 62 in those without hip osteoporosis to 25 in those with osteoporosis.

We conclude that oral clodronate 800mg daily reduces the rate of osteoporotic fractures by a mean of 23% during 3 years of treatment in elderly women unselected for osteoporosis. This effect occurs in women with BMD values above or below the osteoporotic threshold. However, strategies that target treatment to women at increased risk of fracture, including those with low BMD, should be used to direct clodronate therapy.

Salmon Calcitonin Nasal Spray (CT-NS) May Preserve/Improve Trabecular Microarchitecture (TMA) in the Distal Radius through 2 Years in Postmenopausal Osteoporotic Women (PM-OP): High Resolution MRI (HR-MRI) Results from the QUEST Study. C. Chesnut[1], S. Majumdar[2], A. Shields[1], D. Newitt[2], E. Laschansky*[1], A. Kriegman*[3], M. Olson*[4], F. Hornig*[4], M. Azria[4], P. Richardson[3], L. Mindeholm*[4]. [1]University of Washington, Seattle, WA, USA, [2]UCSF, San Francisco, CA, USA, [3]Novartis Pharma, East Hanover, NJ, USA, [4]Novartis Pharma, Basel, Switzerland.

CT-NS reduces spine fracture (fx) frequency in PM-OP♀, but with modest effects on bone quantity (BMD) and bone turnover (BT: markers of bone resorption); to explain this apparent paradox a primary CT-NS effect on bone quality (specifically TMA) has been postulated (JBMR, 2001). The 2 yr double blind placebo (P) controlled randomized QUEST trial in 91 PM-OP♀ examines the effects of CT-NS 200 I.U. q.d. on TMA utilizing HR-MRI.

Assessment of QUEST HR–MRI results (axial images [resolution 156x156x500 um] at 1.5 Tesla using a dedicated wrist coil; 4 regions of interest, 5 mm volume each, extending 12 mm from joint line into distal shaft):

HR-MRI at the distal radius (DR) after 2 years of 200 IU CT-NS or placebo

Parameter	Region of distal radius	N(CT-NS/P)	% change CT-NS/P	p within group CT-NS/P	p between groups

	II	33/35	0.50/-1.05	P=NS/NS	P=NS
	III	34/36	-1.96/-2.57	p=.04**/.02**	p=NS
	IV	33/30	-1.76/-1.45	p=NS/NS	p=NS

†apparent, as measured by HR-MRI **pψ0.05 *0.05<pψ0.10

As expected, trab# and trab spacing varied inversely (r=-.83–-.97, p<.0001). 2 years of CT-NS (last available value, means adjusted for baseline values) increased or preserved bone vol, trab # and thickness at DR, while preserving or decreasing trab spacing; P resulted in significant losses of bone vol, trab # and thickness. The difference between CT-NS and P approached or reached significance in at least one region of DR for all parameters measured except trab thickness; intrasite differences in therapeutic response were noted at DR.

In conclusion, 200 IU CT NS, as compared to P, may preserve/improve TMA through 2 years in PMOP♀, as measured by the unique non-invasive HR-MRI technique at the DR. Such findings, from the first study designed a priori to examine the effects of antiresorptive Rx on TMA, may provide a partial explanation of CT-NS's mechanism of action in reducing OP fx.

Effect of Octreotide on the Skeletal Response to Oral Calcium Supplementation. D. M. Prentis*, J. A. Clowes, N. Nazarina*, H. C. Allen*, R. Eastell, A. Blumsohn. Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom.

Oral intake of several nutrients, including calcium and glucose, results in acute suppression of bone turnover markers. We have previously shown that response of serum β C-terminal telopeptide of type I collagen to glucose is not mediated by insulin and can be abolished by octreotide, a somatostatin analogue. This suggests that another somatostatin inhibitable gut peptide may mediate this response. The acute skeletal response to calcium could be mediated by PTH or by a direct effect of ionized calcium on osteoclast function. We have examined an alternative possibility that an octreotide-inhibitable factor could mediate the response to oral calcium.

Nine subjects (6M, 3F, age 29.2±6.4 SEM) were each studied on 4 occasions in a randomised single blind crossover study. On each occasion each participant received either 1) oral water + iv saline, 2) oral calcium carbonate (1000 mg) + iv saline, 3) oral calcium + iv octreotide (50 μ g/hr) and 4) oral water + iv octreotide. The infusion was started at 09:00 (time -30 min) and oral calcium was given at 09:30 (time 0 min) following an overnight fast. We measured serum β C-terminal telopeptide of type I collagen (sβ CTX), osteocalcin (OC), procollagen type I N-terminal propeptide (PINP), ionised calcium, and PTH over 4 hours following the oral load.

Octreotide completely abolished the decrease in sβ CTX in response to calcium. At 240 minutes sβ CTX decreased 35.65%± 5.39SEM (P<0.001) in response to calcium alone, compared to an increase of 17.44%± 6.61SEM (P>0.05) for calcium and octreotide. Calcium inhibited PTH secretion with a maximum decrease of 42.24 ± 7.01 (P<0.01) at 90min. Pre-treatment with octreotide delayed the decrease in PTH with a maximum response of -30.83± 7.54 (P<0.01) at 240min. Octreotide alone, without calcium, resulted in a 69.64%± 15.47 increase in PTH from baseline (-30min). Octreotide alone increased sβ CTX by 27.15%± 4.75 compared to a 10.79%± 4.74 increase with placebo at 240 minutes (P<0.01). Both response to calcium and inhibition of response with octreotide were less consistent with bone formation markers (OC, PINP).

We conclude that the acute response of serum β CTX to oral calcium is abolished during octreotide infusion, despite a similar PTH response. However, baseline PTH secretion is higher during octreotide infusion, and octreotide may also have a direct effect on bone resorption, skeletal blood flow, or metabolic clearance of collagen fragments. The acute antiresorptive response to oral calcium could be mediated, at least in part, by a somatostatin inhibitable endocrine factor.

Vertebroplasty : Insufficient Diagnosis and Treatment of Osteoporosis Post Procedure. C. Recknor[1], A. B. Klemes[2]. [1]United Osteoporosis Centers, Gainseville, GA, USA, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

Vertebroplasty is being used more frequently for pain relief in vertebral compression fractures. Ideally osteoporosis diagnosis and treatment should occur long before these procedures. It is not known if this is truly what is happening in the centers doing vertebroplasty. We wanted to look at how often DXAs are being done on these patients and how often treatment is being initiated post procedure.

We did a retrospective review of 156 patients who had such procedures between 1999 and 2001. Thirty-nine of these patients (25%) had received follow-up DXAs after the procedure. 35 of the 39 (90%) had T scores below -2. 29 of the 39 (74%) were osteoporotic according to WHO criteria.

We then looked at a subset of these patients on whom DXAs had been performed. A total of four patients had been on therapy prior to the procedure. Their treatment consisted of Salmon Calcitonin nasal spray.

Eight patients commenced therapy after the procedure. Six of these patients were started on oral bisphosphonates, one was started on IV Pamidronate therapy and one was started on Raloxifene. One of the original four on Salmon Calcitonin was switched to a bisphosphonate after the procedure.

Despite the aggressive intervention with vertebroplasty, the underlying diagnosis of osteoporosis was frequently not addressed. Post procedure only 25% of patients had DXA scans performed. In this study even after the diagnosis was made only eight patients were treated.

Estrogen + Progestin Reduces the Risk of Fractures Regardless of Risk Factors: The Women's Health Initiative. N. B. Watts, J. Robbins, Z. Chen, S. R. Cummings, R. Jackson, A. LaCroix, M. LeBoff, C. E. Lewis, J. McGowan, J. Neuner*, J. Pettinger*, M. Stefanick*, J. Wactawski-Wende, J. A. Cauley. University of Cincinnati College of Medicine, Cincinnati, OH, USA.

In the Women's Health Initiative (WHI) Estrogen plus Progestin trial, 16,608 postmenopausal non-hysterectomized women, age 50 to 79 at baseline, were randomized to conjugated equine estrogen 0.625 mg + medroxyprogesterone acetate 2.5 mg/day or placebo and followed for an average of 5.2 years. Hip and vertebral fractures were reduced by 34% and total fractures by 24%. Risk factors for fractures were assessed by questionnaire, interview and clinical examination. To see if clinical risk factors could be used to identify women who experienced greater fracture reduction, we explored over 100 subgroups for potential interactions between baseline characteristics and the effect of therapy. We formed a summary score using 9 risk factors: age (≥70), race (White/Asian), weight (<127 lbs), current smoking, family history of fractures, personal history of fractures; low calcium intake (<600 mg/day), self report of ≥2 falls in the past year; and never use of HRT before the trial. We divided the women into approximate tertiles based on the number of risk factors (0-2, 3, 4-9). The annual incidence of all fractures in control subjects from tertile I (lower risk) through tertile III (higher risk) was 1.4%, 1.8%, and 2.5%,demonstrating the validity of the scores. Estrogen plus progestin on fractures reduced the risk of fractures similarly, regardless of the number of risk factors (table).

Number of risk factors	0-2	3	4-9
Number of subjects	2,748	2,657	3,094
Percent (per year) with any fracture			
Placebo	1.4%	1.8%	2.6%
E+P	1.1%	1.4%	2.0%
Hazard ratio	0.75	0.77	0.75
95% CI	0.62,0.92	0.62,0.92	0.65,0.87

Thus, risk factors for fracture do not permit identification a group of women who might derive a greater anti-fracture benefit from estrogen plus progestin therapy. The overall risks of this therapy must be considered when evaluating its use for prevention of fractures.

Long Term Treatment of Aging Hypogonadal Men with a Unique Testosterone Gel (Testim™) Reduces Osteoporotic Changes and Improves Bone Mineral Density. R. T. Bachand*[1], T. M. Smith*[2], A. R. Secrest*[1], J. P. Rodzvilla*[2]. [1]Auxilium Pharmaceuticals, Inc, Libertyville, IL, USA, [2]Auxilium Pharmaceuticals, Inc, Norristown, PA, USA.

Aging hypogonadal men are at increased risk for osteoporotic fractures. Hypogonadism has been correlated with decreases in bone mineral density (BMD) and has been defined as a risk factor for falls (i.e., as a result of decreased muscular strength and impaired balance). Since a large proportion of elderly men have serum T levels below the normal adult reference range [300 – 1000 ng/dL (10.4 – 34.7 nmol/L)], the potential for improving BMD with testosterone (T) replacement therapy warrants further investigation. In the present study, 291 hypogonadal males (mean age of 58 years) previously enrolled in a 3 month active- and placebo-controlled study were followed in a 12 month, open-label, multi-dose, multi-center study to determine the effects of T replacement therapy on T level maintenance, body composition, sexual functioning, mood, and BMD. Baseline serum T was 258 ± 92 ng/dL (± SD; 9.0 ± 3.2 nmol/L). By month 15, following treatment with 100 mg/d of Testim™, serum T increased to 455 ± 365 ng/dL (15.8 ± 12.7 nmol/L). The mean BMD of the lumbar spine (L1 – L4), measured by dual x-ray absorptiometry, increased significantly ($P < 0.001$) from 1.177 before treatment to 1.214 gm/cm^2 (+ 2.75%) at month 15. Additionally, Testim™ therapy was well tolerated with only the known class effects of T therapy being noted (e.g., mild increases in hemoglobin, hematocrit, RBCs, and prostate specific antigen levels). The results of this study confirm the ability of T replacement therapy utilizing Testim™ to produce significant increases in BMD. T replacement therapy may offer a promising therapeutic option in aging males by preventing future bone loss and the associated risks of fractures. T replacement therapy may also offer additive protection from fractures by reducing the propensity for falls.

PSK3471, a New Anabolic Designer Estrogen Fully Restores Bone Mass in Ovariectomized Mice with Established Osteopenia. P. Clément-Lacroix, D. Minet*, C. Belleville*, L. Lepescheux, F. Nique*, N. Bruyniks, M. Resche-Rigon, R. Baron. ProSkelia Pharmaceuticals, Romainville, France.

Raloxifene (RAL), an early SERM, has proven efficacy in the management of osteoporosis in postmenopausal women, increasing bone mass and reducing the risk of vertebral, but not non-vertebral, fractures. PSK3471 is a novel selective designer estrogen with good safety profile on breast and uterus, which efficiently prevents bone loss in OVX mice. In the present study we have evaluated the potential anabolic effects of PSK3471 by testing its ability to restore bone mass to normal levels in ovariectomized (OVX) mice with established osteopenia.

Eight weeks after ovx, mice displaying a clear osteopenia, were treated with PSK3471 (0.03, 0.1, 0.3 mg/kg/d) or RAL (10 mg/kg/d) p.o. for 8 weeks or with E2 0.25 mg/kg/wk s.c. As expected, significant bone loss was observed in the proximal tibia two months after ovariectomy (-13% and –22% compared to sham controls, for total and trabecular BMD respectively) and was associated with increased bone turn over, as measured by bone markers. Two months later, i.e. 4 months after ovx, no further bone loss was observed and the bone turnover was normalized compared to age-matched sham-operated mice.

After 8 weeks, total and trabecular BMD were similar in sham-operated mice and in mice treated with estradiol, or receiving the lowest dose of PSK3471. Furthermore, increasing the dose of PSK3471 not only fully restored OVX-associated bone loss, but also elicited an increase in trabecular bone mass versus sham-operated mice (+15% vs. sham $p<0.001$, for PSK3471 0.1 and 0.3 mg/kg/d). In contrast to PSK3471, RAL (10 mg/kg/d) only partially restored OVX-induced bone loss (+7.9% vs. OVX; ns). MicroCT analysis confirmed that PSK3471 increased cancellous bone volume (+52% to +68% vs. OVX; $p<0.01$), whereas RAL exhibited only a partial effect (+14% vs. OVX, ns). Most interestingly, and in contrast to RAL, PSK3471 also dose-dependently increased cortical BMD in the tibia (+2.7% to +3.8% vs. OVX; $p=0.03$, at 0.1 and 0.3 mg/kg). Finally, and although E2 treatment significantly increased serum OCN (+20%: $p<0.05$), only trends towards increases were observed in groups treated with PSK3471 as compared to OVX (+9.7%, +19% and +9.2% for 0.03, 0.1, and 0.3mg/kg/d respectively).

Thus, PSK3471 not only protects against ovx-induced bone loss but it is also able to restore bone mass in mice with established osteopenia, acting at both trabecular and cortical bone, whereas RAL was less efficient and acting only at the trabecular bone level. PSK3471 therefore acts as a tissue selective bone anabolic designer estrogen and may provide an advantage in the prevention of non-vertebral fractures.

Response to Treatment with Estrogen Is Related to Endogenous Levels of Serum Testosterone and SHBG. P. B. Rapuri[1], J. C. Gallagher[1], G. Haynatzki*[2]. [1]Bone Metabolism Unit, Creighton University, Omaha, NE, USA, [2]Department of Medicine, Creighton University, Omaha, NE, USA.

Recent evidence suggests that in postmenopausal women, low serum concentrations of endogenous hormones are related to bone mineral density (BMD) and fracture risk. The aim of the present study was to see if the response in BMD to estrogen/hormone therapy (ET/HT) was related to baseline serum testosterone and sex hormone binding globulin (SHBG) levels. 489 elderly women aged 65-77 years were randomly assigned to one of the following regimens, placebo, calcitriol, ET/HT and ET/HT+calcitriol.The endogenous serum total testosterone and SHBG levels were determined by a sensitive RIA. Serum bioavailable testosterone levels were calculated as the difference between total and SHBG bound testosterone. BMD was measured by DEXA and rate of change in BMD in spine and proximal femur after 3 years of treatment was compared between the tertiles of serum total and bioavailable testosterone. The data were analyzed by procedure Mixed from the SAS statistical package. Adjustments were made for appropriate covariates like age, weight etc. There was no relation between the effect of calcitriol treatment and serum total, bioavailable testosterone and SHBG levels. In women receiving ET/HT alone, the lowest tertile of total and bioavailable testosterone had significantly ($p<0.05$) higher increases in BMD at femoral neck, trochanter and total femur compared to the highest tertile. Although, there was a similar trend for spine BMD, the differences were not statistically significant. On the other hand, the highest tertile of SHBG was associated with significantly ($p<0.05$) higher increases in BMD at spine and proximal femur. In women receiving combination treatment with ET/HT+calcitriol, there was no relation between total, bioavailable testosterone levels and rate of change in BMD. However, the highest tertile of SHBG was associated with higher increases in BMD in these women though not statistically significant. These results show that the increase in BMD on ET/HT treatment is significantly higher in women whose pretreatment serum levels of total and bioavailable testosterone are low and SHBG levels are high. Whether testosterone independently has an effect on BMD or through its conversion to estradiol is not known.

The Effects of Estrogen Plus Progestin, on Bone Mineral Density (BMD) in Postmenopausal Women of Different Ages and Ethnic Groups Enrolled in the Women's Health Initiative (WHI). M. S. LeBoff[1], J. Cauley[2], Z. Chen[3], A. LaCroix[4], M. Pettinger*[5], S. Cummings*[6], N. B. Watts[7], C. Lewis[8], J. McGowan[9], M. Stefanick[10], J. Wactawski-Wende[11], J. Robbins[12], R. Jackson[13], J. Neuner*[14]. [1]Endocrine, Diabetes, Hypertension Division, Brigham and Women's Hospital, Boston, MA, USA, [2]U Pitt, Pittsburgh, PA, USA, [3]U AZ, Tucson, AZ, USA, [4]FHCPC, Seattle, WA, USA, [5]FHCRC, Seattle, WA, USA, [6]UCSF, San Francisco, CA, USA, [7]U Cincinnati, Cincinnati, OH, USA, [8]UAB, Birmingham, AL, USA, [9]NIAMS, Bethesda, MD, USA, [10]Stanford, Palo Alto, CA, USA, [11]University at Buffalo, Buffalo, NY, USA, [12]UC Davis, Sacramento, CA, USA, [13]Ohio State University, Columbus, OH, USA, [14]U WI, Milwaukee, WI, USA.

In most longitudinal randomized clinical trials (RCT), estrogen and progestin (E+P) therapy increases BMD. However, many of these RCT are limited by small sample size and lack of inclusion of women over wide age ranges or from different ethnic backgrounds. Data from the WHI, RCT recently showed that E+P (0.625 mg of conjugated equine estrogen plus 2.5 mg medroxyprogesterone acetate) vs placebo for an average of 5.2 years lead to a 34% reduction in hip and clinical spine fractures in a racially diverse group of 16,608 healthy postmenopausal women enrolled between ages 50 to 79 years (JAMA 20002; 288:321). BMD was measured in 3 of the 40 clinical centers (n=854) at baseline and year 1 and year 3 using DXA (Hologic QDR-2000 or 4500). At baseline, 1.55% of the women randomized to receive E+P and 3.25% assigned to the placebo group were osteoporotic (T-score below -2.5), respectively. From baseline to year 3, the increase in spinal BMD was 6.2±5.8%** in women randomized to E+P vs 1.7±5.4 % in those randomized to placebo. In women treated with E +P, BMD of the, hip, and total body also increased significantly from baseline to year 3.

Change (%) in Total Hip BMD (Baseline to year 3)

	N	E+P	N	Placebo
		Mean ±SD (%)		Mean ± SD (%)
Entire Subsample Age	446	3.70 ±4.07**	408	0.14 ± 4.4
50-59	166	3.75 ±4.1**	131	0.05 ±3.7
60 – 69	188	3.68 ±3.9**	179	0.14 ±4.4
70+	92	3.63 ±4.2**	98	0.26 ±5.1
Race/Ethnicity				
White	371	3.68 ±4.0**	335	0.09 ±4.5
Black	36	2.96 ±3.7**	51	0.15 ±3.6
Hispanic	29	4.91 ±5.4**	15	-0.10 ±4.1

There were no significant differences in the change in lumbar spine, total hip (shown in Table), or total body bone density in women according to age or race. In summary, WHI results showed significant increases in BMD in women randomized to E+P from baseline to year 3 and that the effects of estrogen plus progestin on BMD increments were similar across all age ranges and ethnic groups.
E+P vs. Placebo** $p<0.0001$

Bone Response to Treatment with Lower Doses of Conjugated Equine Estrogens With and Without Medroxyprogesterone Acetate in Early Postmenopausal Women. R. Lindsay[1], M. Kleerekoper[2], J. Gallagher[3], J. Pickar*[4]. [1]Internal Medicine, Helen Hayes Hospital, West Haverstraw, NY, USA, [2]Medicine, Wayne State University School of Medicine, Detroit, MI, USA, [3]Medicine, Creighton University Medical Center, Omaha, NE, USA, [4]Clinical Research and Development, Wyeth Research, Collegeville, PA, USA.

Lower doses of conjugated equine estrogens (CEE) alone or combined with lower doses of medroxyprogesterone acetate (MPA) increase mean bone mineral density (BMD) from baseline at the spine and hip in early postmenopausal women. The incidence of continued bone loss (loss of BMD >2% from baseline) among these women using lower doses of CEE and CEE/MPA is unknown. Thus, we assessed the incidence of continued bone loss with lower doses of CEE with and without MPA.

This randomized, double-blind, placebo-controlled, multicenter substudy of the Women's Health, Osteoporosis, Progestin, Estrogen (Women's HOPE) trial included 822 healthy, postmenopausal women with an intact uterus. Patients received CEE 0.625, CEE 0.625/MPA 2.5, CEE 0.45, CEE 0.45/MPA 2.5, CEE 0.45/MPA 1.5, CEE 0.3, CEE 0.3/MPA 1.5 (all doses in mg/d), or placebo for 2 years.

Changes from baseline in spine and total hip BMD were assessed annually and compared among treatment groups in an intent-to-treat analysis. Continued bone loss was defined as a loss in spine BMD or hip BMD of >2% compared to baseline values.

Less than 10% of patients in each active treatment group lost >2% of spinal BMD at 12 months, with the exception of patients on CEE 0.3/MPA 1.5 (15.6%), compared to 41.2% of patients on placebo. At 24 months, the percentages of patients in the active groups who lost >2% of spine BMD ranged from 4.5% with CEE 0.45/MPA 1.5 to 15.6% with CEE 0.3/MPA 1.5, compared to 55.3% of patients on placebo. Over 85% of patients on each of the active treatments did not experience losses of BMD that were >2% at the hip at 12 and 24 months. In contrast, BMD decreased by >2% in 30.6% of patients on placebo at 12 months and 36.5% at 24 months.

These results indicate that continued bone loss among early postmenopausal women treated with lower doses of CEE or CEE/MPA is uncommon.

Risk-Benefit Assessment of Raloxifene: Influence of Baseline Cardiovascular Risk. E. Barrett-Connor[1], J. A. Cauley[2], A. Sashegyi*[3], P. M. Kulkarni*[3], D. A. Cox*[3], M. J. Geiger*[3]. [1]UCSD School of Medicine, La Jolla, CA, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN, USA.

Raloxifene is a selective estrogen receptor modulator (SERM) indicated for the prevention and treatment of osteoporosis in postmenopausal women. We used the global risk index defined in the Women's Health Initiative (WHI) estrogen-progestin trial to assess the overall risk-benefit profile of raloxifene (RLX) and assessed whether this profile is influenced by cardiovascular (CV) risk.

The Multiple Outcomes of Raloxifene Evaluation (MORE) 4-year osteoporosis treatment trial randomized 5133 postmenopausal women (mean age, 67 yrs) to placebo (N=2576) or RLX 60 mg/d (N=2557). Global index events included coronary heart disease (non-fatal MI, coronary death, or silent MI determined by ECG), stroke, pulmonary embolism, invasive breast cancer, endometrial cancer, colorectal cancer, hip fracture, and total mortality. Events were adjudicated by physicians blind to treatment assignment. Cox proportional hazard models were used to analyze the first occurrence of any global index event. Baseline CV risk was assessed by a quantitative risk score based on prior CV event history or CV risk factors.

Women treated with RLX 60 mg/d compared with placebo had a significantly lower risk of experiencing a global index event (HR, 0.75; 95% CI, 0.60-0.96); the risk tended to decrease further as CV risk increased (Table). Contributing to this effect was a lower risk of major CV events (MI, stroke, and coronary death) among women treated with RLX 60 mg/d that also tended to decrease further with increasing CV risk (Table).

The significant reduction in global index with RLX suggests a favorable risk-benefit profile for prevention and treatment of osteoporosis in postmenopausal women overall and in those at increased CV risk.

CV Risk Points	N*	Global Index HR (95% CI)	CV Events† HR (95% CI)
Total Cohort	5133	0.75 (0.60-0.96)	0.71 (0.48-1.06)
≥ 2	3106	0.76 (0.58-1.00)	0.67 (0.44-1.02)
≥ 3	1726	0.66 (0.47-0.92)	0.62 (0.38-1.01)

Both hPTH (1-34) and bFGF Increase Bone Mass in Osteopenic Animals with Different Effects on Trabecular Bone Architecture. N. E. Lane[1], W. Yao[1], M. Balooch*[1], J. H. Kinney[2], T. J. Wronski[3]. [1]Dept. Medicine, UCSF, San Francisco, CA, USA, [2]Dept. Mechanical Engineering, Lawrence Livermore National Lab., Livermore, CA, USA, [3]Dept. Physiological Sciences, University of Florida, Gainesville, FL, USA.

Osteoporosis is a syndrome of excessive skeletal fragility that results from both the loss of trabecular bone mass and trabecular bone connectivity. Recently, basic fibroblast growth factor (bFGF) has been found to increase trabecular bone mass in osteopenic rats (Lane, Ost. Int 2003, Wronski, JBMR 2002). The purpose of this study was to compare how trabecular bone architecture and strength are altered by two different bone anabolic agents, bFGF and hPTH (1-34), in an osteopenic rat model. METHODS: Six-month-old female Sprague Dawley rats were ovariectomized (OVX) or sham-operated (sham) and maintained untreated for 60 days. Then OVX rats were injected sc with 1mg/kg bFGF , 40ug/kg hPTH (1-34), or vehicle 5d/wk for 60 days. At sacrifice, the right proximal tibial metaphysis (PTM) was used for micro-CT scanning and then processed for histomorphometry to assess bone architecture and turnover. The left PTM was used for nanoindentation/mechanical testing of individual trabeculae (Balooch, J Biomed Mat 1998). The data were analyzed with Kruskal Wallis and post-hoc testing. RESULTS: Ovariectomy at day 120 resulted in decreased trabecular bone volume, connectivity and number compared to sham, hPTH(1-34) and bFGF treated groups. Treatment of OVX animals with bFGF and hPTH(1-34) both increased trabecular bone mass compared to OVX but hPTH (1-34) increased trabecular thickness and bFGF increased trabecular number and connectivity. Histomorphometry revealed an increased osteoid volume in bFGF-treated animals compared to both the hPTH(1-34) and OVX animals. Nanoindentation demonstrated that Elastic Modulus and Hardness of the trabeculae in bFGF-treated animals were similar to that of the PTH-treated, OVX and sham animals (see table).

SUMMARY. Both hPTH (1-34) and bFGF are anabolic agents in the osteopenic female rat. However, hPTH (1-34) increases trabecular bone volume primarily by thickening existing trabeculae while bFGF adds trabecular bone mass through increasing trabecular number and trabecular connectivity. These results suggest the possibility of sequential treatment paradigms for severe osteoporosis.

Groups / Treatment	N	Trabecular Bone Volume(%)	Trabecular Connectivity ($1/mm^3$)	Trabecular Number (1/mm)	Osteoid Volume (%)	BFR/BS ($\mu m^3/\mu m^2/d$)	Elastic Modulus (Gpa)

Changes in Serum RANKL, OPG and IL-6 During hPTH (1-34) Administration in Patients with Glucocorticoid Induced Osteoporosis. N. E. Lane, W. Yao, C. D. Arnaud. Dept. Medicine, UCSF, San Francisco, CA, USA.

In vitro and *in vivo* animal studies report both RANKL and IL-6 are produced by osteoblasts in response to PTH stimulation. Since osteoclast maturation and activity are influenced by RANKL, OPG and IL-6, we determined the association of serum levels of sRANKL, OPG, IL-6 and IL-6sR and BMD at multiple time points in patients treated with hPTH (1-34) for 1 yr. and 1yr. follow-up. All subjects had post-menopausal osteoporosis, were treated chronically with glucocorticoid + HRT and were randomized to hPTH (1-34) 40 μg/d (n=28) or control (n=23). Serum sRANKL, OPG, IL-6 and IL-6sR were monitored at baseline (BSL), 1 mo, and then every 3 mos. thereafter. BMD of lumbar spine (SP), total hip region (HIP) and neck of hip region (NKHIP) were obtained at baseline and then every 6 mos thereafter. Differences between and within the hPTH (1-34) and the control groups were analyzed by repeated measurements ANOVA. The relationships between serum sRANKL, OPG and BMD were analyzed by Spearman's correlation.

RESULTS In control group, no significant changes were observed in sRANKL, OPG, IL-6 or IL-6sR levels. However, positive correlations were found between OPG and SP-BMD or NKHIP-BMD at all time points (r = 0.261, p = 0.04 and r = 0.203, p = 0.05), respectively. Negative correlations were found between sRANKL and SP-BMD or HIP-BMD or NKHIP-BMD (r = -0.34, p = 0.02 and r = -0.39, p = 0.01 or r= -0.491, p = 0.0008), respectively. In the hPTH (1-34) group, serum sRANKL increased more than 250% over the BSL level at 3 mos. and was maintained at 150% above BSL for the next 9 mos. The serum OPG level was maintained at the BSL level for the first 3 mos. but decreased by 22% at 6 mos., 38% at 9 mos. and 64% at 12 mos. Serum IL-6 levels increased more than 130% over the BSL level at 3 mo. but returned to BSL level by 9 mos. Serum IL-6sR levels increased about 20% above baseline level by 1 mo. and maintained in this increased level for the next 11 mos. After hPTH (1-34) treatment was discontinued at 12 mos, sRANKL, OPG, IL-6 an IL-6sR returned towards BSL values by 15 mos. (Figure).

SUMMARY Daily hPTH (1-34) injections increased sRANKL and IL-6 production by osteoblasts. Our results support the hypothesis that hPTH (1-34) increases osteoclast activity by stimulating osteoblast production of RANKL and IL-6. Furthermore, serum OPG had a positive while sRANKL had a negative correlation with BMD in the controls.

IkB Kinase Beta (IKKb) Inhibition Prevents Ovariectomy-Induced Bone Loss in Mice. G. Hattersley[1], D. Garnet*[2], R. Fajardo*[3], D. von Stechow*[3], J. Adams*[1], M. Rosenblatt[2], J. M. Alexander[2]. [1]Millennium Pharmaceuticals, Inc, Cambridge, MA, USA, [2]Division of Bone and Mineral Metabolism Research, BIDMC-Harvard Medical School, Boston, MA, USA, [3]Orthopedic Biomechanics Laboratory, BIDMC-Harvard Medical School, Boston, MA, USA.

Nuclear factor (NF)-κB is one of several transcription factors that play a critical role in regulating osteoclast differentiation from hematopoietic progenitor cells. Nuclear translocation and transcriptional activity of NF-κB requires release from an inhibitory protein (IκB) that sequesters NF-κB in the cytoplasm. This process is partly controlled by the activity of IκB kinases that phosphorylate IκB, leading to ubiquitination and subsequent proteolysis, exposing a nuclear localization sequence on NF-κB permitting its translocation to the nucleus and binding to target DNA elements. We explored the hypothesis that a novel non-peptide IκB kinase beta inhibitor would disrupt NF-κB signaling and protect mice from developing ovariectomy (OVX) induced osteopenia by impairing osteoclast differentiation and function. In cultures of mouse bone marrow cells the IKKb inhibitor potently suppressed RANKL/1,25-dihydroxyvitamin D_3 induced osteoclast formation. In addition we also observed significant inhibition of bone resorption by mature osteoclasts isolated from neonatal mouse bone. We next assessed the in vivo protective effects of the IKKb inhibitor on bone mineral density and trabecular architecture in 12-week old OVX Swiss-Webster mice after 5 weeks of treatment initiated immediately after OVX using micro-computed tomography. Vehicle-treated OVX mice showed an 83% loss of distal metaphyseal trabecular bone compared to sham animals. This loss was associated with a marked decrease in trabecular number, thickness, and connectivity. In contrast, daily oral dosing with the IKKb inhibitor fully protected bone density and trabecular architecture, with all trabecular indices not significantly different from sham mice. At the diaphysis, the vehicle-treated OVX mice showed a significant decrease in cortical thickness (Ct.Th) (9%), together with an increased marrow volume (%MV/TV), indicating that bone loss occurs at the endosteal surface of the diaphysis. IKKb inhibitor-treated mice exhibited no loss of cortical bone, with Ct.Th and %MV/TV measurements that were not significantly different from sham mice. In conclusion, we have demonstrated the inhibition of osteoclast formation and function by an IKKb inhibitor in vitro and its efficacy in preventing OVX-induced osteopenia in vivo. Inhibition of IKKb may offer a new strategy to prevent bone resorption in diseases associated with bone loss.

Bone Mineral Density Is Increased Following Monthly Administration of AMG 162 in Cynomolgus Monkeys. J. E. Atkinson[1], P. Cranmer*[1], S. Mohr*[2], M. Niehaus*[2], C. P. Jerome[3], M. E. Cosenza*[1], C. R. Dunstan[4], A. M. DePaoli[1]. [1]Amgen Inc, Thousand Oaks, CA, USA, [2]Covance Laboratories GmBH, Muenster, Germany, [3]SKELETECH, Inc., Bothell, WA, USA, [4]ANZAC Research Institute, Concord, Australia.

AMG 162 is a fully human monoclonal antibody that binds with high affinity and specificity to RANKL (Receptor Activator of NF kappa B Ligand). We have previously demonstrated in cynomologus monkeys that a single subcutaneous dose of AMG 162 was associated with prolonged blood levels, as well as marked and sustained reduction in bone turnover markers. This study determined the effect of monthly dosing on bone turnover markers and bone-mineral density (BMD). Sixty-four cynomolgus monkeys (3-4 yrs old) were assigned to 4 treatment groups (8/sex/group) and received once monthly subcutaneous doses of placebo or 1, 10 or 50-mg/kg body weight of AMG 162. Serum and urine samples were collected at pretreatment, months 3 and 6 for markers of bone turnover [Osteocalcin (OSCL- Metra Osteocalcin™), serum crosslaps (SCRL- Serum Crosslaps ™) and urine N-telopeptide (UNTx- Osteomark®)]. Peripheral QCT(pQCT) was used to measure BMD at the distal radius and proximal tibia.

Treatment with AMG 162 at 10 and 50 mg/kg for 6 months caused highly significant dose dependent reductions in serum and urine markers of bone resorption and formation. pQCT measurements revealed dose-related statistically significant increases in BMD at 3 and 6 months at the 10 and 50 mg/kg doses as noted in the table below.

Treatment Effects on Bone Markers (% of control) and Bone Mineral Density (% change from baseline)

AMG 162 Dose	Month	SCRL	OSCL	UNTx	Total BMD	
					Radius	Tibia
Control	3	-	-	-	-1.23	-5.6
	6	-	-	-	-4.42	-7.9
10 mg/kg	3	-43.9	-59.0	-66.3	+9.4*	+5.0*
	6	-30.5	-30.7	-47.8	+6.4*	+5.1*
50 mg/kg	3	-64.7	-80.7	-91.3	+10.9*	+9.0*
	6	-63.6	-77.5	-79.9	+14.6*	+11.2*

*p<0.05 vs. control

In summary, monthly SC dosing of AMG 162 resulted in a dose-dependent rapid and sustained decrease from baseline in bone turnover and an increase in BMD. AMG 162 has potent anti-resorptive activity and could be a convenient treatment for osteoporosis and/or metastatic bone disease.

Nongenotropic, Anti-Apoptotic Signaling of 1a,25$(OH)_2D_3$ Through the Ligand Binding Domain (LBD) of the Vitamin D Receptor (VDR) in Osteoblasts and Osteocytes: Mediation by Src, PI3 and JNK Kinsases. A. M. Vertino[1], J. Chen[1], S. Kousteni[1], L. Han[1], H. Peng*[1], T. Bellido[1], C. Bula*[2], A. W. Norman[2], S. C. Manolagas[1]. [1]Div Endo/Metab, Center for Osteoporosis and Metabolic Bone Diseases, CA Veterans Healthcare System, Univ of Arkansas for Med Sciences, Little Rock, AR, USA, [2]Dep of Biochem, Univ of California, Riverside, CA, USA.

Because sex steroids regulate the lifespan of bone cells by modulating the activity of cytoplasmic kinases via a nongenotropic action of their classical receptors, we have explored the possibility that other members of the "nuclear receptor" superfamily might exhibit similar nongenotropic actions. We report that 1α,25(OH)2D3 and synthetic analogs like 1α,25(OH)2-lumisterol3, which exhibit low binding affinity for the VDR in standard equilibrium assays and lack transcriptional activity, protected murine osteoblasts, OB-6 osteoblastic cells or MLO-Y4 osteocytic cells from apoptosis induced by the topoisomerase II inhibitor etoposide. Consistent with a nongenotropic mechanism of VDR action, this effect was reproduced in HeLa cells transiently-transfected with either the wild type VDR or a mutant consisting only of the LBD of the VDR. The LBD of the VDR bound 1α,25(OH)2D3 as effectively as the wt VDR, but unlike the full length receptor, was incapable of inducing VDRE-mediated transcription in cells transfected with a osteocalcin promoter containing reporter construct. The anti-apoptotic effect of 1α,25(OH)2D3 and analogs in calvaria cells could be blocked by inhibitors of each one of 3 different cytoplasmic kinases: the Src kinase inhibitor PP1, the PI3 kinase inhibitor Wortmannin, and the JNK kinase inhibitor SP600125. However, inhibition of p38 with SB203580 or ERK with either U0126 or transfection of a dominant negative MEK in VDR-containing HeLa cells, the kinase that phosphorylates ERKs, did not interfere with these anti-apoptotic actions. Further, 1α,25(OH)2D3 induced a rapid (5 min) association of the VDR with the Src kinase in OB-6 cells, as determined by immunoprecipitation of cell extracts with an anti-VDR specific antibody followed by Western blot analysis with an anti-Src antibody. Finally, either actinomycin D or cyclohexamide prevented the anti-apoptotic effect of 1α,25(OH)2D3, indicating that transcriptional events downstream from kinase activation are also required for these phenomena. These findings suggest that nongenotropic modulation of kinase activity is a general property of the nuclear receptor superfamily; and that vitamin D analogs that activate nongenotropic signals, but lack classical transcriptional activity, may exhibit distinct biological profiles compared to those exhibited by the natural ligands of the VDR.

Actinobacillus actinomycetemcomitans' **Cytolethal Distending Toxin Induces Receptor-Activator of NF-kB Ligand Expression by Periodontal Ligament Cells and Gingival Fibroblasts.** G. N. Belibasakis[1], A. Johansson*[2], Y. Wang*[3], C. Chen*[3], U. H. Lerner[4], S. Kalfas*[5]. [1]Divisions of Oral Microbiology and Oral Cell Biology, Umeå University, Faculty of Medicine and Odontology, Umeå, Sweden, [2]Division of Periodontology, Umeå University, Faculty of Medicine and Odontology, Umeå, Sweden, [3]Division of Primary Oral Health Care, University of Southern California, School of Dentistry, Los Angeles, CA, USA, [4]Division of Oral Cell Biology, Umeå University, Faculty of Medicine and Odontology, Umeå, Sweden, [5]Department of Preventive Dentistry and Periodontology, Aristotle University of Thessaloniki, Thessaloniki, Greece.

The Gram-negative, facultative anaerobe *Actinobacillus actinomycetemcomitans* is implicated in the pathogenesis of aggressive periodontitis, a disease entity characterized by

rapid alveolar bone loss in the presence of limited inflammation. The interactions of this bacterium with the resident connective tissue cells of the periodontium, which are anatomically associated with the alveolar bone, are poorly understood. Therefore, the purpose of this study was to investigate the effect of *A. actinomycetemcomitans*' surface components on the expression of receptor-activator of NF-kB ligand (RANKL) and osteoprotegerin (OPG), in periodontal ligament (PDL) cells and gingival fibroblasts (GF). Human primary GF and PDL cell cultures were challenged with the bacterial extract for up to 48 h. The mRNA expression of RANKL and OPG were investigated by semi-quantitative RT-PCR, whereas protein expression of RANKL on the surface of the cells was investigated by flow cytometric analysis, using either anti-RANKL, or rh OPG-Fc chimeric protein. The results showed that RANKL mRNA expression was induced in the bacterially challenged PDL cells and GF, in a time- and concentration-dependent manner. The expression of OPG remained unaffected under the concentrations required for RANKL induction. Up-regulation of RANKL on the cell surface was apparent after 48h of bacterial challenge. A cytolethal distending toxin (CDT) knockout strain of *A. actinomycetemcomitans* did not induce RANKL expression, in contrast to its wild-type strain. In addition, *A. actinomycetemcomitans*' lipopolysaccharide had only limited effect on RANKL expression. In conclusion, these results indicate that *A. actinomycetemcomitans* induces RANKL expression by periodontal connective tissue cells, an event that may be associated to osteoclastogenesis occurring during the progress of aggressive periodontitis. The CDT appeared to play a crucial role in this process, and may therefore be the surface-associated component of *A. actinomycetemcomitans* previously reported to exhibit bone-resorbing activity.

Surface Immobilized Bisphosphonate Improves Implant Fixation. B. Skoglund*[1], P. Tengvall*[2], P. Aspenberg*[1]. [1]Neuroscience and Locomotion/ Section of Orthopaedics and Sports Medicine, Faculty of Health Sciences, Linkoping University, Sweden, Linkoping, Sweden, [2]Department of Physics, Division of Applied Physics, Institute of Technology, Linkoping University, Linkoping, Sweden.

The trauma involved in inserting implants into bone leads to resorption at the interface. The purpose of this study was threefold. First, to establish whether initial resorption around an implant is important for later fixation. Secondly, to improve fixation with the use of a bisphosphonate. Thirdly, to evaluate a new approach for administering drugs locally, via surface immobilization on the implant.

Stainless steel screws were inserted medially in the tibiae of 94 male Sprague-Dawley rats. 20 rats received systemic ibandronate (3 µg) or saline. 58 rats received ibandronate or saline solution directly applied into the screw hole before insertion. Finally, 16 rats received screws with surface immobilized ibandronate or controls. These screws had been roughened and coated with immobilized and cross-linked fibrinogen. Pamidronate was then immobilized to fibrinogen, and finally ibandronate was adsorbed overnight on top of this. Tibiae were harvested at 14 days. Biomechanical tests were performed on 66 tibiae. Systemically treated tibiae were tested for pullout strength. Locally treated tibiae were tested for either pullout or removal torque. 20 tibiae were prepared for histology.

Data was analysed with Student's unpaired t-test. Institutional guidelines for the care and treatment of laboratory animals were adhered to.

Systemic ibandronate increased the pullout force by 30 % (p=0.04). Local treatment increased the pullout force by 15 % (p=0.02) and stiffness by 28 % (p= 0.01). Removal torque was increased by 60 % (p=0.04), and the maximum friction moment by 51 % (p=0.04). Energy was increased by 68 % (p= 0.02). Surface immobilized ibandronate increased pullout force by 28 % (p=0.0009) and energy by 90 % (p=0.0008).

The present study shows that early resorption is important for implant fixation. Further, systemic and local administration of bisphosphonates can counter this initial resorption. Finally, our method of surface immobilisation is a useful approach for administration of drugs at a bone-implant interface.

Surface Immobilization of Ibandronate - Effects on Pullout Strength

Bisphosphonate Treatment (Risedronate) with Conventional Periodontal Treatment Prevents Periodontal Bone Loss: Preliminary Results of a Randomized Placebo Controlled Trial. N. E. Lane, G. C. Armitage*, P. Loomer, S. Hseih*, S. Majumdar, H. Y. Wang*, T. Munoz*. Dept. Medicine, UCSF, San Francisco, CA, USA.

Bone loss in periodontitis results from inflammatory reactions to bacterial plaque resulting in release of cytokines that stimulates osteoclastic bone resorption. Since bisphosphonates inhibit osteoclastic bone resorption, we performed a randomized placebo-controlled trial to determine if 1 yr. of bisphosphonate treatment when used in conjunction with conventional nonsurgical periodontal treatment in subjects with moderate to severe periodontitis will reduce periodontal bone loss compared to subjects receiving conventional therapy and placebo. 73 subjects with moderate to severe periodontitis (mean full-mouth clinical attachment loss [CAL] ≥ 1.5mm) were randomized (2:1) to risedronate (Ris, 5mg/d) or placebo(PL) tablets. Bitewing dental radiographs were obtained at baseline (BSL) and 12 mos. Biochemical markers of bone turnover (deoxypyridinoline crosslinks DPD/Cr) were determined every 3 mos. Conventional periodontal therapy consisted of oral hygiene instructions, scaling and root planing, and routine periodontal maintenance care at 3 mo. intervals. Full-month clinical assessments were done every 6 mos., included CAL, probing depth (PD), bleeding on probing (BOP), and plaque index (PI). Trabecular bone mass in the periodontal bone was assessed by fractal analysis using at least 1 paired site per subject (BSL and 12 mos.) Paired t-tests between treatment and placebo groups were used to assess treatment response. Correlations between different measures were also obtained. RESULTS: The mean age and mean full-mouth CAL measurements of the study subjects in the Ris and PL groups were similar. Improvements in CAL, BOP, and PD were significantly greater in the Ris group compared to the PL. DPD/Cr excretion was significantly lower in Ris compared to the PL group. Significant correlations were found at all time points for low fractal readings and BOP [BSL ($p<0.04$), at 12 mos. ($p<0.0043$)]; and high fractal readings and PD [BSL $p<0.002$, at 12 mos. $P<0.02$]. CAL at BSL was correlated with high fractal readings at BSL and 12 mos. [BSL $p<0.02$, at 12 mos. $P<0.005$]. Bisphosphonate administration improves the clinical outcome of nonsurgical periodontal therapy and may be an appropriate adjunctive treatment to preserve periodontal bone mass.

Neutralization of Intrinsic FGF-23 Action by Antibodies Reveals the Essential Role of FGF-23 in Physiological Phosphate and Vitamin D Metabolism. T. Shimada*[1], Y. Yamazaki*[1], Y. Aono*[2], H. Hasegawa*[1], R. Hino*[1], Y. Takeuchi[3], T. Fujita[3], S. Fukumoto[4], T. Yamashita[1]. [1]Parmaceutical Research Laboratories, KIRIN Brewery, Takasaki, Japan, [2]Parmaceutical Development Laboratories, KIRIN Brewery, Takasaki, Japan, [3]Department of Medicine, University of Tokyo School of Medicine, Tokyo, Japan, [4]Department of Laboratory Medicine, University of Tokyo Hospital, Tokyo, Japan.

FGF-23 is the latest fibroblast growth factor that has been shown to play pathogenetic roles in mineral disorders such as hypophosphatemic rickets/osteomalacia. Recent report concerning FGF-23 null mice demonstrated that lack of FGF-23 resulted in severe hyperphosphatemia and elevated serum 1,25-dihydroxyvitamin D [$1,25(OH)_2D$] level, suggesting the important roles of FGF-23 in physiological homeostasis of phosphate and vitamin D. However, such abnormal phenotypes were outcomes derived from the congenital absence of FGF-23. In addition, FGF-23 null mice demonstrated short life span. Therefore it is still unclear whether FGF-23 is indispensable for mineral homeostasis during adulthood. To address this issue, we neutralized intrinsic FGF-23 activity by anti-FGF-23 antibodies and clarified physiological importance of FGF-23 *in vivo*. We developed three monoclonal antibodies recognizing different part of human FGF-23, termed FN1, FC1 and FC2. FN1 and FC1 could capture mouse recombinant FGF-23 as well as human FGF-23, whereas FC2 could not. To evaluate the neutralizing activity of these antibodies, we administered each antibody into BALB/c mice (8-10w). As a result, FN1- or FC1-treated mice showed significant elevation of serum phosphate and $1,25(OH)_2D$ levels, although administration of FC2 antibodies did not change them at all. Moreover, combinatory use of FN1 and FC1 demonstrated more significant effects to induce hyperphosphatemia and high $1,25(OH)_2D$ levels with enhanced expression of renal sodium dependent phosphate cotransporter (NaPi-2a) protein and 25-hydroxyvitamin D-1alpha-hydroxylase mRNA. These phenomena are consistent with those observed in FGF-23 null mice. Therefore, considering previous studies that recombinant FGF-23 could decrease these serum parameters, it is indicated that FN1 and FC1 neutralized the action of intrinsic mouse FGF-23. Taken together, neutralization of FGF-23 significantly affected phosphate and vitamin D metabolism in normal adult mice, indicating that FGF-23 physiologically plays key roles in regulating these parameters. In addition, present study provides the possibility of neutralizing antibodies against FGF-23 as therapeutic tools for disorders caused by inappropriately excess FGF-23 actions.

Correlated Changes in PPi and Osteopontin Levels in Hypo- and Hypermineralization Disorders: Novel Therapeutic Targets for Hypophosphatasia. L. Hessle*[1], D. Harmey[1], S. Narisawa*[1], K. A. Johnson*[2], R. Terkeltaub[2], J. L. Millan[1]. [1]The Burnham Institute, La Jolla, CA, USA, [2]VAMC/UCSD, San Diego, CA, USA.

Inorganic pyrophosphate (PP_i) is an important inhibitor of hyroxyapaptite deposition and propagation. Tight regulation of PP_i levels is required for controlled deposition of mineral. A key enzyme in the depletion of the extracellular PP_i pool is tissue non-specific alkaline phosphatase (TNAP), which hydrolyzes PP_i thereby promoting mineralization. Deletion of the TNAP gene (*Akp2*) in mice results in hypophosphatasia characterized by elevated levels of PP_i, poorly mineralized bones and spontaneous fractures. In contrast, nucleosidetriphosphate pyrophosphohydrolase (NPP1) and the transmembrane PP_i-channeling protein ANK, elevate the extracellular PP_i pool. Mice lacking either the NPP1 gene

(*Enpp1*), or deficient in the ANK gene (*ank/ank*), show decreased levels of PP_i, and exhibit soft-tissue ossification and osteoarthritis. We examined the expression of osteoblastic genes in primary osteoblasts (MOBs) from NPP1- and ANK-deficient mice, and found expression of the mineralization inhibitor osteopontin (OPN) was decreased. RT-PCR analyses of wild-type MOBs treated with exogenous PP_i revealed an increase in OPN expression and decreased NPP1 and ANK expression. This supports a direct regulation of OPN expression by NPP1 and ANK mediated by PP_i. Further, these data support a negative feedback mechanism by PP_i on NPP1 and ANK expression. As TNAP has a crucial role in regulating PP_i levels, we hypothesized that OPN levels may also be altered in TNAP null (*Akp2*$^{-/-}$) mice. Accordingly, we found that *Akp2*$^{-/-}$ mice demonstrated significant elevations in serum OPN levels compared to wild-type mice, as measured by ELISA. Interestingly, PP_i and OPN levels appeared normal in *Akp2*/*Enpp1* and *Akp2*/*ank/ank* double homozygote mice, suggesting that TNAP, NPP1 and ANK act antagonistically in regulating PP_i and OPN levels. We conclude that under normal conditions the concerted action of TNAP, NPP1 and ANK regulate PP_i levels. Hypophosphatasia arises from deficits in TNAP activity, resulting in an increase in PP_i levels and a concomitant increase in OPN levels; the combined inhibitory effect of these molecules leads to hypomineralization. In contrast, an NPP1 or ANK deficiency lead to a decrease in the extracellular PP_i and OPN pools, thereby promoting hypermineralization. The mineralization defects in Akp2$^{-/-}$ mice, along with elevated PP_i and OPN levels are normalized by ablation of either the NPP1 or ANK gene. Thus, NPP1 and ANK represent rational therapeutic targets for hypophosphatasia, a disease for which to-date there is no treatment.

Association between Vitamin D levels, Activity, Muscle Strength, Falls and Fractures in the Prospective Population-based OPRA Study of Aged Women. P. Gerdhem*, K. A. M. Ringsberg*, K. J. Obrant, K. Akesson. Department of Orthopaedics, Malmo University Hospital, Malmo, Sweden.

Introduction: Vitamin D supplements have been used to prevent falls and fractures. The effect may be mediated through increased bone mass, but also through increased muscle strength. Most studies have involved high-risk individuals with low activity. The aim of this study was to evaluate the association between vitamin D levels, muscle function, falls and fracture in ambulatory, independently living women.

Methods: We investigated the prevalence of 25-OH vitamin D deficiency and the predictivity on falls and fractures in a population-based sample of 1044 exactly 75-year old women (range 75.01-75.99 yrs) in the Osteoporosis Prospective Risk Assessment study in Malmo (latitude 56^0 North) followed for mean 3.0 yrs (range 2.9-3.4 yrs). Baseline assessments occurred all year round.

Results: Only 4% of the women were vitamin D deficient with 25-OH vitamin D levels below 20 ng/mL. Mean levels of vitamin D were highest in September (40.4 ng/mL) and lowest in February (35.9 ng/mL). Vitamin D levels correlated with the fall associated variables gait (r=-0.15, p<0.001), Romberg balance test (r=0.15, p<0.001), self-estimated activity level (r=0.16, p<0.001), but not with thigh muscle strength. After 3 years, 44% had fallen at least once. Vitamin D deficient women were at increased risk of falling during the first year (odds ratio (OR) 2.09; 95%CI 1.03-4.25) but not for the remaining 2 yrs of follow-up (OR 1.14; 0.46-2.79). After 3 years, 12% (126 of 1044 women) had sustained a total of 165 low-energy fractures (30 hip, 29 wrist, 13 proximal humerus, 44 vertebral and 49 other fractures). Vitamin D deficiency predicted hip fractures (OR 4.10; 1.35- 12.46) and having more than 2 low-energy fractures (OR 3.85; 1.09-13.64). The fall and fracture prediction of vitamin D deficiency was independent of season of baseline assessment. Vitamin D deficiency was not independently predictive of falls or fractures when balance, gait or activity level were included in a logistic regression model. Data was comparable when women put on vitamin D supplements during the follow-up period were excluded from the calculations.

Conclusion: 25-OH vitamin D deficiency predicted falls in aged women during the first year of follow-up and predicted hip and multiple fractures during the 3-year follow-up. The predictive ability was related to other fall associated variables. The prevalence of vitamin D deficiency was lower than expected, even though only 5% used vitamin D supplementation. This may be explained by the fortification of dairy products in Sweden and that 98% of the women spent 30 minutes or more outside per day.

A Double Blind Randomized Placebo Controlled Trial of Alendronate in Primary Hyperparathyroidism. A. A. Khan[1], J. P. Bilezikian[2], A. W. C. Kung*[3], M. M. Ahmed*[1], S. J. Dubois*[1], A. Y. Y. Ho*[3], A. Shaikh*[1], M. Rubin*[2], S. J. Silverberg*[2], T. I. Standish*[1], Z. A. Syed*[1]. [1]Medicine, McMaster University, Hamilton, ON, Canada, [2]Columbia University College of Physicians and Surgeons, NY, NY, USA, [3]University of Hong Kong, Hong Kong, China.

A randomized, double blind, placebo-controlled trial was conducted to determine if alendronate 10mg daily (ALN) maintains or improves bone mineral density (BMD) in patients (pts) with primary hyperparathyroidism (PHPT). ALN's effects on serum and urine calcium, PTH and biochemical markers of bone turnover were also evaluated. We now update and complete our results of this 2 year study with biochemical data. Eligible pts were asymptomatic and did not meet surgical guidelines. 44 pts were randomized to placebo (PBO) or ALN for months 1-12 then all received ALN for months 13-24. BMD was measured every 6 months by dual energy X-ray absorptiometry (DEXA). Total and ionized serum calcium, phosphorus, PTH, 25-hydroxy vitamin D (25D), 1,25-dihydroxy vitamin D (1,25D), bone- specific alkaline phosphatase (BSAP), 24-hour urine calcium (UCa) and urine N-telopeptide (NTX) were measured on a three-monthly basis. Primary endpoints were BMD at the lumbar spine (LS), total hip (TH) and distal one-third radius (1/3r), bone markers and serum calcium. 37 pts completed 24 months of the protocol. Paired t-tests were conducted for groups A (ALN years 1 and 2) and B (PBO year 1, ALN year 2). Second year mean differences for primary and repeated measures analysis of variance for secondary outcome indices were utilized. Treatment with ALN rapidly decreased NTX by 66% (p<0.001) at 3 months; it remained suppressed for the two-year period. In the PBO arm, NTX remained elevated until pts were crossed over to ALN. BSAP decreased in the ALN group by 49% at 6 months (p<0.001) and by 54% at 9 and 12 months (p<0.001). bone specific alkaline phosphatase (In the PBO group, BSAP did not decrease until pts were crossed over to ALN when levels declined and remained suppressed. Total serum calcium and ionized calcium did not change for the 2 year period in both ALN and PBO groups. The 24-hour UCa did not change and PTH levels remained stable in both groups. No changes were seen in 25-D or 1,25-D or in serum phosphorus. ALN treatment over two years was associated with a significant increase in the LS BMD by 6.85% (0.05 g/cm^2, p<0.001) and a 2.9% increase in the TH BMD (0.02 g/cm^2, p=0.09). The BMD at the 1/3r site remained stable (0.007g/cm^2, p=0.12) compared to baseline. ALN significantly decreases bone turnover and increases BMD at the lumbar spine after 12 and 24 months of therapy from baseline. Serum and urine calcium, PTH and vitamin D levels remain stable with ALN in PHPT. ALN may be an alternative to surgery in some patients with PHPT.

Pseudohypoparathyroidism without Albright's Hereditary Osteodystrophy Features: A Novel, Autosomal Recessive Form in a Kuwaiti Kindred. L. M. Ward[1], M. Bastepe[2], I. French*[1], S. E. Lawrence*[1], F. H. Glorieux[3], H. Jueppner[2], M. L. Lawson*[1]. [1]Division of Endocrinology and Metabolism, Children's Hospital of Eastern Ontario, Ottawa, ON, Canada, [2]Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA, [3]Genetics Unit, Shriners Hospital for Children, Montreal, PQ, Canada.

Pseudohypoparathyroidism (PHP) is a form of PTH resistance characterized by hypocalcemia and hyperphosphatemia despite elevated PTH levels. We have recently identified a novel form of PHP in a Kuwaiti kindred, where the inheritance follows an autosomal recessive (AR) pattern. The aim of this study was to characterize the phenotype in this novel form through detailed clinical, biochemical and genetic studies. PHP was identified in 4 children (3 girls) of the same generation, from three related, consanguineous Kuwaiti families (referred to as F1, F2 and F3). The parents showed no clinical or biochemical evidence of the disease. All the affected children presented with symptoms of hypocalcemia (including seizures in 1 patient) at mid-puberty (mean age at diagnosis 13.22 ± 1.74 years). At diagnosis, mean ionized calcium, phosphate, and iPTH levels were 0.84± 0.05 mmol/L (N:1.1-1.3), 1.90± 0.36 mmol/L (N:1.1-1.6) and 18.53± 7.07 pmol/L (N:1.1-6.8), respectively. Features of Albright's Hereditary Osteodystrophy (AHO) were absent. PTH infusions tests (Parathar© 3 units/kg), performed in one adolescent from F1 and in one from F2, demonstrated a < 4-fold increase in $_u$cAMP (N: > 10-fold increase) and a 5-6% reduction in percent tubular reabsorption of phosphate (N: 5-15% reduction). There was no clinical or laboratory evidence of additional hormone resistance. Genetic studies were undertaken to determine whether the affected members of the kindred showed the same loss of *GNAS1* exon A/B methylation that has been observed in patients with PHP-1b, another inherited PHP sub-type without AHO features. Southern blot analyses using gDNA from two affected girls (one from F2 and one from F3) showed no loss of methylation at the A/B exon. Analysis of several informative microsatellite markers further demonstrated that two affected and two unaffected members from F3 had inherited the same allele from their mother, thus arguing against linkage to the region on chromosome 20q13.3 which comprises the *GNAS1* gene. In conclusion, we have identified a novel form of PHP characterized by AR inheritance, absent AHO features, a sub-normal $_u$cAMP response and a borderline $_u$phosphate response to PTH. The disease appears to be unlinked to the *GNAS1* region. Further studies to determine the disease locus and to characterize the skeletal phenotype at the bone tissue level are presently underway.

Intrauterine Programming of Urinary Calcium and Magnesium Excretion in Children Born to Mothers with Insulin Dependent Diabetes Mellitus. M. Z. Mughal, J. Eelloo*, S. Sibartie*, S. A. Roberts*, M. Maresh*, C. P. Sibley*, J. E. Adams. Central Manchester & Manchester Children's Hospitals and the University of Manchester, Manchester, United Kingdom.

We have previously shown that offspring of diabetic rats have reduced urinary calcium and magnesium excretion compared to offspring of controls, and these differences persisted up to16 weeks after birth, a time equivalent to young adulthood in humans. In this cross-sectional study, we studied the urinary excretion of calcium & magnesium in 5 to 18 year old children born to mothers with Insulin Dependent Diabetes Mellitus (ChIDDM). Concentrations of calcium (Ca), magnesium (Mg), sodium (Na) and creatinine (Cr) were estimated using the Hitachi 917 analyser in the first urine passed in the morning in 44 (28 male) ChIDDM and 127 (58 male) healthy controls. The ratios of urinary of Ca & Mg to Cr were used in the analysis. Dietary intake of Ca, Mg, phosphate (P), sodium (Na) and protein (Pr) were estimated from 3-day food diaries.

	CONTROLS		ChIDDM		
	Median	CI	Median	CI	P*
Age (yrs)	11.3	10.3 to 12.8	10.9	9.9 to 12.5	0.57
Ca/Cr	0.31	0.23 to 0.40	0.23	0.18 to 0.32	0.20
Mg/Cr	0.56	0.52 to 0.61	0.46	0.42 to 0.55	0.012
Ca intake (mg/day)	810	670 to 900	950	680 to 1180	0.12
Mg intake (mg/day)	230	210 to 250	260	220 to 270	0.034
P intake (mg/day)	1140	1020 to 1240	1400	1080 to 1480	0.007
Na intake (mg/day)	2560	2350 to 2800	2830	2530 to 3020	0.031
Pr intake(mg/day)	61	59 to 64	75	65 to 81	0.001

* Mann-Whitney U-test

Analysis of covariance was used to test for differences in Ca/Cr and Mg/Cr between controls and ChIDDM after allowing for the effects of gender and age (using a cubic spline representation). This showed that Ca/Cr was significantly lower in ChIDDM compared with controls (p=0.041, difference in Ca/Cr 0.099, 95% CI 0.004 to 0.19). Mg/Cr was highly significantly lower in ChIDDM compared with controls (p<0.0001, difference in Mg/Cr 0.15, 95% CI 0.08 to 0.23).

As in the animal studies, urinary excretion of Mg and Ca were lower in ChIDDM compared with controls. These results are not explained by dietary intake of Ca & Mg or other nutrients that are known to influence their urinary excretion. Thus, these results provide a compelling evidence for intrauterine programming of renal Ca and Mg handling in children born to mothers with insulin dependent diabetes mellitus.

Overgrowth in Sotos Syndrome Is Caused by Missense Mutations in the Nsd1-gene, which Is Expressed in Growth Plate Chondrocytes. M. Karperien[1], L. de Boer*[1], J. Tjon*[1], S. G. Kant*[2], M. H. Breuning*[2], J. M. Wit*[1]. [1]Pediatrics, LUMC, Leiden, Netherlands, [2]Clinical Genetics, LUMC, Leiden, Netherlands.

Sotos syndrome is characterized by typical facial features, overgrowth, advanced bone age, macrocephaly, and psychomotor retardation. It is associated with haploinsufficiency of NSD1, a cofactor for Nuclear Hormone Receptor signalling, localized on chromosome 5q35. In the majority of cases in Japan, this is caused by a microdeletion. In order to elucidate the molecular basis of the overgrowth in more detail, we have studied the occurrence of deletions and mutations in the NSD1 gene in a panel of 26 Dutch patients with suspected Sotos syndrome. In addition, we have studied NSD1 expression in human growth plate specimens.

Based on a clinical score, the patients were catagorized in 3 groups: typical (n=8), dubious (n=11) and atypical (n=7) Sotos syndrome by a panel of clinical geneticists and pediatric endocrinologists. Only one patient (of the typical group) contained a chromosomal deletion as determined by fluorescent in situ hybridization. Subsequently, all coding exons of the NSD1-gene were sequenced. We detected heterozygous missense mutations resulting in inactivation of the protein in 5/8 (62,5%) patients in the typical group, 2/11 (18%) in the dubious group and 0/7 (0%) in the atypical group. From 4 patients, DNA of the parents could be analysed. In all cases, the mutations were *de novo* and each patient has its own nucleotide alteration. Of particular interest was a family with two affected children (catagorized in group 1 and 2), who have a similar *de novo* mutation. This was explained by mosaicism of the mother, who had various characteristics typical of Sotos syndrome and contained the mutation in DNA isolated from dermal fibroblasts but not from whole blood. Immunohistochemistry using two NSD1-specific antibodies demonstrated the protein in 3 pubertal growth plate specimens, predominantly in hypertrophic chondrocytes. Identical staining patterns were observed using both antibodies.

In conclusion, in the majority of patients with typical Sotos syndrome (75%) deletions or mutations were detected in the NSD1 gene. In contrast to Japanese Sotos patients, predominantly missense mutations instead of chromosomal deletions were detected. Mutations in NSD1 were rare in the dubious group (18%), and absent in the atypical group. Mosaicism, previously not recognized in Sotos syndrome, may contribute to the heterogenic presentation. The growth fenotype in Sotos syndrome may be explained by disturbed regulation of nuclear hormone receptor signalling, e.g. for estrogen, thyroid hormone and retinoids, in growth plate chondrocytes.

The Calcimimetic Compound, Cinacalcet HCl, Ameliorates Osteitis Fibrosa in Rats with Chronic Renal Insufficiency. M. Wada*, Y. Furuya*, N. Kobayashi*, S. Obana*, M. Ozai*, S. Miyata*, N. Nagano. Pharmacology, Pharmaceutical Development Labs, Kirin Brewery Co., Ltd, Takasaki-shi, Japan.

Osteitis fibrosa is a common complication of chronic renal insufficiency and is characterized by increased bone turnover, bone marrow fibrosis and cortical defects. In this study, we evaluated the effects of the calcimimetic compound AMG 073 (cinacalcet HCl) on osteitis fibrosa in rats with chronic renal insufficiency. Rats were subjected to partial nephrectomy (NX) and orally treated with cinacalcet HCl for consecutive 41 days. After treatment, tibia and femurs were dissected for bone analyses. Tibial fibrosis volume (FbV/TV) and cortical porosity (Ct.Po) were evaluated by a bone histomorphometrical technique, and femoral cortical bone mineral density (Ct.BMD) and bone energy absorption were evaluated by pQCT and a three-point bending test, respectively. At the end of treatment, the serum PTH levels of Nx + Vehicle rats were about more than 1,500 pg/mL. Treatment with cinacalcet HCl reduced serum PTH level by 66% compared to that of the Nx+Vehicle control 90 min after dosing ($P < 0.05$). The FbV/TV of the Nx+Vehicle control was 5.8%, indicating the development of osteitis fibrosa. Moreover, the tibial Ct.Po of the group was about 7-fold greater than that of Sham+Vehicle group. Treatment with cinacalcet HCl reduced tibial FbV/TV and Ct.Po by 78% and 65, respectively, compared to the Nx + Vehicle group. Furthermore, analyses by pQCT and a three-point bending test showed that cinacalcet HCl reversed the reduction in Ct.BMD and cortical bone strength (energy absorption) toward normal. Finally, serum PTH levels were correlated with FbV/TV (r = 0.78) Ct.Po (r = 0.84) Ct.BMD (r = -0.82) and energy absorption (r = -0.48). These results indicate that cinacalcet HCl ameliorates osteitis fibrosa in rats with secondary hyperparathyroidism primarily by reducing PTH levels.

Effects of cinacalcet HCl on bone indices

	Tibial Fb.V / TV (%)	Tibial Ct.Po (%)	Femoral Ct.BMD (mg / cm^3)
Sham + Vehicle	0.0 ± 0.0*	0.8 ± 0.1*	1398 ± 4**
Nx + Vehicle	5.8 ± 1.9	5.4 ± 1.5	1268 ± 29
Nx + 3 mg / kg	3.7 ± 1.0	3.9 ± 1.2	1287 ± 31
Nx + 15 mg / kg	1.3 ± 0.3*	1.9 ± 0.5*	1347 ± 14*

*P < 0.05, **P < 0.01, vs. Nx + Vehicle

NIK Is a Potential Target for Treatment of Arthritis, Controlling Osteoclast and Lymphocyte Activity. K. Aya, O. Kanagawa*, D. V. Novack. Medicine and Pathology, Washington University, St. Louis, MO, USA.

NF-κB inducing kinase (NIK) is a serine/threonine kinase in the MAP3K family. Mice with NIK deficiency have dysfunctional B and T cells, and lack peripheral lymph nodes. We have previously shown that unmanipulated NIK-/- mice have normal osteoclast (OC) numbers and bone architecture, but show resistance to RANKL-stimulated osteoclastogenesis in vivo and in vitro. To determine whether NIK might be involved in pathological bone destruction, we turned to models of arthritis, in which joint inflammation is associated with local bone erosion. Serum transfer arthritis is induced by injection of arthritigenic serum (from KRNxNOD mice) containing pre-formed antibodies, and does not require lymphocyte function in the host. NIK+/+ mice and NIK-/- mice were injected with arthritigenic serum on day 0, day 2 and day 7, with LPS on day 2. At day 14, the clinical score and thickness of hind paws of NIK-/- mice were similar to NIK+/+ mice, as was histological evaluation of inflammation. In contrast, bone erosion was significantly lower in NIK-/- mice, and, histologically, the surface of bone remained flat, suggesting a defect in NIK-/- OC function. Cells from arthritic paws cultured without additional cytokines, yielded TRAP positive multinucleated cells in NIK+/+, and to a lesser extent in NIK-/-, wells. On artificial matrix, NIK-/- cultures showed less resorptive activity than NIK+/+ cultures. Having demonstrated a critical role for NIK in the effector phase of inflammatory arthritis, we asked if NIK is involved in the induction phase, which depends on lymphocyte function. Antigen-induced arthritis (AIA) was induced in NIK+/- and NIK-/- mice. All NIK+/- mice had severe arthritis with bone erosion, but NIK-/- mice had little joint inflammation, and no bone erosion, indicating that NIK is essential for induction of AIA. To determine if the lack of lymph nodes (LN) was responsible for this resistance to arthritis, AIA was induced in lymphotoxin-α -/- mice, which lack LN but have mature lymphocytes, and 3 of 4 had severe arthritis. In contrast, RAG2-/- mice, which have LN but lack mature lymphocytes, were resistant to AIA. We were therefore able to use RAG2-/- mice as recipients in lymphocyte transfer experiments in the context of AIA. RAG2 -/- mice receiving NIK+/+ splenocytes had severe AIA, but mice given NIK-/- splenocytes had little arthritis, indicating that NIK expression in lymphocytes is required for initiation of inflammatory arthritis. Thus, NIK expression is important in both the induction and effector phases of inflammatory arthritis, and might represent an attractive target for the treatment of rheumatoid arthritis. NIK expression in OCs may also be critical in other conditions of pathological bone loss.

Predictive Value of a Cartilage Degradation Marker for Radiologic Osteoarthritis: -The Rotterdam Study. M. Reijman*[1], J. M. W. Hazes*[2], S. M. A. Bierma-Zeinstra*[3], B. W. Koes*[3], S. Christgau*[4], C. Christiansen*[5], A. G. Uitterlinden[6], H. A. P. Pols[6]. [1]Epidemiology and Biostatistics, Erasmus MC, Rotterdam, Netherlands, [2]Rheumatology, Erasmus MC, Rotterdam, Netherlands, [3]General Practice, Erasmus MC, Rotterdam, Netherlands, [4]Osteometer BioTech A/S, Herlev, Denmark, [5]Centre for Clinical and Basic Research A/S, Ballerup, Denmark, [6]Internal Medicine, Erasmus MC, Rotterdam, Netherlands.

Osteoarthritis is a common locomotor disease characterized by degradation of articular cartilage, but accurate prognostic markers are lacking. Recently a specific marker of cartilage degradation, measured as the urinary concentration of C-telopeptide fragments of collagen type II (CTX-II), corrected for creatinine (ng/mmole creatinine), was developed.

The aim of the present study was to investigate the predictive value of CTX-II, for progression of radiological osteoarthritis of the hip and knee.

From all subjects of the Rotterdam study (N = 1238 participants) with available urine samples and X-rays, the radiographs at baseline and follow-up, with a mean follow-up time of 6.6 years, were evaluated for joint space narrowing (JSN) of the knee and hip joints. We used three cut off points for JSN, namely 1.0, 1.5 and 2.0 mm decrease of the joint space width between baseline and follow-up. JSN was evaluated per compartment (knee: medial and lateral, hip: lateral, superior and axial), and a JSN of minimal 1 (out of 5) compartment was defined as positive progression. The association between quartiles CTX-II at baseline and radiological progression of OA was measured by logistic regression analysis to calculate odds ratios as estimation for relative progression risk (predictive value). CTX-II concentrations at baseline differed between sexes (P-value = 0.000), increased with age (P-value for change = 0.033) and increased with BMI (P-value = 0.03). We therefore adjusted the crude odds ratios for age, gender and BMI.
The more JSN at follow-up, the stronger the association we found with CTX-II concentration. Furthermore, the highest quartile CTX-II showed the strongest association with JSN. Increased baseline concentration of CTX-II appears to be a strong predictive factor for radiological progression of osteoarthritis of the knee and hip, suggesting that it could be useful for identifying patients at high risk for cartilage destruction.

Predictive value of quartiles CTX-II for radiological progression of OA

	JSN > 1.5 mm (96 cases)		JSN > 2.0 mm (37 cases)	
	crude	adj	crude	adj
1st (reference)	1	1	1	1
2nd (128-177)	1.8	1.6	4.2	4.4
3rd (178-246)	2.6	2.2	5.9	6.3
4th (247-1277)	3.5	2.7	9.0	8.8

Parathyroid Ablation Upregulates Placental Calcium Transfer whereas Absence of PTH does not. C. S. Noseworthy*[1], J. P. Woodrow*[1], N. J. Fudge*[1], G. Karsenty[2], C. S. Kovacs[1]. [1]Memorial University of Newfoundland, St. John's, NF, Canada, [2]Baylor College of Medicine, Houston, TX, USA.

Fetal calcium metabolism is regulated differently than in the adult, with parathyroid hormone related protein (PTHrP) stimulating placental calcium transfer, and PTHrP and parathyroid hormone (PTH) sharing in the regulation of the fetal blood calcium and skeletal mineral accretion. Studies in fetal lambs have suggested that the parathyroids directly regulate placental calcium transfer through the production of PTHrP, whereas aparathyroid (*Hoxa3* null) fetal mice have no disturbance in the rate of placental calcium transfer or the production of PTHrP.
We studied *Gcm2* null fetuses to determine the effects of parathyroid ablation with persistence of a thymic source of PTH on fetal mineral and bone homeostasis.
Gcm2 mice were placed into the *Black Swiss* (Taconic) background in order to be compared to *Hoxa3* null mice. Studies included ionized Ca (*i*Ca), Mg and P on maternal and fetal blood; placental transfer of ^{45}Ca at 5 min using standard technique; and assessment of the mineral content of the long bones by von Kossa.
Aparathyroid (*Hoxa3* null) fetuses have *i*Ca 1.07 ± 0.07 mmol/l, reduced well below the maternal levels; low Mg and increased P; normal placental calcium transfer; and reduced skeletal mineralization as confirmed by von Kossa and atomic absorption spectroscopy on ashed skeletal residue. In contrast, *i*Ca of *Gcm2* null fetuses was 1.34 ± 0.01 mmol/l, equal to the maternal level but significantly lower than heterozygous (het) and wild-type (wt) siblings (1.82 ± 0.01 and 1.77 ± 0.02 mmol/l respectively, $p < 0.001$). Mg was 0.87 ± 0.01 mmol/l in *Gcm2* null fetuses, modestly reduced below maternal, wt and het levels ($p<0.01$), while P was no different among fetuses. Placental calcium transfer (normalized to het mean value in each litter) was upregulated in *Gcm2* null fetuses (112 ± 7.2 % in null vs 92.4 ± 6.0 % in wt, $p < 0.04$). Skeletal mineral content was not visibly altered among wt, het and null, and the growth plates were of normal length and morphology.
In summary, parathyroid ablation with auxiliary thymic production of PTH in *Gcm2* null leads to modest fetal hypocalcemia and hypomagnesemia, upregulated placental calcium transfer, and no disturbance in skeletal calcium content. These results confirm findings in other murine models that the fetus requires a blood calcium equal to the mother's but no higher in order to sufficiently mineralize the skeleton before birth. These results also suggest that PTH partly regulates placental calcium transfer, because *Gcm2* null mice (which produce PTH) were able to upregulate placental calcium transfer in response to modest hypocalcemia, while *Hoxa3* null mice (which do not produce PTH) were not.

The Anabolic Response to Intermittent PTH (1-34) Requires Connexin43 (Cx43) Mediated Gap Junctional Communication. C. H. M. Castro, J. P. Stains, R. Civitelli. Bone and Mineral Diseases, Washington University, St. Louis, MO, USA.

Recessive (Cx43 gene deletion) or dominant (connexin45 [Cx45] expression) interference with Cx43 function alters osteoblast gene expression and inhibits PTH induced cAMP accumulation and osteoblasts differentiation, whereas PTH up-regulates Cx43. We tested whether Cx43 is involved in the anabolic response to PTH *in vivo* using heterozygous Cx43 null mice ($Cx43^{+/-}$), whose Cx43 abundance and gap junctional communication are reduced relative to wild type ($Cx43^{+/+}$) animals (the homozygous null mutation is perinatally lethal). We administered subcutaneously either 200 or 400 ng/g b.w. of human PTH (1-34) (PTH-200 and PTH-400), or vehicle to 4-months-old $Cx43^{+/-}$ and $Cx43^{+/+}$ mice (n=7 per group) daily (5 days/week). After 4 weeks of treatment, whole body bone mineral density (BMD) measured by DEXA (PIXImus, Lunar-GE) increased 6.4±1.0% and 11.4±1.9% in the PTH-200 and PTH-400 groups, respectively. This response was significantly smaller in $Cx43^{+/-}$ animals (whose baseline BMD was not different than that of $Cx43^{+/+}$ littermates), with 3.6±1.2% and 3.1±0.5% increments from baseline, respectively. No significant changes occurred in vehicle treated animals. Histomorphometric analysis of PTH-400 mice also showed a 2-fold increase of bone volume/total volume in $Cx43^{+/+}$ mice and no significant changes in $Cx43^{+/-}$ littermates. While vigorous activation of bone formation was demonstrated in wild type animals, with increases of osteoblast number (~70%) and all static and dynamic parameters of bone formation, changes in heterozygous animals were marginal at best. Likewise, PTH-400 significantly increased osteoclast number in $Cx43^{+/+}$ but not in $Cx43^{+/-}$ animals. *In vitro*, PTH activation of the rat osteocalcin promoter was significantly reduced in ROS 17/2.8 cells transfected with Cx45, which decreases endogenous Cx43 mediated gap junctional communication, relative to wild type cells. We mapped this connexin sensitivity of PTH response to a proximal region (-199 to +32) of the promoter, but excluded the participation of the CT-element, previously identified as a connexin response element (CxRE). In fact, Cx45 overexpression in these cells reversed PTH response from activation (1.4-fold in ROS 17/2.8 cells) to repression (0.89-fold in ROS/Cx45 cells), when a –199 to +32 promoter sequence was used. Thus, the anabolic response to intermittent PTH administration is curtailed in conditions of Cx43 deficiency, the consequence of an osteoblastic failure to mount a full response to the hormone's anabolic action. Cx43 mediated intercellular signals control response to PTH in part by modulating osteoblast gene transcription via alternative CxREs.

Comparison of Intact and Whole Parathyroid Hormone Levels After Parathyroidectomy Between Patients with Primary and Secondary Hyperparathyroidism. H. Yamashita[1], P. Gao[2], S. Noguchi*[1], S. Uchino*[1], S. Watanabe*[1], T. Ogawa*[1], M. Fukagawa[3]. [1]Surgery, Noguchi Thyroid Clinic, Beppu, Oita, Japan, [2]Scantibodies Laboratory Inc, Santee, CA, USA, [3]Dialysis and Metabolism, Kobe University School of Medicine, Kobe, Japan.

Most current commercial 2nd generation intact PTH (iPTH) assays cross-react with 7-84 PTH and this interference accounts for up to 90% of immunoreactivity in samples obtained from uremic patients. It is reported that 7-84 PTH has an antagonistic action to 1-84 PTH, however, very little is known about the production and metabolism of 7-84 PTH. A new 3rd generation cyclase activating PTH (CAP) novel immunoradiometric assay, was shown to specifically measure 1-84 PTH without any cross reactivity to 7-84 PTH. Using this CAP assay, we studied the production and metabolism of 7-84 PTH in primary hyperparathyroidism (pHPT).
This study comprised 63 patients with pHPT caused by a single adenoma who underwent parathyroidectomy. Preoperatively, blood samples were drawn from the bilateral internal jugular vein by ultrasonographic guidance and from the peripheral vein. During surgery, blood samples were drawn after anesthesia (basal level), before excision (pre-excision level) of one enlarged parathyroid gland, and at 5, 10, and 15 minutes post excision. The 7-84 PTH level was calculated by subtraction of the 3rd generation CAP assay value from the 2nd generation iPTH assay value.
There were 34 patients whose iPTH assay levels differed by more than 10% between the right and left internal jugular. In those 34 patients, the level of 7-84 PTH levels obtained from the adenoma side was significantly higher than those from the contralateral side (124±18 vs. 44±18 pg/ml, $p<0.05$).The plasma CAP and iPTH value had dropped to 25±10 and 32±11% at 5min, 14±7 and 21±7% at 10 min, and 10±5 and 17±7% 15 min after removal of an enlarged gland of pre-excision value, respectively ($p<0.001$). Interestingly, the 7-84 PTH level after 5 min was higher than that at pre-excision in seven of 63 patients (11%). Further, the level at 10 min was higher than that at 5 min 1n 10 (16%) and the level at 15 min was higher than that at 10 min 1n 15 (24%).
Our results suggest that 7-84 PTH may not only be produced by parathyroid adenomas but also may be produced by the metabolism of 1-84 PTH during circulation and the new 3rd generation CAP assay may be a more useful adjunct to parathyroidectomy than the currently used 2nd generation iPTH assay.

Amphiregulin: A Possible Mediator of Parathyroid Hormone's Anabolic Actions in Bone. L. Qin[1], L. Raggatt[1], X. Li*[1], J. Tamasi[2], J. H. M. Feyen[2], N. C. Partridge[1]. [1]Physiology and Biophysics, University of Medicine and Dentistry of NJ, Robert Wood Johnson Medical School, Piscataway, NJ, USA, [2]Bristol-Myers Squibb Pharmaceutical Research Institute, Pennington, NJ, USA.

Parathyroid hormone (PTH) is the major mediator of calcium homeostasis and bone remodeling, having both bone resorption and bone formation actions. It is well documented that intermittent injection of PTH increases bone formation. A number of genes have been found to be regulated by PTH and mediate PTH's functions. Recently we have found that the expression of amphiregulin, a member of the epidermal growth factor (EGF) family, is rapidly and highly up-regulated by PTH in several osteoblastic cells in a PKA-dependent manner. In addition, we report that *in vivo* hPTH (1-38; 8 μg/100g) injection into 28-day old male rats dramatically elevated the level of amphiregulin mRNA in the femoral metaphyses to about 12-fold and 2-fold after 1 h and 4 h, respectively. The up-regulation of amphregulin by PTH in osteoblastic cells is a primary response since it does not require *de novo* protein synthesis. We performed a complete study of the expression patterns of all the EGF-like ligands (EGF, TGF-α, amphiregulin, epiregulin, HB-EGF and betacellulin) and their receptors (EGFR and ErbB2) in UMR 106-01 cells using real-time RT-PCR and found that all of these proteins are expressed but amphiregulin is the only member that is highly regulated by PTH. Functional studies using cell numbers, [^{3}H]thymi-

dine incorporation into DNA and cell cycle analysis demonstrated that amphiregulin is a potent growth factor for rat primary calvarial osteoblastic cells. Furthermore, Western blot analysis showed that amphiregulin strongly and quickly stimulated Akt and ERK phosphorylation, c-fos and c-jun expression in osteoblastic cells (UMR 106-01 and rat primary calvarial osteoblastic cells). All of these functions require the EGFR, since specific inhibitors (compound 32 and compound 56) for the EGFR completely abolished amphiregulin's actions. Finally, μCT analysis of femurs and tibiae from amphiregulin knockout mice revealed that those mice have significantly less tibial trabecular bone than wild-type siblings at 4-weeks while femoral cortical bone is unaffected. Taken together, our results suggest that amphiregulin is a possible mediator of PTH's anabolic functions in bone.

Wnt Signaling Pathway: A Target for PTH Action in Bone and Bone Cells. N. H. Kulkarni*[1], D. H. Halladay*[1], R. R. Miles*[1], C. A. Frolik*[1], R. J. S. Galvin*[1], T. R. Fuson*[1], T. J. Martin*[2], J. E. Onyia*[1]. [1]Gene Regulation, Bone Research & Enabling Biology, Eli Lilly & Company, Indianapolis, IN, USA, [2]St. Vincent's Institute for Medical Research, Fitzroy, Victoria, Australia.

Parathyroid hormone (PTH), a potent modulator of bone metabolism has been shown to increase bone formation in animals and humans. The Wnt signaling pathway has recently been demonstrated to play an important role in bone formation and regulation of bone density. In humans, activating mutations in the low-density lipoprotein receptor-related protein 5 (LRP5) causes a high bone density phenotype. These mutations are thought to inhibit the binding of the Wnt antagonist Dickkopf (DKK-1) to LRP5, preventing formation of endocytic ternary complex with Kremen 1, thus stimulating the Wnt pathway. Since, stimulation of Wnt signaling pathway and PTH treatment both lead to increased bone formation, the anabolic effects of PTH on bone might be mediated in part by the Wnt pathway. To test this hypothesis, we investigated the expression and effects of PTH on components of the Wnt signaling pathway in rat metaphyseal bone, *in vivo;* and primary osteoblast cultures, osteoblastic cells (UMR106) and cultured murine osteoclasts. Northern analysis revealed the expression of Wnt components LRP5, LRP6, frizzled-1 (FZD-1), DKK-1 and Kremen-1 *in vivo* and *in vitro*. PTH upregulated the mRNA expression of LRP6 and FZD-1, while decreasing LRP5 and DKK-1 in rat metaphyseal bone in vivo and in UMR 106 cells in vitro. Since, stimulation of the canonical Wnt pathway results in the accumulation of β-catenin, we analyzed the stabilization of β-catenin using a monoclonal antibody. Western blot analysis showed that PTH (10^{-6} to 10^{-10}M) stabilized β-catenin at (1 to 24h) in UMR 106 cells. Futhermore, the ability of PTH to induce downstream Wnt signaling response was measured by TCF-luciferase reporter gene activity. There was a 6 and 3 fold increase in the reporter gene activity at 8 and 24h respectively, after PTH treatment of UMR 106 cells. These findings suggest that stimulation of canonical Wnt signaling pathway by PTH may occur via differential expression of the receptor complex FZD-1/LRP5 or LRP6 accompanied by down regulation of the antagonist DKK1, resulting in stabilization of β-catenin and activation of the TCF family of transcription factors. Taken together, these results indicate a possible role of the Wnt signaling pathway in PTH anabolic actions in bone.

Tuberoinfundibular Peptide of 39 Residues (TIP39), a Ligand of the PTH Receptor Family, may Be Involved in Early Brain Development in Zebrafish. E. Blind[1], S. Wortmann*[1], I. A. Hansen*[1], S. Meyer*[1], C. Neuner*[2], C. Winkler*[2]. [1]Medicine - Endocrinology, University of Wuerzburg, Wuerzburg, Germany, [2]Physiological Chemistry 1, University of Wuerzburg, Wuerzburg, Germany.

The polypeptide TIP39 (tuberoinfundibular peptide of 39 residues), which has been isolated initially from bovine hypothalamus, is a potent activator of the PTH-2 receptor, but acts as an antagonist on the PTH-1 receptor. Despite the known interaction with the PTH receptor family, the function of this new peptide is largely unknown. Starting from database search results we cloned the cDNA coding for the TIP39 protein precursors from zebrafish (Danio rerio) by RT-PCR and RACE-PCR from total RNA extracted from total adult zebrafish tissue. To study the zebrafish TIP39 expression pattern during embryogenesis, we performed in-situ hybridization with digoxygenin-labeled antisense cRNA probes. To manipulate functional expression levels of TIP39 during the early development of the zebrafish, we used a morpholino-based antisense oligonucleotide strategy. The deduced, processed zebrafish TIP39 has an identical length compared to human TIP39 and is highly conserved with 59% aa identity. In man, TIP39 was found to be expressed (as detected by RT-PCR) in adult brain, kidney, and trachea, as well as in fetal brain and liver (Hansen et al., J Endocrinol 2002, 174: 95-102), with the expression pattern in mouse brain (by in-situ hybridization) being localized in many but not all neuron groups. Similarly, in zebrafish embryos at 23 hours after fertilization, TIP39 expression was detected in restricted domains of the developing brain. The inhibition of TIP39 expression at this stage of development using a morpholino-induced knockdown of TIP39 translation resulted in a severely altered phenotype with abnormal development of anterior head structures. In summary, an undisturbed TIP39 expression seems to be essential for normal brain development during early zebrafish ontogenesis.

Interactions between the Mid-Region of PTH-(1–34) and the Receptor Orient the Hormone for Receptor Activation. A. Wittelsberger[1], M. Corich*[1], B. Lee*[1], A. Barazza*[1], R. Yacobi*[1], P. Czodrowski*[2], D. F. Mierke*[2], J. M. Alexander[1], M. Rosenblatt[1], M. Chorev[1]. [1]Bone and Mineral Metabolism, BIDMC-Harvard Medical School, Boston, MA, USA, [2]Chemistry and Molecular Pharmacology, Brown University, Providence, RI, USA.

Based on structure-activity studies, PTH-(1–34) is comprised of two functional α-helical domains: the N-terminal helix required for activation of the receptor, and the C-terminal helix responsible for binding. Based on our studies, this model now must be re-examined. We used photoaffinity scanning (PAS) to identify key ligand–receptor interactions for residues from the mid-region of PTH-(1–34), an unstructured domain subtended by the two α-helices [1,2]. Four PTH analogs, containing a single photoreactive *p*-benzoylphenylalanine (Bpa) residue in position 11, 15, 18, or 21, all photocrosslinked to the juxtamembrane part of the N-terminal extracellular domain (N-ECD) of the PTH1-Rc, i.e. in the regions [165-174], [183-189], [190-224], and [165-177], respectively. Addition of these mid-region contacts as constraints to our previously proposed model of the PTH–PTH1-Rc complex compels substantial refinement of the model. After extensive molecular simulation experiments, we find: 1) The overall receptor-bound conformation of the hormone is not extended, but bent, with the mid-region more compact than previously thought. 2) Region [165-177] of the N-ECD of the receptor, shown previously to have a propensity to form an amphipatic helix, is re-directed towards the extracellular surface of the helix bundle. 3) The activation domain of the hormone traverses the external surface of the receptor between the top of transmembrane helices (TM) 1 and 2, rather than between TM–7 and TM–1. Elucidation of the novel contact points for the mid-region of PTH-(1–34) significantly alters the view of both the receptor-bound tertiary structure of the hormone as well as the topological orientation of the C-terminal part of the N-ECD in the hormone–receptor bimolecular complex. We conclude that the mid-region of PTH-(1–34) has a critical role in fixing the entry of the N-terminal helical part of the hormone into the heptahelical bundle between TM–1 and TM–2, by extensive contacts with the receptor. This anchorage orients the amino terminus into position to activate the receptor.

NFκB Suppression of VDR Transactivation Requires the Rel Homology Domain of p65. X. Lu*, P. Fiester*, J. Rubin, M. S. Nanes. Division of Endocrinology, Department of Medicine, Emory University, VA Medical Center, Decatur, GA, USA.

Gene transcription stimulated by vitamin D requires binding of the liganded VDR to DNA, assembly of the coactivator complex with pre-initiation factors, and activation of RNA polymerase II. We have shown that suppression of VDR activity by the inflammatory cytokine TNF-α is due to activation of the transcription factor NFκB. Furthermore, suppression of VDR is conferred by the p65 subunit of NFκB. To define active region(s) of p65 that mediate inhibition of VDR function, several deletion and single amino acid mutants of p65 were designed in an expression construct bearing an independent nuclear localization signal and a c-myc tag. Nuclear compartmentalization of the mutant p65 or wild-type proteins was confirmed by western analysis for the myc tag and/or p65. ROS 17/2.8 cells were transiently transfected with a VDREx2-luciferase reporter alone or with the p65 expression vectors. Cells were treated with 10^{-8}M $1,25(OH)_2D_3$ (vitamin D) and luciferase expression was measured as an index of transcription. Forced expressed of p65 or its mutants revealed that the RHD domain of p65 is critical for the inhibition of VDR transactivation. Additionally, neutral amino acid substitution of potentially phosphorylated sites S276, S281, Y257, and Y288, within the RHD domain, prevented the p65 inhibition of VDR transactivation. To determine if p65 competes with the VDR for binding to the transcriptional coactivators CBP or SRC-1, GST-VDR-LBD fusion proteins were used in pull-down assay with in vitro translated [^{35}S]CBP or [^{35}S]SRC-1. CBP failed to bind the VDR-LBD, as reported previously, but increased binding of the liganded VDR-LBD to SRC-1. Addition of in vitro translated wild-type p65 decreased VDR-LBD interaction with SRC-1 in a dose dependent manner. In contrast, RHD-spanning or RHD point mutants of p65 failed to disrupt VDR-SRC-1 binding, suggesting a role for the p65 RHD in the inhibition of VDR transactivation. Additional experiments revealed that p65, which binds CBP directly, interacts with SRC-1 only very weakly, and transient forced expression of SRC-1 in ROS 17/2.8 cells did not, by itself, reverse the p65 inhibition of VDR trans-activation. These results suggest that NfkB p65 inhibits the VDR transcriptional response by weakening the formation of the multiprotein nuclear coactivator complex. p65 may inhibit formation of the complex with VDR, in part, by competitively disrupting VDR-SRC-1 interaction, and also by directly binding to CBP.

Lithocholic Acid Is a New Vitamin D Receptor Ligand that Stimulates Transcription via Novel VDRE Motifs and a Unique Pattern of Coregulator Recruitment. P. W. Jurutka[1], P. D. Thompson*[1], K. Eichhorst*[1], N. Hall*[1], C. Encinas Dominguez*[1], G. K. Whitfield[1], J. C. Hsieh[1], C. A. Haussler*[1], D. J. Mangelsdorf*[2], M. R. Haussler[1]. [1]Biochemistry, University of Arizona, Tucson, AZ, USA, [2]Pharmacology, University of Texas Southwestern Medical Center, Dallas, TX, USA.

The nuclear vitamin D receptor (VDR) mediates the effects of 1,25-dihydroxyvitamin D3 (1,25D) to alter gene transcription and achieve bone mineral homeostasis. In addition, extraosseous actions of 1,25D-VDR are observed in many epithelial cell types, and the cytotoxic bile acid, lithocholic acid (LCA), has been identified as a novel VDR ligand. Both 1,25D and LCA have been reported to induce genes coding for cytochrome P450 (CYP) enzymes involved in cellular detoxification. Herein, we demonstrate that VDR liganded with LCA stimulates transcription of several vitamin D responsive element (VDRE)-linked reporter genes in intestinal, kidney and bone cells. Studies employing human cell lines (HT-29 colon cancer and IN407 embryonic intestine) revealed that both 1,25D- and LCA-VDR elicit transcriptional activation from classical DR3 VDREs as well as from a novel ER6 VDRE located in the promoter region of the human CYP3A4 gene. Each ligand can also upregulate CYP3A4 mRNA and protein levels. Gel mobility shift assays demonstrated that, like 1,25D, LCA enhances retinoid X receptor (RXR) heterodimerization with VDR and subsequent VDRE binding, in vitro. In addition to VDRE binding, the VDR-RXR heterodimer recruits a p160-type coactivator such as SRC-1, subsequently interacting with the DRIP205 mediator to stimulate transcription. We tested the ability of LCA-VDR to associate with these proteins in gel mobility shift and pull-down assays. Whereas both 1,25D and LCA enhanced the association of VDR with DRIP205, LCA-VDR did not interact with SRC-1. This surprising result was also observed in a mammalian two-hybrid system which further revealed that SRC-2 and SRC-3 were ineffective in their interaction with LCA-VDR. Finally, selected residues in the ligand binding domain were altered to create VDR mutants that retain 1,25D binding and transactivation but do not stimulate transcription in response to LCA. Thus, VDR serves as a high affinity "endocrine receptor" for 1,25D and also as an "adopted orphan" nuclear receptor functioning as a lower affinity bile acid sensor that likely employs an alternative set of coregulators for control of gene expression. In conclusion, we propose that VDR is a bifunctional regulator with the 1,25D-liganded conformation facilitating primarily bone mineral homeostasis, and the LCA-liganded configuration mediating cellular detoxification by upregulation of CYP3A4.

Coactivator LxxLL Peptides Derived From VDR-Phage Display Screens Exhibit Ligand-Dependent Characteristics in Cultured Cells. L. A. Zella*, H. Yamamoto, M. Yamazaki*, N. K. Shevde, J. W. Pike. Biochemistry, University of Wisconsin-Madison, Madison, WI, USA.

The vitamin D receptor (VDR) mediates the biological actions of 1,25-dihydroxyvitamin D3 (1,25(OH)2D3) through its capacity to regulate transcription. The VDR is known to bind to specific regulatory regions on numerous target genes in association with the retinoid X receptor (RXR) and to recruit coactivator complexes such as SRC/CBP/p300 and DRIP/Mediator necessary for various facets of transcriptional control. The transactivation domains of both VDR and RXR interact directly with the p160 coactivators and DRIP205 via an LxxLL motif located within the coactivator. In our previous studies, we have shown that small 19-mer peptides containing this LxxLL motif which bind both VDR and RXR can inhibit vitamin D response. In addition, LxxLL peptides selective for RXR can also inhibit vitamin D response. In this report, we screened several phage libraries directly with purified human VDR to identify peptide sequences that displayed higher affinity and selectivity for the VDR. Two classes of LxxLL peptides were obtained: those screened in the presence of VDR agonists and those screened in the presence of the VDR antagonist ZK159222. Agonist-derived peptides contained the consensus sequence Lx E/H x H/F P L/M/I LxxLL and exhibited significant homology to the active LxxLL box found in DRIP205. Antagonist-derived sequences were restricted to the central LxxLL motif. Peptides sequences were then fused in-frame downstream of the Gal4 DNA binding domain, transfected into MC3T3-E1 cells and their activities assessed in a mammalian two-hybrid system for selectivity and ligand dependence using VDR-VP16 and RXR-VP16. While the bulk of the LxxLL peptides interacted with both VDR and RXR, selectivity for VDR was observed with at least one of the peptides. It was also clear that the relative affinity of the peptides differed between the two receptors. The transcriptional activities of the vitamin D agonist-derived peptides were dependent upon 1,25(OH)2D3, but were not induced by the antagonist ZK159222. Analogs of vitamin D3 promoted unique patterns of both potency and efficacy with these peptides. Conversely, the activities of the peptides that were derived from the antagonist screen were largely ligand-independent. We next assessed the ability of these LxxLL peptides to inhibit vitamin D response using activation of a transfected reporter gene fused downstream of the vitamin D-sensitive osteocalcin gene promoter. All agonist peptides inhibited vitamin D response in a dose-dependent manner. Current studies are focused on the use of these peptides to suppress endogenous vitamin D3 responses in osteoblasts and other cell types.

The Intracellular Estradiol Binding Protein: An hsp27-Related Estrogen-Binding, Estrogen Receptor-Interacting Protein that Squelches Estrogen-Directed Transactivation. H. Chen[1], B. Hu[2], M. Hewison[3], L. Nguyen*[1], C. Encinas*[1], J. S. Adams[1]. [1]Division of Endocrinology, Diabetes and Metabolism, Cedars-Sinai Burns and Allen Research Institute, Los Angeles, CA, USA, [2]Pathology, Cedars-Sinai Medical Center, Los Angeles, CA, USA, [3]Division of Medical Sciences, The University of Birmingham, Queen Elizabeth Medical Centre, Birmingham, United Kingdom.

Using estrogen receptor a (ER alpha)-bearing cells from the gonadal steroid-resistant New World primate (NWP), cotton-top marmoset , as an illustrative “experiment of nature”, we have recently identified a novel means of steroid hormone-receptor transregulation embodied by the heat shock protein 27 (hsp27)-related intracellular estradiol (E2) binding protein (IEBP). The aim of these studies was to determine how IEBP influences ER-ERE-directed transactivation. A line of estrogen-responsive primate breast cells were stably transfected with IEBP and overexpression of the transfected protein was confirmed by Western blot. In breast cells stably overexpressing IEBP, E2-stimulated ERE-luciferase reporter activity was significantly reduced 50-70% ($p<0.001$) with no accompanying change in endogenous ER expression; by comparison transfection of the ER alpha significantly increased reporter activity 0.5-fold ($p<0.05$). IEBP transfection increased extractable, specific E2 binding in postnuclear extracts 2-4-fold ($p<0.001$). The increase and decreased of ERE-directed luciferase expression under the influence of ER alpha and IEBP, respectively, was confirmed with fluorescent microscopy of MCF-7 cells stably-transfected with the ERE-luciferase reporter construct. Using yeast two hybrid screening for IEBP-protein interaction partners, 1] IEBP was shown to interact with ERalpha and 2] the IEBP-ER interaction was E2-dependent and reversed with the selective estrogen receptor modulator, tamoxifen. GST pull-down assay confirmed the interaction between ER alpha and IEBP and showed that the IEBP interaction domain resided in the ligand binding domain of the ER alpha (residues 246-595). Co-immunostaining of the ER and IEBP demonstrated 1] co-localization of the two proteins in the cytoplasm in the absence of E2 and 2] translocation and co-localization of the ER and IEBP to the nucleus after incubation with E2. In summary, we have functionally characterized a novel regulator of estrogen action. IEBP is an hsp27-related estrogen-binding, ER-interacting protein which acts to squelch E2-ER-ERE-directed transactivation.

Osteoblast Kinetics In Vivo. T. Kobayashi, E. Hinoi, H. M. Kronenberg. Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA.

During bone modeling and re-modeling, cells of the osteoblast lineage replicate, become bone-forming osteoblasts, and then, in a regulated fashion, die or become lining cells or osteocytes. To understand better the kinetics of these processes, we have developed a method for marking cells of the osteoblast lineage and following them over time. We genetically marked osteoblasts at particular times using the Cre/loxP recombination system in combination with the Rosa 26R (R26R) Cre reporter system. In order to induce Cre activity in osteoblasts at desired times, tamoxifen (TAM)-inducible Cre (Cre-ERt) was expressed under the control of the mouse 3.2kb-long type I (a1) collagen gene promoter. The R26R mice express LacZ in any cells in which Cre removes engineered “stop” sequences. Cre-transgenic mice were crossed with R26R LacZ mice to obtain doubly mutant male mice (Studs). Studs were crossed to 8 week old wild-type CD-1 female mice to obtain doubly mutant pups. To study osteoblasts in the perinatal period, pregnant mothers were injected with 2 mg TAM intra-peritoneally at 18.5 dpc. After vaginal delivery, pups were sacrificed on consecutive days, X-gal stained, and histologically analyzed. To study mice at one months of age, mice doubly heterozygous for Cre and R26R genes were injected with 100mg/kg TAM subcutaneously and sacrificed on consecutive days. Littermates of the same sex were compared. TAM itself had no effect on bone morphology or on TUNEL positivity determined using perinatal mice 2days after TAM injection. At the perinatal stages, basal X-gal staining due to endogenous beta galactosidase activity was minimal. TAM injection at E18.5 induced efficient X-gal staining postnatally, and the maximal staining intensity was obtained at P1.5 in approximately 70% of more than 25 TAM-injected dams. (In the rest of the cases, Xgal staining was not efficiently induced at P1.5 and showed a gradual increase after P2.5.) After the peak number of cells stained at P1.5, the number of stained cells decreased dramatically at P2.5 in both calvaria and tibia. Histological examination showed that X-gal positive cells at P1.5 were matrix-attached osteoblasts, some osteocytes, and cells of tendons and ligaments. At P2.5, numbers of not only of Xgal-stained osteoblasts but also of osteocytes were greatly reduced. In control studies, TAM injection to P0.5 pups produced large amounts of LacZ positive cells at P2.5, suggesting that the decrease in LacZ positive cells at P2.5 was not due to poor LacZ activity. Study using one month old mice also showed patterns similar to those in the perinatal study. Lineage tracing of osteoblasts using this method suggests that osteoblast turnover is surprisingly rapid both in perinatal stages and at the age of one month in the mouse.

Classical Genotropic versus Nongenotropic (Kinase-Initiated) Regulation of Gene Transcription by the Estrogen Receptor (ER): Evidence for Extensive Divergence of Target Gene Population Controlled via the Two Mechanisms. M. Almeida[1], J. D. Shaughnessy[2], F. G. Zhan[2], L. Han[1], H. Peng*[1], S. A. Stewart*[1], C. A. O'Brien[1], R. L. Jilka[1], S. Kousteni[1], S. C. Manolagas[1]. [1]Div Endo/Metab, Center for Osteoporosis and Metabolic Bone Diseases, CA Veterans Healthcare System, Univ of Arkansas for Med Sciences, Little Rock, AR, USA, [2]Myeloma Institute, Univ of Arkansas for Med Sciences, Little Rock, AR, USA.

Elucidation of kinase-initiated routes by which the ER controls gene transcription, along with evidence of distinct biologic outcomes in response to ligands that can selectively activate nongenotropic estrogen-like signaling (ANGELS), suggest that the ER controls a range of genes wider than that regulated by its trans/cis interactions with DNA. To ascertain the extent and significance of nongenotropic ER-mediated transcription, we employed stable transfectants of HeLa cells carrying either the wild type ERα or the ligand binding domain of the ERα localized to the cell membrane (E-Mem), MCF-7 breast carcinoma cells, as well as murine tibiae and uteri from mice treated with 17β-estradiol (E2) or the nongenotropic signaling activator 4-estren-3α,17β-diol (estren) and then subjected them to: a) real time PCR analysis b) an array analysis of 96 genes associated with signal transduction pathways c) an array analysis of 54 selected transcription factors (TFs) and d) a comprehensive array analysis of ~ 40.000 genes and ESTs using the Affymetrix U133 chip. We report that in all 4 specimens nongenotropic ER actions regulated a larger number of genes and TFs than genotropic ER actions, irrespective of the method of analysis. Specifically, the expression of Wnt2, Frizzled10, Egr-1 and c-fos was strongly upregulated in E-Mem-containing HeLa cells treated with E2 or estren, or in ERα-containing HeLa cells treated with estren. Upregulation of Frizzled10 by estren was reproduced in MCF-7 cells. Egr-1 and c-fos were only modestly, if at all, upregulated by activation of ERα with E2. Egr-1 was upregulated by both estren and E2; but complement 3 (C3), only by E2 in the uteri. Estren had no effect on C3, cathepsin D, progesterone receptor, bcl-2 and cyclin D1 in MCF-7 cells, whereas E2 upregulated all these ERE-containing genes. On the other hand, estren selectively activated pten in the tibia whereas the activity of gadd45a, mdm2 and trfr was modulated by both estren and E2. Finally, in tibia estren, but not E2, modulated the activity of AP-1, AP-2, GAS/ISRE, and SP1-binding TFs; and both estren and E2 modulated the activity of MEF-2, Myc-Max, PPAR, Stat5, Stat6 and TFIID. This and interim analysis of the Affymetrix data support an extensive divergence in gene expression depending on the mode of ER activation.

Apparent Pubertal Effects on Mechanosensitivity in Girls but Not Boys: An Estrogen Effect? N. J. Crabtree[1], T. J. Beck[2], K. Uusi-Rasi[2], M. S. Kibirige*[3], J. N. Fordham[3], N. J. Shaw[1]. [1]Birmingham Children's Hospital, Birmingham, United Kingdom, [2]Johns Hopkins University, Baltimore, MD, USA, [3]South Cleveland Hospital, Middlesbrough, United Kingdom.

The skeleton is believed to adapt its strength throughout life to changing mechanical demands. It has been hypothesized that sensitivity to load stimuli might be influenced by hormonal changes. Load sensitivity should be apparent in the relationship between bone strength and load magnitude; pubertal changes in that relationship may signify a hormonal effect. According to the muscle-bone mechanostat theory, skeletal loads mainly arise from muscle forces actuating bony levers and limb muscle mass should be a reasonable measure of skeletal load. The aim of this study was to examine the possible effects of puberty & gender on the strength-load relationship in a group of healthy pre- & post pubertal children.

260 healthy white children aged 5-18 years had whole body DXA. From these, section modulus (an index of bending strength) was derived from manual region analysis at the mid femoral shaft & combined with measurements of femur length & leg lean mass. Section Modulus (Z), Femoral Strength (FS), defined as Z/femoral length, & the ratio of femoral strength to load (FS/lean leg mass) were compared between gender & pubertal groups using MANOVA, including lean body mass, fat body mass, age and height in the model.

After adjustment for body size, there were no significant gender differences in the prepubertal children for Z, FS or FS/lean leg mass. No significant increases in these size-adjusted parameters were observed in post-pubertal boys. However post-pubertal girls showed significant increases for all three parameters. Additionally a significant gender & puberty interaction was seen for the ratio of strength to load with girls having significantly higher post-pubertal values than their male counterparts.

	Girls		Boys	
	Pre-	Post-	Pre-	Post-
$Z(cm^3)$	*1.56 (0.07)	*2.01 (0.09)	1.55 (0.6)	1.66 (0.11)
FS (cm^2) (*100)	*4.1 (0.2)	*5.2 (0.2)	4.1 (0.2)	4.2 (0.3)
FS / Lean (cm^2/kg) (*1000)	*3.6 (0.1)	*‡4.9 (0.2)	3.7 (0.1)	‡4.0 (0.2)

P<0.05 Diff between *pre- & post- puberty, ‡genders

During puberty, both boys & girls show dramatic increases in circulatory sex hormone levels. Post-pubertal differences in girls may be related to body size independent estrogenic effects on bone, while it would appear that androgens do not have a similar effect in boys. Estrogen may increase bone mechanosensitivity, resulting as this data suggests, in relatively greater bone strength for equivalent muscle loads.

Association between 25-OH Vitamin D3 and Periodontal Disease. T. Dietrich*[1], K. J. Joshipura*[2], B. Dawson-Hughes[3], H. A. Bischoff[4]. [1]Periodontology, Charité, HU Berlin, Berlin, Germany, [2]Epidemiology, Harvard School of Public Health, Boston, MA, USA, [3]Jean Mayer U.S. Department of Agriculture Human Nutrition Research Center on Aging, Tufts University, Boston, MA, USA, [4]Arthritis Research Center, Brigham and Women's Hospital, Boston, MA, USA.

Periodontal disease (PD) is a chronic inflammatory disease that is characterized by the loss of periodontal attachment and alveolar bone. It is a major cause of tooth loss, particularly in the elderly. Osteoporosis and low bone mineral density have been associated with an increased risk of PD. Vitamin D has been shown to improve bone mineral density and a randomized controlled trial with vitamin D and calcium decreased tooth loss in the elderly. The purpose of this analysis was to evaluate the association between serum levels of 25-hydroxyvitamin D3 (25-OHD) and PD in a representative sample of the US population (NHANES III).

We analyzed data of 10,899 subjects aged 20+ years who had data on periodontal attachment loss (AL) and serum 25-OHD levels as well as complete data on all covariates. PD was modeled as the dependent variable in a weighted multiple logistic regression (defined as mean AL ≥ 1.5 mm) and in a weighted multiple linear regression (mean AL). Serum OHD levels were categorized as previously published (<37.5, 37.5-<50, 50-<62.5, 62.5-<75, ≥75 nmol/l). The models adjusted for age, gender, race/ethnicity, smoking, gingival bleeding, diabetes, calcium intake, poverty-income ratio, body mass index and estrogen use. Age, gender, race/ethnicity, calcium intake and number of missing teeth were considered as potential effect-modifiers. There was a significant independent association between 25-OHD and PD in both models. Compared to the highest 25-OHD category, subjects with low 25-OHD levels (<37.5 nmol/l) were more likely to have PD (Odds-Ratio: 1.54, 95% CI 1.13-2.11). There was a significant trend across 25-OHD categories (p=0.02). In the linear model, the mean difference in AL was 0.1 (0.02-0.18) mm between the lowest and highest 25-OHD category. No interaction was found with age, gender, race/ethnicity, calcium intake or number of missing teeth. When bone mineral density (BMD) of the total femoral region was entered into the model in a subgroup (n=9,922), BMD was not a significant predictor of PD and did not change the OR estimate for the 25-OHD PD association.

This analysis suggests that low serum levels of 25-OHD are associated with an increased risk for PD. This association could not be fully explained by BMD and was independent of gender, age and race/ethnicity. Given the high prevalence of both vitamin D deficiency and PD, vitamin D supplementation might be a useful prevention strategy for PD.

Antagonistic Actions of TEI-9647 Depend on the Primary Structure of AF-2 domain of Vitamin D Receptors. E. Ochiai*, D. Miura*, H. Eguchi*, K. Takenouchi*, Y. Harada*, Y. Azuma, T. Kamimura*, S. Ishizuka. Teijin Institute for Bio-Medical Research, Tokyo, Japan.

We had reported that the vitamin D analog, (23S)-25-dehydro-1α-hydroxyvitamin D3-26,23-lactone (TEI-9647), functions as an antagonist of the vitamin D receptor (VDR)-mediated genomic actions of 1,25-(OH)2D3. Intriguingly, we recently found that TEI-9647 functions as an agonist, not antagonist in rodent cells, whereas it acts as an antagonist in human cells. The primary structures of the human and rodent ligand binding domain (LBD) of VDR are highly conserved, but there are a few differences. Especially, the difference in AF-2 domain was considered to be important for gene transactivation. These findings lead to us to a hypothesis that differences in VDR sequence between species, especially in AF-2 domain, might be decisive for agonistic/antagonistic effect of TEI-9647 and suggesting important role of interaction between TEI-9647 and AF-2 domain. To elucidate this hypothesis, we examined the effect of TEI-9647 on transactivation by luciferase reporter assay using human osteosarcoma cell line (SaOS-2 cells) or ROS 24/1 cells rat osteosarcoma cell line (ROS 24/1 cells) cotransfected with VDR and human vitamin D 24-hydroxylase promoter-driven luciferase reporter. TEI-9647 acts as an antagonist in SaOS-2 cells and ROS 24/1 cells overexpressed wild type human VDR (WT hVDR). On the contrary, TEI-9647 acts as an agonist in both cell lines overexpressed WT rat VDR (WT rVDR), does not show any antagonistic effect even in 10^{-7} M. And we also investigated using the VDR chimeras composed of the AF-2 domain of hVDR and corresponding residues of rVDR. Each chimeric VDRs had normal transcriptional potency activated by 1,25-(OH)2D3. Displacement of the AF-2 domain of hVDR to corresponding domain of rVDR diminished the antagonistic effect of TEI-9647 and TEI-9647 exhibited agonistic effect. On the contrary, displacement of the AF-2 domain of rVDR (the 25 C-terminal residues) to corresponding residues of hVDR diminished the agonistic effect of TEI-9647 and TEI-9647 exhibited antagonistic effect. Investigation using mutated human VDR (C403S, C410N) revealed that Cys 403 and/or 410 was necessary for antagonistic effect of TEI-9647. These results suggested that the species specificity of VDR, especially in AF-2 doamin, might be decisive for agonistic/antagonistic effect of TEI-9647 and important role of interaction between TEI-9647 and two Cys residues in AF-2 domain of human VDR for antagonistic effect of TEI-9647. This is the first report that not only the identification of critical residues in hVDR for TEI-9647 function but also the species specificity of VDR affects the ligand's activity were discovered.

Assay Variation Confounds Hypovitaminosis D Diagnosis: A Call for Standardization. N. Binkley, D. Krueger, C. Cowgill, K. E. Hansen, M. K. Drezner. UW Osteoporosis Clinical Center and Research Program, University of Wisconsin-Madison, Madison, WI, USA.

Endemic hypovitaminosis D contributes to osteoporosis development. However, variation in 25 hydroxyvitamin D (25OHD) measurement is reported, which likely confounds the diagnosis of deficiency. The purpose of this report is to emphasize the extreme variability observed in serum 25OHD measurement between laboratories.

Initially, marked serum 25OHD variability was noted in subjects screening for osteoporosis clinical trials. Subsequently 10 sera were sent for 25OHD measurement in three different laboratories. Finally, 10 specimens were measured in one laboratory before and after adding a known amount of 25OHD.

In the initial observation, 61 osteoporotic women screened for clinical trials had serum 25OHD determinations (41 lab A, 20 lab B.) Their mean (SEM) serum 25OHD concentration was 46 (2.1) and 21 (2.3) ng/ml in laboratory A and B respectively. Furthermore, there was little overlap in serum 25OHD among these clinically similar individuals. Specifically, using 32 ng/ml as an arbitrary cutoff, 17% of those measured in lab A but 90% in lab B were below this value. Finally, 3 individuals were measured in both labs; their 25OHD values (A/B) were 68/48, 50/13 and 43/16 ng/ml.

Subsequently, 25OHD concentration in 10 sera from nursing home residents were evaluated in three different laboratories; a university research lab and two national referral labs; C, D and E respectively. Laboratories A-D utilized various RIA methodologies, lab E used a chemiluminescent immunoassay. Results (ng/ml) from these 10 specimens are reported below.

ID #	Lab C	Lab D	Lab E	ID #	Lab C	Lab D	Lab E
1	14	20	43	6	17	27	30
2	17	20	29	7	23	27	40
3	17	20	29	8	11	23	24
4	19	21	25	9	16	23	20
5	14	20	27	10	8	12	13

Finally, sera were obtained from 10 healthy adults. Two aliquots from each individual were sent to laboratory D; one aliquot had 20 ng/ml of 25OHD added. The measured 25OHD concentration in all spiked sera was higher; however, this increase varied from 9-27 ng/ml between individuals.

In conclusion, 25OHD assays yield markedly differing results; whether an individual is found to have low or normal vitamin D status may be a function of the laboratory utilized. If progress is to be made in correcting widespread hypovitaminosis D, the bone community must accept the challenge of standardizing 25OHD measurement.

Calcium Absorption Is Similar from Milk and Two Types of Fortified Orange Juice at High Intake Levels. S. A. Abrams, I. J. Griffin*, P. M. Davila*, K. M. Hawthorne*. Pediatrics, Baylor College of Medicine, Houston, TX, USA.

We measured calcium absorption in groups of 9 to 12 year-old children who were given diets including at least 240 ml/day of milk or one of two types of calcium-fortified orange juice. One orange juice (OJ-1) contained calcium citrate malate as the calcium source and the other contained a mixture of calcium phosphate and calcium lactate as the calcium source (OJ-2). Drinks were extrinsically tagged with a calcium stable isotope (46Ca). Beverages were given with a breakfast meal including a total of 350-550 mg of calcium. Complete 24-hour dietary calcium intake was determined using weighed dietary records. Fractional absorption was very similar between groups and total absorption was not significantly different (p=0.31 by ANOVA) despite differences in intake (see Table below). Calcium intake was linearly correlated with total daily absorption (r = 0.63) suggesting a benefit to increased calcium intake on total absorption up to as much as 2.2 g/day (see figure below). These findings suggest that these three sources of calcium provide similar bioavailability and lead to comparable levels of daily calcium absorption when included as part of a mixed diet containing calcium intakes comparable to recent dietary recommendations. Calcium intake up to a gram over current recommendations may lead to increased calcium absorption using bioavailable calcium sources. Funded in part by NIAMS (AR43740). Also funded in part by The Minute Maid Company (Houston, TX).

Calcium absorption

Group	Number of subjects	Calcium intake (mg/d)	Percent Absorption	Total absorption (mg/d)
Milk	40	1268±172	33.7±7.8	429±124
OJ-1	30	1510±255	32.5±10.0	492±157
OJ-2	39	1413±503	33.1±10.3	455±198

Assessment of Muscle Strength and the Bone Muscle Unit in the Tibia in Children. K. M. Howard*, M. DiIenno*, R. M. Herskovitz*, B. S. Zemel, M. B. Leonard. Pediatrics, Children's Hospital of Philadelphia, Philadelphia, PA, USA.

Bone expands in response to biomechanical forces. Therefore, the evaluation of the bone muscle unit should play a significant role in the assessment of skeletal disorders in childhood. The purpose of this study was to compare measures of muscle cross-sectional area and functional muscle strength as they relate to bone mass and dimensions in children and adolescents. Measurements were completed in 20 healthy controls, 38 nephrotic syndrome patients, and 19 Crohn's disease patients, 5-20 years of age (mean 12.0 ± 3.7). Peripheral quantitative computed tomography (pQCT, Stratec XCT-2000) measures of cortical bone dimensions and content were obtained in the left tibia, 38% proximal to the growth plate. Muscle cross-sectional area (CSA, cm^2) was measured at the 66% tibia site. Isometric muscle strength (peak torque, Ft-lbs.) was measured in plantarflexion and in dorsiflexion in the left ankle at 4 positions (10° of dorsiflexion, neutral, 10° of plantarflexion, and 20° of plantarflexion) using the Biodex Multi-Joint System 3 Pro dynamometer. The correlations between bone and muscle measures were assessed with Pearson product-moment estimates. All 8 Biodex strength measures were significantly correlated with muscle CSA on pQCT: $R^2 \geq 0.62$, $p < 0.001$. The correlation with muscle CSA was greatest for dorsiflexion in the 20° position (Dorsi-20): $R^2 = 0.81$, $p < 0.001$. Comparisons of bone and muscle measures demonstrated that Dorsi-20 explained 87% and 84% of the variability in cortical bone content and cross-sectional area, respectively. In contrast, muscle CSA explained 82% and 75% of the variability in these bone measures. The relationship between muscle strength and muscle CSA (i.e. muscle efficiency) relative to tibia length was compared across the 3 groups; no differences were detected. In conclusion: the correlations between functional measures of isometric muscle strength and bone are greater than the correlations between muscle CSA and bone. These functional strength measures may provide additional insight into the impact of chronic diseases on bone mineral accretion.

Vitamin D Status as a Determinant of Peak Bone Mass in Young Finnish Men. V. V. Välimäki*[1], H. Alfthan*[2], E. Löyttyniemi*[3], H. Suominen*[4], M. J. Välimäki*[1]. [1]Division of Endocrinology, Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland, [2]Department of Clinical Chemistry, Helsinki University Central Hospital, Helsinki, Finland, [3]Department of Statistics, University of Turku, Turku, Finland, [4]Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland.

Severe vitamin D deficiency causes rickets, but scarce data is available on to what extent a milder hypovitaminosis D determines the development of the peak bone mass in young adults. Our aim was to evaluate the prevalence of hypovitaminosis D {serum 25-hydroxyvitamin D [25(OH)D] ≤ 37.5 nmol/l} and the relationship between vitamin D status and peak bone mass among young Finnish men.

A cross-sectional study of determinants of peak bone mass with data on lifestyle factors

collected retrospectively was performed in 220 young men, aged 18.3 to 20.6 years. 170 men were recruits of the Finnish Army, and 50 were men of similar age, who had postponed their military service for reasons not related to health. Bone mineral density (BMD) was measured in lumbar spine and upper femur by dual-energy X-ray absorptiometry (DXA). Serum 25(OH)D concentrations were followed prospectively for one year.
In July 2000 26.8% of the men had hypovitaminosis D. Six months later in wintertime the respective percentage was 94.6% and next summer 29.8%. After adjusting for age, height, weight, exercise, smoking, calcium and alcohol intake there existed a positive correlation between serum 25(OH)D and lumbar spine (p=0.035), femoral neck (p=0.061), trochanter (p=0.056), and total hip (p=0.068) BMD. Of the two determinants of areal BMD, bone mineral content (BMC) but not scan area correlated with vitamin D status.
Hypovitaminosis D is very common in Finnish young men, especially during wintertime, and it may have detrimental effects on the acquisition of maximal peak bone mass. Since in Finland vitamin D supplementation to infants is now stopped at the age of three years, it can be asked, whether it at our latitude should be continued from that age onwards, no more for the prevention of rickets but as a prophylaxis of osteoporosis.

Relationship of Calcium Intake and Calcium Retention in Adolescent Boys. M. Braun*[1], B. R. Martin[1], M. Kern*[2], G. P. McCabe*[3], M. Peacock[4], A. Machtan*[1], J. Liesmann*[1], A. Kempa-Steczko*[1], C. M. Weaver[1]. [1]Foods & Nutrition, Purdue University, West Lafayette, IN, USA, [2]San Diego State University, San Diego, CA, USA, [3]Statistics, Purdue University, West Lafayette, IN, USA, [4]Indiana University School of Medicine, Indianapolis, IN, USA.

We previously determined the relationship between calcium (Ca) intake and Ca retention in adolescent girls. The intake where maximal Ca retention occurred was determined by a non-linear regression model. It is not known whether the larger skeletal mass of boys requires more dietary Ca to optimize Ca retention or if boys utilize Ca more efficiently than girls.
Forty-four adolescent males, aged 13-15 were tested on two Ca intakes each that ranged from 800-2100 mg/day in a random order, crossover design. All procedures were approved by the Purdue University and Indiana University School of Medicine Institutional Review Boards. Two 3-week metabolic balance sessions were separated by a 2-week wash-out period. Subjects consumed a controlled diet and Ca intake was varied via fortified beverage. After one week equilibration period, calcium retention was determined as intake minus excreta over the next two weeks.
Compared to girls studied during their period of pubertal growth, boys had higher Ca retention at all intakes. This higher Ca retention was achieved through lower urinary output and higher Ca absorption. Thus, boys attain a higher bone mineral content by increased utilization efficiency. Adding measures of body size into the model did not eliminate gender differences.

Heterodimeric Bone Morphogenic Protein 2/7 Enhances Osteoblastic Differentiation *in Vitro* and Bone Formation *in Vivo*. W. Zhu*[1], J. Arimizu*[1], E. A. Ford*[1], J. R. Lieberman*[2], B. A. Rawlins*[1], O. Boachie-Adjei*[1], R. G. Crystal*[3], C. Hidaka*[1]. [1]Laboratory for Soft Tissue Research, Hospital for Special Surgery, NY, NY, USA, [2]University of California, Los Angeles, CA, USA, [3]Weill Medical College of Cornell University, NY, NY, USA.

While recombinant bone morphogenic proteins (rBMPs) are homodimers, BMP heterodimers resulting from the co-expression of two different BMP genes may be more potent in supporting bone formation. In this study, we tested whether BMP2/7 heterodimer generated by combination gene therapy with adenovirus vectors encoding BMP2 (AdBMP2) and BMP7 (AdBMP7) would be more potent in supporting osteoblastic differentiation and bone formation than either homodimer alone. A549 epithelial cells were transfected with AdBMP2, AdBMP7, or a combination of the two. The secretion of BMP2/7 heterodimer in the supernatant of co-transfected cells was verified by immunoprecipitation with anti-BMP7 antibody followed by enzyme linked immunosorbant assay for BMP2. To test the potency of BMP2/7 *in vitro*, C2C12 myoblastic cells were stimulated with cell supernatants containing BMP2 or BMP7 homodimer, or BMP2/7 heterodimer. Time course studies showed that BMP2/7 increased the alkaline phosphatase (ALP) activity and osteocalcin (OCN) expression at earlier times than either homodimer, indicating an acceleration of osteoblastic differentiation. After 7d, BMP2/7 induced a 200-fold higher ALP activity and 10-fold higher OCN expression than either homodimer ($p<0.05$, all comparisons). Dose response studies showed that a maximal OCN expression and ALP activity could be induced with <7.5 ng/ml of BMP2/7 after 7d. These levels were 3-fold (OCN) and 20-fold (ALP) higher than those which could be induced by maximal stimulation with up to 1 μg/ml of rBMP2 or rBMP7 ($p<0.05$, all comparisons). To test *in vivo* bone formation, we performed single level posterior spine fusion in rats by implantation of bone graft and cellulose sponge soaked with AdBMP2 (n=13, $1.5x10^{10}$ particle units [pu]) or AdBMP7 (n=19, same dose) or a combination of the two (n=15, $0.75x10^{10}$ pu each vector). Fusions were assessed 8 wk post-surgery by x-rays in a blinded fashion. Treatment with both AdBMP2 and AdBMP7 resulted in fusion in 14 out of 15 spines (93%). This was 2-fold higher than that achieved with AdBMP2 alone ($p<0.02$) and 3-fold higher than AdBMP7 alone ($p<0.001$). No bilateral fusion occurred in control spines treated with AdNull (vector with no transgene) or saline. Our findings suggest that BMP2/7 heterodimers have increased osteogenic potency than either BMP2 or BMP7 homodimer. Use of heterodimeric BMPs may be an attractive strategy for improving the clinical efficacy of BMP therapy.

Effects of Cartilage-Derived Morphogenic Proteins (CDMPs) on the Pluripotent Mesenchymal Cell Line C2C12. L. C. Yeh*, A. D. Tsai*, J. C. Lee. Biochemistry, Univ. Texas Health Sci. Ctr. at San Antonio, San Antonio, TX, USA.

The pluripotent mescenchymal cell line C2C12 was used as a model of osteogenesis to examine the effects of cartilage-derived morphogenetic protein (CDMP) -1, -2 and –3. Cells cultured in the presence of CDMPs no longer exhibited the elongated shape characteristic of myoblasts. The patterns of gene expression in C2C12 cells treated with the CDMPs were also altered. In contrast to OP-1, none of the CDMPs affected significantly mRNA expression of MyoD, a known regulator of myogenic differentiation. CDMP-1, -2, and -3 stimulated osteocalcin mRNA by 2.5-, 1.5- and 1.8-fold, respectively. All three CDMPs down-regulated significantly the expression of Scleraxis, a recently identified transcription factor reportedly specific for tendons and ligaments and may be involved in restricting progenitor cells for connective tissues. The three CDMPs regulated differentially the spatial and temporal pattern of expression of different members of the BMP family members as well as the BMP receptors in a dose-dependent manner. At 300 ng/ml, all three CDMPs stimulated significantly alkaline phosphatase (AP) activity and moderately (20-25%) extracellular matrix synthesis as measured by quantitative Alcian Blue staining. A significant synergy (up to about 5-fold) was observed between OP-1 and the individual CDMPs in stimulating AP activity. These data contribute important new basic knowledge on these protein factors in bone biology.

Human Neuralin-2, a Novel BMP Binding Protein, Acts as a BMP Antagonist *In Vitro* and *In Vivo*. J. K. McEntire*[1], E. Su*[2], J. K. Cecil*[2], S. Biolsi*[1], P. Grealish*[1], G. Krishnan[2], M. White*[1], H. Bullock*[2], R. Miles*[2], R. C. Smith*[1]. [1]BioTechnolgies Discovery Research, Eli Lilly and Company, Indianapolis, IN, USA, [2]Gene Regulation and Bone, Eli Lilly and Company, Indianapolis, IN, USA.

The Bone Morphogenetic Proteins (BMPs) have been characterized as essential molecules in embryonic development, bone biology, cartilage biology, and an ever-growing variety of other systems. Modulation of BMPs and other members of the TGF super family are important for differentiation and homeostasis of bone and cartilage tissue. A large family of BMP modulating proteins has been identified including chordin, gremlin, DAN, neuralin-1, CRIM-1, and procollagen IIA. These molecules act as potent BMP antagonists by directly binding BMPs and inhibiting their receptor interaction. We have mined a human cDNA, which we call neuralin-2 due to its high sequence conservation with a mouse Genbank cDNA sequence annotated as neuralin-2. Human neuralin-2 is structurally related to neuralin-1 [(identified as a molecule expressed in the mouse neural plate) Coffinier *et al*. Mech of Dev., 2001, 100:119-122]. Both neuralin-1 and neuralin-2 contain three of the conserved cysteine-rich regions shown in other BMP antagonists to bind various members of the TGF-beta superfamily. Neuralin-2 has a restricted expression pattern in mouse and human tissues. Tissues of expression include heart, bone, and skeletal muscle. *In vitro* binding studies demonstrate that neuralin-2 is able to bind BMP-2 and -4. As predicted for a BMP antagonist, microinjection of neuralin-2 RNA into the ventral side of developing Xenopus embryos causes twinning and hyperdorsalization. Neuralin-2 is able to inhibit the ability of BMP-4 to induce osteoblast differentiation in mouse mesenchymal stem cells *in vitro*. In summary, neuralin-2 is a novel member of a growing family of proteins containing cysteine-rich regions, that function to modulate various members of the TGF-beta superfamily. Neuralin-2 as well as other BMP modulating proteins may be potential therapeutic targets for various bone and cartilage disorders.

Brief rhBMP-2 Treatment of Glucocorticoid-inhibited MC3T3-E1 Osteoblasts Rescues Cell Cycle Progression and Mineralization in a Cbfa1-independent Manner. C. A. Luppen*[1], N. Leclerc*[1], T. Noh*[1], A. L. Boskey[2], E. Smith*[3], B. Frenkel[3]. [1]Biochemistry and Molecular Biology, University of Southern California, Los Angeles, CA, USA, [2]Mineralized Tissues Research Section, Hospital for Special Surgery, New York, NY, USA, [3]Orthopaedic Surgery, University of Southern California, Los Angeles, CA, USA.

Glucocorticoids (GC) inhibit bone formation in vivo. In MC3T3-E1 osteoblasts, chronic administration of 1 μM dexamethasone (DEX) starting at confluency (day 3) results in >98% inhibition of BMP-2 gene expression and apatite mineral deposition. The GC-inhibition of mineralization is counteracted by chronic co-treatment with rhBMP-2, starting on either day 3 or 5. We show here that brief exposure to rhBMP-2 is sufficient to induce irreversible commitment to mineralization. MC3T3-E1 cells were treated with DEX on days 3-14 and rhBMP-2 was administered on day 5 for 15 minutes to 12 hours. Remarkably, 6 hour exposure to 100 (but not 10) ng/ml rhBMP-2 completely rescued mineralization as demonstrated by Alizarin Red staining. Calcium accumulation was accelerated in DEX/rhBMP-2 co-treated cultures even compared to control. The rhBMP-2 rescue of DEX treated cultures was further characterized in terms of collagen accumulation; mineral-to-matrix ratio (FTIR); alkaline phosphatase (ALP) enzymatic activity; Cbfa1 DNA binding (gel shift); Cbfa1 transcriptional activity (luciferase assay); and cell cycle progression (flow cytometry). DEX inhibited collagen accumulation by >80% on days 6-14. Unlike mineralization, rhBMP-2 did not rescue collagen in DEX treated cultures. Rescued cultures had higher mineral-to-matrix ratios compared to control, consistent with the selective rescue of mineralization. The rhBMP-2 rescue did not correlate with ALP activity. Surprisingly, neither DEX nor rhBMP-2 altered Cbfa1 DNA binding activity; and, neither affected Cbfa1 transcriptional activity. Finally, we studied the differentiation-related cell cycle, which persists during commitment to mineralization in untreated, but not DEX treated, cultures. Although rhBMP-2 alone, like DEX, was antimitogenic, rhBMP-2 rescued the differentiation-related cell cycle in DEX inhibited cultures. In conclusion, rhBMP-2 rescues mineralization in DEX inhibited MC3T3-E1 osteoblasts via a mechanism other than Cbfa1 stimulation. The concomitant rescue of the differentiation-related cell cycle offers promising avenues in the study of Cbfa1-independent mechanisms of GC and BMP action in osteoblasts. The efficacy of short term BMP-2 treatment in GC inhibited osteoblasts supports the idea of using short lived BMP vectors for both traditional and gene therapeutic approaches.

Bone Formation Following OP-1 Implantation is Improved by Autogenous Bone Marrow. H. Takigami*[1], L. Latson*[1], D. Togawa*[2], T. W. Bauer*[3], K. Powell*[1], G. F. Muschler[2]. [1]Biomedical Engineering, The Cleveland Clinic Foundation, Cleveland, OH, USA, [2]Department of Orthopaedic Surgery, The Cleveland Clinic Foundation, Cleveland, OH, USA, [3]Departments of Orthopaedic Surgery and Pathology, The Cleveland Clinic Foundation, Cleveland, OH, USA.

INTRODUCTION: Implantation of Osteogenic Protein-1 (OP-1, aka BMP-7) induces bone formation due to OP-1 activation of local cells. This study was designed to test the hypothesis that increasing the target cell population for OP-1 by addition of autogenous bone marrow (BM) containing osteogenic progenitors will increase in bone formation when OP-1 is used as a graft material.

METHODS: Seven beagle dogs underwent grafting. Four 1.0 cm diameter x 1.0 cm long cylindrical drill defects were made in the left proximal femur extending through the lateral femoral cortex into the intramedullary canal. Each site was separated by 1.5 cm of normal bone and intramedullary marrow tissue. OP-1 implants were mixed with an equal volume of clotted blood or with BM aspirated from the proximal humerus. MicroCT images were obtained (~18 micron resolution) at 4 wks. The percent bone volume (%BV) was measured within each defect in 3 dimensions. The %BV was compared in the outer, middle, and central thirds of the grafted cylinders.

RESULT: In the two most proximal defect sites, OP-1+BM (Fig.1) had significantly greater %BV than OP-1+Blood (Fig. 2) (mean 10.5 % vs 7.5 %, p=0.03). This difference was most evident in the middle third of the defect, between 1.5 and 3.25 mm from the graft surface ($p<0.01$). In the two distal sites, where cancellous bone is not normally found, little bone was formed in either group and there were no differences between groups.

DISCUSSION: Addition of BM containing osteogenic cells significantly increased bone formation at the site of OP-1 implantation, especially in the region 1.5 to 3.25 mm from the surface of the defect.

CONCLUSIONS: These data support further investigation of the clinical use of bone marrow aspirates as a means of optimizing the efficacy of OP-1 device implantation. These also support the concept that bone formation in response to OP-1 implantation is site dependent and influenced by the local cell environment.

Conditional Alk-3 Deletion Enhances Cancellous Bone Mass in Long bone and Hypertelorism in the Skull of Adult Mice. C. Chung*[1], T. Maruyama*[2], T. Manabe*[2], T. Miwa*[3], Y. Mishina*[4], K. Nishimori*[2], M. Noda[1]. [1]Molecular pharmachology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Molecular and Cellular Biology, Tohoku University, Sendai, Japan, [3]Genome Information Research Center, Oosaka University, Oosaka, Japan, [4]Laboratory of Reproductive & Developmental Toxicology, NIEHS, Research Triangle Park, NC, USA.

BMP signaling is mediated by 2-types of Ser/Thr kinase receptor(type I and type II), while the specificity of signaling is primarily determined by type I receptor. Alk 3(BMPR-IA) is classified as a BMPR-I receptor, however it's functions for BMP signaling, especially in the adult mice is not fully understood because of the lethal phenotype of the null mice. To investigate the role of BMP/BMPR signaling, conditional knock out mice were created. In these mice, Alk3 was deleted by crossing with Cre-expressing mice using the Cre/lox p system. The Alk3 (fx/) mice were viable and survived normally as it's control littermates. However the conditional knock out mice revealed shorter limbs, smaller body size, and shortening of the midface with hypertelorism suggesting a defect in the cranial sutures. Even though the sagittal suture was still patent when examined by micro CT, the bone morphology around the suture area was less bulky compared to the WT control. Further examination on the bone using soft-x-ray and micro CT revealed significant increase ($p<0.05$) in cancellous bone volume (Bone volume/Tissue volume) in the metaphyseal regions of long bone. Calvarial sutures were less distinct compared to the wild type. To investigate the mechanism of increase in bone volume (BV/TV) in the conditional knockout mice, bone marrow cells were harvested from femur and tibia, and *in vitro* ostoeclastogesis as well as mineralized nodule formation were conducted to evaluate the osteoblastic activity of the bone marrow cells. No major alteration was observed in the cells from conditional knockout mice in terms of osteoclast development and mineralized nodule formation compared to those from wild type. These observations revealed that Alk3 paradoxically acts as an inhibitor for the levels of cancellous bone mass in adult mice.

Bone Formation During Distraction Osteogenesis is Enhanced by Thrombin Peptide (TP508). G. Li[1], J. T. Ryaby[2], D. H. Carney*[3], H. Wang[2]. [1]Department of Trauma and Orthopaedic Surgery, Queen's University of Belfast, Belfast, United Kingdom, [2]Research Department, OrthoLogic Corp., 1275 West Washington Street, Tempe, AZ, USA, [3]R&D Department, Chrysalis BioTechnology, 2200 Market Street, Suite 600, Galveaton, TX, USA.

The thrombin-related peptide, TP508 is a synthetic 23 amino acid peptide, which represents the receptor-binding domain of thrombin. TP508 interacts with specific thrombin receptors on cells to initiate tissue repair. It has been demonstrated that TP508 enhances revascularization of injured tissue and promotes wound healing, cartilage and fracture repair. The long bone consolidation phase of distraction osteogenesis causes considerable morbidity for the patients. The aim of this study was to examine the effect of TP508 on bone regeneration during distraction osteogenesis in a rabbit leg-lengthening model.

Unilateral tibial osteoectomies were performed and stabilised with MX100 Orthofix lengthener in male adult NZW rabbits. Following a latency period of 7 days, distraction was initiated at rate of 1.4 mm / day (in one step) for 6 days. TP508 (100 µg/kg and 10 µg/kg) or saline (300 µl) were injected into the osteotomy / lengthening gap at day 1, day 8 and day 13 post-surgery. Radiography was taken regularly and animals were sacrificed at day 27 post-surgery. The regenerates were assessed by pQCT and paraffin histology.

The radiographic evaluation indicated a significant increase in new bone formation in the distraction regenerates in the TP508 treated groups, compared to the controls post-lengthening. pQCT images at 2 weeks post-lengthening demonstrated a greater bone formation in the TP508 treated groups compared to the controls. The mean bone mineral density (BMD) of the regenerate was significantly greater ($p<0.01$, t-test) in the TP508 treated groups (100 µg/kg, BMD = 498.15 ±19.39 mg/ccm; 10 µg/kg, BMD= 448.65 ±10.39 mg /ccm) than that in the controls (BMD = 355 +/- 2.83 mg/ccm). There was no statistical difference in the BMD between the two treated groups ($p = 0.086$, t-test). For histological evaluation, in the 100 µg/kg treated group, the regenerates were mainly filled with well-vascularized woven bone. In the10 µg/kg treated group, 60-70% of the regenerate was woven bone, and the fibrous tissues and cartilage were seen in the centre of the regenerates. While in the saline control group, the regenerates were mainly fibrous tissues and cartilage with small amount of woven bone present.

This study has demonstrated that TP508 has enhanced bone formation during distraction osteogenesis in the rabbit. The findings indicate that TP508 can be used in accelerating osteogenesis as well as angiogenesis in clinical procedures such as bone lengthening and high-energy fracture treatment.

Biomineralisation Markers During a Phase of Active Growth in Pinctada Margaritifera. M. Rousseau*[1], C. Milet*[1], E. Plouguerné*[2], E. Lopez*[1], M. Fouchereau-Peron*[2]. [1]Department of Aquatic Environments and Populations, Museum National Histoire Naturelle, Paris, France, [2]Department of Aquatic Environments and Populations, Museum National Histoire Naturelle, Concarneau, France.

In order to search for the biochemical parameters involved in calcium and carbonate transport during crystal formation and biomineralisation in nacreous mollusca, the carbonic anhydrase activity , the levels of calciotropic hormones (CT and CGRP) in hemolymph and in tissues and the circulating concentration of calcium was measured in *Pinctada margaritifera* during a phase of active growth.

When carbonic anhydrase activity was measured both in mantle and gill tissue, an increased linear relationship was observed between this enzyme activity and the age of the animals. No variation of this enzyme activity appeared in the mantle.

Age, months	Gill carbonic anhydrase activity, U / mg of proteins	Mantle CGRP-LI, pg / mg of proteins	Circulating CGRP-LI, pg / ml	Total calcium, mM
7	4.5 ± 0.7			
12	7.5 ± 0.5*			
18	6.7 ± 0.2*			
24	11.6 ± 1.5*	189 ± 20	394 ±25	11.5 ± 0.2
36	17.3 ± 3.8*	158 ± 42	503 ± 42	11.3 ± 0.1
48	15.8 ± 2.4*	111± 20*	265 ± 93*	12.3 ± 0.3*

• $p< 0.05$ when compared to the 7 (carbonic anhydrase activity) or 24 (CGRP and calcium concentrations) months group.

Similarly, the circulating level of total calcium increased during the growth of the animals.

Calciotropic hormones were radioimmunoassayed (using an anti salmon CT and an anti human CGRP antibody) in gill, mantle and hemolymph. Only a CGRP-related molecule could be detected. The concentration of this molecule decreased as a function of growth both in hemolymph and in mantle. No variation of this parameter was observed in gill tissue. These immunologically CGRP related molecules were able to interact with the specific CGRP receptors present in rat liver membranes and represent biologically CGRP related molecules.

These data demonstrate that carbonic anhydrase and a molecule biologically and immunologically related to CGRP are involved during the growth of the animals. In addition, this study shows the presence of three main calcium compartments, gill, hemolymph and mantle, involved in the biomineralisation process.

Roles of Lysyl Hydroxylase 2 in Collagen Cross-linking and Mineralization. S. Pornprasertsuk*, W. R. Duarte, Y. Mochida*, M. Yamauchi. Collagen Biochemistry Laboratory, University of North Carolina at Chapel Hill, Chapel Hill, NC, USA.

The hydroxylation of specific lysine (Lys) residues is a post-translational modification critical for glycosylation and cross-linking of collagen. At present, three isoforms of lysyl hydroxylase (LH1, 2, 3), the enzyme that catalyzes this modification, have been identified but their precise roles are still unclear. Based on our previous findings (J Bone Min Res 14:1272-1280, 1999), we hypothesized that *LH2* may regulate the telopeptidyl Lys hydroxylation of collagen, i.e. cross-linking, and collagen mineralization. In order to test this hypothesis, several osteoblastic cell clones constitutively overexpressing *LH2* were generated and characterized. The full-length mouse *LH2* cDNA was ligated into pcDNA3.1/V5-His TOPO vector, and then transfected into MC3T3-E1 cells to generate stable clones overexpressing *LH2*. An empty pcDNA3.1/V5-His vector (Ev) was also transfected into MC3T3-E1 cells and used as a control. The levels of *LH2* in several clones were determined by immunoprecipitation followed by Western blot analysis using antiV5 antibodies. MC3T3-E1 cells, clones overexpressing *LH2* and Ev clones were cultured in the presence of 50 µg/ml ascorbic acid and 2 mM βglycerophosphate for up to 4 weeks and, at several time points, analyzed for the mineralized nodule formation, Lys hydroxylation, and cross-linking of collagen. The expression of type I collagen (COLI), osteocalcin (OCN) and bone sialoprotein (BSP) mRNAs was evaluated by RT-PCR. In both MC3T3-E1 cells and Ev clones, mineralized nodules were formed at 2 weeks and their number increased thereafter. The ratio of two major immature reduced collagen cross-links, dihydroxylysinonorleucine (DHLNL) to hydroxylysinonorleucine (HLNL), from the control cells was 3.4 and 2.7 at 2 and 4 weeks, respectively, similar to murine bone collagen. In comparison with the control groups, the formation of mineralized nodules by *LH2*-overexpressing clones was significantly delayed and the number of nodules formed was fewer. In the clone expressing the highest level of *LH2*, the mineralized nodules were not formed even after 4 weeks of cell culture. Furthermore, the ratio of DHLNL to HLNL in the overexpressing clones was markedly higher (6.3-9.5 and 7.2-10.6 at 2 and 4 weeks, respectively) than that of the control cells. The Lys hydroxylation in the helical domains of the collagen molecules (both α1 and α2 chains) appears to be unaffected. The expression of COLI, OCN, and BSP mRNAs was comparable among clones and control groups. These results indicate that *LH2* may regulate the telopeptidyl Lys hydroxylation of collagen, cross-linking and subsequent matrix mineralization *in vitro*.

Identification and Characterization of Spherical Structures Associated with Mineralization in MLO-A5 Cells. C. Barragan-Adjemian*[1], D. Eick*[1], V. Dusevich*[1], M. Dallas*[1], D. Nicolella[2], L. Bonewald[1]. [1]Oral Biology, University Missouri Kansas City, Kansas city, MO, USA, [2]Southwest Research Institute, San Antonio, TX, USA.

There has been a long-standing controversy as to whether mineralization of bone occurs through extracellular matrix vesicles, exclusively through collagen type 1 and more recently this controversy has expanded to include non-collagenous proteins. The role of matrix vesicles during initiation of calcification has been well characterized in the growth plate. Matrix vesicles are submicroscopic extracellular membrane particles that initiate formation of crystals through the action of phosphatases, calcium binding phospholipids and other proteins. These preformed crystals are exposed to the extracellular matrix, where they grow and expand. However, the presence and function of matrix vesicles in bone mineralization is inconclusive.

The goal of the present study was to determine the mechanism of mineralization used by MLO-A5 cells. These cells mineralize in 3-6 days in culture and are considered to be a good model for the study of mineralization *in vitro*. These cells express large amounts of alkaline phosphatase, approximately 7 to 9 times more than primary osteoblasts, and form a mineralized honey-combed structure in sheets, not nodules. Between 3-6 days in culture, spherical structures (30 nm) were observed by scanning electron microscopy localized on the cytoplasmic membrane of cells that at 6-9 days become associated with collagen fibers. These spherical structures grow in size (up to 1 um) and coalesce following the pattern of collagen type 1 fibers. The spherical structures are of high density as determined by backscatter detection. The content of these spherules was determined to be phosphate and calcium in ratios similar to hydroxyapatite as determined by X-ray energy dispersive analysis. Using transmitted electron microscopy, the spherical structures show needle-like crystal extensions. By atomic force microscopy, again spherical structures were shown to be associated with the collagen fibrils. Collagen mediated mineralization was also observed at later time points in culture. In conclusion, MLO-A5 cells mineralize by three mechanisms. In addition to collagen-mediated mineralization and a small amount of dystrophic mineralization, a major mechanism whereby MLO-A5 cells mineralize is through the production of spherical structures that may be matrix vesicles. This data supports the hypothesis that bone can mineralize through other mechanisms than through collagen.

Bone Mineral Concentration and Appositional Rate in Rapidly Growing Chick Models of Homocystinuria and Vitamin B6 Deficiency (VB6D). P. G. Masse[1], P. G. T. Howell[2], A. Boyde[3], D. E. C. Cole[4], D. S. Howell[5]. [1]Nutrition, Université de Moncton, Moncton, NB, Canada, [2]Eastman Dental Institute, University College London, London, United Kingdom, [3]Anatomy, University College London, London, United Kingdom, [4]Pediatrics (Genetics), University of Toronto, Toronto, ON, Canada, [5]Medecine, University of Miami/VA Medical Center, Miami, FL, USA.

Collagen (Coll) molecular defect associated to hyperhomocysteinemia (0.6% dl-homocysteine-rich diet) and VB6D has been evidenced by TEM/SEM. Changes in coll solubility and coll cross-linking were hallmarks of connective tissue abnormality in both cases. The coll defect has been attributed to the formation of a thiazine ring complex formed from the sulhydryl groups in excess (due to elevations of sulfur amino acids) with the aldehydes generated by lysyl oxidase deamination of lysine (lys) and OH-lys residues on coll molecules. Experimentally-induced homocystinuria was characterized by distinctive alterations of bone growth and skeletal development, including a reduction in bone density and greater radial and longitudinal bone growth. Bone length and diaphyseal diameter of VB6D-animals were not different from controls but dry weight and bone density of tibias were reduced. In the present study, the effect of homocysteine and VB6D on the mineral apposition rate (MAR) and degree of mineralisation of bone was examined. 70% ethanol fixed tibias were cut as 2-3mm thick slices and embedded in PMMA, trimmed in blocks and micromilled to extreme flatness. Block surfaces were imaged using confocal fluorescence microscopy to visualize tetracycline and alizarin labels given at a 48 hour interval. After carbon coating, they were studied by quantitative backscattered electron imaging (qBSE, 20kV, 0.5nA, 17mm working distance, annular solid state BSE detector) using monobrominated and monoiodinated dimethacrylates as standards. Calcified cartilage residues in bone were excluded from this analysis. MAR in trabecular bone of the metaphysis was lower in the VB6D group (4.15 ± 0.72µm/day) compared with control (4.65 ± 0.64 µm/day) and hyperhomocysteinemic groups (4.72 ± 0.53µm/day), but on a per animal basis, this was not significant. The degree of mineralisation of metaphyseal trabecular bone was significantly different between groups, being significantly lower in hyperhomocysteinemic and higher in VB6D than controls ($p < 0.001$). Bone in hyperhomocysteinemia is formed more rapidly and is less well mineralised than controls. Conversely, bone in VB6D is formed more slowly and is better mineralised than controls.

Disclosures: ***P.G. Masse****, None.*

Multi-mode X-ray Investigation of Bone in Regenerated Newt Limbs. S. R. Stock[1], K. Ignatiev*[1], H. G. Simon*[2], F. De Carlo*[3], J. D. Almer*[3]. [1]Institute of Bioengineering and Nanoscience in Advanced Medicine, Northwestern University, Chicago, IL, USA, [2]Dept. of Pediatrics and CMIER, Northwestern University, Chicago, IL, USA, [3]Xor-aps, Argonne National Laboratory, Argonne, IL, USA.

Limbs regenerate in adult newts and salamanders; uncovering how regeneration can be "turned back on" in mammals is of great interest. One aspect of which has been largely neglected is the study of bone formation, specifically the amount and organization of the mineral phase and its spatial distribution with time since the onset of regeneration. This study applies lab and synchrotron microCT and synchrotron microbeam diffraction/scattering to map the mineral and its spatial variation in newt limbs after regeneration (periods between 37 and 85 days) and in controls (contralateral limb from the same animal). We find that the missing limb skeletal elements are restored in a proximal to distal direction, which reiterates the developmental patterning program, except that ossification of the humerus distal to the amputation site lags behind that of the regenerating radius and ulna, metacarpals and phalanges and that carpal bone ossification is still further delayed. Local mineral levels track the macroscopic pattern of mineral onset. Synchrotron microCT of newt hand bones (control limbs) reveals an unexpectedly rich structure and indicates bone in this amphibian is more complex than generally thought. Microbeam diffraction/scattering mapping of the mineral constituent is demonstrated and offers the promise of in vivo mapping of mineral acquisition in individual newts as a function of regeneration time.

Disclosures: ***S.R. Stock****, None.*

Atorvastatin Inhibits Hypercholesterolemia Activation of Cell-Cell Interactions in the Aortic Valve to Induce Cellular Proliferation and Bone Matrix Production. N. M. Rajamannan[1], M. Subramaniam[2], R. S. Bhattacharyya*[3], T. C. Spelsberg[2], P. H. Stern[3]. [1]Cardiology, Northwestern University, Chicago, IL, USA, [2]Molecular Biology and Biochemistry, Mayo Clinic, Rochester, MN, USA, [3]Dept of Pharmacology, Northwestern University, Chicago, IL, USA.

Calcific aortic stenosis involves proliferation and bone matrix expression of the aortic valve. Hypercholesterolemia (chol) is a risk factor for aortic stenosis, but the signaling steps in this process are not known. We postulate that LDL chol inhibits nitric oxide synthesis in the aortic valve endothelial cells (AEC) and that the subendothelial myofibroblast cells (SEC) respond with proliferation and bone matrix production via the MAP kinase pathway. Previously we have shown that PDGF is produced from AEC. We developed an in vitro AEC/SEC cell/cell model to test this hypothesis. Methods: Conditioned media (CM) was collected from AEC treated with serum free (SF) media, LDL chol (10ug/ml), and/or atorvastatin 10-5 M to produce conditioned media (CM). The AEC and the CM were tested for endothelial nitric oxide synthase (eNOS) expression by Western immunoblotting. The CM effects on proliferation and osteopontin (OPN) expression of the SEC were assessed by measurement of 3H-thymidine (3H) incorporation and Western blot. To determine the pathway for the proliferation by CM, effects of PDGF on the SEC on the (3H) incorporation and expression of p42/44 MAP kinase (MK) and was tested by Western blot. The effects of a MK inhibitor PD98059 (PD) on the (3H) and p42/44 expression were assessed. Results: eNOS protein expression were decreased by LDL cholesterol (2-fold) and increased by atorvastatin in the AEC (2-fold). CM from AEC exposed to LDL cholesterol markedly increased (3H) and OPN expression 150%($p<0.05$) whereas CM from the Atorvastatin+LDL treated cells inhibited proliferation and OPN expression by 50% ($p<0.001$). Addition of PDGF stimulated proliferation of the SEC (300% $p<0.001$). PD inhibited proliferation elicited by the PDGF (100%) and p42/44 protein expression (3-fold) ($p<0.001$). Conclusions: These results suggest the AEC cell signals the mitogenic activity and bone matrix expression of aortic valve SEC cells via 2 signaling mechanisms: 1) LDL cholesterol eNOS expression in the AEC, resulting in proliferation and bone matrix production and atorv inhibited this process 2) growth factors produced by the AEC, including PDGF, stimulate proliferation via the MAP kinase pathway.

Involvement of the Nuclear Factor I (NFI) Family of Trascription-Replication Factors in Chondrogenic Differentiation of ATDC5 Cells: Application of Gene-Trap Mutagenesis. T. Uchihashi*[1], M. Watanabe*[1], M. Yamagata*[1], A. Suzuki*[1], H. Kondou*[1], K. Ozono[2], T. Michigami[1]. [1]Department of Environmental Medicine, Osaka Medical Center and Research Institute for Maternal and Child Health, Osaka, Japan, [2]Department of Pediatrics, Osaka University Graduate School of Medicine, Osaka, Japan.

Gene-trap mutagenesis is a genome-wide approach utilized to clarify the gene function based on an idea that random insertion of a trapping vector may disturb the function of inserted genes. In the current study, to identify the molecules involved in chondrocyte differentiation, we applied this approach to the murine mesenchymal cell line ATDC5 cells, which differentiate into mature chondrocytes in the presence of insulin. As the trap vector, we used pPT1-geo, which lacks its own promoter and enhancer, but contains lacZ-neo fusion gene as the reporter and the selection marker. After introducing pPT1-geo into ATDC5 cells by electroporation, the neomycin-resistant clones were screened for high beta-galactosidase activity, and the selected clones were then cultured in the differentiation medium to evaluate the chondrogenic phenotype by alcian blue and alizarin red staining. One of the clones, named UT7-57, exhibited accelerated mineralization compared with parental ATDC5 cells. The expression of type II collagen reached the maximum level earlier in this clone compared with the parental cells. In addition, the expression of chondromodulin-I was decreased in the clone. 5'RACE analysis revealed that pPT1-geo was inserted in the intron 6 of the nuclear factor I-B (NFI-B) gene in the clone. NFI-B belongs to the nuclear factor I (NFI) family of transcription-replication factors, and has been reported to express around developing cartilage. We detected the expression of all the members of the family (NFI-A, -B, -C and -X) in parental ATDC5 cells by RT-PCR. In the clone UT7-57, the trapped allele of NFI-B was assumed to express a fusion protein containing the N-terminal region of NFI-B and lacZ-neo product instead of the C-terminal functional domain of NFI-B, which was confirmed by Western blotting using the antibody against beta-galactosidase. It was speculated that the resulted mutant protein might act as a dominant-negative form against NFI family members. Northern blot analysis demonstrated that the expression of wild -type NFI-B transcript diminished in the process of differentiation of the clone UT7-57, while it persisted in the parental ATDC5 cells. These data suggested the involvement of NFI family transcription factor(s) in chondrogenic differentiation of ATDC5 cells.

CTGF/Hcs24/CCN2, Hypertrophic Chondrocyte-Specific Gene Product, Interacts with Perlecan in Regulating the Proliferation and Differentiation of Chondrocytes. T. Nishida[1], S. Kubota*[1], T. Fukunaga*[2], S. Kondo*[1], G. Yosimichi*[1], T. Nakanishi*[1], T. Takano-Yamamoto*[2], M. Takigawa[1]. [1]Department of Biochemistry and Molecular Dentistry, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan, [2]Department of Orthodontics, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan.

Connective tissue growth factor/hypertrophic chondrocyte-specific gene product 24/CCN family member 2 (CTGF/Hcs24/CCN2) plays important roles in the control of the proliferation and differentiation of chondrocytes *in vitro*. To clarify the mechanisms of regulation by CTGF/Hcs24 with respect to cartilage metabolism, we investigated the interaction between CTGF/Hcs24 and heparan sulfate proteoglycan perlecan. An immunofluorescence study showed that CTGF/Hcs24 was colocalized with heparan sulfate and perlecan in human chondrosarcoma-derived chondrocytic cell line HCS-2/8 *in vitro*. Northern blot analysis showed that perlecan, syndecan-1, -2, and -4 transcripts were detected in HCS-2/8 cells. Particularly, expression of the perlecan gene increased markedly in HCS-2/8 cells by rCTGF/Hcs24 treatment. We also found that CTGF/Hcs24 interacted with perlecan from HCS-2/8 cells *in vitro*. Furthermore, CTGF/Hcs24-stimulated gene

expression of the aggrecan gene, as well as DNA/proteoglycan synthesis, was diminished when HCS-2/8 cells were pretreated with heparinase, indicating that the effects of CTGF/Hcs24 on chondrocytes occurred through the interaction between CTGF/Hcs24 and heparan sulfate on the cells. An *in vivo* study using mouse growth plate revealed that CTGF/Hcs24 produced by hypertrophic chondrocytes was localized from the proliferative to the hypertrophic zone, whereas perlecan was predominantly localized in the prehyphertrophic zone. Consistent with such findings *in vivo*, the binding of ^{125}I-rCTGF/Hcs24 to maturing chondrocytes was at higher levels than that to chondrocytes in hypertrophic stages. These findings suggest that CTGF/Hcs24 produced in the hypertrophic region may act on chondrocytes in the proliferative and maturative zone via some heparan sulfate proteoglycan, such as perlecan.

LIMBIN, a Gene Required for Normal Lengthening of Limbs, Is Expressed in Chondrocytes in Culture and its Levels Are Down-Regulated by BMP2. Y. Maeda[1], H. Takeda*[2], K. Tsuji[1], A. Nifuji*[1], T. Tsuji*[3], T. Kunieda*[4], M. Noda[1]. [1]Dept of Molecular pharmacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Shirakawa Institute of Animal Genetics, Fukushima, Japan, [3]Department of Oral Morphology, Okayama University Graduate School of Medicine and Dentistry, Okayama, Japan, [4]Graduate School of Natural Science and Technology, Okayama University, Okayama, Japan.

LIMBIN (LBN) is a newly identified molecule whose truncation mutation results in short limb phenotype in bovine chondrodysplastic dwarfism (BCD). Structural analysis of LBN revealed the presence of the putative trans-membrane domain and two coiled- coil domain as well as nuclear localization signals. However, how Lbn regulates cartilage and bone metabolism is not known. This paper examines whether bone morphogenetic protein (BMP) regulates expression of this novel gene in chondrocytes. In situ hybridization revealed strong Lbn expression in calvaria and the perichondrium of the developmental vertebrae in day 14.5 mouse embryos. Lbn mRNA expression was detected in the primary cultures of chondrocytes obtained from newborn mice rib and BMP treatment suppressed its expression by about 50% within 24 hours. This effect lasted up to 48hours. Cyclohexamide alone did not significantly suppressed Lbn mRNA expression. However, in the presence of cyclohexamide, BMP no longer suppressed Lbn gene expression suggesting the requirement for new protein synthesis. The basal levels of Lbn gene expression were not altered by the presence of DRB, a transcription inhibitor, while BMP treatment failed to suppress Lbn gene expression in the presence of DRB indicating that BMP suppression of Lbn gene mRNA is not due to the reduction in the stabilization of the transcript. TGFβ treatment similarly suppressed Lbn gene expression in the chondrocyte cultures. Co-treatment with BMP and TGFβ did not further suppressed the levels of the Lbn revealing that common pathways for these two cytokines may exist in terms of their suppression of the Lbn gene expression. These data indicated that this novel regulator, Lbn, is under the control of BMP and TGFβ.

Differential Gene Expression Analysis using Paraffin Embedded Tissues after Laser Capture Microdissection. J. Kim*[1], M. Hwang*[1], Y. Kim*[1], H. Kim*[1], E. Park[1], S. Kim[1], R. Park*[1], H. Shin[2], I. Kim*[1], A. J. van Wijnen[3], J. B. Lian[3], G. S. Stein[3], J. Choi[1]. [1]Biochemistry & SDGRC, School of Medicine, Kyungpook National University, Daegu, Republic of Korea, [2]Pathology & SDGRC, School of Dentistry, Kyungpook National University, Daegu, Republic of Korea, [3]Cell Biology, UMASS Medical School, Worcester, MA, USA.

Recent advance in laser capture microdissection allows to precise removal of pure cell populations from morphologically preserved tissue sections. However, the RNA from the paraffin embedded sample after microdissection is usually degraded. The purpose of this study was to determine the optimal fixative for RNA extraction from the paraffin-embedded sample after the laser microdissection. The integrity of RNA was evaluated with the intactness of 18S and 28S ribosomal RNA by electrophoresis and the length of individual gene transcript by RT-PCR. The various fixatives were ethanol, isopropanol with several concentration and methacarn that was combination of methanol, chloroform and acetic acid. Among fixatives, methacarn was the best for RNA preservation from paraffin-embedded tissues including liver, lung, kidney, muscle, and limb. In RT-PCR analysis, methacarn showed a comparable length of RNA for individual genes such as glyceraldehyde-3-phosphate-dehydrogenase and bone related genes, alkaline phosphatase and osteonectin. The laser microdissection with methacarn fixation technique was applied to analyze the differential gene expression between hypertropic and proliferative chondrocytes in mouse growth plate. The expression of type X collagen, a specific gene for hypertrophic chondrocyte, was observed only in hypertrophic chondrocytes while type II collagen was observed more broadly in growth plate. The laser microdissection combined with the methacarn fixation technique will facilitate the examination of differentially expressed genes from various tissues.

Determining Gene Expression Patterns in Biglycan Deficient Pre-Osteoblasts Using Oligonucleotide Microarrays. X. Chen[1], X. Bian*[2], L. Yang*[3], T. Teslovich*[4], D. Stephan*[4]. [1]Csdb, NIDCR, NIH, Bethesda, MD, USA, [2]Ccr, NCI, NIH, Bethesda, MD, USA, [3]Cbel, CIT, NIH, Bethesda, MD, USA, [4]Rcgm, Children's Hospital, Washington, DC, USA.

Mice deficient in biglycan, a small leucine-rich proteoglycan (SLRP), have a defect in the proliferation and differentiation of osteoblast precursors. In order to identify a set of genes that plays a key role in this abnormality, we determined the global gene expression patterns in bgn-deficient (bgn-KO) pre-osteoblasts using microarray technology. Calvarial cells were harvested from newborn mice and cultured in the presence or absence of BMP-4 for 7 days. The total RNA was labeled and hybridized to AffymetrixTM chips containing ~ 6000 genes, and analyzed with a software GeneSpringTM. Seventy-nine genes were selected, and applied hierarchical clustering to classify these genes according to the similarity of expression levels. Nine of those genes that had expression of at least a 1.5 fold difference between bgn-KO and wild type (Wt), and were grouped as two clusters. One cluster consisted of AU046135 (EST), osteoglycin (Ogn), preproenkephalin (Penk1), and aldehyde dehydrogenase (Aldh1), were expressed significantly lower in bgn-KO than in Wt, and did not respond to BMP-4 in either bgn-KO or Wt cells. Interestingly, mice deficient in Ogn (another SLRP family member) are very similar to the bgn-KO mice, having fragile skin due to defective collagen fibrillogenesis. Penk1 and Aldh1 are important for the differentiation of neonatal cardiac muscle cells, and the development of kidney, stomach and intestine, respectively. A second cluster consisted of osteoblast-specific factor 2 (Osf2), haptoglobin (Hp), secretory leukocyte protease inhibitor (Slpi) and protein synthesis initiation factor 4A (Eisf4a2), were low in bgn-KO cells, but highly up-regulated by BMP-4 compared to Wt cells. Osf2 is a cell adhesion molecule made by pre-osteoblasts thought to be involved in osteoblast recruitment, attachment and spreading, while Slpi is known to suppress inflammation and prevent joint damage. Eifa4 is highly expressed in brain, kidney, lung and heart, while the function of Hp is not clear. In addition, many more genes were stimulated by BMP-4 in bgn-KO cells compared to those in Wt (63 vs. 8). In conclusion, the display of global gene expression patterns presents a broad picture of gene regulation that may control the skeletal defects caused by bgn deficiency. The data also provides valuable new information for selecting novel relevant genes for further investigation. From a global standpoint, our data indicates that bgn deficiency may be involved in multiple organ defects that could partially be rescued by BMP-4.

Up-Regulation of Vimentin, Ribosomal Protein L6 (RPL6) and Type I PTH Receptor (PTH1R) Genes by Intermittent PTH Treatment in MC3T3-E1 Osteoblast-like Cells: Use of Real-Time RT-PCR in Combination with Genearray Analysis. A. Iida-Klein[1], S. S. Lu[1], D. Bischoff[2], D. T. Yamaguchi[2], R. Lindsay[1]. [1]Regional Bone Center, Helen Hayes Hospital, West Haverstraw, NY, USA, [2]Research and Development, Greater Los Angeles Healthcare System, Los Angeles, CA, USA.

We previously demonstrated that the intermittent but not continuous treatment with human parathyroid hormone 1-34 fragment (hPTH1-34) up-regulated expression of bone forming genes including type I procollagen alpha 1 (Col1A1), alkaline phosphatase (ALP) and type I PTH receptor (PTH1R) in mouse osteoblast-like MC3T3-E1 cells, assessed by RT-PCR (ASBMR, 2002). In order to further investigate what other genes are regulated by intermittent PTH treatment, we treated MC3T3-E1 cells with 10 nM hPTH1-34 by pulsing with hPTH1-34 for 6 hours, followed by 2x wash and an additional 42 hr incubation in serum containing, PTH-free medium. This treatment protocol was repeated for 6 cycles. Total RNA was extracted and purified (Qiagen, CA). After the quality and quantity of the purified RNA was determined by optical density and gel electrophoresis, RNA samples were subjected to the mouse Atlas array system (Clontech, CA), and the results analyzed using ImaGene software (4.1 version, BioDiscovery Inc., CA). Out of 1176 genes, vimentin and ribosomal protein L6 (RPL6) genes were highly up-regulated by intermittent PTH treatment in addition to several known bone-related genes such as Col1A1, Col1A2, cathepsin D and fibronectin in two independent experiments. Moreover, the PTH1R gene, whose expression is relatively low in the absence of exogenous PTH, appeared to be up-regulated by intermittent PTH but down-regulated by continuous PTH treatment. To confirm the gene array findings, real-time RT-PCR (rtRT-PCR) was employed using the same RNA samples used for gene array analysis in triplicates. Intermittent PTH tended to up-regulate (24%) but continuous PTH down-regulated (39%) expression of the PTH1R gene. Confirmation of the results using different primer pairs is currently being processed. Thus, use of real-time RT-PCR in combination with gene array analysis may be a useful tool to detect a subtle regulation of the low abundant genes as well as highly inducible genes.

The Transient Receptor Potential Channels TRPV5 and 6 Are Differentially Expressed and Regulated in Osteoblasts and Osteoclasts. B. C. J. van der Eerden[1], H. Charif*[1], T. J. de Vries[2], H. A. P. Pols[1], R. J. M. Bindels*[3], J. P. T. van Leeuwen[1]. [1]Internal Medicine, Erasmus MC, Rotterdam, Netherlands, [2]Periodontology, ACDA, Amsterdam, Netherlands, [3]Cell Physiology, UMC, Nijmegen, Netherlands.

Recently, two new members of the transient receptor potential channel (TRP) family were identified, named TRPV5 and TRPV6, which were recognized as the gatekeepers of active Ca^{2+} transport in kidney and intestine. In analogy, Ca^{2+} transport is also crucial for bone (re)modeling. In this study, we investigated the expression of TRPV5 and 6 along with the known Ca^{2+} transport proteins calbindin (CaBP)-D_{9K} and -D_{28K}, plasma membrane Ca^{2+}-ATPase 1 (PMCA1) and the Na^{+}/Ca^{2+} exchanger 1 (NCX1) in osteoblasts and osteoclasts.

Human osteoblasts (SV-HFO) were cultured for 23 days with β-glycerophosphate (β-GP) in the absence or presence of 1 μM dexamethasone (DEX). Mouse osteoblasts (KS483) supplemented with ascorbic acid and β-GP, were cultured towards mineralization during 21 days. Human and mouse osteoclasts were derived from peripheral blood monocytes and primary bone marrow cultures, in the presence of M-CSF and RANKL during 5 and 21 days, respectively. At various timepoints during osteoblast cultures as well as at the end of the osteoclast cultures, total RNA was isolated, reverse-transcribed into cDNA and expression was studied using real-time PCR.

TRPV5 mRNA was undetectable in human and mouse osteoblasts. In contrast, TRPV6 mRNA was detected throughout differentiation of osteoblasts from both species. TRPV6 expression in human osteoblasts was confirmed by immunostaining. Moreover, TRPV6 mRNA expression in SV-HFO cells increased approximately 5-fold during the DEX-induced mineralization, while no change was observed in cultures without DEX. In analogy to TRPV6, CaBP-D_{28K} and NCX1 mRNA were upregulated in the presence of DEX at all stages but most prominently during mineralization (about 3-fold). In mouse osteoblasts, similar expression patterns were observed in relation to differentiation and mineralization. In human and mouse osteoclasts both TRPV5 and 6, NCX1 and PMCA1 mRNA were detected. In addition, both calbindins were detected in the mouse osteoclasts.

In conclusion, this is the first report to demonstrate mRNA expression of TRPV5 and 6 in bone cells. Interestingly, TRPV5 was only detected in osteoclasts and not in osteoblasts, while TRPV6 was expressed in both cell types, suggesting a cell type specific function. In summary, all intestinal and renal Ca^{2+} transporting proteins are present in osteoclasts and osteoblasts, supporting a role in the movement of Ca^{2+} to and from the bone. The expression of several of the genes indeed correlates with the mineralization of extracellular matrix.

Autoregulation of Bone Sialoprotine (BSP) in Pre-osteoblastic and Non-osteoblastic Cells. Q. Tu, J. Chen. Division of Oral Biology, Tufts School of Dental Medicine, Boston, MA, USA.

Bone sialoprotein (BSP), a phosphorylated and sulfated glycoprotein, represents one of the major non-collagenous, extracellular matrix proteins in bone and other mineralized tissues. BSP is believed to function in the formation and remodeling of the mineralized connective tissue matrix. Matrix components often affect cell function by interacting with members of the intergrin family of cell surface receptors. BSP has RGD sequences that mediate cell attachment through αvβ3 and αvβ5 integrins. Uncertainty, however, exists about the BSP coupled signaling pathway. It has been shown that Runx2/Cbfa1, a transcription factor in osteogenesis, may regulate BSP expression through multiple signal transduction pathways. In this study we report that BSP regulates its own expression through an autoregulative mechanism. We examined the expression of mouse BSP using a 9.0 kb murine BSP promoter linked to a luciferase reporter gene co-transfected with a murine BSP expressing vector, and the effect on transcription was analyzed in transient transfection assays. We found that the forced overexpression of BSP stimulated mouse BSP promoter activity in a dose-dependent manner in both MC3T3-E1 preosteoblast and HEK293 cell lines. The absence of endogenous Cbfa1 expression in HEK293 cells suggested that this stimulation and autoregulation was Cbfa1 independent. To further determine the signaling pathway of BSP autoregulation cells were cultured in the presence of PMA for 20 hours, which reduced PKC activity and almost abolished the luciferase reporter expression in HEK 293 cell line, but had little effect in MC3T3-E1 preosteoblasts. The results indicated that a PKC signaling pathway mediated the BSP autoregualtion. The different affect of reduced PKC activity in MC3T3 cells suggested that other regulatory factor(s) might be operative in MC3T3-E1 preosteoblasts. When HEK 293 and MC3T3-E1 cells were co-transfected with a CMV-Cbfa1 cDNA expression vector, the expression of Cbfa1 gene was increased together with the promoter activity of the BSP reporter construct. Notably, these changes were not inhibited by reduced PKC activity. These results suggest that endogenous expression of Runx2/Cbfa1 might exert a compensative effect since BSP-mediated regulation was not blocked by the reduced PKC levels in MC3T3-E1 cells. Taken together our results indicate that expression of BSP gene can be autoregulated by a positive feedback in a cell-dependent manner and this autoregulation is mediated by a PKC signaling pathway. Further investigation is underway to identify the promoter element(s) involved in this autoregulation. Supported by NIH/NIDCR Grant RO1 DE11088 and partially by PO1 DE13221.

Biglycan Reduces Osteoclast Differentiation. Y. Bi*[1], T. M. Kilts*[1], X. Chen[1], E. M. Greenfield[2], M. F. Young[1]. [1]NIDCR, NIH, Bethesda, MD, USA, [2]Department of Orthopaedics, CWRU, Cleveland, OH, USA.

Small leucine-rich proteoglycans (SLRPs) are extracellular molecules that bind to collagens and growth factors to regulate cell growth and matrix assembly. It has been previously shown that mice deficient in biglycan (bgn), a class I SLRP, develop an age-related osteopenia. This phenotype could be due to impaired bone formation and/or increased bone resorption. Bgn has been shown to play an important role in the proliferation, survival and differentiation of osteoblast precursors. Since osteoblasts and their precursors regulate the differentiation of osteoclasts through cell-cell and cell-matrix contact, we hypothesized that bgn is involved in regulating osteoclast differentiation. To test this, we used a murine calvarial model to compare the induction of osteolysis by LPS in wildtype (WT) and bgn knockout (KO) mice. Titanium particles, as a LPS-carrier, were implanted onto the parietal bones of each mouse. After the indicated periods of time, parietal bones were harvested and processed for X-ray using a Faxitron. The extent of osteolysis in each bone was determined from the X-ray image by computer-assisted histomorphometry. Time course experiments showed that LPS-induced osteolysis occurred more rapidly and extensively in bgn KO mice compared to WT mice. There was 55% less bone resorption in WT mouse parietal bones than that in bgn KO mouse parietal bones when osteolysis reached its peak at day 7. To further understand the mechanism, we determined the effects of bgn on osteoclast differentiation in vitro. For this purpose, we co-cultured spleen-derived osteoclast precursors with primary calvarial cells from either WT or bgn KO mice in the presence of 1a, 25-dihydroxyvitamin D3 (1,25-D3). Time course and dose response experiments showed that TRAP+ multinuclear cells (MNCs) appeared earlier and more extensively in the co-cultures containing calvarial cells from bgn KO mice than WT mice, regardless of the source of spleen cells. Thus, the effect of bgn on osteoclast differentiation is mediated by calvarial cells. Further studies using RT-PCR, northern blot, western blot and ELISA analyses showed that the expression of RANKL and OPG in WT calverial cells was not significantly different from bgn KO cells in the presence of 10 nM 1,25-D3. These data suggest that the increased osteoclast differentiation in the bgn deficient cell culture might occur via a novel RANKL/OPG-independent mechanism. Bgn has been shown to bind and regulate cytokines and growth factors in bone matrix. We propose that biglycan might down-regulate osteoclast differentiation and reduce bone resorption indirectly by modulating the production, storage and/or activity of cytokines that regulate osteoclasts and their precursors.

Bone Acidic Glycoprotein-75 Delineates the Extracellular Sites of Future Bone Sialoprotein Accumulation and Apatite Nucleation in UMR 106-01 BSP Cultures. R. J. Midura*[1], A. Wang*[1], D. Lovitz[2], D. Law*[2], K. Powell*[1], J. P. Gorski[2]. [1]Biomedical Engineering, ND20, The Cleveland Clinic Foundation, Cleveland, OH, USA, [2]School of Biological Sciences, University of Missouri-Kansas City, Kansas City, MO, USA.

The present study was undertaken to determine the kinetic and temporal relationship of bone acidic glycoprotein-75 (BAG-75) deposition as compared to that for bone sialoprotein (BSP) and for hydroxyapatite crystals during de novo biomineralization of UMR 106-01 BSP osteoblastic cultures. Addition of a phosphate source to UMR cultures activates a mineralization program in which BSP localizes to extracellular matrix sites where hydroxyapatite crystals are subsequently nucleated [Wang, A., et al., J. Biol. Chem., 275:11082-11091, 2000]. Using highly specific antibodies for BAG-75 and BSP together with confocal microscopy and electron microscopy, we show for the first time that, prior to phosphate addition in UMR cultures, BAG-75 has already been deposited within these very same sites in two size populations (approximately 15-25 and 150-200 microns in diameter). We refer to these previously unrecognized extracellular structures as biomineralization foci (BMF) precursors. TUNEL data are presented to indicate that these BMF are not the result of a dystrophic process involving dead or dying cells. The shape and size of the smaller population of BMF precursors are similar to structures assembled through self-association of purified BAG-75 protein. Transmission electron microscopy showed the ample presence of 10-nm thin-filaments in BMF, which are similar in size to purified BAG-75 self-assembled filaments. Immediately after phosphate addition, BSP quantitatively accumulates within these BAG-75 defined BMF associated with both thin-filaments and 300-800 nm diameter translucent particles, but not with matrix vesicles. By 8 hours after phosphate addition, calcium phosphate crystals are observed in BMF by EDAX and atomic adsorption spectroscopy. In summary, BAG-75 is the earliest detectable matrix protein biomarker that accurately predicts the sites for de novo biomineralization in UMR cultures. We hypothesize that BAG-75 may perform a key structural role in the assembly of BMF precursors, and the recruitment of BSP necessary for subsequent apatite nucleation.

Osterix (Osx) Regulates Bone Sialoprotein (BSP) Expression in a Novel *in vivo* Model. L. Li*, J. Tang*, J. Chen. Division of Oral Biology, Tufts School of Dental Medicine, Boston, MA, USA.

Osx is a zinc finger-containing transcription factor that is required for osteoblast differentiation and bone formation. It has been suggested that Osx acts downstream of Runx2/Cbfa1, a critical transcriptional factor in osteogenesis. A lack of bone formation is seen in both Osx null and Runx2/Cbfa1 null mice indicating a failure in osteogenic differentiation. It is speculated that Runx2/Cbfa1 regulates osteoblast differentiation and induces the production of extracellular matrix proteins including BSP through its regulation on Osx expression. This study was designed to specifically determine the Osx regulation on BSP gene expression using an in vivo animal model we have recently established. Through microinjection of a construct containing 800 bp avian retroviral receptor gene (TVA) driven by a 4.9 kb mouse BSP promoter a transgenic mouse line BSP/TVA was generated. The distribution of expression of TVA gene expression was found to be consistent with that of endogenous BSP in in situ hybridization of the bone tissues from BSP/TVA mice. A 1.2 kb fragment of mouse Osx was cloned into a RCASBP (A) vector (gifts from Drs. de Crombrugghe and Hughes, respectively). The construct was subsequently used to transfect chicken fibroblasts (DF-1) from which the stock virus was collected. The viral construct RCASBP)/Osx was then introduced into nine 5-day-old BSP/TVA mice by introperitoneal injection. An empty RCASBP vector was also used in the entire experiment serving as a control. The effect of Osx on BSP gene expression was determined by RT-PCR using the bone tissues from the infected mice sacrificed at 9, 14 and 28 days of age, respectively. It was found that, after systemic viral infection, the expression of BSP was increased by 2.3-ad 1.3-folds in mandibular and calvarial bones, respectively, in 9-day-old animals. A 2.1- and 1.4-folds increase was detected in the same bone tissues in 14-day-old mice. However, the increase rate was lower in older BSP/TVA mice (28-day-old) in which only 1.4- and 1.1-folds elevations were observed in their bones. While Osx also stimulated the BSP expression in tibia bone the increase level was not as significant as that in mandibular or calvarial bones. These results indicate that Osx acting downstream of Runx2/Cbfa1 up-regulates BSP expression in bone tissues. This up-regulation is tissue specific and developmental stage dependent. The BSP/TVA transgenic mouse is a unique and versatile model in which various gene expressions and their regulation can be studied in vivo. Supported by NIH/NIDCR Grant RO1 DE11088 and partially by PO1 DE13221.

Bone Morphogenetic Protein-1 Expression and Carboxyl of Pro-Collagen Type I Production During Osteogenesis. P. Manduca, S. Zanotti*, C. Volta*, A. Favre*, O. Barbieri*, S. Marchisio*, S. Astigiano*. Dobig, University of Genova, Genova, Italy.

We previously reported of the chemoattractant role for endothelial cells of the trimeric fragment of procollagen type I (C3), and that C3 is found in the conditioned medium of osteogenic cultures maximally during the phase of highest expression of Alkaline Phospahtase, its detaction decreasing upon nodule formation, before decline of pro-collagen type I synthesis in later osteogenesis (1,2). We here report investigations directed to understand what causes the accumulation of secreted C3 in the conditioned medium., with particular regard to the expression during osteogenesis of the deputate gene for the proteolysis of pro-collagens generating trimeric C3 fragments: the gene codifying for BMP-1 and mTld, two products of differential splicing, differing in their affinity for type I pro-collagen. By RT-PRC, with primers that identify BMP1 and mTld we show that these are produced in osteoblasts cultures differentiating in vitro in developmentally regulated fashion, corresponding to the increase of the concentration of C3 detected in the conditioned medium. In ossifying rats tibiae (from 18 days of fetal life to 10 days after birth) by in situ hybridization, with a probe identifying both BMP1 and mTld transcripts, we show that the gene is expressed in specific times and places both in the developing cartilage model and in forming tibial bone. Gene expression by ISH is accompained by positive immunoperoxidase stain for the protein BMP-1, whose maximal intensity of stain follows in time that of maximal gene expression. In the cartilage bone model the expression of BMP-1 gene and protein is diffuse in proliferating chondrocytes, lost at their hypertrophy, and occurs again in the secondary ossification center. In bone they are expressed by lining osteoblast and osteoblast embedded in recently deposed bone matrix, and undetected at later time of bone growth and in osteocytes. Expression of the BMP1 protein correlates with detection by immunoperoxidase staining of the a1 and a2 chains of C3. In summary, BMP-1 expression is modulated during osteogenesis in vitro and is a developmental feature of the osteogenic phenotype. The expression of BMP-1 in the cells of the bone compartment is compatible with the fact that the production of C3 I could enhance endothelial cells mobility towards and within the forming bone. 1-Stringa E. et al., Bone (1995) 16, 663-670 2-Palmieri D, et al.J: Biol.Chem. (2000) 275, 32658-32663

Bone Sialoprotein Promotes Invasion Through Basement Membrane by Forming a Complex with Both MMP-2 and Integrin-$\alpha_v\beta_3$. A. Karadag[1], N. S. Fedarko*[2], L. W. Fisher[1]. [1]Nidcr, NIH, Bethesda, MD, USA, [2]Deptartment of Medicine, Johns Hopkins University, Baltimore, MD, USA.

It has been known since the mid-1990's that the bone matrix protein, bone sialoprotein (BSP), is strongly up-regulated in breast, prostate, lung, thyroid and a number of other osteotropic cancers. However, the mechanism by which this SIBLING (Small Integrin-Binding LIgand, N-linked Glycoprotein) protein may enhance the metastatic properties of tumors is unknown. In this study we have used a modified Boyden chamber assay of invasion as a model system to study the effects of recombinant human BSP on the invasiveness of several cancer cell lines through an artificial basement membrane (Matrigel).

BSP greatly enhanced (3-10 fold) the invasiveness of many cancer cell lines (e.g. SW-579, PC-3, MDA-MB-231 and NCI-H520) through Matrigel in a dose-dependent manner. Integrins clearly were involved in this enhanced invasion because cells treated with a mutant BSP whose integrin-binding tripeptide, RGD, was modified to the inactive KAE, invaded only as well as untreated controls. Similarly, addition of a blocking antibody for $\alpha_v\beta_3$ integrin negated the BSP effect. Because our previous work had shown that BSP could bind and activate MMP-2, we next hypothesized that this matrix metalloproteinase could also be playing a role in the BSP effect. This was shown to be true for the two cell lines tested because 1) a general MMP inhibitor, 2) a MMP-2 specific inhibitor, and 3) a MMP-2 blocking monoclonal antibody, all completely negated the BSP-enhanced invasion.

To test if both the integrin and MMP-2 observation were due to a single trimeric complex, a pull-down experiment was performed. An $\alpha_v\beta_3$ integrin monoclonal antibody immobilized on immunoaffinity gel matrix was complexed first with recombinant $\alpha_v\beta_3$ integrin, then with BSP (or BSP-KAE), and finally with pro or active MMP-2. The beads were washed after each step and finally analyzed by gelatin zymography. Complexes containing the BSP showed strong bands for both pro and active MMP-2 while untreated or BSP-KAE treated beads showed little or no MMP-2 activity bound. The presence of the same MMP-2-BSP-integrin complex was also verified by FACS analysis using the recombinant BSP and fluorescently labeled MMP-2. Controls for the FACS experiments included BSP-KAE and a blocking antibody for $\alpha_v\beta_3$ integrin.

In conclusion, BSP, MMP-2 and $\alpha_v\beta_3$ integrin are known to be expressed in many osteotropic cancers. We have shown that BSP greatly enhanced the ability of several breast, prostate, lung and thyroid cell lines to invade through an artificial basement membrane by bridging active MMP-2 molecules to the $\alpha_v\beta_3$ integrin on the surface of the cells, presumably at the leading edge of the invasionary processes.

CSF-1 Treatment Corrects Septoclast Abnormalities at the Chondroosseous Junction in the *Toothless* Rat. A. Gartland[1], A. Mason-Savas*[1], C. MacKay*[1], E. R. Lee[2], J. Mort*[2], P. R. Odgren[1], S. C. Marks[1]. [1]Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA, [2]Electron Microscopy Unit, Shriner's Hospital for Children, McGill University, Montreal, PQ, Canada.

The *toothless (tl)* mutation in the rat is a naturally occurring, autosomal recessive mutation in the *CSF*-1 gene resulting in profound deficiencies of bone-resorbing osteoclasts. The *tl* rats have severe, unremitting osteopetrosis with a highly sclerotic skeleton, lack of marrow spaces, the failure of tooth eruption and a progressive, severe growth plate chondrodystrophy. Injections of CSF-1 restore osteoclast populations, bone resorption, and tooth eruption in *tl* rats but do not improve the growth plate phenotype. A variety of cells participate in the advancing osseous front at the chondroosseous junction (COJ) through activities that contribute to the longitudinal growth of long bones. A recently-identified cell, the septoclast, is a unique cell specifically differentiated to facilitate angiogenesis at the chondroosseous junction. This cell is long and slender, lies just outside the invasive capillary sprouts, and stains intensely for the cysteine proteinase cathepsin B. The apex of the septoclast ends on the transverse septum in a structure that resembles the ruffled border of osteoclasts, yet these two cell types are from different cell lineages. Given that the *tl* rats have retarded bone growth at the COJ, accompanied by suppressed angiogenesis and an absence of osteoclasts, we decided to determine if septoclasts were also absent in the *tl* rat. We compared the COJ in the proximal tibia of 2-week old *tl* rats and normal littermates, +/- 1 week CSF-1 treatment, with respect to number, distribution and cathepsin B activity of septoclasts. In normal rats, COJ septoclasts were present as thin cells regularly aligned along the axis of the bone and exhibited strong staining for cathepsin B. *tl* rats had a reduced number of cathepsin B positive cells with morphology similar to septoclasts. These were found somewhat further below the COJ than normal. Treatment of *tl* rats with injections of CSF-1 improved the number and distribution of cathepsin B-positive septoclasts at the COJ. Ultrastructural evaluations of the COJ from the normal and *tl* rats confirmed these cells to be septoclasts. The presence of septoclasts in an osteoclast-free region of the *tl* skeleton confirms that these two catabolic cells are not under identical developmental controls. The reduced number and alignment of septoclasts in *tl* rats and their restoration with CSF-1 treatment implies a role for CSF-1 in the normal differentiation of septoclasts. These data confirm that septoclasts play a significant role in endochondral ossification.

Relation between Bone Morphometric Changes and Pain Perception in Different *in vivo* Models for Bone Cancer-Related Pain. H. Vermeirsch*[1], R. Nuydens*[1], M. Janicot*[2], P. Salmon*[3], L. Andries*[4], T. Meert*[1]. [1]CNS department, Pain & Neurology, Johnson & Johnson Pharmaceutical Research & Development, a division of Janssen Pharmaceutica NV, B-2340 Beerse, Belgium, [2]Oncology, J&J PRD, B-2340 Beerse, Belgium, [3]Skyscan, B-2630 Aartselaar, Belgium, [4]HistoGeneX, B-2650 Edegem, Belgium.

For many patients, pain is the first sign of cancer and 30 to 50 % of all cancer patients will experience moderate to severe pain, this number augments to 75 - 95% when patients with metastatic or advanced cancer are considered. Therefore, to significantly increase patients' quality of life, there is a need for the development of drugs that effectively treat bone cancer pain. The mechanisms of bone cancer pain are poorly understood but osteolysis (bone breakdown) seems to play a major role. Osteoclasts induce an acidic pH that might activate sensory neurons. Also growth factors released during bone resorption may act on sensory neurons. Other mechanisms involve the release of pronociceptive agents from tumor and inflammatory cells.
Several animal models of cancer pain were developed to study the basic neurobiological mechanisms of cancer pain.
We evaluated 3 animal models for bone cancer pain using classical histology and micro CT technology in order to determine the precise location of the tumor and the degree of bone destruction. In vivo testing, to evaluate the development of hyperalgesia and allodynia in the affected hind limb, included different nociceptive tests such as the hot-plate and cold-plate (thermal nociception), the von Frey assay and the pin prick (mechanical nociception). Alterations in the pain measurements correlated with the degree of bone destruction. The increased pain sensation in the bone cancer models could be modulated by morphine treatment. On the other hand subcutaneous tumors, LoVo cells grafted in nude mice, did not induce any signs of increased pain sensation.
The used models and the multidisciplinary approach of this study yield new insights on the development of bone cancer pain and allows the evaluation of potential effects of analgesics.

Calcium-Sensing Receptor Deduces mRNA of Human Securin, Pituitary Tumor Transforming Gene, in Rat Testicular Cancer. J. Tfelt- Hansen*[1], N. Chattopadhyay*[1], P. Scwarz[2], E. Brown[1]. [1]Endocrinology, Brigham and women's hospital, Boston, MA, USA, [2]Clinical Biochemistry and Endocrinology, Copenhagen University Hospital Hvidovre, Copenhagen, Denmark.

Pituitary tumor transforming gene (PTTG), the human securin, is an oncogene. Few normal tissues express PTTG, though in the testis it is abundantly expressed. In cancer, however, its wide expression has been directly correlated to tumor invasiveness. Besides changes during the rat spermatogenic cycle, very little has been described about the regulation of PTTG in testis. Here we investigate the role of the calcium-sensing receptor (CaR) in regulating PTTG in a widely used model of rat testicular cancer (H-500 Leydig cells) for humoral hypercalcemia of malignancy (HHM). In this report we show for the first time that calcium upregulates PTTG mRNA, as assessed by northern blotting and real-time PCR. PTTG mRNA upregulation by calcium has a rapid onset at 0.5 h and remains upregulated until 40 h. A dose-response curve shows the upregulation of PTTG mRNA with an increase of 4.22 ± 1.61, 5.11 ± 1.11, and 5.64± 1.92 (mean ± S.E.) fold at 5, 7.5, and 10 mM calcium, respectively, compared with 0.5 mM Ca^{2+}_{o}. The effect of calcium on PTTG expression was abolished by using a dominant-negative CaR (R185Q) construct, thus showing that the CaR is the main mediator for calcium's effect on PTTG. Another G-protein-coupled receptor (GPCR) agonist, ADP, showed no effect on PTTG expression. In conclusion, we show for the first time that a GPCR, the CaR, stimulates the synthesis of PTTG in a model for HHM.

Immunohistochemical Profile of Osteosarcoma in Adults. M. P. Roudier[1], B. P. Rubin*[2]. [1]Urology, University of Washington, Seattle, WA, USA, [2]Pathology, University of Washington, Seattle, WA, USA.

Osteosarcoma (OS) is rare in adults and many cases of OS present with an extensive soft tissue component with a paucity of osteoid, which can appear as bland spindle cell lesions, small round cell neoplasms, or malignant pleomorphic neoplasms. Limited information regarding the immunohistochemical (IHC) profile of OS is available, thus, IHC studies could be misleading, especially on needle core biopsies.
A 324-core tissue array was constructed with triplicate cores of 94 OS including 40 osteoblastic, 33 fibroblastic, 8 parosteal, 7 chondroblastic, 5 giant cell rich and 1 small cell OS subtypes using a MTA1 tissue arrayer (Beecher Instruments, Sun Prairie, WI). Control tissues (20) included carcinomas, lymphoma and a wide variety of soft tissue neoplasms. Fifty-eight (58) antibodies commonly used in the differential diagnosis of these tissues were studied. Array sections were used when the yield of cores reached 87%. Antibodies were scored on a semi-quantitative scale as follows: 1+ = 0-25% of cells, 2+ = 26-50% of cells, 3+ = >51% of cells.
Vimentin was positive in 100% and osteonectin in 73% of OS cases. Epithelial markers revealed positivity for pan-cytokeratin (AE1/AE3) (20%) and EMA (20%). Other cytokeratins were negative except one OS case with focal positivity for 35βH11. S-100 protein was positive in 20%, predominantly in chondroblastic areas. MelanA was negative in all OS. Microphtalmia transcription factor and tyrosinase were positive in 1% and 2%, respectively. Smooth muscle markers revealed OS positivity for: calponin (57%), smooth muscle actin (43%), smooth muscle myosin (10%), desmin (10%), HHF35 (4%), and caldesmon (1%). Skeletal muscle markers revealed: myogenin (3%) and MyoD1 (0%). Calcitonin and thyroglobulin were positive in 37% and 30% of OS cases respectively. Progesterone receptor was positive in 20% of OS cases, but estrogen receptor was negative in all OS cases. Other positive antibodies included CD99 (100%), NSE (57%), PLAP (24%), WT-1 N terminus (16%), Fli-1 (15%), neurofilaments (11%), GFAP (10%) and AlK-1 (1%). C-KIT (CD117) was negative in all OS cases.
OSs in adults display immunoreactivity for a variety of commonly used diagnostic antibodies, without a characteristic immunohistochemical profile. Therefore great care should be used in interpreting immunohistochemical results in soft tissue tumors in adults, which may represent occult osteosarcomas with a minor, unsampled component of osteoid. Clinical correlation including radiologic examination for signs of bone involvement and calcification can be helpful in excluding the possibility of OS.

Kyphoplasty Enhances Function and Structural Alignment in Multiple Myeloma. J. M. Lane[1], R. E. Hong*[1], T. Kiechle*[1], R. Niesvizky*[2], R. Pearse*[2], D. Siegel*[2]. [1]Orthopaedics, Hospital for Special Surgery, New York, NY, USA, [2]Hematology / Oncology, New York Presbyterian Hospital, New York, NY, USA.

Purpose: Multiple myeloma is associated with vertebral compression fractures and secondary kyphosis. These pathological fractures result in pain and functional disability. Kyphoplasty that utilizes minimal invasive balloon tamps to reduce osteoporotic vertebral compression fractures has been applied to multiple myeloma. This investigation tests the hypothesis that kyphoplasty can significantly restore vertebral height and spinal function.
Materials: 18 consectutive patients with vertebral fractures secondary to multiple myeloma underwent kyphoplasty balloon reduction and stabilization with PMMA. Patients were evaluated prior to treatment and post-operatively with the validated general Oswestry back quesstionnaire. 7 patients with 20 fractures were measure for height restoration on long kyphosis (36 inch) standing films. Over 90% of the fractures were older than 3 months by history and MRI.
Results: By Oswestry analysis the average pre-op score was 48.94 and the average post-op score was 32.70 with an average improvement of 16.23 ($p < .002$). The enhanced function was greatest for patients with the poorest pre-op Oswestry scores and of little improvement for patients with initial scores better than 28. An average height restoration of 25.3% ($p < .001$) and 34.9% ($p < .001$) was achieved in the anterior and medial vertebral body respectively. No patients underwent a major complication. These results will be correlated with stage of disease, cytogenetics, B2M, LDH, proliferation index, treatment with bisphosphonates, and response to systemic therapy.
Conclusions: Kyphoplasty has proven safe and efficacious in treating both acute and chronic vertebral compression fractures secondary to myeloma. This balloon tamp methodology results in vertebral height restoration and enhanced function with no major complications. This prospective cohort study established the functional and structural benefits of kyphoplasty for patients with pathological vertebral fractures related to multiple myeloma.

Radiation Treatment Decreases Bone Cancer Pain, Osteolysis, and Tumor Size. M. Goblirsch*[1], W. Matthews*[1], C. Lynch*[1], P. Alaei*[2], B. J. Gerbi*[2], P. W. Mantyh[3], D. R. Clohisy[1]. [1]Orthopaedic Surgery, University of Minnesota, Minneapolis, MN, USA, [2]Therapeutic Radiology, University of Minnesota, Minneapolis, MN, USA, [3]Preventive Sciences, University of Minnesota, Minneapolis, MN, USA.

Radiotherapy is the most widely used palliative treatment for primary bone cancer in animals and metastatic bone cancer in humans; however, the mechanism(s) responsible for pain relief following radiation are unknown. The effects of radiation on mice with painful bone cancer has been studied to elucidate the mechanism by which said treatment decreases bone cancer pain. Male C3H/HeJ mice received intramedullary injection of 10^5 2472 osteolytic sarcoma cells. Seven days after tumor inoculation, mice were administered a single, localized 20 Gy dose of radiation to the left femur. Radiation was performed in a custom-designed, lead-shrouded restraining apparatus, permitting only the tumor-injected femur to receive radiation. Lithium fluoride thermoluminescent dosimetery was used to verify the efficacy of the delivered dose and lead shielding. Analysis of the effects of 20 Gy treatment was performed through assessment of previously validated behavioral measures, Faxitron radiographs, and tumor areas. Pain behaviors were recorded every third day, post-treatment, for 17 days. Comparison of groups was analyzed by one-way ANOVA and Fisher's PLSD statistical tests. A single 20 Gy treatment dramatically decreased bone cancer pain. Assessment of pre-tumor injection and post-tumor inoculation behaviors (limb

use, Rota-rod, and spontaneous guarding) revealed steady improvement in radiation-treated mice ($p<0.05$) and showed no difference in pain measures with sham-injected mice 8 days post radiation. Evaluation of bone destruction, via Faxitron images, revealed significant reduction in the progression of cancer-induced osteolysis ($p<0.001$). Tumor area was significantly less in sarcoma-injected, radiation-treated mice ($2.8mm^2 \pm 2.4$ vs. $10.0\ mm^2 \pm 1.4$ for the untreated group; $p<0.02$). This investigation describes the initial experimental model in which radiation therapy decreases bone cancer pain. We demonstrate that the administration of a localized, single dose of radiation to the tumorous limb decreases painful behavior and increases limb mobility. Also, decreased cancer-induced osteolysis and decreased tumor burden was evident. Future use of this experimental system should promote ongoing discoveries regarding the cellular and molecular mechanisms responsible for decreasing bone cancer pain after radiation treatment.

Thapsigargin Sensitizes TRAIL-induced Apoptosis in Giant Cell Tumor of Bone. L. Huang*[1], J. K. Xu*[2], Y. Y. Cheng*[1], M. H. Zheng[2], S. M. Kumta*[1]. [1]Dept. of Orthopaedics & Traumatology, The Chinese University of Hong Kong, Shatin, N.T., Hong Kong Special Administrative Region of China, [2]Dept. of Orthopaedic Surgery, The University of Western Australia, Perth, Australia.

Although TNF-related apoptosis-inducing ligand (TRAIL) has attracted great attention in recent years as a promising anti-cancer reagent, several studies showed some tumor cells somehow remain insensitive to TRAIL in *in-vitro* cultures. In this study we examined the sensitization of TRAIL-induced apoptosis in tumour cell of giant cell tumour of bone (GCT). Thirteen GCT specimens and six GCT primary cultures were used to analyze the expression of death signal transducing receptors DR4 and DR5 and decoy receptors DcR1 and DcR2. Thapsigargin (TG), an agent known to cause perturbations in intracellular Ca2+ homeostasis was used to sensitize GCT tumor cells to TRAIL-induced apoptosis. At moderate concentrations (100ng/ml TRAIL and 1uM TG), neither of the two agents alone promotes significant cell death (< 10%) in GCT tumor cells as measured by flow cytometry using Annexin-V-Fluos and propidium iodid (PI) staining. Interestingly, combined treatment markedly enhanced cell death by 4~6 folds. Most noteworthy, in four out of six GCT cultures, pre-treatment of TG for 24 hours further enhanced TRAIL-induced cell death when compared to the co-treatment together. In addition, TG was shown to up-regulate DR5 and DR4 gene expression in time- and dose-dependent manners as evidenced by real-time quantitative RT-PCR analysis. In short, our findings suggest that TG is able to sensitize GCT tumor cells to TRAIL-induced cell death through up-regulation of the expression of death signal transducing receptors, DR5 and DR4. Our findings would be valuable for design of new treatment modalities for patients with GCT.

Parathyroid Hormone-related Protein Promotes Lung Cancer Cell Survival. R. H. Hastings[1], F. Araiza*[2], D. W. Burton[2], L. J. Deftos[3]. [1]Anesthesiology, VA San Diego Healthcare System, San Diego, CA, USA, [2]Research, VA San Diego Healthcare System, San Diego, CA, USA, [3]Medicine, VA San Diego Healthcare System, San Diego, CA, USA.

Parathyroid hormone-related protein (PTHrP) has been studied extensively in lung cancer because of its relation to humoral hypercalcemia of malignancy. Little work has focused on its action as a lung carcinoma growth factor, even though PTHrP is expressed in more advanced, aggressive tumors, and may play an active role in cancer progression. PTHrP has effects on apoptosis in many malignant and non-malignant cells. We investigated the effects of PTHrP on caspase activity after UV irradiation in BEN cells, a human squamous lung carcinoma line. Cells at 70% confluency were treated 24 h with 100 nM PTHrP 1-34, PTHrP 38-64, PTHrP 67-86, PTHrP 107-139, or PTHrP 140-173 in DMEM/FBS. Cells were then exposed 30 min to 50 mJ/cm2 UV-B. Caspase 3, 8, and 9 activities increased 5-fold 24 h after UV. PTHrP 1-34 and 140-173 reduced caspase 3 activity after UV 19 ± 4% and 29 ± 7%, respectively, and increased cell protein 36 ± 12% (mean ± SEM, N = 7), suggesting improved survival. Reductions of caspase 8 and 9 were similar. Other peptides had no effect. Treating cells with caspase 9 inhibitor reduced caspase 3, 8 and 9 activities after UV, but caspase 8 inhibitor affected only caspase 8. These data indicate that caspase 9 acts upstream of caspase 8 and caspase 3 after UV-B exposure in BEN cells, and that apoptosis occurs through a mitochondrial-dependent pathway. PTHrP 1-34 and PTHrP 140-173 both protect against apoptosis, as evidenced by reductions in caspase activities and increases in cell survival. PTHrP protects against mitochondria-mediated apoptosis by increases in Bcl-2 or activation of the Akt/PI3 kinase in other cells (J Cell Biol 136:205 1997, JBC 277:19374 2003), but the mechanism for the protective effect in BEN cells remains to be determined. Protective effects against apoptosis support the hypothesis that PTHrP may contribute to lung cancer cell survival and promote cancer progression.

The Bisphosphonate Risedronate Inhibits Angiogenesis and Tumor Growth In Vivo. P. Fournier*[1], S. Boissier*[1], C. Serre*[1], M. Colombel*[1], F. H. Ebetino[2], P. A. R. Clezardin[1]. [1]INSERM, Lyon, France, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

Bisphosphonates inhibit tumor cell invasion and adhesion to bone in vitro. In the present study, we have investigated the effects of the nitrogen-containing bisphosphonate risedronate (RIS) on angiogenesis and tumor growth in vivo.

RIS dose-dependently reduced endothelial cell survival and inhibited capillary-like tube formation in vitro. We have previously shown that bisphosphonates accumulate in rat kidney and prostate tissues but not in other nonmineralized tissues. Castration induces the regression of the vasculature in the prostate and testosterone treatment of castrated rats causes a rapid vascular regrowth in the prostate. The effect of RIS on the re-vascularization of the prostate gland induced by testosterone in castrated rats was therefore tested. A daily s.c. treatment of castrated rats with testosterone + RIS (20 and 100 microg/kg/day) for 6 days reduced the prostate weight (20% inhibition) compared to that observed with testosterone alone. Morphometric analysis of immunostained blood vessels in prostate tissue sections demonstrated that RIS treatment induced a 45% reduction of the mean vessel area (testosterone + RIS: 865 ± 122 microm2 versus testosterone: 1561 ± 174 microm2). In sharp contrast, clodronate (a bisphosphonate that lack nitrogen in its structure) did not inhibit testosterone-induced prostate regrowth and revascularization when used at a dose up to 20 mg/kg/day.

Angiogenesis is associated with tumor growth and metastasis progression. The effects of RIS were therefore studied on the growth of s.c. tumor xenografts and the formation of bone metastases induced by human MDA-MB-231/B02 breast cancer cells stably transfected to express the green fluorescent protein. Continuous treatment of nude mice with RIS (150 microg/kg/day) did not inhibit the growth of s.c. tumors. In contrast, treatment of animals bearing bone metastases with RIS at a similar dose almost completely inhibited the formation of osteolytic lesions as judged by radiography (RIS: 0 mm2 versus 4.4 ± 1.6 mm2) and histomorphometric analysis using the bone volume (BV) to tissue volume (TV) ratio (RIS: 69.1 ± 10.1% versus placebo: 7.7 ± 4.1%). For comparison, the BV/TV ratio of normal age-matched mice was 12.9 ± 2.3 %. The extent of skeletal tumor burden was also substantially reduced by RIS as judged by fluorescence imaging (RIS: 6.3 ± 6.2 mm2 versus placebo: 20.8 ± 10.3 mm2) and by histomorphometry analysis using the tumor burden (TB) to total soft tissue volume (TV) ratio (RIS: 4.1 ± 6.9 % versus 20.5 ± 10.2 %).

Overall, our results indicate that RIS inhibits angiogenesis and tumor growth in tissues where it accumulates.

Clodronate Prevents Osteolytic Breast Cancer Bone Metastases in a Mouse Model: Effects on Bone Mineral Density. S. M. Käkönen, P. Isaksson*, P. T. Lakkakorpi, T. Österman*, C. Malmström*, M. Suominen*, E. Aho*, B. Sjöholm*, S. Hokkanen*, R. Hannuniemi*. Preclinical R&D, Schering Oy, Turku, Finland.

Oral clodronate has recently been shown to prevent the occurrence of skeletal metastases in primary breast cancer. The aim of this study was to investigate the preventive effects of clodronate in a preclinical mouse model that resembles the characteristics of osteolytic bone metastasis in human breast cancer. Furthermore, the effect of osteolysis and clodronate treatment on bone mineral density (BMD) in tumor bearing mice was examined.

MDA-MB-231 human breast cancer cells were inoculated into the left cardiac ventricle of 5-week-old nude mice and clodronate (10, 20, and 40 mg/kg/d, N=20-23/group) was administered s.c. for 21 days after the inoculation. On day 22, the mice were sacrificed and radiographed, followed by densitometric measurements by pQCT at proximal and diaphyseal (at 30% and 50% of proximal end) sites of tibia. Clodronate-treated groups were compared to untreated positive (cancer cell inoculation) and negative (saline inoculation) control groups.

In the positive control group, 30% of the mice were sacrificed before the day 22 due to paraplegia or cachexia, whereas 22%, 9%, and 4% of the mice in the clodronate groups (10, 20, and 40 mg/kg/d, respectively) were sacrificed before the end of the study. Clodr-

onate significantly reduced the area and number of osteolytic lesions in all treatment groups and totally prevented the occurrence of lesions in mice receiving 20 or 40 mg/kg/d of clodronate as determined by radiography. At proximal tibia, positive control group had significantly lower total and trabecular bone mineral content (BMC) and BMD compared to the negative controls, whereas clodronate groups had significantly higher total and trabecular densitometric parameters compared to both positive and negative control groups. In the positive control group, cortical BMC was lower at proximal and 30% diaphyseal sites compared to the negative controls, whereas no changes were observed in cortical BMD at any of the sites measured. In addition, no differences in the values of densitometric parameters were observed at the 50% diaphyseal site where only few osteolytic lesions were observed.
In conclusion, our data indicate that clodronate prevents tumor-induced osteolysis when determined by radiography and densitometry. In addition, densitometric analyses support the hypotheses that active bone remodeling in trabecular bone areas is favorable for the osteolytic tumor growth and that the tumor-induced osteolytic effects are local. The data support clinical findings and suggest that clodronate offers a potent treatment for the prevention of bone destruction in breast cancer.

A Bone Marrow Stromal Cell Ossicle Model Provides Insight into the Pathophysiology of Prostate Cancer Metastasis. A. Schneider, L. M. Kalikin*, A. C. Mattos*, P. H. Krebsbach, K. J. Pienta*, L. K. McCauley. University of Michigan, Ann Arbor, MI, USA.

One of the most common yet untreatable complications associated with advanced prostate cancer (CaP) is the development of skeletal metastases. Recent studies suggest that interactions between CaP-derived factors and bone cells in the metastatic foci favors the formation of lesions characterized by the presence of immature, woven-like bone. Parathyroid hormone-related protein (PTHrP) is an autocrine, paracrine and intracrine factor that plays a major role in bone remodeling through its anabolic and catabolic actions. In CaP, PTHrP is highly expressed in the primary tumor as well as in the bone metastatic lesion. Therefore, we hypothesized that in the bone microenvironment, CaP-derived PTHrP acts as a key factor responsible for the increased aberrant bone remodeling by altering osteoblast function. A novel in vivo strategy was developed where ectopic ossicles were generated in immunocompromised mice by the coimplantation of murine bone marrow stromal cells (BMSCs) and human CaP cells seeded in gelatin scaffolds. BMSCs were coimplanted with one of the following human CaP cell lines: VCaP, LNCaP (parental), LNCaP stably transfected with full-length PTHrP (LNCaP-PTHrP) or LNCaP with empty vector (LNCaP-pcDNA). BMSCs-only implants served as controls. Six weeks following surgical implantation, ossicles were harvested and analyzed by microradiographic and histomorphometric analyses. Results indicated that human CaP cells form tumor foci in the ectopic ossicle microenvironment. The presence of CaP cells adjacent to the endocortical and trabecular bone was confirmed by PSA+ immunoreactivity. Ossicles generated from the implantation of LNCaP-PTHrP/BMSCs had nearly a six-fold increase in radiopacity, suggesting a higher degree of mineralization as compared to LNCaP-pcDNA/BMSCs implants. In another set of experiments, a non-invasive in vivo bioluminescence imaging system (Xenogen IVIS) was applied to track tumor colonization and growth in mice bearing ossicles. Intracardiac inoculation of PC-3 cells stably expressing luciferase (PC-3Luc) localized and progressively grew in close proximity to the ossicles. These observations suggest that developing osseous structures like the ossicles may provide a suitable environment to attract and support metastatic tumor growth. Similarly, bioluminescence imaging of PC-3Luc/BMSCs coimplants resulted in an effective real-time approach to monitor CaP tumor growth and burden in the bone microenvironment. In summary, the ectopic ossicle model system offers a powerful and versatile strategy to improve our understanding of the pathophysiology of prostate cancer bone metastasis.

The Wnt/Beta-Catenin Pathway Is Expressed in Prostate Cancer and in Bone Metastases. G. Chen*[1], N. Shukeir*[1], A. Potti*[2], K. Sircar*[3], D. Goltzman[1], S. A. Rabbani[1]. [1]Calcium Research Lab, McGill University, Montreal, PQ, Canada, [2]Department of Medicine, Division of Oncology, University of North Dakota School of Medicine, Fargo, ND, USA, [3]Department of Pathology, McGill University Health Centre, Montreal, PQ, Canada.

Prostate carcinoma is one of the most common cancers affecting men and has a high propensity to metastasize to bone where both osteoblastic new bone formation and osteoclastic osteolysis may occur. Recently the Wnt family of growth factors and its effector signaling molecule beta-catenin have been described in several types of malignancy. We assessed protein expression of Wnt1 and beta-catenin by immunohistochemistry and Western blotting in normal and malignant human prostate cancer cell lines, in human samples of normal, hyperplastic and malignant prostate tumors and in human samples of bone with prostate cancer metastases. The majority of beta-catenin is normally located in the cell membrane. Wnt signaling inhibits the multicomponent destruction complex which targets beta-catenin for degradation and leads to nuclear accumulation of this protein where it promotes the formation of transcriptionally active complexes. Compared with expression in normal prostate epithelium cell line, Wnt1 and beta-catenin were both more highly expressed in DU145, LNCap and PC3 prostate cancer cell lines, and especially in the most malignant line (PC3). In five normal prostate tissues Wnt1 was not detected and only membrane staining of beta-catenin was observed. Moderate Wnt1 and beta-catenin expression were observed in benign prostate hyperplasia. In 44 cases of human prostate cancer, positive cytoplasmic and nuclear staining for beta-catenin was observed in 24 (55%). In 23 of these 44 cases (52%) staining of Wnt-1 was also seen. Samples were more likely to be positive and stained more intensely for Wnt1 and for beta-catenin in more aggressive cancers as determined by high Gleason score and serum PSA levels. In bone samples, metastatic cancer cells revealed higher expression of Wnt-1 and cytoplasmic/nuclear beta-catenin than in specimens of primary tumor or lymph node metastases. These studies show that the Wnt/beta-catenin pathway is expressed in malignant but not normal prostate tissue and at higher levels in more aggressive and metastatic cancer. Since components of the Wnt signaling pathway are also present in osteoblasts, Wnt released from prostate cancer metastases may contribute to the stimulation of osteoblastic lesions in bone harboring such metastases.

PTHrP Is Responsible for DNA Repair. N. Ilievska*, T. J. Martin, M. T. Gillespie. St. Vincent's Institute of Medical Research, Fitzroy, Australia.

Parathyroid hormone-related protein (PTHrP) is commonly expressed in breast cancers and its production by cancer cells in bone promotes osteolysis and metastasis establishment and growth. In addition, PTHrP affects cellular functions including differentiation, proliferation and apoptosis. In a clinical study PTHrP expression in primary breast cancers was an independent prognostic indicator for patient survival. To determine whether PTHrP might influence the behaviour of breast cancer, we have examined the effect of PTHrP expression by and upon MCF-7 and MCF-10A cell lines. When PTHrP was overexpressed in these cell lines, several DNA repair (XPG, BRCA1, BRCA2 and Rad51), cell cycle (p21 and p53), and apoptosis-related genes such as Bcl-2 were regulated, both at the mRNA and protein level: the DNA repair genes were elevated. To determine whether this was a result of an intracrine or autocrine action of PTHrP, a range of PTHrP peptides were assessed for their ability to alter gene expression in MCF-7 and MCF-10A cells. PTHrP peptides 1-34, 1-108, 106-139 or 122-139 did not affect mRNA or protein levels for these target genes, whilst PTHrP peptides (107-139 or 107-111 at 100 nM) encompassing osteostatin (TRSAW: 107-111) upregulated the expression of mRNA levels for these genes within 4 to 24 hrs, with parallel increases in protein levels. Mutant peptides of osteostatin (TRSPW, TRGAW, PRSAW, YRSAW, TKSAW and TASAW) identified a requirement for Thr107 and Ser 109 for activity on DNA repair genes.
To determine the signal transduction pathway(s) involved in osteostatin-induced regulation of DNA repair genes, MCF-10A cells were treated with the NFkB inhibitor (N-acetyl-L-cystine), PKA inhibitor (H89), MAPK inhibitor (PD098059) or PKC inhibitor (chelerythrine chloride) with and without TRSAW (100nM). These inhibitors implicated the involvement of PKA, PKC and MAPK pathways in the effects of TRSAW on DNA repair genes.
Finally, to determine if PTHrP was indeed responsible for DNA repair, the ability of osteostatin or mutants peptides to protect against etoposide induced DNA damage was assessed by COMET assays. TRSAW and peptides that elevated DNA repair gene expression protected against etoposide-induced DNA damage, whilst peptides that had no effect upon DNA repair gene expression were ineffective in the COMET assay.
Combined, these data indicate a new function for PTHrP to repair DNA damage, and this activity could account for the widespread distribution of PTHrP, and its association as a prognostic indicator of survival in patients with breast cancer.

Antisense Parathyroid Hormone-related Peptide (PTHrP) Inhibits Invasion and Metastasis and Improves Survival in a Model of Metastatic Prostate Cancer. D. C. Huang[1], J. S. Rhim*[2], R. Kremer[1]. [1]Medicine, Royal Victoria Hospital, McGill University, Montreal, PQ, Canada, [2]Center for Prostate Disease Research, Uniformed Services, University of the Health Sciences, Bethesda, MD, USA.

Previous studies have demonstrated that the Ki-*ras* oncogene induces overexpression of PTHrP in human prostate cancer cell lines (FNC267B1-*ras*) established from normal human neonatal prostate epithelial cells. This cell line is metastatic to liver and lungs. Here we hypothesized that Ki-*ras* induced overexpression of PTHrP may promote prostate cancer metastasis. To test this hypothesis, we first neutralized PTHrP production in FNC267B1-*ras* cells by stable transfection of a CMV promoter driven antisense PTHrP cDNA plasmid vector. Several stable FNC267B1-*ras*/Antisense PTHrP cell lines were established and PTHrP production examined. Cell lines in which PTHrP was inhibited by over 90% were then examined both *in vitro* and *in vivo* for their invasion and metastatic abilities. These FNC267B1-*ras*/Antisense PTHrP cell lines displayed a highly significant inhibition of cell adhesion to Matrigel basement membrane matrix by over 35% ($p<0.005$) as compared to wild type cells transfected with the vector alone. There was also a significant reduction of colony formation in soft agar culture in FNC267B1-*ras*/Antisense PTHrP cells. In order to determine the role of PTHrP in prostate cancer metastasis *in vivo*, we injected wild type FNC267B1-*ras* or FNC267B1-*ras*/Antisense PTHrP cells into the left cardiac ventricle of female Balb/C nude mice. Kaplan-Meier analysis revealed a highly significant survival benefit in mice injected with FNC267B1-*ras*/Antisense PTHrP cells as compared to wild type FNC267B1-*ras* cells ($p<0.005$). Wild type FNC267B1-*ras* cells

injected nude mice displayed significant weight loss and circulating calcium elevations as compared to FNC267B1-*ras*/Antisense PTHrP cell injected nude mice. Macroscopic and microscopic histological analysis demonstrated that PTHrP inhibition resulted in a significant reduction of size and number of metastatic lesions of lungs and liver ($p<0.001$). Our *in vitro* and *in vivo* data therefore demonstrate that PTHrP plays an important role for invasion, metastasis and calcium homeostasis in a metastatic prostate cancer model, and suggest that antisense PTHrP should be further evaluated as a therapeutic agent in human prostate cancer.

In Vivo Imaging of TGF-β-induced RANK Ligand Transcriptional Activation in Prostate Cancer. J. Zhang[1], M. Liu*[1], A. Schneider[2], J. Dai[1], Y. Lu*[1], R. Kitazawa*[3], S. Kitazawa*[3], L. K. McCauley[2], E. T. Keller[1]. [1]Department of Pathology and ULAM, University of Michigan, Ann Arbor, MI, USA, [2]Department of Perio/Prev/Geriatrics, University of Michigan, Ann Arbor, MI, USA, [3]Division of Molecular Pathology, Kobe University, Kobe, Japan.

Prostate cancer (CaP) metastasizes to bone resulting in a mixture of osteoblastic and osteolytic lesions. Receptor activator of NFkB ligand (RANKL) mediates CaP-induced osteoclast activity. The mechanism of RANKL upregulation in CaP cells at bone sites is unknown. Transforming growth factor-β (TGF-β), a protein found in bone, has been reported to increase RANKL mRNA expression in vitro. The goal of this study was to determine if TGF-β modulates RANKL mRNA expression through transcription in vivo. Accordingly, we stably transfected PC3 human CaP cells with the human RANKL 5'-promoter (1.97kb) driving luciferase (lux) and selected several clones for evaluation (PC3-Rp). We initially evaluated RANKL promoter activation in vitro. TGF-β (0.1-10 ng/ml) induced RANKL promoter activity in a dose-dependent manner based on quantitative bioluminescent imaging (BLI). BLI correlated with conventional lux enzyme measurement and both RANKL protein and mRNA expression. To determine if transcriptional activation occurs in vivo we used an ectopic ossicle model. Specifically, gelatin sponges that inoculated with either murine bone marrow stromal cells (BMSCs) alone or with BMSCs and PC3-Rp cells were implanted subcutaneously into 4-6-wk-old male nude mice. Mineralized ossicles (with tumors in co-implanted sponges) were allowed to develop over 6 wks. Vehicle, TGF-β (200ng/mouse), or VitD (100ng/mouse, as positive control for RANKL promoter activation), were administered via i.p injection. Pre-, 1, 6, and 24 hr after administration, the mice were anesthetized for BLI of the whole body and of the excised ossicles at the end of 24 hr. TGF-β and Vit D increased lux activity by 54% and 190% compared to vehicle. Implants were homogenized for RANKL lux activity measurement that paralleled the BLI results. The BLI data were further validated using radiographs and histology to confirm tumor presence and immohistochemistry for the lux enzyme. We conclude that TGF-β induces RANKL mRNA expression through transcriptional activation in CaP cells in vivo. These data support the idea that cross-talk between bone and tumor is an important aspect of bone metastasis development, specifically as TGF-β is released from the resorbing bone matrix it induces RANKL expression, which in turn induces further bone resorption through induction of osteoclastogenesis. Additionally, these data demonstrate that the ossicle model is a useful tool for studying tumor and bone stromal interaction.

Effects of Radiation Therapy on Osteoblasts and Osteoclast Precursors. M. J. Allen*, B. S. Margulies*, T. A. Damron*. Orthopedic Surgery, SUNY Upstate Medical University, Syracuse, NY, USA.

Radiation therapy is generally considered to inhibit new bone formation, yet an "osteoblastic flare response" is commonly seen after radiation therapy in patients with osteolytic bone tumors. The specific aim of this study was to determine whether this response could be the result of differences in the sensitivity of osteoblasts and osteoclast precursor to ionizing radiation. To determine this, we used a cell culture model in which murine MC3T3 osteoblasts and primary human bone marrow monocytes (collected under an IRB approved protocol) were exposed to 0, 1, 2, 5, 10, and 20 Gy of X-irradiation. Measurements of cell number (MTT assay), cytotoxicity (LDH assay), apoptosis (caspase assay, flow cytometry), ALP and osteocalcin were made at intervals up to 120 hours. Data were analyzed using ANOVA (with post-hoc testing where appropriate) at a significance level of $p<0.05$. Monocytes were found to be extremely radiosensitive (>75% decreases in cell number at doses of 1 Gy or more, $p<0.001$). In contrast, osteoblasts were extremely radioresistant (only 30-35% inhibition at 10 and 20 Gy) (Figure 1). Apoptosis was seen in osteoblasts at 24 hours post-irradiation but evidence of cell death was not seen until 72 hours. Interestingly, osteoblast metabolic activity was stimulated by irradiation, with statistically significant, dose-dependent increases in both osteocalcin and ALP at 120 hours (Figure 2).
These data indicate that the two pools of bone cells display profound differences in radiosensitivity. By reducing the pool of available osteoclast precursors, radiation causes significant inhibition of osteoclast formation under M-CSF/RANKL stimulation (data not shown). Since osteoblast activity is stimulated by radiation, the net effect of these changes would likely be a transient increase in net bone mass, thereby explaining the clinical observation that prompted this study. Additional work is now needed to explore the molecular mechanisms by which radiation modulates these changes in osteoblastic activity.

Validation of Dental Panoramic Radiographic Measures to Identify Women with an Increased Risk of Osteoporosis. A. Taguchi[1], Y. Suei*[1], M. Sanada*[2], T. Nakamoto*[1], M. Ohtsuka*[1], H. Sumida*[1], K. Tanimoto*[1], I. Kodama*[2], M. Tsuda*[2], K. Ohama*[2]. [1]Oral & Maxillofacial Radiology, Hiroshima University, Hiroshima, Japan, [2]Obstetrics & Gynecology, Hiroshima University, Hiroshima, Japan.

Recent studies suggest that mandibular inferior cortical shape and width on dental panoramic radiographs may be useful screening tools for low spinal bone mineral density (BMD) in postmenopausal women. However, little is known as to whether these measures are validated in comparison with other risk indices such as the Osteoporosis Self-assessment Tool (OST) developed for postmenopausal Asian women (Koh et al., 2001), and as to whether these measures can be used in postmenopausal women with hysterectomy, oophorectomy and/or estrogen use as well as in normal postmenopausal women. In this study, we calculated sensitivity, specificity, positive predictive value, negative predictive value and accuracy for dental panoramic measures (cortical shape and width) and OST (=integer (0.2*weight)-integer (0.2*age)) using data from 157 normal postmenopausal (group A) (mean age [SD], 57.4 [7.5] years) and 159 postmenopausal with hysterectomy, oophorectomy and/or estrogen use (group B) (56.3 [8.0] years). Spinal BMD was measured by dual x-ray abosrptiometry (DXA, Lunar DPX-alpha). Spinal fracture was not found in all subjects. Osteoporosis (OP) was defined as a BMD T-score of -2.5 or less at the lumbar spine (L2-L4). There were 38 women with OP in group A and 40 in group B. Cortical shape (normal or any cortical erosion) and width were evaluated on dental panoramic radiographs. Reciever operating characteristics (ROC) curve analyses were used to determine the cutpoints of cortical width and OST for the identification of spinal OP. Area under ROC curves to identify women with OP in group A were smaller in cortical width (0.771, SE=0.05) than OST (0.829, SE=0.04). At the thresholds of < 4.5 mm (cortical width) and =< -1.0 (OST), and selecting any cortical erosion, the sensitivity and specificity to identify women with OP were 89.5% and 33.9% for cortical width, 86.8% and 57.8% for OST, and 86.8% and 63.6% for cortical shape in group A. In group B, those were 92.5% and 35.0% for cortical width, 72.5% and 58.1% for OST, and 80.0% and 64.1% for cortical shape. Accuracy was somewhat higher for cortical shape (69.2% in group A, 68.2% in group B) than that for cortical width (47.1%, 49.7%) and OST (64.8%, 61.8%). Our results suggest that women with OP may be identified by cortical shape on dental panoramic radiographs as well as OST. Cortical shape may also be useful in postmenopausal women with hysterectomy, oohorectomy and/or estrogen use.

Bone Mass and Body Composition of Neonates From Fan- and Pencil-Beam Dual Energy X-ray Absorptiometry. M. Hammami*, W. Koo. Pediatrics, Wayne State University School of Medicine, Detroit, MI, USA.

This study aims to determine the ability of physiologic parameters (weight, length, race and gender) to predict dual energy x-ray absorptiometry (DXA) measured bone mass and body composition in human neonates. In addition, we aim to compare the DXA measurements using the fan beam (FB) and pencil beam (PB) DXA techniques.
Bone mineral content (BMC), fat mass (FM) and lean mass (LM) were measured with FB DXA in 73 neonates and were measured with the older PB DXA technique in another cohort of 67 neonates. All subjects were healthy singletons and both cohorts have comparable birth weights and gestational ages. The predictive ability of physiologic parameters including weight, length, race and gender on DXA measurements was determined separately for each cohort with regression analysis. The instrument effect on each body composition measure was determined by univariate analysis of covariance that controlled for weight if there was significant interaction between instrument and profile of body composition measurements. Regression equations based on infants who had PB DXA measurements were used to predict the body composition of infants who had FB DXA measurements. The data in turn were compared to the measured values by paired t test.
Results showed that for each cohort of infants, weight was the dominant predictor of bone mass and body composition. FB and PB measured BMC, FM and LM were different whether controlled for weight or as a fraction of weight ($p<0.01$ for all comparisons). The predicted and measured FB derived BMC, FM and LM were correlated ($r=0.86$, 0.67 and 0.93, $p<0.001$ for all comparisons) although at different mean levels ($p<0.001$).
We conclude that body weight is the best physiologic predictor of bone mass and body composition in human neonates regardless of DXA technique. FB DXA measurements were correlated although differed to that from PB DXA. Thus, group comparison of data from either technique is possible after transformation of one set of data.

Osteoporosis in Chinese-American Women: Risk Factors for Fracture and Development of a Database for Bone Densitometry. M. A. Donovan[1], A. R. Opotowsky*[1], R. B. Babbar*[2], A. L. Rohira*[2], M. Della Badia*[1], G. Liu*[2], J. P. Bilezikian[1]. [1]Medicine, College of Physicians and Surgeons, Columbia University, New York, NY, USA, [2]Medicine, New York University Downtown Hosptial, New York, NY, USA.

Asian women have consistently been shown to have lower BMD than Caucasian women. Yet, studies in Asia and the USA suggest that Chinese women may have a lower rate of hip fracture than Caucasian women. This apparent paradox is rooted in the idea that the relationship between BMD and fracture risk is equivalent for Caucasian and Asian women. But, it is not known whether a given T-score or absolute bone density carries the same fracture risk among Chinese-American women as it does for Caucasian women. The purpose of this study is to develop a clinically useful database for BMD among Chinese-American women in order to establish a relationship between BMD and fracture risk in this population. This information will be compared to databases established for Caucasian women in the USA and to Chinese women in Hong Kong and Beijing, China. Vertebral fracture risk as a function of BMD will also be determined. In addition, hip geometry, and relationships between calcium intake, BMD, country of origin, and years in the USA will be evaluated as other potentially important variables. 280 Chinese-American women between the ages of 20 and 90 (40 women per age decade) are being recruited. Along with DXA of the hip and spine, the study includes completion of a customized bilingual questionnaire that covers numerous demographic, familial, nutritional, behavioral, and attitudinal points. Women over 50 will also be evaluated for morphometric vertebral fracture with IVA and a subset will undergo digital x-ray of the hip for pelvimetry measurements. The project also includes a detailed assessment and case-control comparison of 35 patients who will have sustained a hip fracture. Between 11/02 and 4/03, 140 women have been recruited and their demographic, dietary and DXA results have been incorporated into the database. Preliminary data suggest that bone density rises by decade through the fifth decade (ages 40-49) and then falls progressively at the lumbar spine and hip. These results are consistent with previously published data in an indigenous Chinese population, but are different from databases constructed from Caucasian populations. The results suggest that Chinese-American women may achieve adult peak bone mass later than their Caucasian counterparts, which may have significant consequences for risk assessment and treatment. As this work continues, we expect to have generated, for the first time, a database that has direct relevance to the Chinese population in the United States.

A Pilot Study of the Use of Radiographic Absorptiometry in the Measurement of Cortical and Trabecular Phalangeal Bone Mineral Density in Chinese Men and Women. Z. H. Liu*[1], X. Bi*[2], L. Aldayeh*[2], s. Silverman[3]. [1]Osteoporosis Committee of China Gerontological Society, Beijing, China, [2]CompuMed, Inc., Los Angeles, CA, USA, [3]OMC Clin Res Ctr, Beverly Hills, CA, USA.

Radiographic Absorptiometry (RA) automatically measures volumetric BMD in the 2nd, 3rd, and 4th middle phalanges. A study was conducted to investigate the ability of RA to separate cortical and trabecular phalangeal BMD, offering an inexpensive and safer alternative to QCT. The study was conducted using X-rays from RA tests of 556 patients. These x-rays were analyzed to compare the rate of decline of cortical, trabecular and total phalangeal BMD.
A normal Chinese population with no known osteoporosis or arthritis, of ages 10 to 89, with 277 male and 279 female were considered for the study. A two view standard AP x-ray was acquired for the non-dominant hand of each volunteer with an aluminum reference wedge placed near the hand. Based on the OsteoGram R technology (CompuMed Inc, Los Angeles, CA), which applies RA, a customized module has been developed to perform automated bone tissue segmentation isolating three distinct areas in each phalanx:
1. An axial cylinder, 2.2x2.2 m.m. in size, in the middle of the distal trabecular zone
2. An axial cylinder, 2.2x2.2 m.m. in size, in the middle of the proximal trabecular zone
3. A tube segment in middle of the phalanx that includes the cortical tissue and excludes the central non-cortical tissue.

The module performed BMD assessments in the cortical and the two trabecular areas in addition to the standard total phalangeal BMD. Considering the two radiographic views for each volunteer's hand and the three bones in each view, the unsupervised automated algorithm properly segmented the trabecular and cortical areas with a success rate of 90% for male and 92% for female.
Time courses of unadjusted BMD results showed peaks in the age range of 25-35. Using linear regression analysis the rate of BMD loss was calculated in BMD-AU (Arbitrary Units) per year for all subjects 35 years and older.For males, BMD decreased at the same rate in both trabecular and cortical tissues (~ -0.3), where as total BMD decreased at a higher rate (~ -0.5). For females, trabecular BMD decreased at a slightly higher rate than male (~ -0.4). However, cortical BMD decrease was much higher and close to total BMD decrease at the rate of -1.0. Further development of the module will investigate applying cortical thickness measurements. We believe that adding cortical and trabecular measurements to the RA BMD report could provide useful information to assist clinicians in providing better osteoporosis care.

PIXI Forearm Scan Prescreen for Osteoporosis Case Finding. P. J. Ryan, G. Worcester*. Osteoporosis unit, Medway Maritime Hospital, Gillingham, kent, United Kingdom.

We investigated the PIXI scanner in forearm mode for Osteoporosis case finding, used as a prescreen for axial scanning. A reference population was established from 165 patients attending the Fracture Liaison service who had bone density measured with the PIXI scan and Spine and Hip DXA (Hologic QD4500C). Comparison was made of T scores using the PIXI and axial measurements (References range NHanes 111 female hip and Hologic female spine and men). Patients were of average age 63 years, and 20 male, 143 female. Average T scores were –2.16 PIXI, -1.55 Spine and –1.43 Femoral neck. Regression comparison shows PIXI T scores about –1 SD below Spine and Hip T scores. Threshold values for PIXI T scores were calculated with an attempt to detect and exclude patients with spine or hip T scores <-1.5 (Steroid users), <2.0 (Fractures), <-2.5 (No steroids, No fractures). A lower PIXI threshold to determine those who required treatment without axial scanning could not be established as only very small numbers would be selected. Upper thresholds to determine those who did not require therapy could be established for the T <-2.5 spine and hip threshold. An upper PIXI threshold of T - 1.9 would result in reassurance of 40 % patients (with a misclassification of 1/16) on PIXI scan alone that their Spine and Hip T scores were greater than –2.5. For Axial T scores of –2.0 and -1.5 PIXI thresholds to identify a population that could be reassured was less reliable. The thresholds above were used to screen patients > 65 years in 3 general practices with clinical risk factors. PIXI and axial scans were acquired for those below the thresholds identified above (average age 73 years, 160 pts) and in this older group results supported the notion that a treatment threshold cannot be established. We conclude that PIXI forearm can be used as a prescreen in the elderly for a Spine and Hip –2.5 T score threshold. However, forearm T scores are set too low with respect to spine and hip T scores, and the majority of patients will still require an axial scan.

Does Radius Bone Density Measurement Over-Diagnosis Osteoporosis in Men? N. L. Vallarta-Ast[1], D. Krueger[2], N. Binkley[2]. [1]Radiology, Wm S Middleton VAMC, Madison, WI, USA, [2]Osteoporosis Clinical Center and Research Program, University of Wisconsin, Madison, WI, USA.

Radius bone mineral density (BMD) measurement increases the number of men diagnosed as osteoporotic. However, controversy exists whether this is improving DXA sensi-

tivity or leading to over-diagnosis. This possibility was evaluated by retrospective review in a large densitometric dataset.

Men referred for BMD measurement at the Wm. S. Middleton VAMC from 1997 to 2003 were considered; the 1197 who had spine, femur and radius measurements were included. Patient age ranged from 24 to 93 years (mean 67.2). Previous low trauma fracture was reported to the technologist in 507. All scans were performed using a GE Lunar Expert densitometer; T-scores were obtained using the manufacturer's male normative database.

Osteoporosis, defined as a T-score ≤-2.5 at the spine, total femur, femur neck, trochanter, .3 or ultradistal radius, was identified at one or more sites in 521 men. Of these men, osteoporosis was present at the spine in 201, femur in 389 and radius in 294. The prevalence of prior low-trauma fracture in those with "densitometric osteoporosis" at the spine, femur and radius was 58%, 52% and 53% respectively. Similarly, in men classified as osteoporotic only at the spine, femur or radius, the prior fracture prevalence was 49%, 49% and 53%. Thus, the prevalence of prior low-trauma fracture did not differ in either the entire osteoporotic group or in those uniquely identified at any single site. Furthermore, the percentage uniquely diagnosed as osteoporotic at the radius is very similar in the entire group, those with prior low-trauma fracture, vertebral fracture or hip fracture (Table). Finally, of the 5 men with normal femur and spine BMD but osteoporosis at the radius, 4 had a prior low-trauma fracture.

In conclusion, men diagnosed with osteoporosis at any site have a comparable prevalence of prior low trauma fracture. Similarly, fracture prevalence does not differ in those uniquely diagnosed as osteoporotic at the radius. Furthermore, the percentage of men uniquely diagnosed as osteoporotic at the radius is remarkably similar in those with prior fracture as in the entire group. Thus, these data suggest that radius measurement does not overdiagnose osteoporosis. Until prospective fracture risk data becomes available, use of radial sites for osteoporosis diagnosis in men seems appropriate.

Percentage of men uniquely diagnosed at each site as osteoporotic

Group	n	%≤-2.5@spine	%≤-2.5@femur	%≤-2.5@radius
Entire	1197	3	12	7
Prior Low trauma Fx	507	4	13	7
Prior vertebral Fx	167	5	11	7
Prior hip Fx	48	0	21	4

A Comparison of Lumbar Vertebral T-scores by Three Methods: Average L1-L4 BMD, Lumbar BMD by ISCD Criteria, and Lowest Vertebral Body T-score. K. E. Hansen[1], N. Vallarta-Ast[2], D. Krueger[1], M. Drezner[1], N. Binkley[1]. [1]Osteoprososis Clinical Center and Research Program, Univeristy of Wisconsin, Madison, WI, USA, [2]Radiology, Wm. S. Middleton VAMC, Madison, WI, USA.

The ISCD recommends exclusion of abnormal vertebrae from analysis to allow more accurate determination of lumbar bone mass, although in clinical practice the L1-4 T-score is often reported. Herein we compare three different methods of lumbar spine T-score interpretation, and how these results might influence therapy in men. Scans obtained with a GE Lunar Expert-XL densitometer were reviewed on 211 male veterans (mean age 67.6 years) undergoing bone densitometry at the Wm. S. Middleton VAMC. Prior low-trauma fracture was reported in 84 men. Spine T-scores were obtained using the L1-L4 average, the lowest vertebral T-score and after vertebra exclusion based on ISCD recommendations. Resulting diagnoses are summarized in the table. No men had osteoporosis using the L1-4 method; conversely, no men had normal bone mass utilizing the lowest vertebral T-score. Furthermore, 3 scans were unevaluable by ISCD criteria due to severe scoliosis. A focal structural defect led to exclusion of one or more vertebra in 164 (78%) of 211 men, 80 (38%) due to a lack of increase in bone mineral content or area and 82 (39%) secondary to unusual discrepancy in T-score between adjacent vertebra. The fourth lumbar vertebra was most often excluded (164 men or 78%), followed by the L3, L2 and L1 vertebra (48%, 34%, and 33% respectively). An arbitrary threshold for pharmacological therapy (T-score < -2) was met less frequently, using the average L1-L4 T-score (40/19%), than using the ISCD criteria (91/43%), and the lowest vertebral body T-score (112/53%) ($p < 0.0001$). Additionally, more men with prior fracture were identified for treatment using the latter methods (49% and 60% respectively). The lowest lumbar T-score method was most likely to diagnose osteoporosis ($p<0.0001$).

In these male veterans, implementing ISCD criteria or lowest T-score methods resulted in a greater percent of men, with or without prior fracture, being diagnosed with osteoporosis and meeting therapy guidelines. Further study evaluating prospective fracture rates using these two approaches is appropriate to determine the ideal interpretation method.

Diagnosis and treatment categorized by method

	L1-L4 T-Score	Lumbar T-score by ISCD Criteria	Lowest Lumbar T-score
Osteoporosis	0	59 including 27 with prior fracture*	89 including 36 with prior fracture*
Osteopenia	75	101	122
Normal	136	48	0
Met Threshold for Therapy	40 including 18 with fracture	91 including 41 with fracture*	112 including 50 with fracture*

*$p < 0.0001$ comparing ISCD to either L1-L4 or Lowest Lumbar T-score.

Spinal Bone Mineral Density in Healthy Urban Asian Indian Women Presenting for a Preventive Health Check-Up. A. Keramet*[1], R. Bhambri*[1], D. Chakravarty*[2], A. Mithal[1]. [1]Endocrinology, Max MedCentres, New Delhi, India, [2]Radiology, Max MedCentres, New Delhi, India.

Bone mineral density (BMD) measurement is an important tool in the diagnosis and management of osteoporosis. Ethnic differences in BMD are well documented and may be due to factors such as genetic traits, body composition, calcium and vitamin D nutrition and metabolism. There is a lack of normative BMD reference values for the Asian Indian population and the guidelines for the diagnosis of osteoporosis in Caucasians may not apply to this population.

In this cross-sectional study we report the lumbar spine (L1-L4) BMD values of 974 female subjects in the New Delhi area (urban, north India). The subjects, who were otherwise healthy, had spinal BMD measurements as part of a preventive health check-up. The anterio-posterior lumbar spine (L1-L4) BMD was measured by axial dual energy X-ray absorptiometry (DXA) using a Lunar Prodigy machine.

The spinal BMD measurements are shown in the table along with the normal Caucasian female reference values and the percent difference between these two groups.

Available data, although limited, suggests the presence of lower BMD values (by 5-15%) in Asian Indian women compared to their Caucasian counterparts. However, in this study population, comprising exclusively economically well to do urban Asian Indian women, the difference in the mean spinal BMD with the normal Caucasian reference values was marginal across all the age groups studied, particularly in women over 40. This information highlights the urgent need for large multicentric population based studies in India, incorporating fracture-BMD correlations, to determine whether we need a different BMD reference range for Asian Indians.

Keywords: bone mineral density, Asian Indian women

Spinal BMD of Asian Indian women compared to manufacturer's database

Age Group (years)	N	Lumbar Spine BMD (g/cm^{2}) +/-1 sd	Reference mean BMD (Caucasian)	Percent difference
20-29	22	1.148+/-0.17	1.188	-3.4%
30-39	47	1.144+/-0.13	1.207	-5.2%
40-49	353	1.163+/-0.16	1.170	-0.6%
50-59	350	1.072+/-0.16	1.081	-0.8%
60-69	156	0.989+/-0.19	0.995	-0.6%

Screening Tools and Bone Mineral Density in the Evaluation of Osteoporosis in a Family Medicine Office. C. M. Jachna[1], S. Agrawal*[2]. [1]Internal Medicine, KU Medical Center, Kansas City, KS, USA, [2]Family Medicine, KU Medical Center, Kansas City, KS, USA.

To demonstrate the potential use of the Osteoporosis Self-Assessment Tool (OST) and the Osteoporosis Risk Assessment Instrument (ORAI) to identify women under age 65 for bone mineral density testing who are at risk for developing osteoporosis.

This study was retrospective chart review of 119 women ages 45-65 that presented for an annual well woman visit at a family medicine clinic. Demographic data and identifiable National Osteoporosis Foundation (NOF) risk factors for osteoporosis were collected. Age, weight, and hormone replacement therapy status were used to calculate each woman's individual score on the OST and the ORAI and to identify women who met criteria, using the screening tools, for bone mineral density (BMD) testing. In addition, BMD results of the women who had received testing at the discretion of the physician were collected. Recommendations for osteoporosis prevention or treatment were identified. Descriptive statistics were used to characterize the study population. Using Fisher's exact test the woman who received BMD testing were compared to the women who met criteria for screening by the OST and ORAI.

On average, women were 53 years old with an average BMI of 27. Two percent had a diagnosis of osteoporosis. The most common identified NOF risk factors for osteoporosis were tobacco abuse (17%), premature menopause (16%) and low body weight (14%). Sixty (50%) of women had osteoporosis prevention documented during their well woman visit. Twenty percent of women were on calcium, 51% were on hormone replacement therapy, and 2% were on a bisphosphonate. Nineteen percent and 15% of women, respectively, met criteria for BMD testing by ORAI and OST screening tool scores. Seventeen percent of women had previously received BMD testing and of these 11 (55%) were normal, 7 (35%) had osteopenia, and one had osteoporosis. The majority of women (70%) who had received BMD testing did not meet criteria for screening by the ORAI or OST. Those who received BMD testing did not have significantly more identified NOF risk factors compared with those who were not screened. Women who met OST criteria for BMD screening, were significantly more likely to have received BMD testing compared with women who did not

meet OST criteria. (p=0.013) There was no significant association between those who met screening criteria by ORAI and those who received BMD testing. Eleven (9%) women and 18 (15%) of women who potentially could have been identified for BMD testing with the use of the OST and ORAI screening tools respectively did not receive screening.
The OST and ORAI can be used to efficiently identify a group of women at risk for osteoporosis that are currently not being screened.

Hip Axis Length Assessed by the Norland DXA Scanner in Normal Chinese. J. M. Wang*[1], H. M. Ju*[2], T. V. Sanchez[3]. [1]Research and Development, Norland--a CooperSurgical Company, Beijing, China, [2]Harbin Orthopedic and Trauma Hospital, Harbin, China, [3]Research and Development, Norland--a CooperSurgical Company, Socorro, NM, USA.

Hip Axis Length (HAL) as assessed by DXA is known to be significantly related to hip fracture risk. This study examines HAL in a normal Chinese population using standard procedures.
A population of 50 females, without a history of hip fractures, over 22 years of age from the Harbin area of China underwent examination of the proximal femur area using the Norland XR-36. All scans were performed using Research Scan Software with a point resolution of 1.0 x 1.0 mm and a measurement scan speed of 90 mm/s with subjects positioned with the Hip Positioning Sling. Analysis of the HAL was performed on-screen using the Ruler Tool system. Repeatability of HAL studies, with repositioning, was 1.8%. Analysis repeatability of HAL studies was 0.9%. All studies in this report were audited and analyzed by the same factory trained operator (JMW).
As expected, HAL was not significantly related to age, body height, body weight or body mass index. HAL in this Chinese population averaged 9.18 cm (SD = 0.44 cm) which is substantially shorter than the reported average HAL of 10.67 cm (SD = 0.67 cm), assessed on Norland equipment, in Caucasian subjects.
In conclusion, it would seem that Chinese women have a significantly shorter HAL than is seen in the Caucasian population. Given this substantial difference in HAL and given the reported relationship between HAL and fracture risk (Faulkner, KG, et al. J Bone Mineral Res. 9:1065-1070, 1994), we might expect this Chinese population has a reduced hip fracture risk.

Human Lactation: Changes in Hip Bone Geometry but Not Bone Density Depend on Calcium Intake. B. C. C. Khoo*[1], R. I. Price[1], T. J. Beck[2], G. N. Kent[3], D. H. Gutteridge[1], J. Allen*[1], K. P. Singer*[4], S. S. Dhaliwal*[1]. [1]Charles Gairdner Hospital, Perth, Australia, [2]Johns Hopkins University, Baltimore, MD, USA, [3]Path Centre, Perth, Australia, [4]University of WA, Perth, Australia.

Human lactation (lac) delivers 5-8 mmol/d of milk calcium (Ca). Maternal Ca homeostasis taps (i) increased dietary Ca (+/- increased Ca gut absorption efficiency [Fα; ~0.25-0.3]); (ii) decreased urinary Ca excretion; (iii) bone mass loss. We and others showed (ii) & (iii) are relevant; maternal DXA areal (a) BMD decreases (eg; 0-6% in hip) at peak lac (PL) (~6mo postpartum [PP]), with postweaning (PW) recovery (1), but dietary Ca affects neither bone loss nor Fα (2). Unlike aBMD, Hip Structural Analysis (HSA, 3) describes bone structural geometry, including section modulus (Z; a strength index). This study applied HSA to human lactation.
From 100 pregnant women at 36 wk, randomised to Ca (25mmol/d) and studied through lac to 12mo PW, those N=47 with Fα measured (stable Ca isotopes; 2) at PL were triaged into tertiles of "Abs Ca" = {(Dietary Ca +/- 25mmol Ca x [Ca compliance]) x Fα} (tertile means 6.6, 11.8 & 15.8 mmol/d). % changes (Δ%; = PL minus 2wk PP) in aBMD & HSA, at the femoral neck, inter-troch. (IT) and shaft (Sh) were compared between tertiles. %Δ for 6-12 mo PW minus PL (N=29) were also analysed by tertiles of "Abs Ca".
Main findings; (i) Δ%"narrow neck" Z=6.3% loss ($p<0.01$) by PL, with NS between tertiles & no recovery PW; (ii) Δ%IT Z unchanged at PL but increased by PW (1.9-5.3%, $p<0.05$) (iii) mid-tertile Sh Z decreased (2.4%, $p<0.05$) at PL (flanking tertiles NS), tending towards recovery, PW. The "U-shaped" response of Sh Z by PL arose from a combined thresholded increase in Sh bone width, only at high Ca intake (1.4%, $p<0.05$), and a linear increase in Sh endosteal width with Ca intake (1.2 – 3.9%, $p<0.05$) (iv) aBMD fell by PL at all sites except troch., with part recovery by PW. There were no Ca-dependent differences in Δ%aBMD (v) For changes in Sh Z at PL, ANCOVA with shaft aBMD, treatment (Ca or placebo), height & weight as covariates showed only height ($p<0.01$) as a predictor of "change in Sh Z", in addition to the latter's quadratic dependence on Abs Ca ($R^2 = 0.25$, $p=0.005$). The nadir in Δ%Sh Z was at 10.4 mmol/d Abs Ca (~1.4 g/d Ca dietary intake).
We conclude that lactation-induced changes in Z, but not aBMD, are Ca-intake dependent. In the femoral shaft these changes show a "U-shaped" dependence on Ca intake. The IT Z increase by postweaning suggests a possible site-selective long term lactation-induced protection of bone strength. 1. Kent GN etal 1993 Osteo Int S1:44-7; 2. Femoral Neck Strength Comparison between Subjects with and without Down Syndrome. F. Baptista*, P. Nogueira*, A. Varela*, L. B. Sardinha*. Exercise & Health Laboratory, Faculty of Human Movement, Lisbon, Portugal.

It has been reported that children and adults with Down syndrome (DS) have lower bone mass in the lumbar spine, compared to their peers without mental retardation or with mental retardation but without DS. However, regarding femoral neck there is no published data. This study was designed to compare structural measures of femoral neck strength, as suggested by Karlamangla et al. (2002), between males and females with and without DS. Due to the disproportionate shortening of the long bones of the legs in DS, it is necessary to avoid size related artifacts in the analysis of bone data when comparison between different groups are made on this skeletal region. Subjects were 51 females (20 with DS) and 56 males (23 with DS), 14-40 yr. Assessment of femoral neck bone mineral density (BMD), femoral neck width (FNW), and hip axis length (HAL) was performed with dual x-ray absorptiomatry (QDR 1500). ANCOVA was used to analyze the data. For this purpose, compressive, bending and impact strengths were used as dependent variables adjusted for age. Compressive strength (BMD*FNW/weight) and bending strength (BMD* $(FNW)^2$/HAL*weight) express the forces that femoral neck has to withstand in weight bearing, while impact strength (BMD*FNW*HAL/(height*weight) expresses the energy that femoral neck has to absorb in an impact from standing height. Mean differences between the control group (CG) and the DS group were -29% for compressive strength (DS 3.754±0.132 vs. CG 4.835±0.105 g/kgm, $p<.0001$), -34% for bending strength (DS 1.031±0.046 vs. CG 1.379±0.037 g/kgm, $p<.0001$), and -24% for impact strength (DS 0.249±0.008 vs. CG 0.309±0.249 g/kgm, $p<.0001$). The mean of each strength measures was lower in DS subjects than in CG. It was not found any interaction effect between subjects with and without DS and gender.We concluded that mineral density and femoral neck size in DS subjects did not adjust for body size variables with the same rate that was observed in CG. These results suggest that DS subjects may be at higher risk for a lower femoral neck strength.

Preprocessing and Fractal Analysis in Radiographic Texture Analysis (RTA) of the Calcaneus in Evaluating Patients with and without Vertebral Fractures. M. L. Giger*[1], V. Jaros*[1], T. Vokes[2], M. Chinander*[1], J. Wilkie*[1]. [1]Radiology, University of Chicago, Chicago, IL, USA, [2]Medicine, University of Chicago, Chicago, IL, USA.

We have developed radiographic texture analysis (RTA) methods for the assessment of bone structure from radiographic images of the spine, hip, and heel. Presently, we have reported that the combined analysis of BMD and RTA on images obtained using a clinical densitometer for the calcaneus shows promise in differentiating patients with and without vertebral fractures. In this study, we present our latest methods for optimizing the preprocessing and texture features involved in RTA.
Our database includes images of the calcaneus from 160 subjects (44 with and 116 without vertebral fractures) acquired with a peripheral densitometer system. In addition, BMD of the lumbar spine, femoral neck, and calcaneus are obtained. Radiographic texture analysis consists of (1) extracting a region of interest (ROI) from the digital radiographic image of the heel, (2) preprocessing the ROI of the trabecular structure, (3) characterizing the fractal nature of the trabecular pattern using a Baysian neural network, and (4) estimating the probability that a fracture exists. ROC analysis was employed to evaluate the performance of BMD and RTA in the task of distinguishing between patients with and without vertebral fractures. A resubstitution (self consistency) method was used to determine an upper bound in the performance and a leave-on-out jackknife method was used to determine the robustness of the method.
Az values (area under the ROC curve) of 0.59, 0.65, 0.54 were obtained for spine, hip, and heel BMD alone, respectively in the task of differentiating cases without and with a vertebral fracture. Compared to BMD values alone, texture analysis using a Bayesian neural network to characterise the fractal nature of the radiographic trabecular pattern after preprocessing (Az = 0.78, resubstitution; Az = 0.70, leave-one-out jackknife) was better than spine, hip, and heel BMDs with p-values less than 0.05 (in resubstitution) and with p-values of 0.16, 0.53, 0.08, for spine, hip, and heel, respectively (in the jackknife evaluation).
In conclusion, RTA has the potential to perform as well as hip BMD (and better than heel BMD) in the task of predicting those at risk for vertebral fracture. Continued improvement is expected as new filters and larger databases are obtained.

Variation of Site-Specific Trabecular Bone Architecture in Regions Requiring Tendon-to-Bone Healing. D. J. Adams, S. A. Santangelo*. Orthopaedic Surgery, University of Connecticut Health Center, Farmington, CT, USA.

Tunnels are drilled into or cored from trabecular bone routinely for surgical repair of tendons and ligaments torn at their osseous insertion, as well as for reconstructing intra-articular tissues with tendon grafts; e.g., the cruciate ligaments of the knee. The initial integrity of fixation and subsequent bone-tendon healing are dependent on the integrity of bone surrounding the tunnel. With the advent of high-resolution micro-computed tomographic imaging (μCT), it is possible to quantify the three-dimensional architecture of bone cores removed during surgical procedures.

In this study, μCT imaging at 15 μm resolution and bone densitometry via high-resolution QCT were used to measure trabecular morphometry and volumetric bone density (mg/cm^3) of 10 mm diameter cylindrical trabecular cores removed at tibial tunnel sites of 19 subjects undergoing surgical reconstruction of a torn anterior cruciate ligament (14-57 years old, 7 male, 12 female). Morphometric measurements were computed for the entire three-dimensional field and subregions of the cores. To estimate the morphometric integrity of the remaining tunnel wall (the interface with tendon and fixation), an outer annulus of each cylindrical core image was "unrolled" computationally, providing images of the host tunnel walls. From this subset of two-dimensional image data, the architectural integrity of the receiving tunnels also was quantified.

Full-field measurements of trabecular bone volume fraction and density from the spectrum of subjects revealed a 2.5-fold range in magnitude at longitudinally matched sites within the cylindrical cores (26-64 % and 147-366 mg/cm^3, respectively), differences that were associated with variation in both trabecular thickness and number. Density of the trabecular bone tissue itself, excluding marrow space, revealed site-matched variation ranging 44% (e.g., 423 – 608 mg/ cm^3). Measurements at the tunnel wall, the region of host bone that would appose tendon in the initial phase of tendon-to-bone healing, revealed a smaller range in bone area fraction of 26-38%.

Morphometric data obtained in this and future micro-imaging studies of otherwise discarded bone samples can accurately quantify the integrity of surgical site-specific trabecular architecture. The information obtained is particularly helpful toward elucidating the interaction of surgical hardware and tissue grafts with host bone, as well as for choosing animal models of tendon-to-bone healing and validating benchtop models of fixation performance. Interfacial bone surface area available at the tunnel wall may also influence the initial rate of tendon-to-bone integration and subsequent functional outcome.

Disclosures: ***D.J. Adams****, None.*

Serum Tartrate-resistant Acid Phosphatase 5b as a Marker of Bone Metastases in Prostate Cancer. S. L. Alatalo*[1], M. Ala-Houhala*[2], J. Korpela*[2], J. M. Halleen[1], H. K. Väänänen*[1], A. Koskinen*[3], H. Helenius*[3], E. Salminen*[2]. [1]Institution of Biomedicine, Department of Anatomy, University of Turku, Turku, Finland, [2]Department of Oncology, University Hospital, University of Turku, Turku, Finland, [3]Biostatistics, University of Turku, Turku, Finland.

Tartrate-resistant acid phosphatase 5b (TRACP 5b) is a bone resorption marker secreted by osteoclasts during bone resorption. The purpose of this cross-sectional study was to evaluate the potential value of serum TRACP 5b as a marker of bone metastases in prostate cancer. Serum levels of TRACP 5b, total alkaline phosphatase (AFOS), and prostate specific antigen (PSA) were measured from 131 prostate cancer patients. Based upon scintigraphic and radiological findings and clinical follow-up the patients were divided into two groups: patients with verified single or multiple bone metastases (N = 25) and patients without bone metastases (N = 106). Bone marker levels were correlated with the presence or absence of bone metastases. Serum TRACP 5b activity was measured with a solid-phase immunofixed enzyme activity assay. Comparison between groups was done with the non-parametric Wilcoxon's test. Patients with bone metastases group had higher TRACP 5b level 7.81 ± 5.5 U/l compared with patients without bone metastases 3.39 ± 1.24 U/l ($p<0.0001$). The mean serum levels of AFOS were 1152 ± 1614 U/l and 164 ± 49 U/l, respectively ($p<0.0001$), and PSA 328 ± 161 and 12.7 ± 31.9 ($p<0.0001$). Data showed strong association between serum TRACP 5b and bone metastases, and the correlation between TRACP 5b and AFOS was statistically significant, Spearman coefficient 0.556, $p<0.0001$. The clinical specificity of TRACP 5b (percentage of prostate cancer patients without bone metastases within reference values) was 94.3 % (100/106), and the clinical sensitivity (percentage of prostate cancer patients with bone metastases above reference values) was 60.0 % (15/25). These results suggest that serum TRACP 5b is a powerful marker of bone metastases in prostate cancer patients with radiological skeletal metastases. Its role in prediction of dormant bone metastases needs further prospective studies.

Serum Tartrate-resistant Acid Phosphatase 5b and Osteocalcin in Naturally Occurring Osteopetrotic Rats. S. L. Alatalo*[1], K. K. Ivaska*[1], Z. Peng[1], J. M. Halleen[1], S. C. Marks*[2], H. K. Väänänen*[1]. [1]Institute of Biomedicine, Department of Anatomy, University of Turku, Turku, Finland, [2]Department of Cell Biology, University of Massachusetts Medical Center, Worcester, MA, USA.

Three different naturally occurring osteopetrotic rat strains have been identified; toothless (tl/tl), containing severely reduced number of osteoclasts with normal ruffled borders, osteopetrotic (op/op), containing slightly reduced number of osteoclasts with poorly developed ruffled borders and incisors absent (ia/ia), containing markedly increased number of osteoclasts without ruffled borders. The tl/tl mutation is a defect in colony-stimulating factor (CSF-1 or M-CSF), but the mutations in op/op and ia/ia rats are still unknown. We measured the bone resorption marker tartrate-resistant acid phosphatase 5b (TRACP 5b) and the bone formation marker total osteocalcin from the serum of 2-week-old osteopetrotic rats and their normal littermate controls (nlm). The results are shown in table 1. TRACP 5b was significantly decreased and osteocalcin significantly increased in tl/tl rats, while both markers were unchanged in op/op rats. In ia/ia rats, TRACP 5b was significantly increased and osteocalcin unchanged. In vitro osteoclast cultures were made from long bones of 1- to 4-day-old ia/ia rat pups. Despite of their inability to resorb bone, osteoclasts from ia/ia rats secreted more TRACP 5b into the culture medium than osteoclasts from nlm controls. TRACP 5b activities in the soft tissues (liver, spleen and lungs) of adult ia/ia rats were normal, which suggests that serum TRACP 5b originates form osteoclasts. Osteopetrotic phenotype in ia/ia rats was sustained up to 8 months of age, studied by peripheral quantitative computed tomography (pQCT). These results suggest that in various osteopetrosis rat strains, secreted TRACP 5b might reflect the number of osteoclasts rather than their activity. Osteocalcin measurements suggest that bone formation is increased in tl/tl rats but not affected in op/op or ia/ia rats.

Table 1. Serum TRACP 5b and osteocalcin levels in tl/tl, op/op, and ia/ia rats

Mutation	n	TRACP 5b (U/L) (mean ± SD)	Osteocalcin (ng/ml) (mean ± SD)
tl/tl	10	2.7 ± 0.4***	32.7 ± 2.7**
nlm	10	118.4 ± 29.5	26.0 ± 4.7
op/op	4	100.4 ± 16.2	27.0 ± 3.5
nlm	4	115.25 ± 6.7	29.0 ± 6.9
ia/ia	7	482.6 ± 76.1***	22.8 ± 3.2
nlm	6	122.2 ± 18.1	19.7 ± 3.1

A Novel Precise and Sensitive Method for the Determination of Vitamin K Homologues in Human Plasma Using High-Performance Liquid Chromatography-Tandem Mass Spectrometry (LC/MS/MS). Y. Suhara*, M. Kamao*, N. Tsugawa*, T. Okano. Department of Hygienic Sciences, Kobe Pharmaceutical University, Kobe, Japan.

Vitamin K is believed to be involved in posttranslational modification of the bone matrix protein osteocalcin and its insufficiency is frequently associated with low bone mineral density (BMD) and higher incidence of hip-fracture. Assessment of vitamin K status can be achieved by measuring plasma levels of either vitamin K or undercarboxylated osteocalcin that is predictive of vitamin K deficiency. There was, however, no direct evidence that undercarboxylated osteocalcin is involved in impaired bone mineralization in vitamin K deficiency. Therefore, measurement of vitamin K is as of now the preferred method for establishing a basis for the treatment and prevention of osteoporosis with vitamin K. Plasma vitamin K levels are usually extremely low and require a highly sensitive method for the assay. High-performance liquid chromatography (HPLC) using either a combination of platinum oxide catalyst reduction with fluorescence detection or electrochemical detection has been employed for this purpose, but the separation of concomitants existed in blood samples from vitamin K homologue, especially menaquinone-4, is sometimes difficult in these assays. We report here the development of a novel precise and sensitive method for the determination of vitamin K homologues including phylloquinone, menaquinone-4 and menaquinone-7 in human plasma using HPLC-tandem mass-mass spectrometry with atmospheric-pressure chemical ionization (LC/MS/MS-APCI). The method includes the use of stable isotope (^{18}O) labeled internal standard compounds that were synthesized in our laboratory and the selection of precursor and product ion with a MS/MS multiple reaction monitoring method. Average intra-assay and inter-assay variations (CV) for PK, MK-4 and MK-7 were <10 %. Average spiked recoveries from authentic compounds added to normal human plasma samples for PK, MK-4 and MK-7 were 98-102 %. Mean plasma concentrations of PK, MK-4 and MK-7 from unselected healthy subjects (n=20) were 1.39±0.86 ng/mL, 3.22±0.57 ng/mL and 6.37±7.45 ng/mL, respectively. We conclude that this novel LC/MS/MS-APCI method should be useful for the evaluation of vitamin K status in postmenopausal women and elderly subjects and provides useful information for the treatment and prevention of osteoporosis with vitamin K.

Validation of the ELISA CrossLaps™ Assay for the Quantification of C-Terminal Telopeptides in Dog Urine. J. Mayer*, P. Oldfield, A. Bartlett*, S. Y. Smith. CTBR, Montreal, PQ, Canada.

The purpose of this study was to validate an assay for bone resorption in dogs. The CrossLaps enzyme-linked immunosorbent assay (ELISA) was validated for the determination of C-terminal telopeptides of type-1 collagen (CTx) in dog urine. This test is designed to measure collagen type-1 fragments generated by osteoclast activity. Its use will be important in the preclinical testing of medicinal products to support osteoporosis, arthritis

and toxicology studies in which dogs are frequently used and where bone resorption is a required end-point.
The assay is performed using the CrossLaps ELISA kit (cat. no: ICRL-4000, Nordic Bioscience Diagnostics, Denmark). The wells of the plate are pre-coated with a synthetic CrossLaps to which calibrators and quality controls are added followed by the anti-CrossLaps and allowed to incubate. The wells are washed, followed by the addition of the second antibody conjugated with peroxidase, and after further incubation followed by a washing step, a chromogenic substrate is added. The reaction is subsequently stopped using sulfuric acid and the absorbance at 450 measured.
The lower limit of quantitation (LLOQ) of the assay was 248 µg/L. The method has been shown to be highly specific for the determination of bone-related degradation products from C-terminal telopeptides of type I collagen in dog urine. Accuracy and precision are summarized as follows:

QC Sample	Intra-assay	(3 times n=6)	Inter-assay (n=18)	
(µg/L)	CV (%)	Recovery (%)	CV (%)	Recovery (%)
248	9.4-18.9	93.8-104.8	15.1	100.6
552	3.7-8.2	118.0-120.8	5.6	119.9
1104	5.0-6.1	102.2-124.0	9.6	113.4
2208	7.4-9.6	87.2-109.6	12.5	100.0
5037	3.4-5.9	87.5-108.1	10.1	100.0

CTx was shown to be stable in dog urine after three freeze-thaw cycles, at room temperature for at least 6 hours, and at 4°C for at least 23 hours. Long-term storage stability at -20°C is currently on-going.
The use of the CrossLaps assay has been validated for the determination of CTx of type-1 collagen in dog urine. This assay provides a sensitive tool to monitor bone resorption and the effect of bone active agents on resorption activity.

Disclosures: ***J. Mayer****, None.*

Urinary Gamma-Glutamyl Transpeptidase (GGT) Activity Measurement Is Useful as a New Biochemical Marker for Bone Resorption. I. Kodama, M. Sanada*, M. Tsuda*, K. Ohama*. Obstetrics and Gynecology, Hiroshima University, Hiroshima City, Japan.

The purpose of this study is to investigate the measurement of urinary gamma-glutamyl transpeptidase (GGT) activity is useful as a biochemical marker for bone resorption in postmenopausal women.
A total of 45 postmenopausal Japanese women, aged 48 to 57 years, were admitted to study. Each subject had experienced natural menopause for at least 1 year but not longer than 5 years. All participants were followed up for 12 months of without any lifestyle modification. A total of 26 women (mean age 52.3±1.3) received conjugated equine estrogen (Premarin), 0.625 mg daily each morning for 12 months. Urinary cross-linked N-telopeptides (NTx), GGT activity and serum GGT activity were measured on all subjects before the start of therapy and for 3, 6 and 12 months after therapy. Lumber spine (L2-L4) bone mineral density (BMD) and femoral neck BMD were measured using a dual X-ray absorptiometer (Lunar DPX). These parameters were measured on all subjects before the start of therapy and for 6 and 12 months after therapy.
Correlation between urinary GGT activity and NTx were significant at before the start of therapy, and those relations were being maintained within the period of therapy.
L2-L4 BMD was increased after the start of the HRT, averaging +3.23% and +5.88%, at the 6 months and 12 months, respectively.
Femoral neck BMD was slightly increased compared with baseline value, averaging +0.98 % and +1.96 %, at the 6 months and 12 months after HRT (statistically not significant). In conclusion, we now report that urinary GGT activity measurement is useful as a new biochemical marker for bone resorption.

Bone Mineral Density and Bone Biochemical Markers in Lupus and Control Women Stratified by Menopause Status. A. B. Chadha[1], E. Shamiyeh*[1], C. Langman[2], H. Price*[2], S. Spies*[1], R. Ramsey-Goldman[1]. [1]Feinberg School of Medicine, Chicago, IL, USA, [2]Childrens' Memorial Hospital, Chicago, IL, USA.

Over the past 2 decades improved survival of lupus women (LW) lead researchers to focus on minimizing morbidity associated with disease and its treatment. Of the various complications facing women with lupus, osteoporosis remains a continuing challenge for clinicians. The goal of this study was to determine if bone mineral density (BMD) correlated with bone biochemical markers (BBM) in LW and control women (CW) matched for age, race, and menopause status. In this cross-sectional study, data collected included: a lifestyle questionnaire and medication survey, BMD of the hip, spine, and distal forearm, urine for N-telopeptide (NTx), and serum for Osteocalcin (OC), and bone alkaline phosphatase (BAP). 80 pairs were studied, 33 postmenopausal (PM) and 47 still menstruating (M). The mean age of LW and CW was 44.3 years, (SD 11.7) and 44.5 years, (SD 11.3) respectively; the mean disease duration for LW was 9.3 years, (SD 8.3). The mean age of menopause was 41.3 years, (SD 7.8) for LW and 44.4 years, (SD 5.8) for CW (NS). When stratified by menopause status, BMD was lower in M LW vs. CW at the hip (0.927 vs. 0.944 g/cm^2) and spine (1.020 vs. 1.047 g/cm^2), and in PM LW vs. CW BMD was lower at the hip (0.848 vs. 0.852 g/cm^2), spine (0.937 vs. 0.982 g/cm^2) and distal forearm(0.645 vs. 0.673 g/cm^2).
There were no significant differences in median BBM between LW and CW stratified by menopause status (data not shown). In PM LW multiple BBMs correlated with BMD at various sites: higher NTx with lower BMD at the hip (r= -0.550, p= 0.001) and spine (r= -0.419, p= 0.02), higher BAP with lower BMD at the hip (r= -0.436, p=0.012) and distal forearm (r= -0.376, p= 0.04), and higher OC with lower BMD at the hip (r= -0.492, p= 0.004). In PM CW multiple BBMs also correlated with various BMD sites: higher NTx with lower BMD at the hip (r= -0.367, p= 0.04), spine (r= -0.346, p= 0.05), and distal forearm (r= -0.518, p= 0.002), higher BAP with lower BMD at the distal forearm (r= -0.609, p= 0.0002), and higher OC with lower BMD at the distal forearm (r= -0.482, p= 0.005). In M LW, higher NTx (r= -0.295, p= 0.05) and BAP (r= -0.336, p=0.02) correlated with lower BMD at the distal forearm. In contrast, in M CW there were no correlations between BBM and BMD. LW had lower BMD than CW at most sites regardless of menopause status. Higher BBMs were associated with lower BMDs in PM and M LW, and only PM CW suggesting higher bone turnover in these groups. Measuring BBMs in addition to BMD many help identify LW at risk for low BMD, especially young M LW. Future studies include longitudinal analysis of LW at baseline and two years and determining weather baseline BBMs are predictors of future BMD.

A Comparative Study of Volumetric, CTx-beta and Helical Peptide Resorption Assays. S. A. Nesbitt, B. M. Nicholls*, G. T. Charras*, M. A. Horton. Medicine, UCL, London, United Kingdom.

Many clinical diagnostic kits monitor skeletal turnover by analysing collagen degradation products. Herein, using an in vitro model, we have used CTx-beta (CTx) and Helical peptide (HP) ELISA assays to measure resorption and compared them with volumetric changes in resorption pits.
Rabbit osteoclasts were cultured on dentine slices for 1, 3, 7 and 10 days and also for 3 days with resorption regulators at doses that altered resorption while maintaining cell numbers (0.05 mM E-64, a cathepsin K inhibitor; 0.1 mM alendronate, a bisphosphonate; 25 nM kistrin, an integrin antagonist; 50 pM TIMP1 protein, a matrix metalloproteinase inhibitor). Resorption culture media were assessed for CTx (Nordic BioSciences, Denmark) and HP (Quidel, USA) by ELISA. Volumetric analysis of 13,589 stained resorption pits was done with an established in-house assay using 3D immunofluorescence confocal microscopy. Percentage changes were calculated from controls and assessed by Mann-Whitney statistics (n = 9-18).
The volumetric and ELISA assays detected significant changes ($p < 0.05$) for resorption in all experiments, except for HP using TIMP1. However, the resorption percentages varied between the assays. Firstly, resorption measured by time with the ELISAs (rows 2-4) showed greater increases (3-20 fold). These data suggest additional processing of the collagen matrix is occuring after resorption. Secondly, the ELISAs produced variable results for the resorption regulators (rows 5-8). Thus, biochemical changes in the resorbed matrix given by the regulators can produce an underestimate (eg. CTx with alendronate, TIMP1 with CTx and HP) or an overestimate of resorption (eg. kistrin with HP) when compared to the volumetric analysis.
In summary, these data suggest that several markers of bone resorption should be used in clinical diagnosis and treatment to account for the variability of measurements given by different ELISA assays.

Resorption % Changes (* relative to day 1, ** relative to day 3 without compounds)

	% Volume change	% CTx change	% Helical peptide change

Alternate Immunoassay for Tartrate-Resistant Acid Phosphatase 5b Activity. R. M. Simons*[1], A. J. Janckila[2], L. T. Yam*[1]. [1]Medicine, University of Louisville, Louisville, KY, USA, [2]Medicine, VAMC, Louisville, KY, USA.

Objective: Osteoclastic tartrate-resistant acid phosphatase (TRACP) isoform 5b may be useful as a serum marker of bone turnover. Immunoassays (EIA) in use for serum TRACP using p-nitrophenyl phosphate (pNPP) as substrate are not entirely specific for TRACP isoform 5b. Our purpose was to develop an alternate immunoassay for TRACP using naphthol ASBI-phosphate (ASBI-P) as a selective substrate for isoform 5b and heparin as a selective inhibitor of isoform 5a.
Methods: Partially purified serum TRACP 5a and 5b were used to determine optimal reaction conditions for TRACP 5b with ASBI-P and heparin. TRACP immunoassay with ASBI-P was then standardized in terms of linearity, analytical recovery, sensitivity and reproducibility. To measure specificity of bone resorption, TRACP levels were correlated with those of bone alkaline phosphatase (BAP) and N-telopeptides of type-I collagen

(NTx) in both end-stage renal disease (ESRD) and rheumatoid arthritis (RA) sera.
Results: Optimum TRACP 5b activity was achieved at pH 6.3 with 10mM ASBI-P and 25 U/mL heparin. The relative biochemical specificity for isoform 5b was greater than 2-fold higher using ASBI-P compared to pNPP. The specificity increased a further 2-fold when heparin was included into either substrate solution. TRACP Immunoassay using ASBI-P followed a quadratic dose-response curve from 0 to 25 U/L with a least detectable limit of 0.24 U/L. The analytical recovery over the range of the assay was 76% with an average coefficient of variation of 16.6%. ASBI-P-based immunoassays of sera from both RA and ESRD correlated highly with standard pNPP EIA (r=0.94). TRACP EIA using ASBI-P and pNPP correlated significantly and to the same degree with BAP and NTx in both RA and ESRD cohorts.
Conclusions: ASBI-P is biochemically more specific for TRACP isoform 5b than pNPP and has equivalent sensitivity. However, in practice, TRACP 5b activity in sera measured with either substrate correlates with other bone turnover markers approximately equally. Larger studies of different diseases are required to determine if this alternate TRACP assay offers significantly greater diagnostic specificity over the well-established assay for osteoclastic TRACP 5b.

Comparison of Serum Tartrate-resistant Acid Phosphatase 5b with Other Markers of Bone Turnover in Monitoring Alendronate Therapy. J. M. Halleen[1], A. M. Nenonen*[2], S. L. Alatalo*[3], K. K. Ivaska*[3], S. Cheng[4], H. Schmidt-Gayk*[5], K. Uusi-Rasi*[2], A. Heinonen[2], P. Kannus*[2], H. Sievänen*[2], K. Väänänen*[3]. [1]Pharmatest Services Ltd, Turku, Finland, [2]The UKK Institute for Health Promotion Research, Tampere, Finland, [3]Institute of Biomedicine, University of Turku, Turku, Finland, [4]Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland, [5]Department of Endocrinology and Oncology, Laboratory group, Heidelberg, Germany.

The purpose of this study was to compare serum tartrate-resistant acid phosphatase isoform 5b (TRACP 5b) with other markers of bone turnover in monitoring alendronate therapy. This double-blinded study included 164 healthy postmenopausal women that were randomly assigned into two groups, one receiving 5 mg alendronate daily, and the other receiving placebo. All subjects received calcium and vitamin D daily. The resorption markers serum TRACP 5b, serum C-terminal crosslinked telopeptides of type I collagen (CTX), total urinary deoxypyridinoline (DPD), and the serum formation markers procollagen I N-terminal propeptide (PINP), bone-specific alkaline phosphatase (BAP), and total osteocalcin (OC) were assessed at baseline and at 3 months after start of treatment. Bone mineral density (BMD) of the lumbar spine was measured at baseline and at 12 months. Compared with the placebo-group, BMD increased and the markers decreased significantly more in the alendronate-group ($p<0.001$ for each parameter). Least significant change (LSC) was determined for each marker based on its analytical and biological variability. Those subjects that showed a decrease of more than LSC were defined as responders for the treatment. Clinical specificity was determined as the relative amount of non-responders in the placebo-group, and clinical sensitivity as the relative amount of responders in the alendronate-group. The results are summarized in table 1. The column "combined" shows values obtained by multiplying the specificity of each marker with its sensitivity. The highest combined values were obtained for TRACP 5b (0.74) and PINP (0.72). These results suggest that serum TRACP 5b is a specific and sensitive marker for monitoring alendronate treatment.

Table 1: Bone markers in alendronate therapy

Marker	LSC (%)	Specificity	Sensitivity	Combined
TRACP 5b	29,0	0,90	0,82	0,74
PINP	33,8	0,83	0,87	0,72
CTX	60,8	1,00	0,63	0,63
DPD	30,7	0,92	0,61	0,56
OC	19,4	0,70	0,75	0,53
BAP	25,1	0,93	0,55	0,52

CTX and Osteocalcin in a Simple Model for Improved Assessment of Skeletal Response to Hormone Replacement Therapy. P. Qvist[1], I. Byrjaldsen*[1], C. Christiansen[2]. [1]Nordic Bioscience, Herlev, Denmark, [2]Center for Clinical and Basic Research, Ballerup, Denmark.

Biochemical markers of bone turnover have been applied for monitoring of anti-resorptive therapy partly because they, in contrast to image technologies, respond rapidly to medical intervention. Several studies have demonstrated that early change in markers following anti-resorptive therapy predict treatment efficacy as assessed by measurements of bone mineral density over several years. The objective of the present study was to investigate if a combined model using both a bone resorption and a bone formation marker could improve accuracy and consistency in the prediction of the long-term skeletal effect of hormone replacement therapy in postmenopausal women.
Two hundred seventy-eight healthy women within 1-6 years after menopause were included in a double-blind, three year monocenter study of treatment with various doses of 17β-estradiol + gestodene or placebo (Bjarnasson et al., 2000). One hundred and fifty three women completed the study and 135 of those were available for the present analysis.
With cut offs defined as 1%, 35% and 25% for αBMD, CTX and Osteocalcin, respectively, the combined biochemical model, requiring a response in either the resorption or the formation marker, provided sensitivities and specificities in the range 68-95%, for prediction of BMD response and 91-100% for prediction of compliance. This was similar to CTX alone. However, the analysis demonstrated higher sensitivities of the combined model at the 12 months visit, also reflected in an increase in the consistency of the response status reported by the combined biochemical model between the 6 and 12 months visit.

Model	Visit	Prediction of BMD response		Prediction of compliance (HRT vs placebo)		Biochemical Response Consistency	
	(months)	SEN (%)	SPE (%)	SEN (%)	SPE (%)	RESP: (%)	NON-RESP. (%)
Combined Model	6	94.1	76.4	93.9	91.9		
	12	95.2	68.6	96.9	97.3	97.9	90.2
CTX alone	6	94.0	72.5	93.9	97.3		
	12	90.5	76.5	89.8	100.0	91.4	90.2

Fragments of C-telopeptides of Type I Collagen (CTX) Are Stable in Serum and Plasma Samples during Storage at Low Temperatures for Three Years. P. Qvist[1], N. From*[1], M. Munk*[1], N. Hoyle*[2], C. Christiansen[3]. [1]Nordic Bioscience, Herlev, Denmark, [2]Roche Diagnostics, Penzberg, Germany, [3]Center for Clinical and Basic Research, Ballerup, Denmark.

BACKGROUND: Control of pre-analytical variables is essential for successful application of biological markers, including bone resorption markers, in clinical trials and routine use. The effect of storage temperature on stability of bone resorption markers have not been subject of systematically investigation, and therefore the present study determined the stability of serum CTX in frozen serum and plasma samples stored for three years. METHODS: Serum and EDTA plasma samples were aliquoted and stored at -20°C, -80°C or -150°C until testing for CTX by the microtitre plate or the automated ElecSys formate of the Serum CrossLaps test..RESULTS: No decrease in CTX could be detected in neither serum nor plasma samples after three years of storage at -20°C, -80°C or -150°C, as recoveries were in the range 87-126% compared to baseline. CONCLUSIONS: CTX is stable in frozen serum and plasma samples for at least three years.

Exclusion of 5 Candidate Genes for Familial Benign Hypercalcaemia, Type 3, Located on Chromosome 19q13. J. J. O. Turner[1], J. M. Stacey*[1], M. P. Whyte[2], R. V. Takker[1]. [1]Nuffield Department of Medicine, Oxford University, Oxford, United Kingdom, [2]Center for Metabolic Bone Disease and Molecular Research, Shriners Hospitals for Children, St. Louis, MO, USA.

Familial benign hypercalcaemia (FBH), also referred to as familial hypocalciuric hypercalcaemia (FHH), is a genetically heterogeneous disorder that consists of three types designated, FBH1, FBH2 and FBH3 whose chromosomal locations are 3q21-q24, 19p13.3 and 19q13, respectively. FBH1 is caused by mutations of the calcium sensing receptor (CaSR), but the abnormalities underlying FBH2 and FBH3 are unknown. FBH3, also referred to as the Oklahoma variant (FBHOk), has been mapped to a 10 centimorgan (cM) interval on chromosome 19q13 flanked centromerically by D19S112 and telomerically by D19S317. This interval contains over 100 genes and we have utilised a bioinformatics approach to identify candidate genes based on tissue expression patterns and likely functions of the encoded proteins. This revealed 5 potential candidate genes and DNA sequence analysis of the coding regions and intron/exon boundaries of each of these 5 genes was undertaken using leukocyte DNA from an affected and an unaffected family member. These 5 candidate genes consisted of:1) Histidine Rich Calcium Binding protein (HRC) which has 6 exons and a coding region of 2.1 Kb, and is expressed in muscle and kidney, with a role in intra-cellular calcium binding; 2) rRAS which has 6 exons and a coding region of 0.6 Kb, and is expressed ubiquitously, with a role as a GTPase; 3) G-protein receptor 4 (GPR4) which has 1 exon and a coding region of 1.1 Kb, and is expressed in kidney and lung, with a possible role as a Sphingosylphosphorylcholine receptor; 4) Pleckstrin Homolgy Sec7 Coiled Domain 2 protein (PSCD2) which has 12 exons and a coding region of 1.2 Kb and is expressed ubiquitously, with a role as a cellular adhesion molecule; 5) Tuberoinfundibular peptide of 39 amino acids (TIP39) which has 2 exons and a coding region of 0.1 Kb and is expressed in the CNS and kidney, with a role as a PTH receptor antagonist. DNA sequence analysis did not detect any FBH3-associated mutations involving these 5 candidate genes, but 5 polymorphisms (3 for rRAS and 2 for HRC) with allele frequencies ranging from 24% to 48% were found. Thus, our studies have excluded these 5 candidate genes for FBH3. The identification of the gene causing FBH3 will help to facilitate the characterisation of another CaSR or a mediator of calcium homeostasis.

Functional Phenomics of Bone: High-throughput Determination of Bone Strength. G. H. van Lenthe*[1], T. Kohler*[1], L. R. Donahue[2], R. Müller[1]. [1]Swiss Federal Institute of Technology (ETH) and University of Zurich, Zurich, Switzerland, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

It has been shown that bone strength is under genetic control and that it is a polygenic trait. To elucidate one pathway of skeletal genetic regulation, our long-term goal is to identify genes that regulate bone strength independent of growth hormone (GH) and insulin-like growth factor-1 (IGF-1). We have recently used a spontaneous mutation in the mouse, known as *little*. In *lit/lit* mice (on C57BL/6J background), GH is not detectable, IGF-1 is fixed at low levels, and bone strength is reduced. In a congenic *little* mouse (*little* transferred on C3H/HeJ background; C3.B6-*lit/lit*) we have shown that bone phenotype can vary independently of IGF-1. By crossing these two strains regulatory loci for adult bone strength can be located, provided that both genotype and phenotype can be assessed accurately. Although huge progress has been made for fast acquisition of genomic information, only few approaches have dealt with increasing throughput for phenotypic characterization, let alone for characterization of bone function. Therefore, the aim of this study was to develop and validate analysis tools needed to automatically determine bone phenotype at a functional level.

Using micro-computed tomography, we accurately measured complete femora of males and females of the two parental strains and their heterozygous (*lit/+*) littermates. Microstructural finite element models were created by direct voxel conversion; loading conditions resembled single-legged stance. The elastic behavior of the bone models was correlated to real mechanical tests of femoral neck failure.

The results of our analysis showed that bone stiffness could be determined from mechanical simulations in a fast and fully automated fashion. We found many distinct differences amongst the GH deficient parental strains as well as between the *lit/lit* and *lit/+* littermates. Those differences seemed to be gender specific and were more pronounced on the tissue level than the apparent level.

In conclusion, in this study we have developed a *functional phenomics* approach, a nondestructive technique for high-throughput characterization of bone function. We believe this to be a critical step in determining bone-strength related genes, as direct mechanical testing of these very small femora will be extremely demanding; furthermore, it allows for automated characterization for the large numbers of bones typically required for genetic linkage studies. Additionally, this novel approach will be crucial to interpret results from upcoming small animal *in vivo* imaging systems, where destructive testing cannot be performed but individual bone strength can be assessed over time.

False Positive Rates in Association Studies as a Function of Degree of Admixture. D. L. Koller[1], M. Peacock[2], T. Foroud[1], M. J. Econs[2]. [1]Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Medicine, Indiana University School of Medicine, Indianapolis, IN, USA.

Studies of association between a genetic polymorphism in a candidate gene and bone-related traits such as BMD and fracture are commonly performed in order to identify genes that influence these traits. It is not clear how results from these studies should be interpreted. For example, population stratification or racial admixture can cause false positive results when the population sampled contains two or more subpopulations, usually unobservable, that differ in both polymorphism allele frequency and trait value.

To explore the degree to which stratification can cause spurious positive association results, we used an unrelated sample of 381 Caucasian and 126 African-American females with femoral neck BMD measured by DEXA and 373 microsatellite markers genotyped. Each multi-allelic marker was reduced to a bi-allelic marker for simplicity of interpretation, using the most common allele as one allele and binning all other alleles as the second allele. The mean allele frequency difference between Caucasians and African-Americans for the 373 reduced bi-allelic markers was 0.1. African-Americans have higher mean BMD than Caucasians, and in our sample the African Americans had one-half standard deviation higher mean BMD. Samples were generated with increasing degrees of Caucasian/African-American admixture, with 0%, 1%, 2%, 5%, 10%, 15%, and 20% African-American subjects in the total sample. An ANOVA test of association of BMD with the three marker genotypes (1/1, 1/2, 2/2) was performed in each admixed sample for each of the 373 markers. The rate of positive results for the association test were observed to double as the proportion of admixture increased, with substantial increases even for amounts of admixture as small as 2-5%. These results demonstrate the great importance of controlling for racial admixture where the trait and the allele frequency of the races are different. They also suggest that unobserved admixture may lead to an increase in the nominal false positive rate of an association test.

An ENU Mutant Mouse Characterized by the Combination of a Dcerease in Bone Size and Increase in Fat Mass with Evidence of Gender Differences. A. K. Srivastava, S. Mohan, J. Wergedal, D. J. Baylink. Musculoskeletal Disease Center, J. L. Pettis VAMC, Loma Linda, CA, USA.

The N-ethyl-N-nitrosourea (ENU) mouse mutagenesis provides a powerful platform for gene function studies. In our ENU mutagenesis screen for dominant musculoskeletal phenotypes using a C57BL/6J (B6) strain of mice, a phenodeviant was discovered which exhibited a highly significant decrease in bone size attended by an increase in fat mass. This mutant phenotype was confirmed in two generations of inheritance-test crosses with wild type B6 females. The affected progeny from inheritance-tests have 8-9% lower body weight. However, three main parameters that assess bone size such as bone area, bone mineral content (BMC), and periosteal circumference were all significantly lower in affected mice even after adjustment for decreased body weight as shown in the table. Interestingly, the total body bone area phenotype was consistently expressed in males (92% affected), whereas only 6% of females exhibited the phenotype (partial). The males with decreased bone size also showed a 15-20% increase ($p<0.01$ both at 10-weeks and 16-weeks age) in fat mass and a 10% decrease in lean mass, as compared to age and sex matched control male mice. The normal WT B6 males have 10-20% higher bone area ($p<0.0001$) and 6% lower fat mass ($p<0.05$) compared to WT B6 females, whereas mutant males were similar to females littermates in total body bone area (8.79 cm^2 in male Vs 8.96 cm^2 in females, $p>0.05$) and a similar (slightly higher) percent fat mass (15.4% in male Vs 14.0% in female, $p<0.05$). These compositional changes in male mutant mice indicate that the mutant gene may regulate gender differences in bone size and fat mass. In conclusion: 1) a germ line mutant mouse with reduced bone size and increased fat content has been identified using genome wide ENU mutagenesis screen for musculoskeletal disorders; 2) gender specific differences in bone size and fat mass were observed in progeny from a mutant mouse; and 3) based on the past findings, we speculate that mutation may involve the gene(s) pathway accounting for male/female differences in bone size and fat mass.

Mean difference in BW adjusted bone area parameters in 16-week old phenodeviant mice compared to WT

Evidence for Genetic Regulation of Bone Loss Following Ovariectomy in Mice. K. S. Myers*[1], W. G. Beamer[2], K. L. Shultz[2], L. R. Donahue[2], V. Glatt*[1], C. J. Rosen[2], M. L. Bouxsein[1]. [1]Orthopedic Biomechanics, Beth Israel Deaconess Med Ctr, Boston, MA, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

Bone loss following the menopause is variable, with some individuals showing dramatic and rapid bone loss and others appearing relatively resistant to bone loss induced by estrogen deficiency. Whereas it is clear that genetic factors play an important role in determining many skeletal characteristics, including peak bone mass, bone size and bone turnover, less is known about the genetic contributions to age- and menopause-related bone loss [Garnero, JCEM 1996; Li, ASBMR 2002; Beamer, ASBMR 2002]. Thus, we used inbred mouse strains to test the hypothesis that genetic factors play a role in determining bone loss associated with estrogen deficiency. Female mice from five inbred strains (C57Bl/6J (B6), C3H/HeJ (C3H), BALB/cByJ (Balb/c), DBA/2J (DBA) and Castaneus (CAST)) were ovariectomized (OVX) or sham-operated at 4 months of age and euthanized one month later (n=5 to 9 per group). OVX was confirmed by uterine weight at necropsy. Bone loss was assessed by μCT at the mid-femur, 5th lumbar vertebrae and proximal tibia. As shown before, bone density in the sham mice varied with strain ($p<0.0001$ for strain-effect at all trabecular sites). Vertebral trabecular BV/TV (V.BV/TV) was highest in BALB/c (34.2± 1.4%), intermediate in B6 (23.5 ± 0.6%) and DBA (21.7± 1.5%), and lowest in C3H (14.5 ± 1.5%). In comparison, tibia trabecular BV/TV (T.BV/TV) was highest in BalbC and C3H (17.3 and 15.2%, respectively), intermediate in B6 (4.0 ± 0.3%) and DBA (3.6 ± 0.2%), and lowest in CAST (1.5 ± 0.4%). Femoral cortical thickness (CortTh) was highest in C3H (387±6 μm), intermediate in BalbC (278±7 μm) and Cast (302±8 μm), and lowest in B6 (205±6 μm) and DBA (225±4 μm). Vertebral and tibial bone loss following OVX was highly strain dependent (strain x treatment interaction, $p<0.005$ for both sites). DBA and BalbC had the greatest OVX-induced loss in V.BV/TV (-30 and –24% vs sham, respectively, $p<0.001$), whereas C3H had only a 5% decline (ns). Similar results were seen for trabecular number and thickness. In contrast, C3H had 50-100% greater bone loss at the proximal tibia (-39% versus sham, $p<0.005$) than the other strains (-16 to 27% vs sham, $p<0.05$). Femoral CortTh declined only in B6 (-10%, $p<0.01$). These findings confirm that trabecular and cortical bone loss following estrogen-deficiency is genetically regulated, and may be skeletal site-specific. Thus, the search for genes contributing to the regulation of bone loss following estrogen deficiency may ultimately lead to identification of those at greatest risk for rapid bone loss following menopause, and therefore afford the opportunity for early preventative interventions.

GH/IGF-I Independent Genetic Effects on BMD and Skeletal Morphology are Both Gender Dependent and Independent. L. R. Donahue[1], V. E. Guido*[1], C. J. Rosen[2], L. G. Horton*[1], C. L. Ackert-Bicknell*[1], M. L. Bouxsein[1], K. L. Shultz*[1], W. G. Beamer[1]. [1]The Jackson Laboratory, Bar Harbor, ME, USA, [2]St. Joseph Hospital, Bangor, ME, USA.

The interaction between IGF-I, sex steroids, and bone is comprised of autocrine loops whereby IGF-I levels are regulated by sex steroids via the hypothalamus and by aromatization of androgen to estrogen. Thus, the direct effect of steroids on bone independent of IGF-I is not easily discerned, particularly since steroids can affect the local synthesis of IGF-I in target tissues. The aromatization of androgens to estrogens by osteoblasts provides another autocrine loop for interaction with IGF-I to regulate bone physiology. A genetic model of steroid regulation of bone without the influence of IGF-I could provide insight into gender-specific interventions to impact bone health.

To determine the gender specificity of GH/IGF-I independent skeletal phenotypes, we are utilizing a spontaneous mouse mutation, *little,* with a non-functional GHRHR. A congenic strain has been made by transferring the *little* mutation from the low BMD C57BL/6J (B6) to the high BMD C3H/HeJ (C3) background. In both B6-*lit/lit* and C3.B6-*lit/lit* mice, circulating GH is undetectable, serum IGF-I is low, and femoral BMD (pQCT), areal BMD (PIXImus), femur length, and body mass are reduced compared to *lit/+* mice. Although C3.B6-*lit/lit* mice are of the same body weight and have the same femur length as B6-*lit/lit* mice, C3.B6-*lit/lit* mice have higher areal and femoral BMD. Within B6-*lit/lit* there are no gender differences in these phenotypes, whereas C3.B6-*lit/lit* females have greater femoral BMD than males, while areal BMD and femur length are not different.

A cross between B6-*lit/lit* and C3.B6-*lit/lit* has been made to generate F2s where all mice have low IGF-I but segregating genes from B6 and C3. Preliminary data from 550 F2s indicate that when IGF-I is held constant at low levels (<10% normal), gender-specific and gender independent regulatory loci for the skeleton can be detected. Data are first analyzed with genders together and then separately as shown below.

We would hypothesize that the gender specific loci are sex steroid driven and are independent of interaction with IGF-I. (Linkage Criteria 0.0001; values within table are LOD scores; n=235-253 males; 246-271 females)

Heritability of Hip Structural Phenotypes in the Old Order Amish. E. A. Streeten[1], D. J. McBride[1], J. R. O'Connell*[1], T. I. Pollin*[1], T. J. Beck[2], K. Uusi-Rasi[2], A. R. Shuldiner*[1], A. R. Shuldiner*[1], B. D. Mitchell[1]. [1]Medicine, University of Maryland School of Medicine, Baltimore, MD, USA, [2]Radiology, Johns Hopkins University, Baltimore, MD, USA.

Ambiguities in the dimensions underlying BMD can complicate efforts to identify the genetic contributions to bone mechanical strength and osteoporotic fragility. Structural geometry should provide insights into this issue although the heritability of bone structural dimensions has not been studied. The purpose of this study was to assess heritability of geometric indices of hip structural strength.

Hip Structure Analysis (HSA) was used to analyze DXA images yielding: BMD, bone cross-sectional area (CSA) section modulus (Z), subperiosteal width (W), and buckling ratio (BR). These parameters were measured in the narrow-neck and proximal shaft regions of the hip in 903 men and women, aged 19-91, recruited from large Amish families in Lancaster County, PA. Heritability (h2) was calculated using variance component methods to partition the total phenotypic variation into components attributable to individual-specific covariates, including height, weight, age and sex, and a component due to the additive effects of genes, or heritability.

Adjusted h2 are listed in the table. Independent of age, gender and body size, all of the geometric phenotypes in the femoral neck and shaft regions were highly heritable ($p < 0.0001$). With further adjustment for BMD, heritability estimates were reduced only modestly for most of these parameters, and remained significantly greater than zero.

We conclude that geometric indices of bone strength of the proximal femur derived from DXA data are highly heritable, especially at the proximal shaft. The higher heritability at the shaft may be due to greater measurement precision at that region. The use of hip structural dimensions may help clarify the genetic contributions to bone strength and osteoporotic fragility and should provide additional information over BMD alone.

	Heritability (h2)			
Hip region	CSA	W	Z	BR
Narrow-neck	0.44	0.52	0.34	0.53
Shaft	0.66	0.70	0.84	0.70

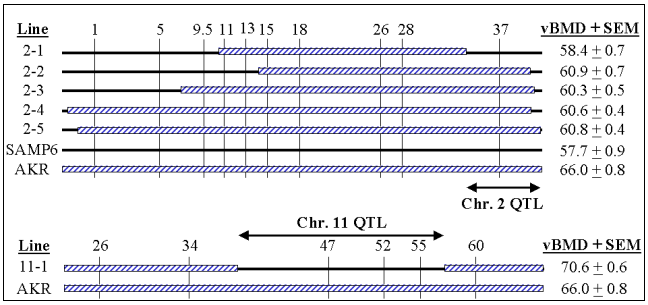
Quantitative Trait Loci for Murine Vertebral BMD, Mapped in Interstrain Cross Progeny, Confer Distinct Allelic Effects on Bone Density After Isolation in Congenic Lines. D. Szumska*[1], P. Kang*[2], R. S. Shelton*[3], R. S. Weinstein[3], R. L. Jilka[3], S. C. Manolagas[3], R. J. Shmookler Reis[2]. [1]Geriatrics, Univ. of Arkansas for Medical Sciences and CAVHS, Little Rock, AR, USA, [2]Geriatrics, and Biochem./Molec. Biol., Univ. of Arkansas for Medical Sciences and CAVHS, Little Rock, AR, USA, [3]Center for Osteoporosis and Metabolic Bone Diseases, Univ. of Arkansas for Medical Sciences and CAVHS, Little Rock, AR, USA.

We recently mapped quantitative trait loci (QTLs) for BMD of the mouse spine, measured in mature (4-month) F2 progeny of SAMP6 x AKR and SAMP6 x SAMR1 crosses (Beneš *et al.*, JBMR 15:26–33, 2000). Five significant QTLs were defined, on chromosomes 2, 7, 11, 13 and 16. For major peaks on chromosomes 2 and 11, we have now constructed multiple congenic lines by marker-directed selection of backcross progeny. In each case, a "donor" QTL allele is isolated in the genetic background derived from the other, recipient parental strain. By comparison of vertebral BMD in overlapping recombinants across these QTL regions, the major loci affecting each region have been localized to intervals that can be precisely determined by fine-mapping of introgressed segments. Highly significant allelic effects (each $p<0.01$) were observed on mineral density in the spine. Introduction of an AKR chromosome-2 QTL region in a SAMP6 background increased spine BMD by ~30 μg/mm^2 (Figure, top), most of which is attributable to a QTL near 37 cM, while insertion of a SAMP6 chromosome-11 QTL into an AKR background increased spine BMD by ~46 μg/mm^2 (Figure, bottom). Boundaries between recipient and



donor DNA regions are at present defined only approximately, by genotyping at markers indicated by vertical lines with genetic positions (in cM) above them. Additional markers and recombinant lines will be evaluated to more precisely position the QTLs. Other measures of bone structure and strength, at this and other skeletal sites, are also being assessed for the most informative congenic lines demarcating each implicated QTL region. These measures include bone formation rate, clonogenic assays of osteoblast precursors, self-renewal of mesenchymal stem cells, resistance of femur to three-point bending, and resistance of vertebrae to compression fracture.

Heritability and Familial Correlations of the Bone Synthesis Marker, Serum N-Terminal COL1A1 Propeptide (P1NP). L. J. Miles*[1], A. Blumsohn[2], R. Eastell[2], E. L. Duncan[3], J. A. H. Wass[3], M. A. Brown*[1]. [1]Spondyloarthritis and Bone Disease Research Group, Oxford University Institute of Musculoskeletal Sciences, Oxford, United Kingdom, [2]Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom, [3]Department of Endocrinology and Metabolism, Nuffield Orthopaedic Centre, Oxford, United Kingdom.

Whilst there is clear evidence of the heritability of bone mineral density (BMD), the inheritance of bone turnover is less well established. We measured serum procollagen type I N-terminal propeptide (PINP) in serum by immunoassay (Roche Elecsys), a marker of type 1 collagen synthesis, in 427 individuals belonging to 115 families recruited with probands with low BMD (T-score <-2.5, Z-scores <-2.0) in whom secondary causes of osteoporosis had been excluded. Cases with serum P1NP >3 SD from the mean were excluded (n=2). Multiple linear regression demonstrated correlation between serum P1NP and age+age^2, but not with gender, BMD, height, weight or BMI. Heritability and within family correlations were assessed using the program PAP[1].

Serum P1NP levels were significantly heritable (additive heritability 0.35, p=0.0007). Correlation between siblings was much greater than between parent-offspring pairs (0.35 vs 0.02, p=0.002). Correlations were more positive between same-gender compared with opposite gender pairs. Sister-sister correlation was 0.41, compared with brother-brother correlation of 0.24. Father-son correlation was 0.19 whereas father-daughter correlation was 0.06, and mother-daughter correlation was 0, whereas mother-son correlation was -0.12.

These findings support the hypothesis that gender specific effects influence the inheritance of skeletal phenotypes including BMD and bone turnover. Studies of the COL1A1 Sp1 polymorphism in these families (Miles *et.al*, ASBMR Conference Abstracts 2003) suggest

the presence of parent-of-origin effects on the association of this marker with BMD and serum P1NP levels, consistent with the differences reported here in within-family correlations of P1NP.

Five Novel QTLs for Bone Mineral Density and Biomechanical Strength Discovered in an Intercross of Red Jungle Fowl and White Leghorn Chicken. H. Brändström*[1], U. Gunnarsson*[1], E. Grundberg*[1], C. Ohlsson*[2], H. Mallmin[3], S. Larsson*[3], L. Andersson*[4], P. Jensen*[5], R. Fredriksson*[4], A. Kindmark[1]. [1]Dept of Medical Sciences, Uppsala University Hospital, Uppsala, Sweden, [2]Division of Endocrinology, Department of Internal Medicine, Sahlgrenska University Hospital, Gothenburg, Sweden, [3]Dept of Orthopedics, Uppsala University Hospital, Uppsala, Sweden, [4]Department of Animal Breeding and Genetics, Swedish University of Agricultural Sciences, Uppsala, Sweden, [5]Department of biology, IFM, Linköping university, Linköping, Sweden.

Osteoporosis is the cause of skeletal problems in hens. Up to 90% of hens in commercial flocks display broken bones during life. Short generation time and large resource pedigrees make it an attractive model for genetic dissection of multifactorial traits. The genome size (~1200 Mbp) is smaller than in mammals, but has approximately the same gene number.

This Functional Genomics of the Chicken (FunChick) program is based on a unique pedigree, an intercross between 2 divergent populations: the Red Jungle Fowl (RJF, the ancestor of the domestic chicken) and White Leghorn (SLU13, selected for egg production). The pedigree comprises 1,000 animals from 3 generations. The populations differ markedly in growth and body composition.

DNA samples are collected, and genome scans using 120 microsatellite markers have been performed. Bone phenotypic traits: determination of BMD by DXA and volumetric BMD and composition by pQCT have been performed. Also, biomechanical strength is determined by three-point bending and torsion testing.

QTL analyses revealed a large number of chromosomal regions linked to bone phenotypes, with five regions on four chromosomes showing linkage values at the 1% level of significance. The results remain statistically significant after adjustment for body size (weight), and also after including the major QTLs affecting animal growth in the model.LOD scores for these five QTLs range between 3.36-4.10 for BMC, BMD and biomechanical strength parameters. These main bone phenotypic QTLs are located on chicken chromosome 1, 8, 26 and 28.

In the continuation of the project, transcript profiling, positional cloning and functional analysis will be performed to identify the genes controlling these traits. A Unigene array using high-quality cDNA libraries from tissue has been produced using sequences from 30,000 cDNA clones.

The ongoing chicken genome project will provide the full chicken genomic sequence during the coming year. This gives a unique opportunity to find novel candidate genes affecting bone metabolism and biomechanical strength of bone in chicken, whereafter comparative genomics can be used in other model animals and in human genetic studies.

Gender Dependent QTL for Femoral BMD in Mice. K. L. Shultz[1], L. G. Horton*[1], C. L. Ackert-Bicknell[1], L. R. Donahue[1], C. J. Rosen[2], W. G. Beamer[1]. [1]The Jackson Laboratory, Bar Harbor, ME, USA, [2]St. Joseph Hospital, Bangor, ME, USA.

Susceptibility to osteoporosis is apparent for both women and men, however the genetic basis is unknown. In young adult C57BL/6J (B6) inbred mice, males have a significantly greater ($p<0.0001$) femoral BMD (0.510±0.008) than females (0.477±0.005). Conversely, in C3H/HeJ mice, females have a significantly greater ($p<0.03$) femoral BMD (0.721±0.007) than males (0.699±0.008). Based on female genetic analyses, we reported that B6.C3H-1T (1T) congenic mice has two femoral BMD QTLs, *Bmd5* and *Bmd19* (Shultz et al JBMR, 2003). The 1T females have a significantly greater ($p<0.0001$) femoral BMD (0.507± 0.004) than B6 female controls (0.471 ± 0.005).), whereas the 1T males (0.479 ± 0.006) have a lower BMD ($p < 0.003$) than B6 male controls (0.510 ± 0.008). We subdivided 1T into nested congenic sublines to narrow the regions containing the femoral BMD QTLs.

We found that there was a different pattern of BMD for females and males across the sublines (Table below). Among the 7 sublines, only B6.C3H-1-1, B6.C3H-1-5, B6.C3H-1-8, and B6.C3H-1-9 females show a significantly greater femoral BMD than B6 controls. Whereas, in males, only the sublines 1-3, 1-5, and 1-7 show a difference in BMD when compared to B6 controls, and in all case BMD was reduced. Three patterns of BMD changes within the sublines are: a) females increase, males not different; b) females not different, males decrease; and c) females increase, males decrease. The subline, 1-1, is the only subline to contain *Bmd19* and expression appears only in females. Sublines 1-5,1-8 and 1-9 carry a second BMD locus whose expression appears only in females. Sublines 1-3, 1-5, and 1-7 carry two or more BMD QTL that affect male BMD.

These data demonstrate that mapping genes for BMD in one gender will not necessarily generalize to the opposite sex. Haplotype analysis has proven to be a powerful tool for the purpose of characterizing the genotype verses phenotype for each subline by aiding in defining genetic overlap between sublines. As we continue to narrow the regions encompassing each QTL in the hunt for candidate genes, each gender must be considered separately.

Comparison of BMD in B6.C3H sublines for Chr 1 with B6 controls.
Direction of arrow indicates significant increase (↑) or decrease (↓).

Spinal Osteophytosis and Serum Measures of Bone Turnover in Pedigreed Baboons: Evidence for Pleiotropy and Linkage to Human Chromosome 22q. M. C. Mahaney, L. M. Havill, J. Rogers*. Genetics, Southwest Foundation for Biomedical Research, San Antonio, TX, USA.

In pedigreed baboons, we have observed radiographic evidence for osteophytosis of the lumbar spine in association with spinal arthritis and diffuse idiopathic hyperostosis. In earlier statistical genetic analyses we detected a significant additive genetic component to variation in susceptibility to osteophytosis when it was treated as a dichotomous trait. To further characterize the genetic contributions to this trait in a non-human primate model for age-related changes and pathology in bone, we conducted bivariate quantitative genetic analyses of data on osteophytosis (Ost) of lumbar vertebrae 2 through 4, measured on a 4-point ordinal scale (0="absent" - 4="most severe"), in 672 pedigreed baboons for whom we also assayed serum concentrations of 3 measures of bone formation and turnover -- i.e., bone-specific alkaline phosphatase (Bone ALP), osteocalcin (OC), and human cartilage glycoprotein 39 (YKL40), a marker of both skeletal remodeling and cartilage degeneration in osteoarthritis. All 4 traits had significant heritable components (Ost h^2=0.32, Bone ALP h^2=0.18, OC h^2=0.31, YKL40 h^2=0.24) and Ost exhibited significant ($p<0.05$) additive genetic correlations (ρ_G), indicative of pleiotropy, with all three serum measures (Ost-Bone ALP ρ_G=-0.48, Ost-OC ρ_G=-0.59, and Ost-YKL40 ρ_G=0.33). Obtained as ρ_G^2, estimates of the proportion of the additive genetic effect on variance in lumbar vertebral osteophytosis attributable to genes that also affect each of these 3 bone formation/turnover measures range from approximately 10% to 33%. While univariate linkage screens detect only tentative evidence of QTLs influencing Ost (maximum LOD=1.82), bivariate whole genome linkage screens allowing for these correlations yield significant evidence for a QTL with pleiotropic effects on Ost and one of the serum measures -- YKL40 (LOD=2.71, genome-wide P=0.048). The hypothesis of coincident linkage was rejected (p=0.003). This QTL with pleiotropic effects on Ost and YKL40 is localized to a region of the baboon genome between human microsatellite marker loci D22S304 and D22S280, corresponding to an area of human chromosome 22q11.2-q12; an area containing several possible candidate genes, including 2 related to the Wnt signaling pathway (*KREMEN1*, *MAP3K7IP1*), 2 related to cell cycle regulation (*APOBEC36*, *RRP22*), and 1 (*TFIP11*) that may interact with genes involved in odontogenesis and ossification.

A Large-scale Genome Wide Scan for QTLs Underlying BMD Variation in an Extended Sample. P. Xiao[1], H. Shen*[1], J. R. Long*[2], F. H. Xu*[1], L. J. Zhao*[1], Y. J. Liu*[1], Y. Y. Zhang*[2], D. H. Xiong[1], S. Araujo*[2], Y. Z. Liu*[1], V. Dvornyk*[2], Q. Zhou*[2], K. M. Davies[2], T. Conway*[2], R. R. Recker[2], H. W. Deng[1]. [1]Biomedical Sciences,Osteoporosis Research Center, Creighton University, Omaha, NE, USA, [2]Osteoporosis Research Center, Creighton University, Omaha, NE, USA.

Low bone mineral density (BMD) is a major risk factor for osteoporosis and is under strong genetic control. Previously, we reported a genomewide linkage scan for BMD in 53 pedigrees with 630 Caucasian subjects that contained more than 10,000 informative relative pairs including 1,249 sibling pairs (Deng et al., JCEM. 2002). We observed several regions with suggestive linkage. To confirm the previous results and to identify those genomic regions that may have been undetected in the previous study, we performed another whole genome scan in an extended large sample of 79 pedigrees, in which 1,816 individuals were genotyped using 432 microsatellite markers. This current sample contains more than 70,000 relative pairs informative for linkage analyses including 3,846 sibling pairs, which yields dramatic increase in the statistical power and leads to more reliable results for whole genome linkage scan analyses compared to our earlier whole genome linkage study. The number of informative relative pairs contained in this sample represents one of the largest in the human genetics field in whole-genome linkage scan studies for any complex trait. The raw BMD values at spine (L_{1-4}), hip (combined femoral neck, trochanter, and intertrochanteric region), and wrist (ultra-distal forearm) were adjusted for age, sex, weight, and other significant covariates. Two- and multi-point linkage analyses were performed using a maximum likelihood based variance components method implemented in the computer package SOLAR. Several genomic regions showed suggestive linkage for spine BMD (18q22, 7p15, and 20q13 with maximum LOD score (MLS >1.5) and wrist BMD (7p15, 20p13, and 10p13, MLS > 1.0). Compared with our early genome

scan, linkage to the genomic region 7p15 (44cM) appears to be replicated (MLS=1.5). (Significance for confirmation is different from initial whole genome scan). 1p36 that has been identified in other groups' genome-wide linkage studies (Devoto et al., HMG 2001; Wilson et al., AJHG 2003), also showed suggestive evidence for linkage with wrist BMD in this study (two-point LOD = 1.51 at D1S2660; multi-point MLS = 0.82). This study is one of a few genome scans performed in extended samples with larger statistical power. The results highlight the importance and difficulties of confirming results of genome scans in replicate populations as a prelude to positional gene cloning.

SA124

A Large-scale Whole Genome Scan for QTLs Influencing Bone Size Variation in an Extended Sample. D. H. Xiong[1], F. H. Xu*[1], J. R. Long*[2], H. Shen*[1], P. Xiao[1], L. J. Zhao*[1], Y. Y. Zhang*[2], Q. Zhou*[2], S. Araujo*[2], Y. J. Liu*[1], Y. Z. Liu*[1], V. Dvornyk*[2], K. M. Davies*[2], T. Conway*[2], R. R. Recker*[2], H. W. Deng[1]. [1]Biomedical Sciences, Osteoporosis Research Center, Creighton University, Omaha, NE, USA, [2]Osteoporosis Research Center, Creighton University, Omaha, NE, USA.

Bone size, as an important risk factor for osteoporotic fractures, is highly heritable. Previously, we reported a genome wide linkage scan for bone area phenotypes (measured by DXA) in 53 pedigrees with 630 Caucasian subjects that contained more than 10,000 informative relative pairs including 1,249 sibling pairs (Deng et al., AJMG, 2002). A significant linkage was found in genomic region 17q22 for the wrist bone size. We also observed several regions with suggestive linkage. To confirm the previous results and to identify those genomic regions that may have been undetected in the previous study, we performed another whole genome scan in an extended large sample of 79 pedigrees, in which 1,816 individuals were genotyped using 432 microsatellite markers. This current sample contains more than 70,000 relative pairs informative for linkage analyses including 3,846 sibling pairs, which yields dramatic increase in the statistical power and leads to more reliable results for whole genome linkage scan analyses compared to our earlier whole genome linkage study. The number of informative relative pairs contained in this sample represents one of the largest in the human genetics field in whole-genome linkage scan studies for any complex trait. One previously detected region on 17q22 near marker D17S787 was confirmed in this extended sample with a LOD score of 2.27 for two-point analyses and maximum LOD score (MLS) of 1.78 for multi-point analyses. (Significance for confirmation is different from initial genome scan search). This region was also reported for femur head width (one-dimensional measure of bone size) in an earlier whole genome scan study, and it is very close to the candidate gene COL1A1. In addition, we detected suggestive linkage for the following genomic regions that were not detected in our earlier whole genome scan: 14q32 near marker D14S65 (two-point LOD = 1.99, MLS = 2.61) for the spine bone size, 7q36 near marker D7S798 (two-point LOD = 1.98, MLS = 2.20) and 11q12 near marker D11S4191 (two-point LOD = 3.40, MLS = 2.38) for the wrist bone size. However, some genomic regions found earlier with suggestive evidence of linkage did not show any apparent linkage signal in this large-scale extended whole genome linkage study. These findings demonstrate the importance of large sample size and high statistical power in the whole genome scans to search for genes underlying the complex traits such as bone size.

4cM Linkage Map of Chromosome 1q and Lumbar Spine BMD. M. J. Econs[1], D. L. Koller[2], S. L. Hui[1], T. M. Fishburn*[1], P. M. Conneally*[2], C. C. Johnston[1], M. Peacock[1], T. Foroud[2]. [1]Medicine, Indiana University School of Medicine, Indianapolis, IN, USA, [2]Medical and Molecular Genetics, Indiana University School of Medicine, Indianapolis, IN, USA.

BMD of the spine is a major risk factor for fracture and has high heritability. We previously performed a genome screen in pre-menopausal Caucasian sister pairs and found significant evidence of linkage of peak BMD at the lumbar spine to markers on chromosome 1q. Since the region of linkage was relatively broad and only a portion of our sample had been genotyped for the markers in this region, we genotyped 16 polymorphic microsatellite markers on chromosome 1q in all available samples. The goal of these analyses was to perform linkage analysis to confirm and refine our previous linkage results using a substantially enlarged sample that had been genotyped for a common set of markers.

BMD, BMC and area for L2-4 was measured using a Lunar DPXL densitometer and was weight and age-adjusted. We used 16 highly polymorphic, microsatellite markers in 938 pre-menopausal, Caucasian sister pairs. Average marker spacing in the critical interval between markers D1S2777 and D1S2823 was 4cM. Multipoint, nonparametric linkage analysis was performed using the maximum likelihood variance components method (Mapmaker/SIBS). Results demonstrated linkage for spine BMD with a maximum LOD score of 4.3 at position 181 cM on the Marshfield map. The multipoint LOD score for the corresponding BMC was 2.8, with the peak in approximately the same position as the peak for BMD. There was no evidence for linkage with bone area, suggesting that the gene(s) affecting BMD on chromosome 1q do not affect bone size.

In summary, our data provide strong evidence that a gene (or genes) on chromosome 1q affects peak BMD of the lumbar spine in pre-menopausal white women.

Skeletal Fragility in Laboratory Mice: Affect of Sex and Genotype. M. Shea[1], B. L. Hansen*[1], D. A. Olson*[2], D. Dinulescu*[2], B. Orwoll*[2], J. K. Belknap*[2], E. S. Orwoll[2], R. F. Klein[2]. [1]Orthopaedic Biomechanics Laboratory, Oregon Health & Science University, Portland, OR, USA, [2]Bone and Mineral Unit, Oregon Health & Science University, Portland, OR, USA.

The genetics of skeletal fragility has been pursued with increasing intensity over the past decade. Genetic factors play an important role in determining bone size, shape, and bone mineral density (BMD), all key contributors to bone strength. There is now an ongoing effort using modern genetic analyses to map the chromosomal loci of genes responsible for the heritable differences in BMD. However, much less is known about the specific biomechanical characteristics that more completely describe the integrity of skeletal tissue. In this study we examined sex- and strain-dependent differences in femoral BMD (by pixiMus), geometry (by μCT) and failure properties (by 3-point bending) in 4 mo-old male (M) and female (F) mice from 8 inbred mouse strains: 129S1, Castaneus (Cast), BALB/cByJ (Balb/c), C57Bl/6J (B6), C3H/HeJ, DBA/2J (D2), A/J and AKR/J (n=13-20/gr). Strain and gender differences were determined using two-way ANOVA. Body weight (BW) differed significantly between strains and gender, and there were significant correlations between BW and all parameters. Consequently, within each gender all femoral parameters were corrected for BW. In both M and F datasets, narrow-sense heritability estimates were high for weight-corrected femoral BMD ($h^2 = 0.78$ for both), geometric parameters ($h^2 = 0.66$ to 0.90) and strength ($h^2 = 0.57$ to 0.84). The effect of strain, sex, and strain x sex was significant for all femoral traits ($p < 0.0001$ for all). For example, femoral failure load was highest in C3H/HeJ (31.5 ± 0.7 N), intermediate in A/J, AKR, Balb/c, Cast and DBA (17 to 26 N) and lowest in B6 (16.4 ± 0.6 N) and was higher in M (7/8 strains). Ixx varied 2.5-fold between strains, and similar to failure load was higher in M (7/8 strains). Femoral strength and modulus (intrinsic properties of the bone material) also varied across strains (1.7 – 1.9 fold) but interestingly were both higher in F (8/8 strains). In both M and F mice, femoral failure load correlated strongly with femoral BMD, cortical area and thickness and Ixx (Pearson correlation coefficients 0.66 – 0.86; $p < 0.0001$ for all). These data indicate that the key determinants of bone strength are under significant genetic control. Moreover, the present data highlight the important role of gender in the inheritance of skeletal strength. Since the male phenotype is associated with considerable fracture risk reduction in humans, an improved understanding of the nature of the gender divergence in murine skeletal traits could provide for novel diagnostic, preventative or therapeutic approaches.

Heritability of Calcaneal Quantitative Ultrasound Measures in Healthy Adults from The Fels Longitudinal Study. M. Lee, S. A. Czerwinski*, B. Towne*, E. W. Demerath*, W. C. Chumlea*, S. S. Sun*, R. M. Siervogel. Community Health, Wright State University, Kettering, OH, USA.

Quantitative ultrasound (QUS) measurements have been reported to predict osteoporotic fracture risk in postmenopausal women and older men. In addition, QUS measures may reflect important aspects of the internal structure of the calcaneal bone. Many studies have found significant heritabilities of bone mineral density obtained from single or dual-energy X-ray absorptiometry, for example, but few studies have estimated the heritability of calcaneal QUS phenotypes. In the present study, we estimate the heritability of calcaneal QUS measures in healthy adults. The study population includes 200 men and 235 women aged 18 to 60 years (mean ± SD: 40 ± 12 yrs) who belong to 98 extended and nuclear families participating in the Fels Longitudinal Study. Three measures of calcaneal structure were collected from the right and left heel using the Sahara ® bone sonometer (Hologic, Inc., Waltham, MA). These measures include speed of sound (SOS), broadband ultrasound attenuation (BUA), and quantitative ultrasound index (QUI). We used a variance components-based maximum likelihood method (SOLAR) to estimate the heritability of QUS measures while simultaneously adjusting for the effects of age, sex, age*sex, age^2, and age^2*sex.

All QUS measures demonstrated statistically significant heritabilities ($p< 0.0001$). For the right heel, heritability estimates ($h^2 \pm$ SE) were $h^2 = 0.49 \pm 0.13$ for BUA, $h^2 = 0.67 \pm 0.13$ for SOS, $h^2 = 0.64 \pm 0.14$ for QUI. For the left heel, heritabilites were 0.53 ± 0.12 for BUA, 0.59 ± 0.12 for SOS, and 0.57 ± 0.12 for QUI. There was little influence of age and sex on BUA and QUI. For example, sex explained only 4 % of the phenotypic variance for BUA in the right heel ($p< 0.01$). Age had a significant effect on SOS in both the right and left heel ($p < 0.05$). Other covariates, such as age-squared and interactions between age and sex, did not contribute significantly to the variation of QUS measures. This study demonstrates that QUS measures of bone among healthy men and women are highly heritable.

Heritability of Peak Bone Mineral Density and Bone Structure in Men. M. Peacock[1], D. Koller[2], S. Hui[1], C. Johnston[1], T. Foroud[2], M. Econs[1]. [1]Medicine, Indiana University, Indianapolis, IN, USA, [2]Medical and Molecular Genetics, Indiana University, Indianapolis, IN, USA.

We have shown that peak bone mineral density (BMD) and bone structure at the hip and spine are highly heritable phenotypes in both white and black women (Endo Rev 2002 23; 303). There are few comparable data in men. Thus the purpose of this study was to establish the heritability of peak BMD and bone structure in men.

BMD was measured on the same DXA machine at lumbar spine (ls) and femoral neck (fn) in 271 pairs of white brothers aged 18-61, median age 33 and 58 pairs of black brothers

aged 20-59, median age 35. . Bone structural variables at the hip including , pelvic axis length (pal), femoral medullary width (fmw), femoral total width (ftw), femoral neck width (fnw) femoral head width (fhw), calcar femorale width (cfw) were measured from radiographs of the hip in 15 degrees internal rotation.
Heritability was calculated using the computer program SOLAR (Am J Hum Genet 1998 62:1198). For BMD, age and weight were used as covariates and for structure, height was used as covariate.
As shown in the table peak BMD at the hip and spine in both white and black brothers was highly heritable and equivalent to the values we have previously reported in women. The structural variables at the hip and spine were also highly heritable and equivalent to the values we have reported in women.
It is concluded that these high heritability estimates in the components of peak bone strength in men warrant not only the identification of QTL underlying BMD and bone structure but also the identification of sex specific QTL by comparing men and women.

Phenotype	White pairs	Black pairs
ls BMD	0.87	0.61
fn BMD	0.83	0.74
pal	0.72	0.57
fmw	0.76	1.00
ftw	1.00	0.96
fnw	0.86	0.99
fhw	1.00	0.78
cfw	0.39	1.00

Estrogen Receptor β Dinucleotide (CA) Repeat Polymorphism Is Significantly Associated with Bone Mineral Density in Postmenopausal Women. J. K. Scariano[1], S. G. Simplicio*[2], G. D. Montoya*[1], P. J. Garry*[1], R. N. Baumgartner[2]. [1]Pathology, University of New Mexico School of Medicine, Albuquerque, NM, USA, [2]Medicine, University of New Mexico School of Medicine, Albuquerque, NM, USA.

Modest associations between the length of a highly polymorphic dinucleotide (CA) repeat located near the human estrogen receptor beta gene (hERβ) on chromosome 14, spinal bone mineral density in postmenopausal women and androgen levels in premenopausal women have previously been reported. We measured the size of the hERβ CA repeat in 226 healthy women (age 60-98 yrs). After adjustment for age, body mass index (BMI), hormone replacement (HRT) status and circulating levels of 17-β estradiol (E_2), subjects with shorter CA repeat number (< 25 repeats) had significantly higher bone mineral density measured in the total skeleton (Mean+/–S.E.: 1.022+/-0.015 vs. 0.983+/–0.017 gm/cm^2, p = 0.02), lumbar spine (1.049+/–0.036 vs. 0.959+/–0.042 gm/cm^2, p = 0.03) and femoral neck (0.752+/–0.018 vs. 0.703+/–0.021gm/cm^2, p = 0.02) when compared with women having longer alleles. Women with shorter alleles also had higher circulating estrone and E_2 levels that approached statistical significance as compared with women harboring longer alleles after adjustment for age, BMI, HRT and circulating levels of sex hormone binding globulin. A dosage effect of either a beneficial or detrimental allele was apparent in women having both short and long CA repeats. The hERβ CA repeat size was not associated with the 5-7 year change in BMD we monitored, nor did it correlate with serum levels of biochemical markers of bone turnover such as crosslinked N-telopeptides of type-I collagen (NTx) or bone-specific alkaline phosphatase. Accordingly, hERβ genotype more likely influences the attainment of peak bone mass rather than the rate of decline in BMD after menopause. Our results warrant further investigation of the hERβ CA repeat size in larger populations of women and men with low BMD.

Endogenous Estrogen and Estrogen Receptor Alpha Gene Polymorphisms Predict Renal Calcium and Phosphorus Handling and Intestinal Calcium Absorption in Postmenopausal Women. R. L. Prince[1], I. M. Dick*[1], A. Devine[1], S. S. Dhaliwal*[2]. [1]Medicine, University of Western Australia, Western Australia, Australia, [2]Endocrinology and Diabetes, Sir Charles Gairdner Hospital, Western Australia, Australia.

Postmenopausal endogenous estrogen production is a determinant of bone mass and fracture in elderly women. In addition to effects on bone, estrogen may have direct effects on kidney and bowel. The interaction between circulating estrogen concentrations and estrogen receptor (ER) gene polymorphisms in relation to the renal handling of calcium and phosphorus and intestinal calcium absorption was investigated.
As part of a population based study ER TA repeat genotyping was performed on 483 postmenopausal women. A fasting blood and urine sample was collected in 259 of these subjects. Factors associated with renal calcium and phosphate excretion were measured including estradiol, SHBG and PTH. The free estradiol index (FEI) was calculated. Intestinal calcium absorption (% dose) was estimated in 118 fasting subjects by measuring the appearance of an orally administered ^{45}Ca tracer in the blood. The ^{45}Ca tracer was administered with a 10 mg calcium load.
High plasma estradiol and FEI concentrations were associated with a high total calcium concentration and a high calculated ultrafiltrable calcium concentration. However a low urine calcium excretion was associated with a high FEI after adjustment for ultrafiltrable calcium, PTH and weight (partial r= -0.16, p=0.01). Addition of the TA repeat (> 20/<=20) to the model further improved the prediction of calcium excretion. Mean urinary calcium excretion, after adjustment for weight, PTH, ultrafiltrable calcium and free estradiol concentration, was higher in the group that did not have an ER (TA)n> 20 allele (16.8 µmol/LGF, 95% CI 14.1-19.81) than in the group that had at least one ER (TA)n> 20 allele present (13.4 µmol/LGF, 95% CI 12.0-15.0). After adjustment for PTH and plasma calcium concentrations in a multiple linear regression analysis, a high FEI was associated with a low TmP (partial r = -0.15 p = 0.02), indicating that high FEI was associated with a decreased renal phosphate reabsorption. Intestinal calcium absorption was not associated with the FEI but was higher in the group with an ER TA repeat >20 (41%, 95% CI 37-45) compared to the group that did not have an ER (TA)n> 20 (34%, 95% CI 32-37), after adjustment for the FEI.
An association of the ER receptor TA repeat allele > 20 with increased renal calcium reabsorption and increased intestinal calcium absorption was observed. Thus non-bone effects of estrogen and the estrogen receptor may play a significant role in calcium and phosphorus homeostasis and may be implicated in the pathogenesis of osteoporosis.

The CYP19 TTTA Repeat Polymorphism Is Associated with Reduced Bone Mineral Density and Fracture. R. L. Prince[1], A. Devine[1], I. M. Dick*[1], S. S. Dhaliwal*[2]. [1]Medicine, University of Western Australia, Western Australia, Australia, [2]Endocrinology and Diabetes, Sir Charles Gairdner Hospital, Western Australia, Australia.

Osteoporosis is a disease that is strongly genetically determined so that polymorphisms present in a range of candidate genes may be involved. The human Aromatase (CYP19) gene, localized on 15q21.2, catalyzes the conversion of testosterone to estradiol, and androstenedione to estrone. A variable number of tandem repeat (VNTR) polymorphism of the CYP19 gene has been associated with reduced bone mineral density (BMD) and increased fracture in early postmenopausal women but the importance of this has not been determined in older women.

We examined the CYP19 TTTA VNTR in a population based study of 1257 Caucasian women over age 70. DXA bone mineral density (BMD) data and calcaneal quantitative ultrasound (QUS) data was obtained. The number of atraumatic prevalent fractures at entry into the study and the number of atraumatic incident fractures during the following three years was assessed. Genotyping of the CYP19 TTTA VNTR was done by PCR amplification.

Genotyping resulted in 10 different PCR fragments ranging in size from 142 to 182 bp, designated A1 to A11. Based on the results of an initial statistical analysis, the data was stratified based on the presence or absence of A4 (158 bp, number of TA repeats=9). A4 was present in 27% of subjects and was associated with higher BMD at all sites of the hip (3.8% total hip, 2.6% femoral neck, 3.8% intertrochanter, 4.5% trochanter) and the lumbar spine (14.7%) compared to the absence of A4. A4 was also associated with higher values for the calcaneal quantitative ultrasound (QUS) parameters BUA (1.8%), SOS (0.5%) and stiffness (4.5%) compared to the absence of A4. A4 was associated with a decreased risk of osteoporosis as defined by WHO criteria (OR 0.56, 95% CI 0.34-0.93). A4 was associated with a decrease in the deoxypryridinoline creatinine ratio (DpdCr) (30.3 ± 10.6 vs 26.9 ± 8.9, p=0.02) and an increase in the Free Estradiol Index (FEI) (0.64 ±0.57 vs 0.71 ± 0.59, p=0.049). Despite the association of A4 with increased BMD and QUS, there was no decrease in prevalent fractures or incident fractures recorded over 3 years observed. However, a significant interaction between BMD and the presence or absence of A4 was observed, such that subjects with low BMD (osteopenia or osteoporosis) and the presence of A4 were protected against incident fracture compared to subjects with a low BMD who did not have an A4 allele (R.R. 0.31, 95% CI 0.1-1.0).

Therefore, a Cyp19 A4 allele was associated with increased FEI, BMD and QUS parameters and reduced bone resorption. Importantly the A4 allele enhanced prediction of incident fracture in women with low BMD.

Promoter Polymorphism of the COLIA1 Gene Is Associated with Spine BMD in Women. F. E. A. McGuigan*[1], T. L. Stewart*[1], D. M. Reid[1], S. C. Main*[1], N. Garcia-Giralt*[2], S. Balcells*[2], X. Nogues*[3], A. Diez-Perez[3], D. Grinberg*[2], S. H. Ralston[1]. [1]Medicine & Therapeutics, University of Aberdeen, Aberdeen, United Kingdom, [2]Genetics, University of Barcelona, Barcelona, Spain, [3]Hospital del Mar, University of Barcelona, Barcelona, Spain.

The COLIA1 gene, which encodes the alpha 1 chain of type I collagen is an important candidate gene for regulation of BMD and bone fragility. A G/T polymorphism affecting an Sp1 binding site within intron 1 of COLIA1 (+1245G/T) has been found to predict fractures independent of BMD, and more recently, two polymorphisms were identified in the COLIA1 promoter (–1997G/T and -1663T7/T8) that have been associated with BMD in Spanish postmenopausal women. In this study, we investigated associations between the promoter and intron 1 polymorphisms of COLIA1 and BMD in a population-based sample of 962 women aged 45-55 years (mean 47.5 +/- 1.42 years) from the UK. There was strong linkage disequilibrium between the +1245G/T and -1663T7/T8 polymorphisms (D' 0.81; p< 10-8) and weaker LD between -1663T7/T8 and –1997G/T (D' 0.17, p< 10-5) and +1245G/T and –1997G/T (D' 0.20, p<10-5). After adjusting for age, weight, height, menopausal status, and HRT use, we found that –1997 T/T homozygotes had significantly higher spine BMD values than –1997 G/T heterozygotes and –1997 G/G homozygotes (Table 1). There was no association between the -1663T7/T8 or +1245G/T polymorphisms and BMD and no association between any polymorphism and hip BMD (not shown). We identified three common haplotypes that together accounted for 89.2% of the alleles. They were (ordered 5' to 3'): G-T8-G (59.2%); T-T7-T (7.2%) and T-T8-G (22.9%). All three haplotypes were significantly associated with BMD (p=0.021-0.024), but the association was primarily driven by variation at the -1997G/T site (not shown). In this study, we found no association between the COLIA1 Sp1 polymorphism and BMD, but found a strong association between –1997 G/T promoter polymorphism and spine BMD. This raises the possibility that these different polymorphisms in COLIA1 may have differential effects on bone mass and bone quality.

Table 1: BMD and COLIA1 Genotype data

	G / G (n=696)	G / T (n=243)	T / T (n=23)	ANOVA p-value
-1997 G / T	1.05 + / - 0.14	1.06 + / -0.16	1.15 + / -0.13	p=0.002
	T8 / T8 (n=657)	T8 / T7 (n=261)	T7 / T7 (n=44)	
-1663T7 / T8	1.05 + / - 0.15	1.05 + / -0.14	1.05 + / - 0.15	p=0.802
	G / G (n=663)	G / T (n=261)	T / T (n=36)	
+1245G / T	1.06 + / - 0.15	1.05 + / - 0.14	1.02 + / - 0.14	p=0.328

The Interleukin 6 G-174C Promoter Polymorphism Is Associated with Hip Bone Loss in Older Men. K. Y. Z. Forrest*[1], J. M. Zmuda[2], J. A. Cauley[2], S. M. Roth*[3], R. E. Ferrell*[2]. [1]Slippery Rock University of Pennsylvania, Slippery Rock, PA, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA, [3]University of Maryland, Pittsburgh, PA, USA.

Interleukin 6 (IL6) plays an important role in osteoclast formation and bone resorption. A G to C polymorphism at position -174 in the IL6 promoter region has been associated with IL6 gene transcription, plasma IL6 levels, and with bone metabolism and the rate of bone loss in women. In the present study, we examined the association between the IL6 G-174C polymorphism and the rate of hip bone loss in 296 men aged 50 years and older (mean ± SD, 66 ± 7 years). Total hip bone mineral density (BMD) was measured at baseline and after an average of 7 years, and the annualized percentage (%/yr) and absolute (mg/cm^2/yr) rates of change in BMD calculated. The G-174C polymorphism was genotyped using polymerase chain reaction and fluorescence polarization. Despite similar initial BMD, men with the GG or GC genotypes (n=255) had a significantly greater rate of decline in hip BMD (-0.16 ± 0.67 %/yr) compared to men with the CC genotype (n=41) (0.07 ± 0.51 %/yr). These results remained statistically significant after adjusting for age, baseline BMD, and weight change during follow-up (P≤0.05). We found similar patterns for the annual absolute rate of change in hip BMD by IL6 genotype (P≤0.07). These findings suggest that older men with the IL6 -174G allele may experience an accelerated rate of decline in hip BMD with aging, similar to previous findings reported for older women.

Correlations of the Estrogen Receptor Alpha Coactivator RIZ1 Deletion with Bone Mineral Density in Men and Women. E. Grundberg*[1], H. Brändström*[1], E. L. Ribom*[2], O. Johnell[3], E. Orwoll[4], Ö. Ljunggren[1], H. Mallmin[2], T. Carling*[2], A. Kindmark[1]. [1]Dept of Medical Sciences, Uppsala University, Uppsala, Sweden, [2]Dept of Surgical Sciences, Uppsala University, Uppsala, Sweden, [3]Dept of Orthopedics, Malmo University Hospital, Malmo, Sweden, [4]Oregon Health and Science University, Portland, OR, USA.

ER-alpha is one of the candidate genes that have been most extensively studied in relation to bone mineral density (BMD). ER-alpha requires a number of cofactor for activation of target genes. Recently it has been shown that RIZ1 (Rb-interacting zinc finger) is a coactivator of ER-alpha and strongly enhances ER-alpha function. RIZ1 was initially characterized as a tumor suppressor gene, and maps to chromosome 1p36, which has been reported as a QTL for BMD. Also, in vitro studies have demonstrated that a deleted form of the RIZ1 gene, lacking a proline (P704) at exon 8, responds in a decreased manner to estrogen compared to the wild-type gene. Consequently, we have investigated the correlations of the P704 deletion in the RIZ1 gene with BMD in a population based study of 317 young women and in a subset of 295 men from the Swedish part of the ongoing MrOS study. BMD was measured by dual x-ray absorbtiomtery (DXA) at spine, total body, total hip and heel and by Quantitative Ultrasound (QUS) at the heel. The RIZ1 deletion was amplified by PCR from the individual's leukocyte DNA and analysed for genotype. Individuals homozygous for the deletion were denoted P704- hom, individuals with absence of the deletion on both alleles were denoted P704+ hom and individuals heterozygous for the deletion were denoted Het. The RIZ1 deletion was in Hardy-Weinberg equilibrium in both study populations and the genotype frequencies were P704+ hom 19%, Het 50%, P704- hom 31% in the female cohort and P704+ hom 19%, Het 54%, P704- hom 27% in the male cohort. The results show that after adjustments for height, age, fat and lean mass, BMD at the heel was significantly higher (p=0.02) in women homozygous for the P704+ allele compared to the heterozygous group. Same pattern was shown in men regarding BMD at the heel in relation to RIZ1 genotype, although not statistically significant. A borderline significant (p=0.06) correlation of QUS at the heel with RIZ1 genotype was observed in men after adjustments for BMI, indicating that also men homozygous for the P704+ allele have higher BMD compared to the heterozygous group. No correlations were found between the RIZ1 deletion and total hip either in the female cohort or in the male cohort. Taken together, these findings support the hypothesis that the RIZ1 deletion, lacking a proline at position 704, has an impaired capacity to bind ER-alpha, resulting in a decreased response to estrogen and thus lower BMD of the heel.

Analysis of Polymorphisms of Vitamin D Receptor (VDR) and Estrogen Receptor A (ERa) Genes in an Italian Population From Lampedusa Island (Sicily). G. Di Fede*[1], A. Falchetti*[2], L. Masi[2], F. Del Monte*[2], F. Marini*[2], A. Gozzini*[2], C. Berni*[3], V. Ghinoi*[2], N. Napoli*[1], G. B. Rini[1], G. Cusumano*[1], S. Bucchieri*[1], C. Sferrazza*[1], M. C. Pandolfo*[1], M. L. Brandi[2]. [1]Internal Medicine, University of Palermo, Palermo, Italy, [2]Internal Medicine, University of Florence, Florence, Italy, [3]Clinical Physiopathology, University of Florence, Florence, Italy.

Vitamin D receptor (VDR) and Estrogen Receptor a (ERa) gene polymorphisms have been thoroughly reported to account for most of the well established genetic influence BMD, although conflicting results appeared in literature on the possible role that such polymorphisms may play in BMD control. The purpose of this study was to assess the role of VDR and ERa gene polymorphisms in a Lampedusa island postmenopausl women cohort. Total population of Lampedusa consists of 5908 individuals with 2867 women. We analyzed 229 postmenopausal women for VDR and ERa genotypes. Analyses have been performed according to described methods. For FOK1 polymorphism of VDR gene we observed frequencies of F allele equal to 64% and f allele 36%. FF, Ff and ff genotypes were, respectively, 34%, 60% and 6%. PvuII and XbaI polymorphisms of ERa gene exhibit the following frequencies: P 46%, p 54%, X 40% and x 60%. The frequencies of genotypes were: PP 20%, Pp 53%, pp 27%, XX 15%, Xx 50 and xx 35%. In a subgroup of 156 subjects (age range 58.7±9.15 yrs.) BMD was evaluated at lumbar spine (LS) by DXA (Hologic, 2000) and by QUS (Hologic, Achilles) at calcaneal level.
Ancova analysis (including age, age from menopause, weight and height as covariates) was performed to evaluate the association between genotypes and BMD expressed as T-score for DEXA and QUS evaluations. We observed that subjects with ff genotype had a significant lower T-score for BUA, SoS, and LS in comparison with Ff and FF genotypes (BUA: -2.54 SD vs. –1.39 SD and vs. –1.25 SD; p= 0.005; SoS: -1.88 SD, vs. –1.52 SD and vs. –0.81 SD; p= 0.003; LS: -2.82 SD, vs. –1.12 SD and vs. 0.36 SD; p= 0.0008). No statistically significant associations were observed for ERa genotypes both with QUS and DEXA BMD. Finally, when we combined the 3 polymorphisms we found that subjects with association of ff with xx or Xx and with pp genotypes exhibited BMD values significantly lower than single ff genotype (BUA: ffppxx –4.07 SD, ffppXx -3.26 SD; p=0,0005; SoS: ffppxx –2.09 SD, ffppXx –2.24 SD; p=0.0001; LS: ffppxx –3.17 SD, ffppXx –4.99 SD; p=0,002). In conclusion, our preliminary findings strongly suggest that VDR FOK1 polymorphism may play an important role to influence BMD values in postmenopausal women and that interaction between VDR and ERa gene polymorphisms may be important for identification of individuals at higher susceptibility risk for bone loss and fracture.

Study of Osteonectin Gene Polymorphisms in Men with Idiopathic Osteoporosis. A. M. Delany[1], J. Shubert-Coleman*[2], R. Bahl*[2], T. L. Colvin*[3], J. Powell*[3], E. S. Kurland[3]. [1]St. Francis Hospital & Medical Center, Hartford, CT, USA, [2]Univ. Connecticut Health Center, Farmington, CT, USA, [3]Columbia University College of Physicians & Surgeons, New York, NY, USA.

Osteonectin (SPARC, BM-40) is one of the most abundant non-collagen matrix components in bone. Mice bearing a null mutation in the osteonectin gene develop low turnover osteopenia, indicating that osteonectin is important for the maintenance of bone mass. In addition, decreased levels of osteonectin are associated with several animal models of bone fragility and with cultured osteoblasts from patients with osteogenesis imperfecta. For these reasons, we performed a candidate gene study to determine whether polymorphisms in the osteonectin gene are associated with low bone mass in a group of well characterized middle-aged men with idiopathic, low turnover osteoporosis. All patients had Z scores < -2.0 at the lumbar spine, hip or radial shaft, with markers of bone turnover in the low normal range, and reduced indices of bone formation assessed by histomorphometry. Genomic DNA was isolated from patients and from healthy, non-osteoporotic controls (with Z scores > -1.0 at all sites), matched for age, body mass index, and ethnicity (45 and 46 men, respectively). DNA was also isolated from a random sample population reflecting the ethnic mix of the suburban Hartford, CT region (147 individuals). Polymerase chain reaction-single strand conformation polymorphism (PCR-SSCP) analysis was used to screen the coding exons and splice junctions for variations in osteonectin gene sequence, and polymorphisms were confirmed by sequencing. The human osteonectin gene has 10 exons, 9 of which contain protein coding regions, and we found exons 3 and 10 were polymorphic in our analysis. Exon 3 had 1 single nucleotide polymorphism (SNP) which was silent and 1 SNP in intron C, and their allele frequencies were similar among the osteoporosis patients, matched controls, and random population sample. Exon 10 yielded 1 SNP at base +998 (C to G), in the 3' untranslated region, which is associated with RNA stability. 100% of the random sample population and matched controls were homozygous for the C allele, compared with 91% of the patients. The remaining 9% of the patients had the C/G genotype (different from controls, $p < 0.05$, Fisher's Exact test). It was previously reported that the stability of osteonectin RNA in fibroblasts with the +998 C/C genotype is twice that found in cells with the C/G genotype, providing a mechanism for decreased osteonectin expression in the C/G cells. These data suggest that SNPs in exon 10 of the osteonectin gene may provide a genetic component to the development of idiopathic osteoporosis in a subset of men affected by this heterogeneous disorder.

Genetic Geterminants of the Homocysteine Metabolism in Relation to Bone Mineral Density and Fracture Risk. J. B. J. van Meurs[1], F. van Rooij*[2], P. Arp*[1], A. Hofman*[2], H. A. P. Pols[1], A. G. Uitterlinden[1]. [1]Internal Medicine, Erasmus MC, Rotterdam, Netherlands, [2]Epidemiology and Biostatistics, Erasmus MC, Rotterdam, Netherlands.

Osteoporosis has a strong genetic component. Previously, we saw that homocysteine levels predict fracture risk. We therefore examined whether genetic determinants of the homocysteine metabolism are associated with BMD and fracture risk. We analysed 6 polymorphisms in four key enzymes of the homocysteine metabolism which were reported previously to affect the homocysteine (hcys) serum level (see figure). We determined these polymorphisms in a population-based sample of 1058 postmenopausal women (aged 55-80 years) and analysed the relation to BMD and incident fractures (n=129, mean follow-up time 7 years). In a subset of 365 women we studied hcys levels in relation to the polymorphisms. All analyses were adjusted for age and BMI.
For the MTRR G66A polymorphism, we observed an allele-dose effect of the A-allele leading to a higher hcys level, but none of the other polymorphisms showed an association with hcys levels. We found a significant association between femoral neck BMD and the MTRR polymorphism (allele-dose=-0.015g/cm^2, p-trend= 0.003). In addition, both the MTHFR polymorphisms were associated with BMD differences. The T-allele of the MTHFR 677 polymorphism was associated with decreased femoral neck BMD (p-trend=0.03) and lumbar spine BMD (p-trend=0.02), while the C-allele of the MTHFR 1298 polymorphism was associated with increased lumbar spine BMD (p-trend=0.05). None of the 6 polymorphisms studied were associated with fracture risk. We conclude that in this study the MTRR G66A polymorphism is associated with hcys levels and BMD. In addition two polymorphisms in another key enzyme of the homocysteine metabolism, MTHFR C677Tand A1298, are associated with BMD differences, but none of the studied polymorphisms were associated with fracture risk. Future analyses of interaction effects will have to be done in larger samples of our population-based study.

Normative Values of Soluble RANKL in the Serum of Healthy Adults and Correlation with Various Parameters of Bone Metabolism. S. Kudlacek*[1], P. Pietschmann[2], W. Woloszczuk[3], R. Willvonseder*[1]. [1]Medical Department and LBI of Aging Research, Hospital Barmherzige Brüder Wien, Vienna, Austria, [2]Department of Pathophysiology, University of Vienna, Vienna, Austria, [3]LBI of Endocrinology, University of Vienna, Vienna, Austria.

RANKL (receptor activator of nuclear factor-kappa B ligand) is expressed on stromal and osteoblastic cells and in concert with osteoprotegerin, bone metabolism is regulated. OPG functions as a decoy receptor binding RANKL. This interaction results in inhibition of osteoclast differentiation and finally of bone resorption. Recently those components of bone turnover can be measured in serum samples by commercial available ELISA. Biochemical analysis of skeletal tissue has already been performed but its clinical approach remains further investigation. A sandwich ELISA (Biomedica®, detection limit 0,4 pmol/l) for sRANKL (soluble RANKL) was used, tests were performed in triplicates and samples were incubated overnight. For statistical evaluation we used SAS softare package. We determined soluble serum levels of RANKL and OPG, bone density (lumbar, spine DXA) and basic biochemical parameters of bone metabolism in 1029 normal individuals of a normal Austrian population (1). Overall, serum samples of sRANKL in females (n=635) and males (n=394) were determined. sRANKL levels were 0.37 ± 0.36 pmol/l (10.–90. percentile range 0.04–0.71 pmol/l) for females and 0.46 ± 0.46 pml/l (10.–90.percentile range 0.04–0.85 pmol/l) for males. When we determined sRANKL by decades for females and males seperately and used median we observed a certain decrease in males, whereas sRANKL levels in females kept constant over decades (see Tab.). Correlation with serum parameters and bone density showed a negative correlation of sRANKL with age in females and males ($p<0.05$). sRANKL and OPG were negtively correlated in females whereas positively in males suggesting different mechanisms of osteoporosis between genders. We investigated a certain influence of age on serum levels of bone matrix proteins. Certain levels of RANKL were quantifiable in serum of healthy adults. A wide variation sRANKL levels and their clinical impact has to be investigated.

Serum Osteoprotegerin as a Novel Marker of Metabolic Bone Disease. F. M. Hannan*[1], A. Fairney[1], P. Kyd*[1], A. Patel*[2]. [1]Endocrinology and Metabolic Medicine, Imperial College, London W2 1NY, United Kingdom, [2]Urology, St. Mary's NHS Trust, London W2 1NY, United Kingdom.

Osteoprotegerin (OPG) is a member of a recently discovered family of cytokines expressed by bone cells and is central to the regulation of bone remodelling. OPG is a soluble protein and is detectable in human serum by enzyme linked immunosorbent assay (ELISA). The relationship between serum OPG and disorders associated with abnormal bone remodelling is unclear.

Using a commercially available OPG ELISA, this study assessed whether serum OPG concentrations are altered in patients with the following metabolic bone disorders: post-menopausal osteoporosis, carcinoma of the prostate (CaP) with skeletal metastases, primary hyperparathyroidism (PHPT) and renal osteodystrophy.

Serum OPG concentrations did not significantly differ in patients with post-menopausal osteoporosis compared with age-matched subjects with no bone disease (median value 3.8pmol/l, range 2.2-7.5 pmol/l vs. median value 3.7pmol/l, range 1.4-5.7pmol/l; p=NS) and OPG levels did not significantly change in osteoporosis patients treated with the anti-resorptive agent alendronate. However, OPG levels were significantly elevated in patients with CaP skeletal metastases compared with patient with locally advanced CaP (median value 7.8pmol/l, range 3.2-17.3pmol/l vs. median value 5.0pmol/l, range 1.8-6.9pmol/l; p=0.024). Serum OPG was also significantly raised in PHPT patients compared with subjects with no bone disease (median value 5.3pmol/l, range 3.4-9.7pmol/l vs. median value 3.4pmol/l, range 1.84-5.21pmol/l; p=0.0008). End stage renal failure (ESRF) patients had markedly elevated OPG concentrations compared with subjects with no renal or bone disease (median 8.1pmol/l, range 2.9-27.4pmol/l vs. median 3.6pmol/l, range 1.3-7.4pmol/l; p<0.0001).

Serum OPG levels appeared to be elevated in disorders with profoundly abnormal remodelling such as skeletal metastatic disease. Whereas post-menopausal osteoporosis, which is associated with mildly abnormal bone turnover did not affect OPG concentrations. It is uncertain whether the markedly raised serum OPG in patients with ESRF represents underlying renal osteodystrophy or is secondary to reduced renal clearance.OPG shows promise as a novel biochemical marker of bone remodelling. However, more work is required to elucidate the metabolism and clearance of this cytokine and larger scale prospective clinical studies are recommended to evaluate the role of serum OPG in the management of metabolic bone disease.

Cytokine Composition of Commercial Platelet Rich Plasma Concentrates. L. S. Kidder, A. H. Schmidt*, R. F. Kyle*. Midwest Orthropedic & Minneapolis Medical Res Fdns, Minneapolis, MN, USA.

The initial response to a bone injury is the local aggregation of platelets, serving to immediately stem bleeding via clot formation. As the platelets at the site are entrapped within a fibrin meshwork, they begin to degranulate releasing a suite of osteotropic cytokines. In the US, there are currently two commercial methods designed to replicate and enhance this process by extracorporeally concentrating a patient's circulating platelets and placing them at the surgical site. One, (J&J DePuy Biologics; Raynham, MA), employs a centrifuge designed to separate the platelet fraction from an aliquot of whole blood. The other (ICI; Irvine, CA), concentrates the buffy coat fraction pheresised via cell-saver by removing a portion of the water from the plasma by hemoconcentrator filtration. This investigation evaluated the relative ability to of these two processes to concentrate certain osteotropic growth factors. Using quantitative sandwich enzyme immunoassay (ELISA), a survey of 18 orthopaedic patients found that both techniques successfully concentrated Fibroblast Growth Factor-basic (ICI: 258% of baseline; J&J: 275%) and Platelet Derived Growth Factor-BB (126% / 184%) above preconcentration levels. Vascular Endothelial Growth Factor was likewise concentrated by ICI's technique (249%), though the DePuy process failed to do so (97%). By concentrating autologous cytokines, both of these systems may be useful in encouraging bone formation in difficult orthopaedic applications. The relative clinical significance of differences in VEGF concentration remain unknown and a subject for further study.

Osteoprotegerin Levels of Bone Marrow: Associations with Peripheral Blood OPG levels and Bone Metabolism Markers. K. H. Baek*[1], W. Y. Lee*[2], M. I. Kang[1], K. W. Oh[3], J. H. Han[1], K. W. Lee*[1], H. Y. Son*[1], S. K. Kang*[1]. [1]Internal medicine, The Catholic University of Korea, College of Medicine, Seoul, Republic of Korea, [2]Internal medicine, Sungkunkwan University, Seoul, Republic of Korea, [3]Internal medicine, Mizmedi Hospital, Seoul, Republic of Korea.

Osteoprotegerin (OPG) is a potent antiresorptive molecule that binds the final effector for osteoclastogenesis, receptor activator of NF-κB ligand (RANKL). There are some data regarding possible relationships between peripheral blood OPG levels and various markers of bone metabolism. But there has been no study observing OPG levels of bone marrow where cellular interactions are continually occurring as part of bone remodeling process. The present study was carried out to clarify the interrelationships between bone marrow OPG levles and peripheral blood OPG levels and other markers of bone metabolism. In 19 patients (11 men, 8 women; 49.4±12.5 years old; 35 to 75 years old), bone marrow was sampled in order to determine the OPG levels. At the same time, markers of bone metabolism, including serum OPG, osteocalcin, carboxy-terminal cross linked telopeptide of type I collagen (ICTP) and parathyroid hormone, were measured from peripheral blood of each patients. DEXA was performed in all patients to determine the BMD of lumbar spine and femur. The mean bone marrow OPG levels are significantly lower than mean peripheral blood OPG levels (687.4±157.7 pg/ml, 836.5±191.9 pg/ml, $p<0.05$) and the bone marrow OPG correlated well with the peripheral blood OPG ($r=0.61$, $p<0.01$). Both bone marrow and peripheral OPG levels increased with age but more strong correlations were found between marrow OPG levels and age ($r=0.72$, $P<0.01$; $r=0.59$, $P<0.01$). There was significant correlations between the bone marrow OPG and blood PTH levels($r=0.53$, $p<0.05$) but not between the peripheral blood OPG and PTH levels. Bone marrow OPG levels correlated inversely with BMD of femoral neck and ward ($r=-0.48$, $p<0.05$; $r=-0.58$ $p<0.11$), and there was a trend for bone marrow OPG levels to be associated positively with bone resorption marker, ICTP. Peripheral blood OPG levels also correlated inversely with femoral neck BMD, but statistically not significant. Collectively, although bone marrow OPG is mirrored relatively well to peripheral blood OPG, bone marrow OPG may reflect more accurately the bone marrow microenvironment and bone marrow OPG levles better correlate with various markers of bone metabolism than peripheral blood OPG levels.

An In Vivo Model of T-cell Dependent Accelerated Bone Remodeling. W. Huang*, R. O' Keefe, R. Rosier*, E. Schwarz. Orthopedics, URMC, Rochester, NY, USA.

Several human diseases including ankylosing spondylitis, inflammatory arthritides, and fibrodysplasia ossificans progressiva are characterized by an enigmatic inflammatory T-cell response associated with new bone formation and altered local bone remodeling. To understand this process, we developed a new in vivo model of T-cell dependent accelerated bone remodeling based upon immunization with the classical contact hypersensitivity agent, dinitrofluorobenzene (DNFB). Immunization and challenge with DNFB elicits a strong T-cell dependent (type IV hypersensitivity) inflammatory response. Calvarial injection of minute quantities of DNFB into sensitized mice induced robust inflammation and proliferation of the subcalvarial periosteum within 72 hours. At 4 days, significant osteoclast recruitment and new bone formation had begun. By day 7, the extensive osteoclastic bone resorption and new bone formation caused a full-thickness calvarial defect localized to the site of antigenic injection (Figure). Inflammation and bone loss were greatly attenuated in T cell deficient RAG -/- and CD4 -/- mice, confirming a role for T-cells in the process. TNF-alpha over-expressing mice exhibited greatly increased bone resorption compared to wild type mice, suggesting an exacerbating role for TNF in bone loss. Our results support a paradigm in which antigen dependent T-cell activation induces focal periosteal inflammation and subsequently accelerate bone remodeling.

Loss of c-Kit Ligand Function Results in Low Bone Mass and Density in Mice. S. Lotinun, G. L. Evans*, T. E. Hefferan, R. T. Turner. Orthopedic Research, Mayo Clinic, Rochester, MN, USA.

The c-Kit tyrosine kinase receptor ligand, known as stem cell factor (SCF), is expressed in many cells including osteoblasts. However, its action on bone metabolism remains largely unknown. To examine the functional role of SCF/c-Kit signaling in bone growth, we used 6-week-old male mice with a loss of function mutation in the *Steel* (*Sl*) locus that encodes the Kit ligand. *Sl/Sl*^{d} mice grow slower and have shorter bones than wild type (WT) littermates. Bone mineral density (BMD) measured by double energy X-ray absorptiometry using PIXImus small animal densitometer indicates that mice that lack SCF had significantly ($P<0.05$) decreased BMD in tibia (0.047±0.002 vs 0.039±0.001) and femur (0.060±0.002 vs 0.046±0.002), but not lumbar vertebra, largely due to a reduction in bone mineral content. Histomorphometric analysis showed that bone formation rate was suppressed in both cortical and cancellous bone. Cancellous bone volume was 37% lower due to a significant decrease in osteoblast number (Ob.S/BS, 11.8±1.2 vs 7.6±1.6) and activity (MAR, 2.6±0.1 vs 1.8±0.2) and significant increase in osteoclast number (Oc.S/BS, 12.6±1.4 vs 20.0±2.1). To further investigate the cellular mechanism of SCF deficiency-induced osteopenia, we compared functions of osteoblasts derived from humerus of WT and *Sl/Sl*^{d} mice. [^{3}H]Thymidine incorporation studies showed that proliferation of primary osteoblasts derived from mutant mice was significantly suppressed by 46%. Moreover, a decrease in mineralization per DNA content was observed in *Sl/Sl*^{d} osteoblast culture. These results suggest that SCF plays a critical role in bone accretion during growth. Lack of SCF signaling-induced osteopenia is mediated by a combination of suppressed bone formation and increased bone resorption.

Insulin-Like Growth Factor (IGF)-I is Correlated with the Bone Size, but not with Bone Density. J. Son*[1], B. Kim[1], G. Kim*[1], S. Kim*[2], D. Lee*[2]. [1]Family Practice and Community Health, College of Medicine, Ajou University, Suwon, Republic of Korea, [2]Family medicine, Sungkyunkwan School of Medicine, Seoul, Republic of Korea.

IGF-I is related with bone mass. Bone mass is a function of bone size and volumetric bone mineral density (vBMD). We investigated whether IGF-I is related with bone size or vBMD. 300 men were recruited for this study. Bone mineral density (BMD) was measured at 3rd lumbar vertebra by dual-energy X-ray absorptiometry. Blood was sampled for measuring IGF-I and IGF binding protein (IGFBP)-3. Bone volume were calculated by Carter's method. IGF-I was significantly correlated with age, body mass index (BMI), bone mineral content (BMC), areal BMD (aBMD), height, area, bone volume, and vBMD at the L3 spine($r=-0.404$, 0.135, 0.235, 0.193, 0.329, 0.138, 0.136, 0.144, $P< 0.05$, respectively). After adjusting age and BMI, IGF-I was still correlated with BMC, and bone volume ($r=0.117$, 0.143, $P< 0.05$), but not with aBMD and vBMD ($r=0.056$, 0.096). IGFBP-3 was not correlated with any parameters at the L3 spine($r=0.125$, $P<0.05$), after adjusting age and BMI. We conclude that IGF-I is correlated with BMC, because of bone size, not because of Bone density.

Key words: Insulin growth factor-I, volumetric bone mineral density, bone volume

IGFBP-2 Is PTH Responsive and may Mediate the Anabolic Actions Of IGF-I in Bone. L. G. Horton*[1], K. L. Shultz*[1], C. L. Ackert-Bicknell*[1], W. G. Beamer[1], L. R. Donahue[1], M. L. Adamo[2], X. Ma*[2], D. Clemmons[3], J. Rubin[4], J. Burgess*[5], M. L. Bouxsein[1], C. J. Rosen[5]. [1]The Jackson Laboratory, Bar Harbor, ME, USA, [2]University of Texas Health Science Center, San Antonio, TX, USA, [3]University of North Carolina, Chapel Hill, NC, USA, [4]Emory University Medical School, Decatur, GA, USA, [5]St. Joseph Hospital, Bangor, ME, USA.

Insulin-like growth factor binding protein 2 (IGFBP-2) is a 34 kilodalton binding protein that circulates in relatively high concentrations and is expressed in many tissues, including bone. IGFBP-2 also binds to extracellular matrices, heparin, vitronectin and hydroxyapatite. IGF-II co-administered with IGFBP-2 prevents bone loss in rats, and high levels of IGFBP-2 plus a "big" form of IGF-II in hepatitis C is associated with osteosclerosis. The *Igfbp2* gene is located on Chr 1 in mice at 34.5cM and is a candidate gene for quanitative trait loci (QTL) related to both bone density and serum IGF-I in B6C3HF2 mice. Hence, we postulated that IGFBP-2 is important in mediating the anabolic effects of IGF-I on bone. Since C3H/HeJ (C3H) has higher circulating IGF-I and greater hepatic IGF-I expression than C57BL/6J (B6), we first performed western immunoblots (WIB) for serum IGFBP-2 in females of both strains. Serum IGFBP-2 by WIB was greater in C3H than B6. Additionally, liver IGFBP-2 mRNA by RNAse protection (RPA) was nearly 2-fold higher in female C3H than in female B6 ($p < 0.05$). To define the role of IGFBP-2 and IGF-I in bone *ex vivo,* we studied the effects of PTH and cAMP on calvarial IGF-I and IGFBP-2 from B6 and congenic B6.C3H-6T (6T), a B6 mouse constructed with a portion from Chr 6 of C3H exhibiting low serum IGF-I and reduced BMD [Bouxsein et al, JBMR 2002]. IGF-I secretion at 24 hours in 3-day old B6 and 6T hemi-calvariae cultures was dose dependent and optimal at 25nM PTH and 100μM cAMP. IGF-I in conditioned media

(CM) from hemi-calvariae did not differ by strain, and increased three to four fold over untreated CM after PTH, cAMP, or PTH+cAMP in both B6 and 6T ($p<0.001$). IGFBP-2 secretion did not differ by strain in the untreated CM, but increased nearly two fold ($p<0.05$) in the CM of B6, but not 6T, in response to PTH and cAMP+PTH treatment. Real time PCR from cultured calvariae revealed markedly elevated IGF-I mRNA levels in both strains in response to PTH, cAMP or both, whereas IGFBP-2 mRNA increased only in B6 calvariae (3-fold). OPGL expression increased with all treatments in both strains. We conclude that IGFBP-2 may play a key role in mediating the anabolic activities of IGF-I, both systemically and locally. The absence of an IGFBP-2 response to PTH in 6T calvariae may be important in the pathogenesis of low BMD in this congenic strain.

Parallel PI-3 Kinase and p42/44 MAP Kinase Signaling Pathways Subserve the Mitogenic and Anti-apoptotic Actions of IGF-1 in Osteoblastic Cells. A. Grey, Q. Chen*, X. Xu*, J. Cornish. Medicine, University of Auckland, Auckland, New Zealand.

Insulin-like growth factor 1 (IGF-1) is an endocrine and paracrine regulator of skeletal homeostasis, principally by virtue of its anabolic effects on osteoblastic cells. The molecular mechanisms by which IGF-1 regulates cellular processes vary in a cell-type specific fashion. In the current study we examined the intracellular signaling pathways by which IGF-1 promotes proliferation and survival in SaOS-2 human osteoblastic cells. Inhibition of each of the phosphatidylinositol-3 kinase (PI-3 kinase), p42/44 mitogen-activated protein (MAP) kinase and p70s6 kinase pathways partially inhibited the ability of IGF-1 to stimulate osteoblast proliferation and survival. Since activation of p70s6 kinase is downstream of both PI-3 kinase and p42/44 MAP kinase activation in osteoblasts treated with IGF-1, this ribosomal kinase represents a convergence point for IGF-1 induced PI-3 kinase and p42/44 MAP kinase signaling in osteoblastic cells. In addition, abrogation of PI-3 kinase-dependent Akt signaling, which does not inhibit IGF-1-induced p70s6 kinase phosphorylation, also inhibited the anti-apoptotic effects of IGF-1 in osteoblasts. Finally, interruption of $G_{\beta\gamma}$ signaling partially abrogated the ability of IGF-1 to promote osteoblast survival, without inhibiting signaling through PI-3 kinase/Akt, p42/44 MAP kinases or p70s6 kinase. These data suggest that IGF-1 signals osteoblast mitogenesis and survival through parallel, partly overlapping intracellular pathways involving PI-3 kinase, p42/44 MAP kinases and $G_{\beta\gamma}$ subunits.

TGF-b Improves Composite Cortical Bone Grafts Osteointegration in a Rat Model. M. L. E. Faria*[1], S. E. Weisbrode*[2], S. Stevenson*[3]. [1]Comparative Orthopaedic Research Laboratory, University of Wisconsin, Madison, WI, USA, [2]Pathobiology and Veterinary Clinical Sciences, The Ohio State University, Columbus, OH, USA, [3]Orthopaedics, Case Western Reserve University, Cleveland, OH, USA.

TGF-β is a potent multifunctional cytokine capable of immunesuppression and strong osteoinduction. This study was designed to determine the effects of TGF-β1 on histological parameters of cortical bone graft osteointegration. Seventy two Fischer rats were randomly assigned to three treatments groups as recipients of frozen cortical composite femoral bone transplants. Experimental groups received either (I) a single dose of 25ng of TGF-β1, locally administered during bone transplantation; or (II) the same 25ng intraoperatively, followed by continuous local administration of TGF-β 1 during 14 days. Control animals received no TGF-β. All rats were bilaterally implanted with subcutaneous minosmotic pumps delivering either PBS (control and group I rats) or TGF-β1-containing PBS (2ng TGF–1/ µl of PBS), into the center of the femoral grafts. All grafts were composites of frozen cortical bone and fresh syngeneic marrow cells ($1.5x10^8$ cells/ graft). One leg was transplanted with an allogeneic graft (Brown-Norway strain, H-1^n), while the contralateral leg received a syngeneic graft (Fisher strain. H-1^l). Bones were harvested at 1, 2 and 4 months after transplantation. Qualitative and quantitative histology were performed on nondecalcified, toluidine blue stained sections. One, two and three-way ANOVA was used to compare parametric data for main and interactive effects. Host-graft interface healing score were compared by Kruskal-Wallis ANOVA by ranks.
Effects of TGF–1 were most evident at 4 months after surgery. Marrow cell population was decreased by TGF–1 exposure. Allograft bones not exposed to TGF– had higher intracortical porosity than all other grafts and a striking individual variability in this parameter. Total bone area increased in all TGF–1 treated groups. New bone formed mostly on the peiosteum side of the grafts, even in animals receiving TGF–1 intramedullarely. Single administration of TGF–1 was sufficient to induce significant increase in new bone. Continuous administration of TGF–1 did not add to this effect. Grafts exposed to prolonged administration of TGF–1 showed a new bone of a more compact lamellar aspect than groups (where woven appearance predominated). Finally, decreased resorption of the originally transplanted cortex was observed in TGF–1- treated grafts.
Although the mechanisms underlying these results were not identified in here, we concluded that local TGF-β administration enhances bone graft incorporation. We propose possible pathways for these results.

Expression of Bone Morphogenetic Proteins and their Antagonists during Bone Regeneration. X. Chang*, Y. Shibata*, T. Tsukazaki, A. Yamaguchi. Oral Pathology and Bone Metabolism, Nagasaki University Graduat, Nagasaki, Japan.

Biological activity of bone morphogenetic proteins (BMPs) is regulated by several factors at both extracellular and intracellular levels. Although several lines of evidence demonstrated that BMPs play important roles in bone regeneration, the regulatory mechanism of BMP activity has not been clarified well during bone regeneration. To explore molecular mechanism of BMP action during bone regeneration, we investigated the expressions of mRNAs for BMPs and their possible antagonists that interact with BMPs at extracellular level by GeneChip (affimetrix) and real-time PCR analyses. We made a round hole, 1 mm in a diameter, at diaphysis of femur of 8-week-old male C57BL/6J mice. To verify the reproducibility of the experiments, the bone-healing process was examined daily by histological sections and Northern blot analysis for bone-related mRNAs. These studies revealed that numerous fibroblastic cells appeared on days 3, abundant osteoprogenitors appeared and bone formation occurred on day 5, then abundant bones filled bone defects on day 10. Expression levels of several bone-related mRNAs including osteocalcin increased after day 5. Thus we isolated mRNAs from normal bone (day 0) and regenerating bones 5 and 10 days after injury, and these mRNAs were subjected to GeneChip analysis, which covered 12424 genes. GeneChip analysis revealed up-regulation of BMP-4 and several BMP antagonists including BMP-1, Tolloid-like (Tll), Twisted gastrulation (Tsg), Follistatin (Fst)and Follistatin-like (Fstl) during bone regeneration. This analysis suggested no apparent changes in expression levels of noggin (Nog) and chordin (Chrd). To confirm expression profiles obtained from GeneChip analysis, we investigated the expression levels of these mRNAs by real-time PCR using tissues isolated from days 0, 2, 5 and 10 after injury. Real-time PCR analysis demonstrated that all of the genes above described including Nog and Chrd were up-regulated during bone regeneration, though the expression patterns are slightly different among genes examined. These results demonstrated that not only BMPs but also their antagonists were up-regulated during bone regeneration. The integrated expression profile of genes regulating BMP activity as shown in the present study might conduct proper bone healing.

Collagen V(α1) and Nephronectin are Regulated by TGF-β in Osteoblasts. S. Kahai*[1], A. Seth[2]. [1]Laboratory Medicine and Pathobiology and CIHR Group in Matrix Dynamics, University of Toronto, Toronto, ON, Canada, [2]Division of Molecular and Cell Biology Research and Laboratory of Molecular Pathology, Sunnybrook and Women's College Health Sciences Centre, Toronto, ON, Canada.

Production of extracellular organic matrix and its mineralization to form bone are key steps during osteogenesis. Bone matrix contains high concentrations of growth factors, particularly transforming growth factor β (TGF-β), which is known to play important regulatory roles during osteogenesis. Divergent effects of TGF-β1 on bone formation have been reported both in vitro and in vivo depending upon experimental conditions, cells employed, and their stage of maturation. The genome wide expression analysis provided by microarray based methods could reveal the involvement of genes previously not known to be involved in the TGF-β signal transduction network. In this study, cDNA microarray technology has been used to identify and study the expression profile of 8470 genes, some of which could be targets of TGF-β during osteogenesis. Microarray analysis of 8470 genes revealed 97 cDNAs to be differentially expressed in the clonal osteoblastic cell line MC3T3-E1 that had been treated with TGF-β1. From the 97 differentially expressed genes, we selected Collagen V(α1) {Differential expression = + 4.9} and Nephronectin {Differential expression = - 5.2} for further studies. Using Northern Blotting and Real-Time PCR we found that, when MC3T3-E1 cells were treated with TGF-β1, Collagen V(α1) was up-regulated and Nephronectin was down-regulated during the differentiation of preosteoblasts to osteoblasts. By Immunohistochemistry we found significant expression of the Nephronectin protein in the basement membrane of the developing tooth and the developing kidney, and in the developing long bone of E16.5 mouse embryos. Significant Collagen V(α1) mRNA and protein expression were seen by RNA *in-situ* hybridization and Immunohistochemistry respectively, in the developing long bone of E17.5 mouse embryos. In conclusion, by the use of in vivo and in vitro approaches we have discovered that, the Collagen V(α1) and Nephronectin genes are potential targets of TGF-β during osteogenesis.

TGF-ß regulates chondrocyte proliferation and differentiation via FGF and Smad2 in the perichondrium. R. A. Serra, J. Alvarez*, A. Murkherjee*. Cell Biology, University of Alabama, Birmingham, Birmingham, AL, USA.

TGF-ß inhibits chondrocyte proliferation and hypertrophic differentiation in metatarsal organ cultures by a perichondrium dependent mechanism, suggesting that factors synthesized in the perichondrium are involved. We previously showed that TGF-ß acts through PTHrP to regulate cartilage hypertrophic differentiation. To begin to identify the perichondrial factors that are involved in regulating proliferation by TGF-ß, we studied the effects of IGF-I and FGF on metatarsal organ cultures. As expected, increased proliferation as measured by BrdU incorporation was observed after treatment of organ cultures with IGF-I. A similar effect was seen after the perichondrium was removed from the metatarsals suggesting IGF-I acts directly on the chondrocytes. Treatment with FGF2 resulted in decreased BrdU incorporation into chondrocytes and increased BrdU incorporation in perichondrial cells, similar to what is observed after treatment with TGF-ß. BrdU incorporation was altered after FGF treatment when the perichondrium was removed suggesting FGF acts directly on chondrocytes. To determine if treatment with TGF-ß regulates IGF or FGF signaling, IGF and FGF receptor levels and activation were measured by immunoprecipitation/ immunoblot assays. Treatment with TGF-ß resulted in increased activation as measured by phosphorylation of FGFR3. The overall levels of FGFR3 were not altered by treatment with TGF-ß. In contrast, treatment with TGF-ß resulted in a reduction in the overall levels of IGFR1. The data suggest a model where TGF-ß regulates chondrocyte proliferation by regulating FGF signaling. TGF-ß acts via the Smad family of transcriptional regulators. To determine the mechanism of TGF-ß signaling in the perichondrium, we next tested the role of TGF-ß restricted Smad2 and Smad 3 in chondrocyte proliferation and differentiation in metatarsal cultures. Perichondrium of metatarsals was infected with adenoviruses that express dominant-negative forms of the TGF-ß type II receptor (Ad-DNIIR), Smad2 (Ad-DNS2), and Smad3 (AD-DNS3) as well as a control virus expressing the ß-galacotsidase reporter (Ad-ß-GAL). Infection was detected in about 70% of perichondrial cells in each case. Infection with AD-DNIIR and Ad-DNS2 completely blocked the effects of TGF-ß on chondrocyte proliferation and differentiation. In contrast, infection with Ad-DNS3 only partially blocked signaling by TGF-ß even though high levels of DNS3 were detected by immunoblot. Similar results were observed in metatarsal bones from Smad3-null mice suggesting that Smad3 in the chondrocytes does not contribute to this effect. The data suggest that primarily Smad2 mediates TGF-ß signaling in the perichondrium.

Mitogenic Mechanical Strain Activates Tyrosine Kinases FAK and PYK2/CAK Beta in Osteoblastic Cells. N. Boutahar*, A. Rattner*, A. Guignandon*, L. Vico, M. Lafage-Proust. Laboratoire de Biologie du Tissu Osseux, INSERM 0366, Saint-Etienne cedex 2, France.

Integrin signaling is one of the mechanisms thought to be involved in the mechanical loading-induced increase in bone formation. However the molecular events involved remain unclear. In this context, we studied the effects of radial cyclic strain (CS)(10 min, 1% @ 0.25Hz) on ROS 17/2.8 and rat primary osteoblastic cells, plated for 72 h on Type I collagen coated silicone membranes, using a FLEXCELL FX-3000 unit. The CS-induced increase in ROS 17/2.8 and primary cell proliferation observed by day 1, was blocked by MAPK inhibitor PD98059 (20µM). Signaling events were then assessed at various time points (0, 30 min, 4 h), after one CS with Western blotting (WB) and co-immunoprecipitation (CI) experiments on cells, serum-starved overnight. CS rapidly and time-dependently promoted phosphorylation of ERK2 at Tyr-187, focal adhesion kinase (FAK) at Tyr-397, the major autophosphorylation site, and at Tyr-925 located in the paxillin binding domain leading to activation of the Ras/Raf/MEK pathway. Cell transfection with FAK mutated at Tyr 397 strongly reduced phosphorylation of ERK2 at Tyr-187. CS also induced Src phosphorylation at Tyr-418 located at the Src catalytic domain. Treatment with the selective Src family kinase inhibitor pyrazolopyrimidine 2 (PP2, 10 µM) markedly reduced the phosphorylation of FAK Tyr-397 in basal conditions. In contrast, PP2 did not prevent FAK phosphorylation at Tyr-397 induced by mechanical strain suggesting a Src-independent activation of FAK. In order to identify other proteins involved in strain-induced signaling, we performed a WB with anti P-Tyr Ab (PY99). We found that, besides the 125 Kd band corresponding to FAK, another 110 Kd protein was highly phosphorylated in both ROS17/2.8 and rat primary cells. We identified this protein as PYK2 , a protein kinase highly homologous to FAK, phosphorylated at Tyr 402. Strain promoted the FAK to PYK association in a time-dependent manner as well as the phosphorylation of effectors of their adhesion-targeting domains, such as the highly homologous proteins paxillin and Hic-5.
In conclusion we found that a mitogenic mechanical stimulus induced phosphorylation of the focal contact proteins FAK and PYK2 that might be at the origin of the activation of the MAPK pathway. Thus, osteoblastic cells may use this PYK2-FAK cooperation to orchestrate cytoskeleton regulation and signaling in response to mechanical strain transmitted in part by extracellular matrix.

Gene Expression Profilingafter Mechanical Loading in the Mouse Ulna Model. S. E. Harris[1], M. A. Harris[1], D. Guo*[1], A. G. Robling*[2], L. F. Bonewald[1], C. H. Turner[2]. [1]Oral Biology, UMKC SOD, Kansas City, MO, USA, [2]Orthopedic Surgery, Indiana Univ School of Med, Indianopolis, IN, USA.

Mechanical loading of bone results in various osteogenic stimuli to bone cells, but frequency, amplitude, and intervals between loading bouts can play critical roles in the extent of new bone formation. To begin to understand the genomic regulatory network that is altered after mechanical loading, we have begun an investigation of the gene expression profiles after various times of loading using the mouse ulna loading model. The right ulna was loaded for 1 bout of 60 cycles (2 Hz; peak force of 2.4 N). The left ulna served as an internal control. We developed a method to efficiently extract total RNA, with a yield of 10-15 ug, by combining extract from the diaphyseal region of 5 ulnaes. From 500 ng of total RNA, a full length cDNA population was generated with RACE type primers using a temperature resistant reverse transcriptase at 55°C. From the cDNA population, we determined an optimal PCR strategy to amplify the cDNA to the 1 to 3 ug range using only 19 cycles. From this amplified cDNA, P^{33} probes were prepared for microarray analysis. We have analyzed the gene expression profile at 1 and 2 hrs after a single loading bout using 5K oligonucleotide plastic arrays and for analysis, *Atlas Image Software, Excel, Access,* and the bioinformatics software, *Biomine*. We have been able to analyze approximately 600 genes that are at least 1.5 times above background. For example in the first data set, the osteocyte selective genes, Dentin Matrix Protein1 (Dmp1) and osteoblast/osteocyte factor 45, also known as MEPE are highly expressed. Dmp1 increases approximately 2 fold at 1 hr after loading. CD44 is decreased while several ribosomal protein genes are increased in a coordinate manner. Two annexin genes are upregulated. Most interestingly the cdc42 gene is increased 3 fold, suggesting that after loading the osteocytes and/or periosteal cells are initiating a program for generating cellular extensions such as filapodia or dendritic processes. Cdc42 is also known to increase β-catenin activity. Initial analysis indicates that several muscle-related genes are activated on loading, possibly due to the small muscle contamination in the RNA preparations. Further analysis of these genes and other time points should allow us to begin a systematic search for genes that may be downstream of mechanical stimuli in bone.

Mechanotransduction via Glutamate Receptors: Regulation of Osteoclast Activity in Response to Mechanical Stimulation. K. M. Black[1], B. L. Theriault*[2], G. I. Anderson[2]. [1]Pharmacology, Dalhousie University, Halifax, NS, Canada, [2]Pharmacology, Surgery, Biomedical Engineering, Dalhousie University, Halifax, NS, Canada.

The actions of glutamate, an excitatory neurotransmitter involved in pathways of learning and memory, are mediated by a variety of glutamate receptors (gluRs). GluRs expressed in osteoblasts and osteoclasts of the long bones of rat, rabbit, and mouse have are sensitive to mechanical stimulation, the driving force for maintenance of normal bone density. We postulate that gluRs mediate mechanical stimulation to increase bone density in a manner analogous to their role in mediating CNS synaptic plasticity. Marrow-derived murine osteoclasts express glutamate receptors belonging to the NMDA, AMPA, and metabotropic subgroups. Immunocytochemical data suggest that mechanical stimulation decreases the expression of gluRs. In our cultures, gluR antagonists MK801 and NBQX inhibit osteoclast differentiation and to some extent function, implying that these receptors are functional. We wished to further characterize the role and extent of gluR mechanosensitivity in our cultured osteoclasts. Bone marrow cells from femora and tibiae of 7-week old female CD1 mice were seeded onto collagen-I coated silastic membranes, and grown for 6-7 days with mechanical stimulation on days 4, 5, and 6 (1 Hz, 900 cycles). Mature osteoclasts were partially purified from harvested cells using anti-RANK coated immunomagnetic beads and total RNA (day 6) or total protein (day 7) was isolated. Cells were cultured at the same density on glass coverslips for 7 days, immunostained for gluRs and actin or vinculin, and examined using confocal microscopy. Using RT-PCR and Western blots, we confirmed our preliminary immunocytochemical results showing that the expression of osteoclast gluRs is sensitive to mechanical stimulation. Additionally, we were able to show, using RT-PCR analysis of TRAP and calcitonin receptor mRNA, that the bead-purified isolates were highly osteoclast-enriched when compared with unseparated isolates, demonstrating the utility of this strategy to isolate osteoclasts following growth in mixed culture. Using confocal microscopy we found that the gluRs on osteoclasts appear to colocalize with actin and vinculin, which suggests they exist near focal adhesions, further strengthening their hypothesized role as mechanotransducers. Studies are ongoing to elucidate the exact mechanism by which gluRs convert mechanical stimulation into intracellular signals to regulate osteoclast function, and ultimately how they contribute to the maintenance of bone density.

Hypergravity Stimulates the Extracellular Matrix/Integrin-Signaling Axis and Proliferation in Primary Osteoblasts. M. Parra*[1], W. Vercoutere*[1], C. Roden*[1], I. Banerjee*[1], W. Krauser*[2], E. Holton[1], N. Searby*[1], R. Globus[1], E. Almeida*[1]. [1]NASA Ames Research Center, Moffett Field, CA, USA, [2]NASA Astrobiology Institute, Moffett Field, CA, USA.

We set out to determine the molecular mechanisms involved in the proliferative response of primary rat osteoblasts to mechanical stimulation using cell culture centrifugation as a model for hypergravity. We hypothesized that this proliferative response is mediated by specific integrin/Extracellular Matrix (ECM) interactions. To investigate this question we developed a cell culture centrifuge and an automated system that performs cell fixation during hypergravity loading. We generated expression vectors for various focal adhesion and cytoskeletal proteins fused to GFP or dsRed and visualized these structures in transfected (or infected) osteoblasts. The actin cytoskeleton was also visualized using rhodamine-phalloidin staining and Focal Adhesion Kinase (FAK) levels were assessed biochemically. We observed that a 24 hour exposure to 50-g stimulated proliferation compared to the 1-g control when cells were plated on fibronectin, collagen Type I, and collagen Type IV, but not on uncoated tissue culture plastic surfaces. This proliferative response was greatest for osteoblasts grown on fibronectin (2-fold increase over 1-g control) and collagen Type I (1.4 fold increase over 1-g control), suggesting that specific matrices and integrins are involved in the signaling pathways required for proliferation. Exposing osteoblasts grown on different matrices to 10-g or 25-g showed that effects on proliferation depended on both matrix type and loading level. We found that osteoblasts exposed to a short pulse of hypergravity during adhesion spread further and had more GFP-FAK containing focal adhesions compared to their 1-g controls. While overall levels of FAK did not change, more FAK was in the active (phosphorylated) form under hypergravity than in the 1-g controls. Cytoskeletal F-actin organization into filaments was also more prominent after brief exposures to hypergravity during the first five minutes of adhesion. These results suggest that specific integrins sense hypergravity and activate distinct matrix-dependent FAK signaling pathways that can enhance proliferation. Our results also imply that brief exposures to hypergravity accelerate cell adhesion and spreading processes via the focal adhesion-signaling axis. These results support the role of the ECM/integrin-signaling axis in osteoblast response to hypergravity loading.

Alterations in Gene Expression as Induced by the Presence/Absence of Mechanical Loads. N. Zhong*[1], M. Squire[1], L. Donahue[2], C. Rubin[1], S. Judex[1], M. Hadjiargyrou[1]. [1]Biomedical Engineering, SUNY, Stony Brook, NY, USA, [2]The Jackson Laboratory, Bar Harbor, ME, USA.

Maintenance of normal bone density requires the coordinated activity of osteoblasts and osteoclasts, influenced by functional loading bearing. Attenuation of these loads, which occurs under conditions such as microgravity, can lead to osteopenia, while increases in load, through stimuli such as vibration, can be strongly anabolic. While the bone tissue and cell response to changes in function are well characterized, little is known of the transcriptional activity which regulates these responses. Previously we have shown that 10 minutes per day of whole body vibration at 45 Hz (0.3g) increased trabecular bone formation rates in the tibia of BALB/cByJ by 32%, while hind limb suspension (disuse) decreased bone formation rates by 55%. Here, quantitative real-time RT-PCR was used to explore the underlying molecular basis for these rapid changes in bone cell activity. Sixteen-week old female BALB mice were randomly assigned to control, disuse, and mechanical stimulation groups (n=6 each). Mechanically stimulated mice were placed on a vibrating platform (0.25g, 45 Hz) for 10 min/d, 5 d/wk. After 4 and 21 days, RNA was extracted from the entire left tibiae (including bone marrow and cartilage). For each time point, RNA samples were pooled (2 groups of n=3) and processed for real-time RT-PCR analysis (n=2). All results were normalized to GAPDH. The 15 candidate genes selected for this study were categorized into 3 groups: 1) Bone formation related: BMP-2, collagen type I, osteopontin, osteonectin, cbfa-1, osterix, IGF-1, Nos-2; 2) Bone resorption related: RANKL, cathepsin K, MMP-2, 9, 13; 3) Miscellaneous: Integrin β3 and a novel gene. Following four days of disuse, the largest transcriptional changes were observed with collagen type I (-55%), BMP-2 (-26%), osteonectin (- 44%), osteopontin (+ 28%), MMP-2 (- 35%), and osterix (- 36%). Large changes in gene expression were also observed at 21 days of disuse, especially for Osterix (- 24%) and the novel gene (- 48%). In contrast, 4 days of mechanical stimulation resulted in relatively small increases (<18%) with several genes, while at 21 days of mechanical stimulation - the largest changes in transcriptional activity were seen with MMP-2 (+ 54%), MMP-13 (+ 35%), RANKL (+23%), collagen type I (+20%), BMP-2 (+18%), and Nos-2 (+ 41%). Based on these data, we conclude that a complex, and temporally sensitive, series of transcriptional changes precedes both resorptive and formative adaptations to mechanical challenges. The significance of these molecular changes in defining the anabolic and/or catabolic response remains to be determined.

Fresh Femoral Neck Fractures Treated by Osteosynthesis and Fibular Autograft. S. Singh*. Orthopaedics, B.P.K.I.H.S., Dharan, Nepal.

Introduction: Femoral neck fractures in younger adults have a poor prognosis because of high incidence of non-union and aseptic necrosis. Prosthetic replacement of the femoral head is reserved for the older patients. Osteosynthesis is the treatment of choice for displaced fracture neck femur in younger adults. Various types of bone graft supplementation have been advocated to reduce the incidence of nonunion and avascular necrosis. We tried cannulated cancellous screw fixation supplemented by primary fibular autografting in femoral neck fractures to overcome the problems of nonunion and avascular necrosis.
Materials and methods: Thirty-five (M:18, F:17) skeletally mature patients (mean age 49.38 years) of fresh femoral neck fracture were treated by closed reduction and one/two cancellous screw fixation along with ipsilateral fibular autograft between January1999 to September 2002. Weight bearing was allowed only after 3 months, or later if the radiological signs of union was not seen.
Results: Twenty-five patients who had completed a follow-up of two and a half years (mean-32.7 months) were analysed. Twenty-three of the twenty-five patients showed union. In two patients the fracture did not unite. Only two cases showed asymptomatic avascular necrosis. Fibular graft was broken in three cases, screw back out with collapse was seen in two cases. Post-operative radiographs showed penetration of the articular surface by screw and graft in one cases each .
Conclusion: Cancellous screw fixation and primary fibular autografting is a safe, effective and reliable surgical technique for treating fresh femoral neck fractures in younger patients.
Key words: Fractures; Femur neck; Fibular autograft; Cancellous screw

Total and Lean Body Mass Determine Appendicular BMD and BMC in Ad Libitum-Fed and Diet Restricted SENCAR, C57, and DBA Mice. E. J. B. Murray[1], S. S. Murray*[1], M. E. L. Duarte[2]. [1]GRECC/Medicine, VAGLAHS/University of California, Los Angeles, Sepulveda, CA, USA, [2]Histology and Embryology, Universidade Federal do Rio de Janeiro, Rio de Janeiro, Brazil.

Dietary restriction (DR) prolongs the lifespan by up to 50% and retards the development of age-related diseases. The effects of DR on bone range from deleterious to beneficial, depending upon the animal model tested, the age at which DR is instituted, and the composition of the diet. In all cases, DR is associated with low body mass, one of the major risk factors for low bone mass and density. The purpose of this research was to determine the effects of aging and DR on axial and appendicular BMD and BMC in three strains of mice that differ in body mass, free radical generation capacity and down-stream oxidative damage (SENCAR > C57 > DBA). Male mice of each strain were killed at 2.5 months of age or randomized to an *ad libitum*-fed or a 30% diet restricted feeding group for up to 1 year. DR mice were fed a diet normalized vs. the *ad libitum*-fed diet with respect to Ca, P, vitamins, and micronutrients. Body composition, BMD, and BMC were determined by high-resolution small animal densitometry with a PixiMUS. The relationships between total body, femoral, humeral, mandibular, and vertebral BMC or BMD and body mass (total, lean, or fat) were determined using the least squares linear regression method with fitting to the polynomial equation $f = y_0 + ax$, where f is the BMD (g/cm^2) or BMD (g) and x is the mass indicated (grams). The major result of the study is the observation that a single regression line describes the relationships between total and lean body mass and total body, femoral, and humeral BMD and BMC in all strains. R values ranged from 0.879 (lean body mass x femoral BMC; $p < 0.0001$) and 0.757 (total body mass x femoral BMC; $p < 0.0001$) to 0.419 (total body mass x total body BMD; $p = 0.0011$). In contrast, fat mass was less significantly correlated with bone mass, with R values ranging from 0.418 (fat mass x vertebral BMD, $p = 0.0011$) to 0.321 (fat mass x femoral BMD, $p = 0.0139$). Thus, our results confirm previous studies indicating that the low BMDs and BMCs observed in DR animals can be accounted for based on body mass and demonstrate that the mechanostat appears to be "set" at a similar level for all strains within a single species. Furthermore, the correlation between fat mass and BMD at a nonweight-bearing site (vertebrae) supports a significant role for adipose cell-derived factors, such as leptin, in regulating bone mass in these three strains of mice.

Skeletal Responses to Altered Loading of Growing Transgenic Mice that Express a Function-Perturbing Form of Beta-1 Integrin in Osteoblasts. R. K. Globus[1], D. Amblard[1], Y. Nishimura*[1], J. Litzenberger*[1], M. L. Corcoran*[1], E. A. C. Almeida*[1], C. E. Wade*[1], E. Morey-Holton[1], C. D. Damsky*[2], J. B. Kim*[2], T. J. Wronski[3], U. T. Iwaniec*[3], M. C. H. van der Meulen[4]. [1]NASA Ames Research Center, Moffett Field, CA, USA, [2]University of CA., San Francisco, CA, USA, [3]University of Florida, Gainesville, FL, USA, [4]Cornell University, Ithaca, NY, USA.

Cell culture studies demonstrate that integrins mediate critical cell functions, including mechanotransduction, although their roles in responding to mechanical forces in bone are not known. To address this, we analyzed skeletal responses to altered weightbearing in transgenic mice (TG) engineered to express the transmembrane domain and cytoplasmic tail of beta-1 integrin driven by the osteocalcin promoter. When expressed in cultured MLOY4 osteocytes, this fragment was dominant negative for adhesion and migration. To manipulate loading, TG and wildtype mice (WT) were hindlimb unloaded by tail suspension for 1wk (63d old) or 4wk (35d old) with normally–loaded, age-matched controls (CT).

To evaluate recovery from 4wk hindlimb unloading, mice were released to ambulate normally (reloaded). Bones were analyzed for dry mass, ash mass, mineral fraction (ash/dry), and tibial curvature. Comparison of 90d old CT groups revealed TG had a lower body mass (-9.8%), lower tibial ash mass (-14.4%) and lower tibial curvature (-10.1%) compared to WT. In WT, hindlimb unloading for 1wk reduced body mass (-9.0%) and raised serum corticosterone (+121%) compared to CT. Hindlimb unloading for 1wk also caused a significant decrement in mineral fraction (-2.7%) of unloaded tibiae relative to CT, but did not affect loaded humeri. In contrast, hindlimb unloading for 4wk caused lower body mass, bone mass and mineral fraction of both tibiae and humeri compared to CT. TG showed similar, but lesser, effects of hindlimb unloading than WT. Reloading of WT and TG resulted in a partial recovery from the adverse effects of hindlimb unloading. In addition, reloaded mice of both genotypes had lower tibial curvature than CT. We propose skeletal changes due to hindlimb unloading resulted from both reduced mechanical loading and systemic stress. The observed differences due to genotype support the hypothesis that expression of a function-perturbing form of beta-1 integrin in mature osteoblasts reduced sensitivity to mechanical loading.

Influence of Physical Activity on Quantitative Ultrasound Variables from 5 Devices: the OPUS-Study. F. E. Thomasius[1], A. Stewart*[2], D. Felsenberg*[1], D. M. Reed*[2], R. Eastell*[3], C. Roux*[4], C. C. Glüer*[5]. [1]Freie Universität, Berlin, Germany, [2]University of Aberdeen, Aberdeen, United Kingdom, [3]University of Sheffield, Sheffield, United Kingdom, [4]René Descartes University, Paris, France, [5]University Hospital Schleswig-Holstein, Kiel, Germany.

Immobility is an important risk factor for bone mineral density loss. We examined the influence of physical activity on quantitative ultrasound (QUS) results in the Osteoporosis & Ultrasound Study (OPUS) which is a European population based study of 2374 postmenopausal women aged 55 to 79 years. Each woman answered a questionnaire including questions on physical activity: 1. hours of walking or bicycling per day (WB) (groups analysed: none (WB-) or > 1 hour (WB+)), 2. physical activity (PA) since leaving school (groups analysed: none (PA-) or > 2 hrs per week (PA+)), 3. Number of months having been confined to bed. QUS scans of the heel (Lunar Achilles+ (Ach), UBIS 5000 (UBIS), OSI/Osteometer DTU-one (DTU), Quidel/Metra QUS-2 (QUS-2)) and of the finger (Igea DBM Sonic Bone Profiler (IGEA)) were performed. Broadband ultrasound attenuation (BUA), speed of sound (SOS), stiffness index (STIFF IND), amplitude dependent speed of sound finger (AD-SoS), ultrasound profile index finger (UBPI), and bone transmission time finger (BTT) were measured. Weak correlations between physical activity and QUS results were shown (correlation coefficients $r < 0.1$, $p<0.05$ except for AD-SoS, BTT and UBPI for number of months confined to bed). Comparison of the mean values of QUS results (groups indicated above) showed significantly higher QUS results for the groups with the higher physical activity.

Table 1: Mean QUS results +/- standard deviation for PA and WB, n= number of cases

QUS results	PA+ (n)	PA- (n)	WB+ (n)	WB- (n)
Ach BUA in dB/MHz	109 +/- 10 * (397)	106 +/- 9 (645)	108 +/- 10 ((968)	105 +/- 11 (50)

Skeletal Response to Mechanical Loading and Subsequent Deconditioning in Young and Adult Rats. I. Pajamaki*[1], H. Sievanen*[2], T. Vuohelainen*[1], J. Tuukkanen[3], M. Jarvinen*[1], P. Kannus*[1], T. L. N. Järvinen[1]. [1]Department of Surgery, University of Tampere, Tampere, Finland, [2]UKK Institute, Tampere, Finland, [3]University of Oulu, Oulu, Finland.

Fifty young (5-19-week-old) and 50 adult (33-47-week-old) male Sprague-Dawley rats were used to test whether aging modulates the skeletal responsiveness to loading either *quantitatively* or *qualitatively*, and to assess whether the possible mechanical loading-induced changes are better preserved in the young than adult skeleton.

At entry, the rats were randomly assigned into eight groups: Four control groups and four exercise (+deconditioning) groups. Rats in the exercise groups were subjected to 14-week period of progressive running program at the age of 5- or 33- weeks, after which half of the exercised rats (both young and adult) were sacrificed while the remaining rats were allowed to move freely in their cages for a subsequent deconditioning period of 14 weeks. The control rats were kept free in their cages for the entire study period and sacrificed with their respective exercise group (14, 28, 42 and 56 weeks after the entry). At each time point, peripheral quantitative computed tomography and mechanical testing of the femoral neck was performed and total cross-sectional area (tCSA), total bone mineral content (tBMC), total bone mineral density (vBMD), and the breaking load of the femoral neck (Fmax) were determined.

The results are summarized in the Table. No difference was observed in the skeletal responses between the young and adult rats.Similarly, the ability to maintain exercise-induced bone gain did not differ between the age-groups.

In conclusion, this study showed that there was no difference in the skeletal responsiveness to loading between young and adult rats. However, the young skeletons seem to adapt through geometrical changes (increase in bone size) whereas adult skeletons showed increase in bone density. Age did not seem to modulate the ability of the skeleton to maintain the exercise-induced bone benefits, since no difference was observed in the loss of bone in the young and adult rats after cessation of the exercise.

The response (EX vs. CTR, %) of young and adult rats to mechanical loading and deconditioning

	tCSA	tBMC	vBMD	Fmax
Young, exercised	+25***	+28***	+11*	+30**
Adult, exercised	+10	+18***	+23***	+28**
Young, deconditioned	+17*	+18*	+2	+11

Acute Effects of Moderate Intensity Resistance Exercise on Bone Cell Activity. T. J. Whipple*[1], B. Le*[1], L. Demers*[2], M. A. Petit[3], N. Sharkey*[4], N. I. Williams*[4]. [1]Dept. of Orthopaedics, Penn State University, University Park, PA, USA, [2]College of Medicine, Penn State University, Hershey, PA, USA, [3]Dept. of Health Evaluation Sciences, Penn State University, Hershey, PA, USA, [4]Dept. of Kinesiology, Penn State University, University Park, PA, USA.

Resistance exercise is considered to have positive long-term effects on bone mass, but little is known about the mechanisms by which this occurs. The purpose of this study was to determine whether the performance of a single bout of moderate intensity resistance exercise alters biochemical markers of bone cell activity. Indices of bone turnover were measured in nine healthy, untrained young men, before and following a single session of resistance exercise and during a control trial. Blood samples were collected immediately before, immediately after, and at 1, 8, 24, and 48 hours post exercise and analyzed for bone-specific alkaline phosphatase (BAP), type I collagen propeptide (PICP), and type I collagen N-telopeptide (SNTX). Urine from the second morning void was collected over four days (day before, day of, and two days following exercise) and analyzed for type I collagen N-telopeptide (UNTX). **Results:** Exercise resulted in a significant increase ($P < 0.05$) in the ratio of biochemical markers of bone formation to bone resorption eight hours post exercise. **Conclusion:** A single session of moderate intensity resistance exercise performed by untrained young men appears to have stimulated a transient perturbation in biochemical markers of bone cell activity favoring bone formation in the absence of antecedent bone resorption.

Protein Kinase A Coordinates Ion Channel Activities to Enhance the Intracellular Calcium Response to PTH or Fluid Shear in Osteoblasts. R. L. Duncan, J. Zhang*, J. A. Bethel*, N. A. Ajubi. Orthopaedic Surgery, Indiana University School of Medicine, Indianapolis, IN, USA.

PTH increases the $[Ca^{2+}]_i$ response of osteoblasts to shear that can be mimicked by activation of PKA with forskolin or 8 br-cAMP. While we have previously reported that PTH and cAMP produce increased activation of mechanosensitive channels (MSCC) we postulate that PKA interacts with other ion channels to further enhance the $[Ca^{2+}]_i$ response. We used both patch clamp and $[Ca^{2+}]_i$ imaging of MC3T3-E1 or UMR106.01 osteoblasts to examine the effects of PKA on channel activity and $[Ca^{2+}]_i$. Fluid flow (0.3 ml/min) or PTH treatment (50 nM) increased the activity of a 5-6 pS channel from NP_o values of 0.12 $\pm$ 0.04 to 1.63 $\pm$ 0.41 ($p<0.05$). Addition of 8 br-cAMP (100 μM) or forskolin (10 μM) produced a similar increase. This channel conductance is the same as the increase in single channel conductance we had previously reported for the MSCC in PTH-stimulated UMR106.01 cells. These data suggest that PTH-induced PKA activation is activating this smaller channel, rather than introducing a subconductance state of the MSCC channel. Whole cell patch studies of L-type voltage-sensitive Ca^{2+} channels (VSCC) in the presence of forskolin demonstrated a significant increase in peak currents (263 $\pm$ 37 nA to 407 $\pm$ 59 nA; $p<0.05$) with a slight, but not significant reduction in the depolarization required for activation. We also found that PKA activation was responsible for changes in channel kinetics of an outwardly rectifying K^+ channel. Addition of forskolin or 8 br-cAMP reduced whole cell K^+ currents by 40% within 10 min of treatment. To determine how PKA-induced reduction of the outwardly rectifying K^+ current would influence the $[Ca^{2+}]_i$ response to mechanical stimulation, we hypotonically challenged UMR106.01 cells in the presence of the K^+ channel inhibitors triethylammonium chloride (TEA; 1 mM) or 4-aminopyridine (4-AP; 1mM) and measured the resultant $[Ca^{2+}]_i$ response. K^+ channel inhibition increased the baseline $[Ca^{2+}]_i$, but reduced the peak $[Ca^{2+}]_i$ response to hypotonic challenge. While the hypotonic-induced increase in $[Ca^{2+}]_i$ returned to baseline after 10 min in control cells, inhibition of the outwardly rectifying K^+ channel prolonged the $[Ca^{2+}]_i$ response such that $[Ca^{2+}]_i$ did not return to basal levels after 25 min. These data would suggest that shear activates PKA to increase the activity of a small conductance channel which enhances the shear-induced depolarization. PKA also increases Ca^{2+} entry by altering L-type VSCC kinetics. The Ca^{2+} response is further enhanced by reduced K^+ currents to prevent rapid return of the membrane potential to resting levels.

Study of the Effects Produced by 17-Beta-Estradiol and Raloxifene on Fas-Mediated Apoptosis in Primary Human Osteoblast in Culture. C. Garcia-Moreno*[1], M. P. Catalan*[2], A. Ortiz*[2], L. Alvarez*[3], C. de la Piedra[1]. [1]Bone Pathophysiology Lab, Fundacion Jimenez Diaz, Madrid, Spain, [2]Nephrology Department, Fundacion Jimenez Diaz, Madrid, Spain, [3]Orthopaedics Department, Fundacion Jimenez Diaz, Madrid, Spain.

It is known that estrogen deficiency produces an increase in the production of the proinflammatory cytokine TNF-alfa in bone. TNF-alfa stimulates bone resorption and is implicated in bone loss after menopause. TNF-alfa can induce apoptosis in cells of the osteoblast lineage and this mechanism could regulate osteoblast cell number and bone loss. We investigated the effects produced by 17-beta estradiol (E) and raloxifene (R) on Fas-mediated apoptosis in cultured human primary osteoblast-like cells (HOB) primed with TNF-alfa.

Fas-mediated apoptosis induced by agonistic anti-Fas IgM (CH-11) was determined by flow cytometry of permeabilized, propidium iodide stained cells. HOB Fas mRNA levels were measured by semiquantitative rt-PCR, using Fas primers that amplify mRNA from Fas bound to membrane (with death activity). HOB cell membrane Fas receptor expression was analyzed by flow cytometry. HOB were obtained from postmenopausal women (n=3) without bone disease undergoing orthopedic surgery. HOB were cultured in DMEM (Dulbecco´s Modified Eagle Medium) without FBS and pretreated with TNF-alfa (200U/ml) and 10-8M E or R during 48h. Then, we examined Fas-mediated apoptosis induced by CH-11 (1microg/ml) during 24h.

TNF-alfa did not modify spontaneous HOB apoptosis. The combination of CH-11 plus TNF-alfa increased HOB apoptosis 679+/-316% with respect to untreated cells. The addition of 10-8M E or R did not produce any significant effect in the level of apoptosis induced by CH-11 and TNF-alfa. Fas mRNA expression significantly increased in cells pretreated with TNF-alfa at 6, 24, 30 y 48 hours versus untreated cells. Expression of Fas receptor increased significantly (152+/-23%) in cells pretreated with TNF-alfa with respect to HOB (100%). Neither E nor R modulated TNF-alfa induced Fas expression at the mRNA or protein level.

In conclusion, treatment of HOB with TNF-alfa could increase the Fas-mediated apoptosis. Increased Fas mRNA and receptor expression may account for this effect. These events are not affected by E or R, an observation that suggests that these compounds did not impact Fas-mediated apoptosis.

Decreased Osteoblast Apoptosis and Increased Bone Formation in Implants of Marrow-Derived Osteoblast Progenitors Overexpressing Bcl-2: *In Vivo* Evidence for a Pivotal Role of Apoptosis in Bone Formation. I. Gubrij, A. A. Ali, T. M. Chambers*, S. B. Berryhill*, X. Liu*, P. Roberson*, C. A. O'Brien, R. S. Weinstein, S. C. Manolagas, R. L. Jilka. Div. Endo&Metab, Center for Osteoporosis and Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. of Arkansas for Medical Sciences, Little Rock, AR, USA.

Increased or decreased osteoblast apoptosis is associated with corresponding changes in osteoblast number caused by glucocorticoid excess, or intermittent administration of PTH, or activation of non-genotropic estrogen-like signaling. Here, we tested directly whether programmed cell death is an important determinant of the rate of bone formation by overexpressing the anti-apoptotic protein Bcl-2 in murine bone marrow-derived osteoblast progenitors, and measuring the amount of bone they form following implantation into mice. Marrow progenitors were transduced with a murine replication-deficient retrovirus expressing human Bcl-2 (hBcl-2), and neomycin phosphotransferase to permit selection of transduced cells. The transduced cells exhibited uniform immunocytochemical staining for hBcl-2, and expression of hBcl-2 was 20-fold higher than the endogenous protein, as measured by Western blotting. The overexpressed hBcl-2 protein was evidently functional as the transduced progenitors were protected from etoposide-induced apoptosis, determined by in situ end labeling (ISEL). The basal level of apoptosis was also decreased from 5% to 2%, whereas proliferation measured by BrdU labeling was unaffected. Bcl-2-transduced progenitors exhibited increased osteoblastogenic capacity following 25 days of culture as evidenced by a 5-fold increase in osteocalcin secretion and calcified bone nodule formation, as compared to progenitors transduced with green fluorescent protein (GFP). To establish the impact of Bcl-2 overexpression on bone formation *in vivo*, hBcl-2-transduced progenitors or GFP controls were embedded in collagen and implanted subcutaneously into immunodeficient mice. Serial undecalcified sections from bone spicules that formed after 4 or 8 weeks were analyzed for the prevalence of osteoblast apoptosis, and bone architecture was measured by image analysis after Von Kossa staining. At both time points, osteoblast apoptosis in spicules from hBcl-2-transduced progenitors was attenuated by 2-fold. Moreover, bone made by Bcl-2-transduced cells exhibited a significant ($P<0.05$) increase in trabecular thickness at 4 weeks (GFP: 16.6 ± 1.7 μm vs. Bcl-2: 20.0 ± 1.8 μm) and at 8 weeks (GFP: 26.1 ± 1.5 μm vs. Bcl-2: 29.7 ± 1.5 μm). We conclude that programmed cell death of osteoblasts, osteoblast progenitors, or both is a major determinant of bone formation.

Raloxifene Protects Osteoblasts from Apoptosis Induced by Sodium Nitroprusside: Potential Involvement of Ceramide. S. M. P. Olivier*[1], M. Fillet*[2], M. G. Malaise*[1], J. Piette*[2], V. Bours*[2], M. Merville*[2], N. Franchimont[1]. [1]Rheumatology, University of Liège, Liège, Belgium, [2]Center for Cellular and Molecular Therapy, University of Liège, Liège, Belgium.

Raloxifene is a selective estrogen receptor modulator (SERM) possessing estrogen-like agonist effects on bone but its exact cellular mode of action remains unclear. We tested the possibility that raloxifene modifies MC3T3-E1 osteoblastic cell viability induced by two NO-donors, sodium nitroprusside (SNP) and S-nitroso-N-acetyl-penicillamine (SNAP). SNP (1-4mM) and SNAP (0.3-0.5mM) dose-dependently decreased MC3T3-E1 cell viability. Cell viability was maintained when MC3T3-E1 cells were pretreated with raloxifene but not with 17B-estradiol or the bisphosphonate pamidronate. Annexin-V labeling demonstrated that cell death mediated by SNP resulted from apoptosis and raloxifene protected these cells from apoptosis. SNP induced an increase in intracellular ceramide (C22 - C24) that was inhibited by raloxifene. In contrast, in the presence of SNAP, raloxifene had no significant effect on MC3T3-E1 cell viability. However, SNAP induced cell death by late apoptosis or necrosis, enhanced NO production with a different kinetic than SNP and did not modify intracellular ceramide levels. SNP treatment was associated with an increased AP-1 activity that was partially inhibited by both raloxifene and 17B-estradiol indicating that AP-1 modulation was not associated with raloxifene anti-apoptotic effect. Our data demonstrate that raloxifene prevents osteoblast apoptosis induced by SNP, underlining a positive effect of raloxifene on bone quality.

Ghrelin Stimulates Proliferation and Inhibits Apoptosis in MC3T3-E1 Cells. S. W. Kim*, J. A. Kim*, S. J. Heo*, M. J. Jeon*, D. H. Kim*, S. Y. Kim*, C. S. Shin. Internal Medicine, Seoul National University College of Medicine, Seoul, Republic of Korea.

Ghrelin is a 28-amino acid peptide that has recently been discovered in human and rat stomach. Ghrelin strongly stimulates the release of growth hormone and is a natural ligand of the growth hormone secretagogue receptor (GHSR), which belongs to a seven transmembrane receptor family. Previous studies have shown that GHSRs are expressed mainly in the brain and pituitary, but are also detected in a variety of tissues including myocardium, adrenal, and gonads. This study was undertaken to investigate the expression and role of ghrelin and GHSR in osteoblasts using mouse calvarial osteoblast cell line MC3T3-E1. We have identified the expression of both ghrelin and GHSR by RT-PCR analysis of MC3T3-E1 cells. Treatment of these cells with ghrelin from 10^{-11} to 10^{-8} M showed dose-dependent stimulation of proliferation as assessed by MTT assay. [^{3}H]-Thymidine uptake was also increased by 41 % after treatment with 10^{-12} M of ghrelin. Moreover, when apop-

tosis was evaluated using fluorescence microscopy and flow cytometry after cell staining with DAPI or Hoechst 33342, ghrelin treatment suppressed serum deprivation- and TNFalpha-induced apoptosis in this cell line.
We examined the mitogen-activated protein kinase (MAPK) pathway as a possible downstream signaling of ghrelin in the regulation of proliferation and apoptosis. Ghrelin (10^{-9}M) elicited a rapid phosphorylation of Erk1/2 (p42/p44 MAPK) in MC3T3-E1 cells, which was abolished by treatment with MEK inhibitor, PD98059 and U0126. Activation of MAPK pathway by ghrelin was abolished by treatment with PKC inhibitor, staurosporin, suggesting that PKC-MEK cascade is used for ghrelin signaling via its receptor in osteoblasts. Ghrelin treatment has no effect on the differentiation of osteoblasts as assessed by alkaline phosphatase activity and expression of osteocalcin. Taken together, ghrelin stimulates cell growth as well as inhibits apoptosis without apparent effect on differentiation. We suggest ghrelin as a direct mitogen and survival factor of osteoblast.

Dexamethasone Induces Caspase Activation in Murine Osteoblastic MC3T3-E1 Cells. C. Chua*, B. Chua*, Z. Chen*, C. Landy*, R. C. Hamdy. Osteoporosis Center, James H. Quillen College of Medicine, East Tennessee State University, Johnson City, TN, USA.

Glucocorticoids are widely used as anti-inflammatory and chemotherapeutic agents. However, prolonged use of glucocorticoids leads to osteoporosis. This study was designed to examine the mechanism of dexamethasone (DEX)-induced apoptosis in murine osteoblastic MC3T3-E1 cells. Total RNA was extracted from MC3T3-E1 cells treated with 10^{-7} M DEX for 6 h. DEX exerted a variety of effects on apoptotic gene expression in osteoblasts. Ribonuclease protection assays revealed that DEX upregulated mRNA levels of caspases-1, -3, -6, -8, -11, -12, and bcl-X_L. Western blot analysis showed enhanced processing of these caspases, with the appearance of their activated enzymes 8 h after DEX treatment. In addition, DEX also induced the activation of caspase-9. DEX elevated the levels of cleaved poly(ADP-ribose) polymerase and lamin A, a caspase-3 and a caspase-6 substrate, respectively. Expression of bcl-X_L protein level was upregulated by DEX. Cytochrome c release was detected in the cytosol of DEX-treated cells. Furthermore, caspase-3 enzyme activity was elevated by 2-fold after DEX treatment for 7 h. Finally, early apoptotic cells were detected in cells treated with DEX for 3 h. Our results demonstrate that DEX-induced apoptosis involves gene activation of a number of caspases and bcl-X_L.

Defect of Bone Formation/Remodeling in CDK4 Null Mice. M. C. Rico, J. L. Castaneda*, S. N. Popoff, F. F. Safadi. Anatomy and Cell Biology, Temple University School of Medicine, Philadelphia, PA, USA.

For normal skeletal growth and development the relationship between cell proliferation and differentiation must be tightly regulated. Osteoblasts are committed to enter the cell cycle and proliferate under specific regulatory signals, then differentiate and produce a mineralized matrix. Various cyclins, cyclin dependent kinases (CDKs) and cyclin dependent kinase inhibitors (CDKIs) have been postulated to play a role in osteoblast proliferation and differentiation. Among them is CDK4, a cell cycle protein that plays a major role in the transition of cells from the G_0 phase to the S phase. Previous studies showed that CDK4 null (CDK4-/-) mice develop type I diabetes associated with stunted growth. These animals also exhibited cancellous osteopenia. Western blot analysis was used to confirm the lack of CDK4 protein in bone from CDK4-/- when compared with wild type (WT) animals. In this study, we performed histomorphometric analyses of distal femoral metaphysis, which demonstrated a significant decrease in bone volume and osteoid surface in CDK4-/- compared with WT bones. Densitometry by peripheral quantitative computerized tomography (pQCT) showed a reduction in trabecular bone density in CDK4-/- compared to WT mice. We also examined the expression of osteoblast-related genes, such as alkaline phosphatase, osteocalcin, osteopontin, and type I collagen in bone from CDK4-/- and WT animals. The expression of all these genes were markedly decreased in CDK4-/- compared with WT mice. We also evaluated the expression of Cyclin D, p27 and p21. Cyclin D is a protein involved in the formation of the cyclin D/CDK4 complex, p27 is an inhibitor of cyclin D/CDK4 complex formation and p21 is an inhibitor of the Cyclin D/CDK4/6 complex formation. Western blot analyses demonstrated a decrease of cyclin D, p27 and p21 expression in CDK4-/- compared to WT mice. Cell proliferation was measured using Bromo-deoxyuridine (BrdU) *in vivo*. Cell proliferation was slightly decreased in cells in the periosteum of CDK4-/- compared to WT mice. Expression of ED1 in macrophages/osteoclasts revealed a significant increase in the size and number of the osteoclasts present at the periosteum of CDK4-/- compared with WT mice, suggesting an increase in bone resorption. Our data suggest that CDK4 plays an important role in bone formation/remodeling. Additional studies are being pursued to understand the precise role of CDK4 and its mechanism of action in osteoblasts/osteoclasts.

Osteopontin Plays a Role in Regulating Apoptosis and Mineralization under the Control of Inorganic Phosphate. Y. Koyama*[1], K. Kitahara[1], S. R. Ritting[2], K. Tsuji[1], T. Yano*[3], Y. Taketani*[3], A. Nifuji[1], D. T. Denhardt[2], M. Noda[1]. [1]Dpt. of Molecular Phamacology, Tokyo Medical and Dental University, Tokyo, Japan, [2]Dept.of Nutritional Sciences, Rutgers University, Piscataway, NJ, USA, [3]University of Tokyo, Tokyo, Japan.

Inorganic phosphate(Pi) is a major component of bone extracellular matrix. Pi has a role in bone remodeling. High levels of Pi induced apoptosis of osteoblasts, and Pi is required for mineralization. Osteopontin is a phosphorylated glycoprotein secreted to the mineralizing extracellular matrix by osteoblasts during bone development. It is reported that OPN may enhance cell survival by inhibiting apoptosis and may have relation with mineralization. Osteopontin RNA and protein in osteoblast are induced in response to elevated extracellular phosphate levels. We investigated whether osteopontin had relation to regulate Pi induced osteoblast apoptosis and mineralization. First, cell survival was estimated by MTT assay. Calvaria out growth cells of wild type (WT) mice and osteopontin knock out (OPN-KO) mice was cultured in the presence of phosphate from 1mM to 10mM. After four days, cell survival was estimated by MTT assay. Cell survival of both WT and OPN-KO was inhibited at high concentration of Pi, but cell survival of OPN-KO was significantly inhibited in moderate concentration of Pi compared to WT. In TUNEL analysis, TUNEL-positive cells were seen after treatment with 3-10 mM/L Pi. As the Pi concentration was raised, there was a profound increase in TUNEL-postive cells. Cell death was identified to cause to apoptosis. Secondly, we investigated mineralization. Calvaria out growth cells of WT and OPN-KO were cultured in the presence of phosphate from 1mM to 10mM. After twelve days, the cells were treated with 1-10 mM Pi. After 48 hours, matrix mineralization was assessed by Alizarin Red staining. High levels of Pi induced in vitro mineralization, but mineralization in OPN-KO cell culture was significantly inhibited in moderate concentration of Pi in compared to WT. This time, cell survival was estimated by MTT. Cell survival was almost not chaged in 1-10 mM Pi. Present study suggests that OPN plays a negative role in Pi induced osteoblast apoptosis, while it promotes mineralization. At the sites of bone remodeling, osteoblasts may be exposed to high concentration of Pi. When Pi concentration was raised, OPN expression may be induced in osteoblasts and OPN could enhance cell survival by inhibiting apoptosis and induce mineralization. Thus, osteopontin plays a role in regulating apoptosis and mineralization under the control of inorganic phosphate.

Bone-specific Runx2 Levels Are Tightly Regulated during the Cell Cycle to Support a Novel Function in Control of the Switch from Proliferation to Quiescence in Osteoblasts. M. Galindo*, J. L. Stein*, J. B. Lian, G. S. Stein, A. J. van Wijnen. Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA.

The Runx2 (CBFA1/AML3/PEBP2αA) transcription factor promotes skeletal cell differentiation by activating bone phenotypic genes in post-proliferative osteoblasts. However, Runx2 is also present in actively dividing osteoprogenitor cells, and recent genetic evidence from our group indicates that the factor performs a dual regulatory role in control of osteoblast growth and differentiation. We addressed here whether this novel cell growth regulatory function of Runx2 is functionally linked to the cell cycle related mechanisms that drive normal osteoblast proliferation.
We show by western and northern blot analyses that serum deprivation of MC3T3 osteoblastic cells, which mediates cell cycle exit into G_0/G_1, upregulates Runx2 protein and mRNA levels. In contrast, Runx2 levels are downregulated within 4 to 8 hr after quiescent cells are induced to proliferate by the reintroduction of serum, and further suppressed prior to entry into S phase. Hence, Runx2 expression is acutely responsive to cessation and stimulation of cell growth. Inhibitor experiments with agents that cause cell cycle arrest in S phase (e.g., hydroxyurea, aphidicolin), G1 phase (e.g., mimosine) or mitosis (e.g., nocodazole) reveal that Runx2 destabilized at the G1/S phase transition. Destabilization of Runx2 is prevented in the presence of the proteasome inhibitor MG132 which is consistent with control of Runx2 levels by specific degradation via the ubiquitin-proteosome pathway prior to S phase. Thus, Runx2 is tightly regulated during the cell cycle. Anti-sense mediated reduction of the low physiological levels of Runx2 in proliferating MC3T3 cells does not accelerate cell cycle progression, but elevation of Runx2 levels by forced expression significantly decreases the rate of cell proliferation. These data establish that Runx2 activity is functionally coupled to osteoblast proliferation and may support exit from the cell cycle to induce a post-proliferative quiescent stage during normal osteoblast differentiation.

Osteoblast Apoptosis and Survival Is Regulated by Integrin-mediated Surface Attachment. V. Grigoriou*[1], C. S. Adams[2], I. M. Shapiro[2], E. A. Cavalcanti-Adam*[3]. [1]Department of Orthodontics, University of Pennsylvania, School of Dental Medicine, Philadelphia, PA, USA, [2]Department of Orthopaedic Surgery, Thomas Jefferson University, Philadelphia, PA, USA, [3]Institut für Physikalische Chemie, Universität Heidelberg, Heidelberg, Germany.

Although it is recognized that most osteoblasts end their life history by apoptosis, the mechanism by which bone cell apoptosis is regulated remains elusive. Herein we test the hypothesis that cellular attachment chemistry regulates the sensitivity of osteoblasts to the

activity of apoptogens. We use a novel method of grafting RGD molecules to a culture surface to upregulate integrin binding in osteoblasts. Integrin and integrin signaling component expression levels were evaluated in MC3T3E1 osteoblast-like cells cultured on RGD-treated membranes in comparison to RGE-treated membranes for 0.5h, 3h, 24h and 72h. The RGD-modified surface exhibited upregulation of $\alpha_v\beta_3$ integrin and of the β_3 subunit. There was a marked increase in activation of Akt in cells bound to RGD peptides, after 3 days in culture. While there was no change in protein levels of both the proapoptotic protein Bad nor the anti apoptotic protein Bcl-2, there was an increase in pBad, the inactive form of Bad. Apoptotic sensitivity was assessed by MTT assay. Incubation of cells on the RGD-treated membrane completely inhibited apoptosis induced by 0.1 and 0.5 μM staurosporine; 3 mM Pi and 2.4 mM and 2.9 mM Ca^{2+}; and 0.5 mM and 0.1 mM SNP. However, surface modification has no effect on RGD peptide or serum-free induced apoptosis. Furthermore surface modification significantly increased the sensitivity of cells to etoposide. When PI3 kinase was inhibited by LY294002 the surface-stimulated resistance to apoptosis was abrogated. The data presented in this investigation clearly indicate that tethered RGD peptides suppress apoptosis and upregulate osteoblast survival via integrin-mediated attachment.

Inhibition of MEK-ERK-Elk Signaling by Androgens may Influence Osteoblast Apoptosis. K. Wiren, A. Toombs*, X. W. Zhang. Portland VA Medical Center, OHSU, Portland, OR, USA.

While non-aromatizable androgens have significant beneficial effects on skeletal homeostasis independent of conversion to estradiol, the effects of androgens on bone cell metabolism are still poorly understood. The aim of this study is to elucidate the effects of the non-aromatizable androgen 5α-dihydrotestosterone (DHT) on osteoblast viability. We used an osteoblastic model with enhanced androgen responsiveness: MC3T3-E1 cells stably transfected with androgen receptor (AR) under the control of the rat 3.6-kb α1(I)-collagen promoter fragment (colAR-MC3T3). Previously we had demonstrated DHT inhibition of the MEK-ERK-Elk phosphorylation cascade using mitogenic pathway-specific cDNA microarrays, confirmed by Western and reporter analyses. Since the MAPK signaling can modulate both proliferation and apoptosis, we first determined the effect of DHT on osteoblast viability. ColAR-MC3T3 cultures were treated with DHT and the effects on osteoblast viability were measured by MTT assay. A complex response was observed in that continuous short-term DHT treatment (10–^{8}M DHT; 2d) enhanced osteoblast viability ($P<0.05$), but inhibition was observed with longer-term DHT treatment (3 and 5d; $P<0.01$). The inhibition by DHT was abrogated in the presence of the specific androgen receptor antagonist hydroxyflutamide, and was also observed in primary cultures of normal rat calvarial osteoblasts assessed with ^{3}H-thymidine incorporation. A downstream target of Elk-1 is c-*fos*, a component of AP-1. AP-1/luciferase reporter activity also demonstrated complex DHT modulation, with short-term treatment (6 h) activating but extended treatment (24, 48h) inhibiting activity. Apoptosis was assessed after induction by etoposide treatment (50μM; 18h) by measuring either accumulation of cytoplasmic mono- and oligonucelosomes or caspase-3 activity using DEVD cleavage. Continuous treatment with DHT (10–^{8}M DHT; 5 days) enhanced apoptosis over two-fold ($P<0.001$), but as expected similar treatment with 17ß-estradiol inhibited apoptosis. Interestingly, by day 20, continuous treatment with DHT had no significant effect on apoptosis. In conclusion, we have demonstrated that non-aromatizable androgens influence bone cell viability through an effect on MAP kinase signaling. This data further discriminates the effects of androgens (enhances apoptosis) and estrogens (inhibits apoptosis) in proliferating osteoblasts. These observations may help generate hypotheses for investigating the mechanisms of sexual dimorphism in skeletal development and aging.

Cloning and Identification of Novel CREM Isoforms Expressed by Osteoblasts. F. Liu*, Y. Huang, B. E. Kream. Medicine, University of Connecticut Health Center, Farmington, CT, USA.

CREM, the cAMP response element modulator, is a member of the CREB/CREM/ATF family of transcription factors. The CREM gene encodes both antagonists and activators of cAMP-dependent transcription by alternative splicing and the differential use of 4 promoters (P1-P4). The expression of CREM isoforms transcribed from the P1 promoter is cell, tissue and developmental stage specific. We previously showed that osteoblasts express ICER, a dominant negative transcriptional attenuator that is cAMP inducible and transcribed from the P2 promoter of CREM gene. Moreover, preliminary data from our laboratory showed that male CREM knockout mice might have a blunted anabolic response to PTH. Therefore, the goal of the present study was to identify the repertoire of CREM transcripts expressed in osteoblasts. Using RT-PCR and primers that should amplify all P1 promoter initiated full-length transcripts, we cloned and identified 14 CREM isoforms expressed in osteoblastic MC3T3-E1 cells. Interestingly, of the 14 isoforms, 6 were previously unidentified CREM isoforms: CREMτα/γ, CREM-x, CREMτ2α, CREM τ1α, CREM τ1α/γ and CREM τ1γ. CREMτα/γ, and CREM τ1γ are alternative splice variants of CREMτα and CREM τ1, respectively, which contain the γ domain. CREMτ2α is a splice variant of CREM τ2α/γ that excludes the γ domain. CREM τ1α has the similar structure to CREM τ1 except that it contains both of the 2 alternative DNA binding domains of CREM. CREMτ1α/γ is a splice variant of CREM τ1α without the γ domain. Interestingly, CREM-x contains the θ1 exon, which was previously identified only in P3 promoter initiated transcripts, and a previously unidentified exon, termed the L exon, located 100 nucleotides upstream of the θ1 exon and 16.9 k nucleotides downstream of the B exon. Using RT-PCR, we also showed that the expression of CREM P1 promoter initiated transcripts was similar among MC3T3- E1 cells, 6-8 day old mouse calvariae, 2 month old mouse calvariae, primary calvarial osteoblasts and bone marrow stromal cells that had undergone osteogenic differentiation. In conclusion, at least 14 P1 promoter initiated isoforms of the CREM gene were expressed in several murine osteoblast models. Of these, 6 were novel transcripts while 5 resulted from alternative splicing or usage of the γ domain and/or alterative usage of the first DNA binding domain. One new transcript, CREM-x, contains a novel L exon. We speculate that CREM transcription factors may play a regulatory role in PTH-dependent signal transduction in osteoblasts.

Fibroblast Growth Factor 2 Directly Inhibits Expression of Osterix mRNA in Osteoblastic Cells. E. Abugunde*, K. Lee, T. Naganawa*, L. Xiao, M. Hurley. Medicine, University of Connecticut Health Center, Farmington, CT, USA.

Osterix is a recently identified novel zinc finger-transcription factor that is essential for osteoblast differentiation and specifically expressed in all developing intramembranous and endochondral bones. Osterix acts downstream of the transcription factor RunX2/Cbfa1 that was previously shown to be required for osteoblast differentiation and bone formation. Currently, there are limited data of regulation of Osterix by growth factors, which influence osteoblast function. Previous studies have shown that continuous treatment with basic fibroblast growth factor (FGF-2) inhibited osteoblast differentiation and bone nodule formation in vitro. We examined whether FGF-2 regulates the expression of Osterix in mouse bone marrow stromal cell cultures. For time course studies, marrow stromal cells harvested from female mice were plated at 10 x106 cells/ well in 6 well dishes in aMEM and 10% FCS and grown to confluence. Cultures were serum deprived and treated with FGF-2 for 30 min to 2 h. Osterix mRNA was determined by RT-PCR analysis using specific primers that were designed according to published sequence. Treatment with FGF-2 (10 nM) decreased the level of Osterix mRNA expression by 60% within 30 min and by 72% at 1 h, and this reduction was maintained at 2 h. Dose response studies showed that treatment with as little as FGF-2 (0.001nM) for 1 h caused maximal reduction in Osterix mRNA. To assess whether new protein synthesis was required for the effect, cultures were pretreated with the protein synthesis inhibitor cycloheximide (CHX 5 μg/ml) prior to addition of FGF-2. CHX did not abrogate the inhibitory effect of FGF-2 on Osterix expression. Since new protein synthesis was not required and a decrease in Osterix mRNA expression was observed within 30 min of FGF-2 treatment, these results suggest that FGF-2 regulated Osterix mRNA at the level of gene transcription. We speculate that inhibition of Osterix expression may play a role in the inhibitory effects of FGF-2 in osteoblast differentiation.

Transcriptional Profiling of Estrogen- and PTH-Regulated Genes During Bone Formation in OVX Mice. D. von Stechow[1], T. Libermann*[2], G. Hattersley[3], J. M. Alexander[4]. [1]Orthopedic Biomechanics Laboratory, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA, [2]Genomics Center, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA, [3]Millennium Pharmaceuticals, Inc., Cambridge, MA, USA, [4]Division of Bone and Mineral Research, Beth Israel Deaconess Medical Center and Harvard Medical School, Boston, MA, USA.

The aim of this study was to identify the transcriptional mechanisms in bone underlying the anabolic effects of supraphysiologic estradiol (E2) treatment versus intermittent parathyroid hormone[1-34] (PTH) therapy. We utilized an ovariectomized (OVX) mouse model of osteoporosis and transcriptional profiling to identify genes upregulated by either E2 or PTH. Swiss-Webster mice underwent either OVX or Sham operation. Five weeks post-OVX, the mice were administered either E2 and/or PTH, or vehicle for 4 weeks. Femoral bones were analyzed by microCT to confirm the anabolic effect of each treatment. OVX vehicle-treated control mice lost metaphyseal trabecular bone, with significant decrease in trabecular number, thickness, and connectivity. Both E2 and PTH treatments increased trabecular and cortical bone indices above the level of the sham operated controls, fully restoring both bone volume and bone mineral density. Moreover, PTH/E2 combination treatment led to significantly greater increase in cancellous bone and BMD than would be expected from adding together their separate effects. To determine whether PTH and E2 treatments were stimulating similar bone anabolic mechanisms, or were activating

distinct signaling pathways, we compared patterns of gene expression using transcriptional profiling after either E2 or PTH treatment. After 4, 11, and 24 days of treatment, total RNA was collected from both the distal femoral metaphysis and diaphysis. Transcriptional profiling was performed using Affymetrix GeneChip probe arrays, comprised of approximately 36,000 full-length mouse genes and EST clusters from the UniGene database. Several markers of osteoblast activity, including c-fos, RANKL, PHEX, and PTHR1, were consistently upregulated by PTH in both skeletal sites. PTH treatment also increased expression of Cathespin K, confirming the predicted increase in osteoclastic activity. E2 treatment upregulated a largely distinct set of genes, including TGFbeta-3, and BMP1, as well as several genes critical for cell cycle control, including Cyclin D1 and CDK inhibitor 1A. Overall, comparison of transcriptional profiles suggest that anabolic responses in bone to PTH and E2 treatment after OVX-induced osteoporosis involve largely distinct patterns of gene regulation that each result in restoration of bone mass.

Requirement of the SWI/SNF Chromatin Remodeling Complex to Initiate BMP-2 Induced Skeletal Gene Expression for Osteoblast Differentiation. D. W. Young[1], A. N. Imbalzano*[2], A. J. van Wijnen[1], M. A. Montecino[3], G. S. Stein[1], J. B. Lian[1], J. L. Stein[1]. [1]Department of Cell Biology and Cancer Center, University of Massachusetts Medical School, Worcester, MA, USA, [2]Department of Cell Biology, University of Massachusetts Medical School, Worcester, MA, USA, [3]Departmento de Biologia Molecular, Universidad de Concepcion, Concepcion, Chile.

Bone Morphogenetic Proteins (BMP) are key regulators of osteoblast differentiation and skeletal-tissue developmental. BMP signals are directed to the nucleus through Smad heterodimers that converge at gene promoters together with tissue specific transcription factors to regulate transcriptional activity. As yet, little is known regarding the mechanisms by which BMP signals are integrated at promoter regulatory regions to induce phenotypic gene activation. In particular, the role of factors that alter chromatin structure has not been addressed in the context of BMP signaling. SWI/SNF chromatin remodeling complexes have emerged as essential machinery to facilitate transcriptional control of cellular differentiation. These multisubunit complexes have been shown to alter nucleosome organization in an ATP dependent manner. Here we addressed the role of SWI/SNF chromatin remodeling factors as effectors in the BMP/SMAD signaling cascade using the alkaline phosphatase (ALP) gene, which is an established model for BMP2 responsive gene regulation and an early marker of the osteoblast phenotype. We used an NIH3T3 derived cell line (B22) that contains a stably integrated tetracycline inducible transgene encoding a Brg1 protein with a mutation in the ATP binding domain. Brg1 is an essential ATPase subunit of the SWI/SNF complex and this mutant has a dominant negative effect on SWI/SNF complex function. We find that treatment of control B22 cells (wild-type SWI/SNF) with recombinant human BMP2 induces alkaline phosphatase activity as detected by histochemical staining and RT-PCR. In sharp contrast, when the mutant Brg1 protein is expressed, causing inhibition of SWI/SNF function, ALP activity and gene expression is not induced by BMP2. Furthermore, even after 14 days of chronic BMP2 treatment ALP activity was undetectable, indicating that this dominant negative effect does not represent a delay in activation. Together these data indicate that SWI/SNF chromatin remodeling complexes are required for induction of alkaline phosphatase gene activation, an early marker of BMP mediated osteogenesis. Our results suggest this activation reflects a requirement for SWI/SNF mediated chromatin remodeling to support the program of gene expression obligatory for osteoblast differentiation.

Differential Regulation of Gene Expression and Differentiation by Homo- and Heterodimers of the bHLH Protein Twist. Y. Leshem*, V. Andreeva*, C. Muentener*, M. Connerney*, D. Spicer. Center for Molecular Medicine, Maine Medical Center Research Institute, Scarborough, ME, USA.

Saethre-Chotzen syndrome is the most common autosomal dominant disorder of craniosynostosis, or premature fusion of the cranial sutures. This syndrome is primarily associated with haploinsufficiency of the basic-Helix-Loop-Helix (bHLH) transcription factor TWIST, however the mechanism underlying suture closure due to TWIST haploinsufficiency remains unclear. Twist can form both homodimers (TT) and heterodimers with ubiquitously expressed bHLH E proteins (TE) and we and others have suggested that these dimers may mediate different activities of Twist. Here we propose that the regulation of Twist dimer formation may regulate closure of the cranial sutures and haploinsufficiency of Twist alters the balance of these dimers to promote fusion. Twist is expressed in the suture mesenchyme and osteogenic fronts while the HLH inhibitor Id is only expressed in the osteogenic fronts. Id preferentially dimerizes with E proteins, and thus we hypothesize that within the osteogenic fronts Id dimerizes with the available E proteins forcing Twist to form homodimers, while in the intervening suture mesenchyme Twist forms heterodimers with free E proteins. We have begun to test this hypothesis by creating "forced" homo and heterodimers of Twist and the E protein E12, where the members of the dimers are attached by a linker. Our data with cell lines expressing the different dimers supports this conjecture and indicates that the cellular response to factors such as FGF and BMP differs profoundly dependent on which Twist dimer is expressed. Specifically we find that TE expression causes cell to proliferate and migrate slower, while TT promotes these events. Furthermore, while both Twist dimers inhibit calcification TT promotes early differentiation by inducing Cbfa1 expression and TE inhibits this. We have also identified genes that are differentially regulated by the two dimers and their expression patterns within the sutures are consistent with this regulation and are altered in Twist +/- mice.

Lentivirus Delivered RNAi Targeting Dlx5 Inhibits Mineralization of Primary Mouse Calvarial Osteoblast Cultures. H. Li*, M. S. Kronenberg, M. Stover*, A. C. Lichtler. Genetics and Developmental Biology, University of Connecticut Health Center, Farmington, CT, USA.

Previous studies have shown that Dlx5 induces osteoblast differentiation of calvarial osteoblasts and bone marrow stromal cells. Dlx5 knockout mice have defective calvarial development, which is more strongly manifested in Dlx5 and 6 double knockout mice. This phenotype has been attributed to defects in osteoblastic differentiation. This conclusion is not definite, because Dlx5 is expressed at earlier stages of development, and defects in calvaria could be due to improper development of osteoblast precursors or adjacent cell types, rather than a failure of terminal differentiation. The ability to inhibit expression of Dlx5, and other Dlx genes, in primary osteoblast cultures would provide a powerful means for addressing this question. We have chosen to use lentivirus vectors expressing RNAi to achieve this goal. RNAi can efficiently target specific mRNAs for degradation. Pol III promoters are especially suited for delivering small RNAs with hairpin loops containing double stranded RNA regions complementary to specific mRNAs; these are converted into RNAis within the target cell. Lentivirus vectors can deliver stably integrated expression constructs, including Pol III promoters, into non-dividing cells, thus they have the potential for delivering RNAi to essentially all of the cells of a primary osteoblast culture. We obtained the LentiLox RNAi-expressing lentivirus vector from Dr. Luc van Parijis, and cloned two Dlx5 targeted sequences into the vector. This vector also constitutively expresses eGFP. We produced high titer vector preparations from one of those vectors, and transduced primary mouse calvarial osteoblasts during the proliferative phase of culture. This particular vector targets a region of the Dlx5 gene that is conserved in some other Dlx genes, which may produce greater effects on osteoblast differentiation if multiple Dlx gene have the ability to induce this process. Visual assessment of eGFP expression by fluorescence microscopy indicated that transduction efficiency was greater than 80%, which is greater than we have previously achieved with retrovirus vectors. Xylenol Orange staining of a 17 day culture demonstrated very little mineralization, while a parallel culture transduced with a control GFP expressing vector was highly mineralized. Northern blot analysis showed that Dlx5 and Dlx3 mRNA levels were strongly inhibited in the RNAi transduced culture compared to the control. These studies support the importance of Dlx5 in calvarial osteoblast differentiation, and indicate that lentivirus delivered RNAi will be a valuable tool for studying gene function during osteoblast differentiation.

Microarray Analysis of Subpopulations of Cells Within Differentiating Murine Osteoblast Cultures. I. Kalajzic*[1], A. Stahl*[2], W. Yang*[2], S. Wu*[2], S. Johnson*[2], J. Feyen[2], D. Rowe[1]. [1]Genetics and developmental Biology, University of Connecticut Health Center, Farmington, CT, USA, [2]Bristol-Myers Squibb, Princeton, NJ, USA.

The heterogeneity of bone cell cultures complicates the interpretation of microarray studies of osteoblast differentiation. We have utilized mice transgenic for pOBCol3.6GFP and pOBCol2.3GFP to identify preosteoblasts (3.6 low expressing at day 7), early osteoblasts (3.6 high expressing at day 17) and mature osteoblasts (2.3 positive at day 17) in mCOB cultures. Time points were FACS sorted for positive and negative 3.6 and 2.3 cells (at day 7 and 17 respectively) and negative, low positive and strong positive 3.6 cells (day 17). The sorting step increased the representation of GFP positive cells from 30->95% for

3.6 positive cells, 3->98% in 3.6 strongly expressing cells and 8.5->88% in 2.3 expressing cells while the nonfluorescent sorted populations were 99%. Total RNA was extracted from unsorted cells from sister plates of day 7 and 17 cultures. RNA extracted from each population was assessed by Affymetric microarrays using the 74 A, B and C chips. Day 7 and 17 cultures were performed in triplicate and the r^2 correlation between replicate points was greater than 0.98. This study reports the results from the 74A chip which contains 11,916 Ests and approximately 8000 nonredundant unigenes. The arbitrary dynamic range of expression exceeds 3 orders with Col1a1 representing 10^5, integrin ß1 receptor 10^4, cbfa1 10^3, and calcitonin receptor 10^2 (background) and none of these genes show significant variation during differentiation. For genes that are known markers of late osteoblastic differentiation, cell sorting does not greatly increase the sensitivity although it does distinguish which population is responsible for the increase. Genes that are strikingly elevated in late differentiation are DMP, BSP, OC, AP and a number of undefined ESTs. Dkk1, an inhibitor of the Wnt pathway and Dlx3 show a 10-20 fold increase that occurred primarily in 2.3+ cells. No genes of note were induced during the transition of 3.6- to 3.6+ cells. The striking finding was the suppression (10-20 fold) of number of genes in isolated populations as differentiation progressed that was not reflected in the total cell populations. Examples include genes that modify the extracellular matrix, regulate intracellular proteolysis and a variety of growth factor receptors and secreted growth factors. Significant down regulation of Wnt and Igf1 signaling pathways occurred during late differentiation. We anticipate the analysis will be further enriched when the data from Chip B and C are analyzed but the value of using sorted populations of cells for microarray analysis appears to be well founded.

Bone Marrow Stem Cells (MSC) and Growth Factors Impregnated in Biodegradable Scaffold for Bone Repair. S. Srouji*[1], M. Peled*[2], I. Blumenfeld*[3], E. Livne[1]. [1]Anatomy and Cell Biology, Technion, Haifa, Israel, [2]Maxillofacial surgery Department, Rambam, Haifa, Israel, [3]Maxillofacial Surgery Department, Rambam, Haifa, Israel.

The need for bone repair is one of the major concerns of reconstructive surgery and in aging and disease. Fracture healing is regulated by osteogenic cells and growth factors. The ability to enhance healing of bone defects and fractures can contribute to prevent the complications of long-term immobilization that are especially fatal in old age. Our aim was to test the ability of biological scaffold containing committed osteogenic stem cells and growth factors to serve as a bone graft substitute for bone repair.
Isolated bone marrow stem cells (MSC) were used for selection of osteogeprogenitor subpopulation, were cultured (1 w) in DMEM medium supplemented with 10% FCS, antibiotics, ascorbic acid, β-glycerophosphate, and dexamethasone. Selected osteogenic subpopulation was identified using Alizarin red, von Kossa staining, osteonectin immunolocalization and mineral deposition. Committed osteoprogenitor cells were cultured (1 w) on hydrogel scaffold, transplanted with growth factors (TGF-β1 10 ng/ml; IGF-I 25 ng/ml) in rat tibia segmental bone defect using an external fixation device for stabilization of the defect site and examined after 2, 4 and 6 weeks by morphology, radiology, 3-D CT and mineral deposition by electron dispersive spectroscopy (EDS). Results indicated biocompatibility of hydrogel scaffold for cultured MSC-derived osteoprogenitor as identified by their proliferation, osteogenic properties and by mineral deposition by EDS in the culture and in the scaffold. Morphology revealed that after 2 weeks calcified material was observed in defects treated with TGF-β. By that time the scaffold was partially degraded and new bone formation was present in the margins of the defect. Biodegradation of the hydrogel was shown to be mediated by matrix metalloproteinases (MMPs).
Radiological images revealed that bone was present in the former site of the defect after 6 weeks of treatment with TGF-β + IGF-I or TGF-β alone. Less pronounced bone induction was observed in IGF-I-treated bone defect, and control specimens revealed partial healing of the bone defect. 3D-CT revealed that the bone restored its shape.
It is concluded that biodegradable scaffold can serve as biocompatible matrix for MSC-derived osteoprogenitor cells and growth factors and that it also provides space for bone regeneration. The biodegradable scaffold containing committed stem cells and growth factors is thus a promising surgical tool for enhancement of bone defect reconstruction and tissue engineering, and will enhance the repair of bone fracture in aging and disease.

Mechanism of PTHrP Mediated Inhibition of KS483 Osteoblastic Differentiation. G. van der Horst, C. Lowik, M. Karperien. Endocrinology, Leiden University Medical Center, Leiden, Netherlands.

PTH(rP) has been shown earlier to inhibit osteoblastic differentiation *in vitro*. However, the mechanism by which PTH(rP) exerts these effects is not yet known. In this study we investigated the mechanism of PTH(rP) mediated inhibition of osteoblastic differentiation in mouse pre-osteoblastic KS483 cells.
First, we analyzed effects of PTH (1-34), PTH (3-34) and PTHrP (1-34) on osteoblastic differentiation of KS483 cells. PTH(rP) dose dependently inhibited alkaline phosphatase activity (ALP) measured after 72 hrs. In long term differentiation assays, PTH(rP) blocked the formation of ALP positive and mineralized nodule formation dose dependently. No differences were seen when PTH(rP) was administered either continuously or in 1hr pulses at 3 to 4 days intervals. The inhibition required an intact N-terminus of PTH(rP). Furthermore, mRNA expression of Runx2, an essential transcription factor for osteoblastic differentiation, was downregulated by PTH(rP) in KS483 cells treated with PTH(rP) for 72hrs or in long term differentiation assays. Since autocrine BMP signaling has been shown to be crucial for osteoblastic differentiation of KS483 cells, we investigated crosstalk between BMPs and PTH(rP) signaling. Both BMP-4 and BMP-6 induced ALP activity was inhibited by PTH(rP) dose-dependently. In addition, BMPs could reverse inhibition by PTH(rP). Immediate early BMP signaling was not involved since PTH(rP) had no effect on BMP induced phosphorylation of Smads 1,5 and 8. Furthermore, no effect of PTH(rP) was seen on basal or BMP-4 and –6 induced luciferase expression of the BMP reporters Msx2-luc and BRE-luc. The p38 MAPK pathway is also involved in basal and BMP induced osteoblastic differentiation. In KS483 cells, no effects of PTH(rP) were seen on phosphorylation of p38. The p38 MAPK inhibitor SB203580 blocked ALP activity, ALP positive and mineralized nodule formation as well as basal and BMP-induced luciferase expression of Msx2-luc and BRE-luc dose dependently. These data suggest that p38 MAPK is not involved in the inhibitory effect of PTH(rP).
PTHrP could also inhibit differentiation by interfering with another osteogenic pathway, the hedgehog (Hh) signaling pathway. In KS483 cells, recombinant sonic hedgehog (rSHh) induced ALP activity was inhibited by PTH(rP) dose-dependently and rSHh could reverse PTH(rP) mediated inhibition. Furthermore, PTH(rP) decreased mRNA expression of Hh in KS483 cells.
In conclusion, PTH(rP) containing an intact N-terminus, inhibits both basal as well as BMP and Hh stimulated osteoblastic differentiation of KS483 cells. This inhibition is downstream of immediate early BMP signaling and results in a decrease in Runx2 expression.

Maintenance of Differentiation Potential of Human Bone Marrow Stromal Cells Immortalized by Human Telomerase Reverse Transcriptase Gene in Spite of Extensive Proliferation. B. M. Abdallah*[1], M. Azadali*[1], F. Jacob*[1], P. Hokland*[2], M. Kassem[1]. [1]Endocrinology, Odense university hospital, Odense, Denmark, [2]Department of Hematology, Aarhus University Hospital, Aarhus, Denmark.

Human bone marrow stromal cells (hMSC) contain a population of stem cells that are capable for differentiation into multiple lineages. However, these cells exhibit senescence-associated growth arrest and phenotypic changes during in vitro culture. We have recently demonstrated that human telomerase reverse transcriptase over-expression (hTERT) in hMSC reconstitutes telomerase activity and extend life span of the cells (Simonsen,J.L. *et al*. Nature Biotech. 20, 592-596, 2002). In the present study we have performed extensive characterization of this cell line at different population doubling levels (PDL) with respect to growth rate, cell morphology, surface markers, ability to differentiate into osteoblasts, adipocytes, chondrocytes, endothelial cells, myocytes and neuronal cells as well as the effect of growth in human serum. Three different cell populations of cells were examined hMSC-TERT2 (PDL 60), hMSC-TERT4(PDL160) and hMSC-TERT20(PDL260). In spite of the presence of differences in the growth rates between these different cell lines, all cells were able to be induced to differentiation into different lineages. In conclusion, hTERT immortalization is a useful method for obtaining enough number of cells with a stable phenotype for mechanistic studies on cell differentiation.

Potential Paracrine Loop in Bone Involving the Synthesis of ACTH in Osteoclasts and the Presence of Functional ACTH Receptors in Osteoblastic Cells. O. Zhong[1], R. Ling*[2], K. Ding[1], S. Sridhar[1], D. Xie[1], K. Insogna[3], R. Bollag*[1], C. M. Isales[4]. [1]Institute of Molecular Medicine and Genetics, Medical College of Georgia, Augusta, GA, USA, [2]Medical Genomics, Medical College of Georgia, Augusta, GA, USA, [3]Medicine, Yale University School of Medicine, New Haven, CT, USA, [4]Medicine, Medical College of Georgia and the Augusta VA Hospital, Augusta, GA, USA.

Melanocortin receptors belong to the seven transmembrane domain, G-protein coupled family of receptors. Five melanocortin receptors have been described which are widely expressed in the body, including skin, brain, adrenal glands, adipocytes, gut and other peripheral tissues. These receptors are activated by fragments derived from a larger molecule, pro-opiomelanocortin (POMC) and include: ACTH, a b and g-MSH, and b endorphin. Traditional roles for these peptide hormones include regulation of cortisol secretion, skin pigmentation and pain perception. Although the pituitary gland is the traditional site for synthesis, secretion and processing of POMC-derived fragments, it has become clear that other tissues can also synthesize and secrete POMC fragments including keratinocytes, melanocytes, endothelial cells and immune cells among others. Among the latter both lymphocytes and macrophages have been reported to express and secrete POMC fragments. Since osteoclasts in bone are derived from macrophages we investigated whether POMC and the melanocortin receptors were expressed in bone and bone cells. We report that the

five known melanocortin receptors are expressed in normal rat bone as assessed by in situ hybridization. These receptors were variably expressed in different osteoblastic-like cell lines with the MG63 cell line expressing four out of five melanocortin receptors as assessed by Northern blot. 125ACTH, a and b MSH and b endorphin demonstrated high affinity binding to MG63 cells. In attempt to determine the source of ligand for these melanocortin receptors, normal rat osteoclasts were probed for the POMC gene by Northern blot. Osteoclasts did in fact express the POMC gene although at a lower level than normal rat pituitary. Thus, bone cells contain the elements for a novel paracrine hormonal loop where osteoclasts express POMC and osteoblasts express melanocortin receptors.

Functional Properties of Cultured Normal and Vitamin D Receptor Knockout Mice Calvarial Osteoblasts. T. Okano[1], N. Tsugawa*[1], C. Hirami*[1], S. Kato[2]. [1]Department of Hygienic Sciences, Kobe Pharmaceutical University, Kobe, Japan, [2]Nuclear Information, IMCBM CREST, Tokyo, Japan.

Vitamin D is believed to be essential for bone mineralization and promotes osteogenesis by activation of osteoblast function and stimulation of osteoclast formation. There is, however, little evidence indicating that vitamin D is operative in vivo as a key factor involved in bone metabolism. Inoue et al. reported at the 24th ASBMR annual meeting that ectopically implanted femora of vitamin D receptor knockout (VDRKO) mice in wild-type mice showed a remarkable increase in bone volume compared to those of wild-type mice. Furthermore, in organ culture study, bone volume of fetal VDRKO mice calvaria was already greater than that of wild-type mice before initiation of culture and remarkably increased after 7 days culture. These findings clearly indicate that the role of vitamin D in bone mineralization should be re-evaluated. To clarify the direct effect of $1,25(OH)_2D_3$ on bone metabolism, osteoblastic cells were isolated from calvaria of normal (wild-type) and VDRKO mice by repeated collagenase digestion. Cells were cultured in α-MEM medium with 10 % fetal calf serum. Upon light microscopy, the above two types of primary osteoblastic cells appeared similar, showing rapid proliferation by 5 day, differentiation by 15 day, and mineralization by 20 day of culture. The mRNA levels of bone metabolic markers were measured by real-time RT-PCR at 5, 15, and 20 day of culture. In addition, the degree of mineralization was assessed by von Kossa staining. As the results, the bone formation markers such as alkaline phosphatase, Runx2, Mepe and Phex were strongly expressed in the osteoblastic cells from VDRKO mice compared to those from wild-type mice. On the other hand, the expression of RANKL mRNA was extremely suppressed in the whole stages of proliferation, differentiation and mineralization in the osteoblastic cells from VDRKO mice compared to those from wild-type mice. No significant changes in osteocalcin and osteopontin mRNA gene expression were noted in both wild-type and VDRKO osteoblastic cells. These results suggest that $1,25(OH)_2D_3$ might not be essential for bone mineralization and may work primarily as a negative regulator for bone mineralization by suppression of bone formation and stimulation of bone resorption.

The Role of Splice-Variants of Periostin in Bone Development and Disease. J. Litvin*, A. Selim*, M. O. Montgomery*, M. C. Rico*, K. Lehmann*, F. F. Safadi. Anatomy and Cell Biology, Temple Medical School, Philadelphia, PA, USA.

A splice-variant of Periostin, henceforth referred to as Periostin-Like-Factor (PLF) was identified by using the 'READS' differential display of mRNAs isolated from mouse tissues during various stages of development. Comparison of the predicted amino acid sequence of Periostin in mouse and human tissues with Periostin-Like-Factor in mouse tissues, showed differences in two regions at the carboxy-terminus. These differences are consistent with the two proteins being isoforms resulting from an alternately spliced gene. The alterations in amino acid sequence in these regions are probably functionally significant since the rest of the amino acids are highly conserved across species. During normal mouse embryogenesis and in osteopetrotic bone the temporal and spatial patterns of expression of these isoforms were determined using in situ hybridization and immunohistochemical analyses. We found that they were expressed during embryogenesis in preosteoblast mesenchymal cells and in bone precursor cells in the peri- and endosteum in osteopetrotic bone. Levels of these isoforms were significantly up regulated in osteopetrotic bone compared to normal controls. The expression of these isoforms in preosteoblasts suggests a role in the early stages of osteoblast differentiation. In MC3T3-E1 osteoblast-like cells these proteins were highly expressed at the early stages of differentiation. Western blot analysis of proteins from bone isolated at various stages during development showed two isoforms. We evaluated the effect(s) of second-generation anti-sense PLF and Periostin oligonucleotides on several functional parameters associated with differentiation in MC3T3-E1 cells. Levels of alkaline phosphatase, osteopontin, Cbfa1 and osteocalcin and collagen type I were significantly reduced in anti-sense treated cells compared to controls. It has been shown that as an extracellular matrix product these proteins regulate osteoblast-extracellular matrix interactions. Since they are also located within cells we expect that they are involved in signal transduction via binding to integrin receptors. Collectively, data from our experiments suggest a role for PLF and Periostin in osteoblast differentiation and function.

Oligomeric RANKL Induces Bone Formation via the ERK Pathway. R. Faccio, J. Lam, K. Aya, K. Homes*, P. Zhou, J. Chappel*, S. L. Cheng, F. P. Ross, S. L. Teitelbaum. Washington University, St Louis, MO, USA.

We have explored the mechanisms underlying the osteogenic ability of RANKL administered to mice as a GST fusion protein. We find that GST-RANKL specifically enhances Col1a1 expression by primary calvarial osteoblasts (pOBs) within 12 hours of exposure, an effect requiring the ERK pathway, since the increase is abrogated following transduction with dominant negative ERK. We next analyzed two signaling molecules downstream of ERK, c-Fos and Fra-1, whose overexpression in vivo leads to osteogenic sarcomas and osteosclerosis, respectively. GST-RANKL, but neither GST nor the soluble extracellular domain of RANKL (sRANKL), induces expression of both c-Fos mRNA and protein, and Fra1 mRNA in pOBs. Downregulation of RANK (and other TNFR) signals involves internalization of the receptor-ligand complex. Our finding that GST-RANKL, but not sRANKL, is an oligomerized molecule suggests that the larger form may be more resistant to endocytosis. This hypothesis was tested by performing confocal microscopy of pOBs, treated with GST-RANKL or sRANKL. Cells were immuno-stained for RANK and co-stained with a lipophilic fluorescent dye to detect the cell membrane. While the GST-RANKL:RANK complex remains on the cell surface for at least one hour, sRANKL:RANK complexes are rapidly internalized. This result suggests that oligomerized RANKL stimulates prolonged intracellular signaling. Whereas sRANKL-induced ERK activation dissipates within 20 min in pOBs, the signal persists for 1-2 hrs when stimulated by GST-RANKL. To establish that the anabolic effect of GST-RANKL does not reflect the GST moiety, we expressed GST-TNFα, another TNF-family GST-fusion protein. We find that GST-TNFα does not impact Col1a1 or Cbfa-1 expression in circumstances in which these moieties are induced by GST-RANKL. Finally, addition of OPG to pOBs in the presence of PTH abrogates the hormone's ability to induce Col1a1 synthesis, establishing that PTH exerts its bone anabolic effect via RANKL. In summary 1) GST-RANKL is a potent inducer of collagen synthesis by pOBs; 2) the bone forming capacity of GST-RANKL reflects its oligomerized state, which leads to prolonged activation of the ERK/c-Fos/Fra-1 signaling pathway; 3) it is the RANKL and not GST component of the fusion protein which specifies its anabolic effect; and 4) PTH exerts its bone anabolic effect via enhancement of RANKL expression. Finally, the recent report that human osteoblasts, like their murine counterparts, express RANK is consistent with the therapeutical potentials of oligomerized RANKL in man. Thus, oligomeric RANKL, a model for the native integral membrane form of the protein, exerts its bone anabolic effect via prolonged activation of the ERK signaling pathway.

Regulated Expression of SFRP-1 by the GeneSwitch System. R. A. Bhat*, B. Stauffer*, H. Ponce-de-Leon*, B. S. Komm*, P. Bodine*. Women's Health Research Institute, Wyeth, Collegeville, PA, USA.

SFRP-1 is a secreted Wnt antagonist. The role of SFRP1 in bone formation has been shown earlier by the targeted disruption of SFRP-1 in mice, which led to decreased osteoblast and osteocyte apoptosis and increased trabacular bone formation. In the present work, we have used the GeneSwitch system to develop methods for the conditional expression of SFRP-1 and the isolation of conditioned media rich in functional SFRP-1 protein.
The GeneSwitch™ system is an inducible expression system that provides exceptionally low uninduced and high-induced expression levels in mammalian cells. The GeneSwitch regulatory protein binds to the Gal4-E1b promoter to activate transcription upon the addition of mifepristone. We have developed an adenovirus recombinant containing the GeneSwitch protein driven by the Gal4-tk promoter, as well as recombinants containing SFRP-1 and the luciferase reporter under the control of the Gal4- E1b promoter. Luciferase activity in A549 cells infected with the GeneSwitch and Luciferase viruses was very low in ethanol treated cells, while the level of luciferase activity increased 200-fold in cells treated with mifepristone. Conditional expression of functional SFRP-1 was demonstrated in A549, human osteoblast (HOB) and CHO cell lines by either co-infection of the cells with the Ad5 SFRP-1 and GeneSwitch viruses or by the infection of GeneSwitch-expressing cell lines with the Adeno recombinant SFRP-1 virus and subsequent treatment with mifepristone. The results are summarized as follows: (a) A 30-fold increase in SFRP-1 transcripts in mifepristone-treated cells compared to minimal or undetectable expression in ethanol-treated cells. (b) Expression of SFRP-1 seen as early as 4 hours post-treatment, with increasing expression reaching the highest level at 20 hours and plateauing thereafter. (c) Demonstration of SFRP-1 protein in conditioned media by Western blotting. (d) Inhibition of Wnt signaling in a paracrine fashion in a co-culture assay. (e) Dose-dependent inhibition of Wnt 3-mediated activation of TCF-Luciferase activity by the conditioned media.
The regulated expression of functional SFRP-1 by the GeneSwitch system and the isolation of SFRP-1 rich conditioned media provide valuable tools for studying SFRP-1 function in osteoblasts and the genes controlled by its expression.

Identification of the Signalling Pathways Required for Interleukin-1 Beta Stimulation of Osteoprotegerin Synthesis in Osteoblastic Cells. C. J. Lambert*[1], C. Ribbens[1], V. Bours*[2], M. Merville*[2], M. G. Malaise*[1], N. Franchimont[1]. [1]Rheumatology, University of Liège, Liège, Belgium, [2]Center of cellular and molecular therapy, University of Liège, Liège, Belgium.

OPG (osteoprotegerin) binds to its natural ligand RANK-L (receptor activator of NF-kB - ligand) and prevents RANK-L from activating its receptor RANK, which is required for osteoclast differentiation, activation and survival. OPG production is finely regulated by osteoresorptive factors. IL-1b (interleukin-1beta), a proinflammatory cytokine, stimulates bone resorption, enhances RANK-L and surpringly OPG expression in osteoblastic cells. The meaning of OPG stimulation by IL-1b is unclear and the mechanisms of OPG gene regulation by proinflammatory cytokines have not been studied extensively. In this study, we confirmed that IL-1b stimulates OPG mRNA expression in MG63 osteoblastic cells, we demonstrated that IL-1b also induces a marked increase in OPG protein levels measured by ELISA and we studied the IL-1b signal transduction pathways required for OPG synthesis. We examined the MAPK (mitogen activated protein kinase) signalling pathway by Western blot analysis and showed that MG63 cells treatment with IL-1b resulted in the phosphorylation of the kinase p38 and ATF-2 (activating transcription factor-2). Phosphorylations of MEK-1 (MAPK extracellular signal-related kinase) and ERK (extracellular signal-related kinase) were also demonstrated but no phosphorylation of JNK (c-Jun N-terminal kinase) was reported after IL-1b treatment. To determine the relevance of the MAPK in OPG stimulation, we studied the effects of SB 203580, PD 98059 and SP 600125, specific inhibitors of the p38, ERK and JNK pathways respectively, on OPG protein levels. We found that ERK signalling pathway is necessary for IL-1b-induced OPG production whereas the p38 signalling pathway is required for both basal and IL-1b-induced OPG production. As expected, JNK inhibition did not decrease OPG protein levels. We next examined the relevance of the nuclear factor NF-kB by using BAY 11-7085 and MG132, two NF-kB inhibitors. In the presence of these inhibitors, OPG protein levels were decreased in IL-1b-treated cultures at concentrations that inhibited NF-kB DNA-binding. In the presence of IL-1b, a concomitant decrease in NF-kB inhibitor IkB-alpha levels was demonstrated by Western blotting. Infecting MG63 cells with an adenovirus expressing a dominant negative IkB-alpha resulted in a marked decrease in OPG protein levels, confirming NF-kB requirement for OPG synthesis.
In conclusion, IL-1b stimulates OPG production by mechanisms dependent on the activation of the kinases p38 and ERK as well as of NF-kB.

Impact of the MAPK pathway on PTHrP Actions in Osteoblasts. C. Chen*[1], A. J. Koh*[2], J. Zhang*[2], E. T. Keller*[3], N. J. D'Silva*[2], L. K. McCauley[1]. [1]Periodontics/Prevention/Geriatrics, University of Michigan, Ann Arbor, MI, USA, [2]University of Michigan, Ann Arbor, MI, USA, [3]Unit for Laboratory Animal Medicin, University of Michigan, Ann Arbor, MI, USA.

Parathyroid hormone-related protein (PTHrP) regulates proliferation and differentiation of osteoblastic cells via binding to the PTH/PTHrP receptor (PTH1R). The PKA pathway governs a majority of the PTHrP effects, but recent evidence also implicates the mitogen-activated protein kinase (MAPK) pathway. The goal of this study was to evaluate the role of MAPK in PTHrP-mediated gene expression and regulation of apoptosis. A specific ERK1/2 phosphorylation inhibitor U0126 was used to block MAPK in differentiated MC3T3-E1 cells. Northern blot analyses indicated that gene expression for osteocalcin (OCN), bone sialoprotein (BSP), and the PTH1R were downregulated by PTHrP, but were not affected by U0126. Gene expression for c-fos, fra-2 and interleukin-6 (IL-6) were all induced by PTHrP. Pre-incubation with U0126 slightly and significantly blocked the upregulation of fra-2 and IL-6 by PTHrP respectively, suggesting that the MAPK pathway is at least in part responsible for these PTHrP actions. Inhibitors of PKA (H-89), PKC (GF109203X), and MAPK (U0126) were used to evaluate PTHrP regulation of IL-6 luciferase promoter constructs. The PKA and MAPK, but not the PKC pathways were found to be responsible for activating IL-6 transcription. Cells transfected with CREB133 (a dominant negative mutant of CREB) or Rap1GAP (an inhibitor of Rap1 activation) demonstrated lower PTHrP-induced IL-6 luciferase activity, but treatment with a cAMP analogue that activates Epac and not PKA did not alter the PTHrP response. Using deletion constructs of the IL-6 promoter, further analysis suggested that both an AP-1 site and a NFkB transcription site were necessary for PTHrP-induced IL-6 gene expression. We have previously shown that PTHrP induces apoptosis in differentiated MC3T3-E1 cells. The cell viability assay indicated that U0126 partially blocked the acute reduction in cell number by PTHrP, whereas western blot analysis indicated that U0126 did not alter the PTHrP-mediated inhibition of AKT (an inhibitor of apoptosis in the phosphorylated state). These data indicate that inactivation of the MAPK pathway by U0126 shows differential regulation of PTHrP-stimulated AP-1 members (affecting fra-2 but not c-fos), and notably reduces PTHrP-stimulated IL-6 transcription. Furthermore, the small GTPase Rap1 and the transcription factors NFkB and CREB also play important roles in the downstream actions of a subset of genes that are regulated by PTHrP.

SA232

Activation of Phospholipase A_2 Is Required for P2X7-Mediated Membrane Blebbing in Murine Osteoblasts. N. Panupinthu*[1], H. Z. Ke[2], S. M. Sims*[1], S. J. Dixon[1]. [1]CIHR Group in Skeletal Development and Remodeling, The University of Western Ontario, London, ON, Canada, [2]Global Research and Development, Groton Laboratories, Pfizer Inc., Groton, CT, USA.

Osteoblast activity is tightly controlled by local and systemic factors. In response to inflammatory and mechanical stimuli, nucleotides are released into the extracellular fluid where they can signal through P2 nucleotide receptors on the surface of many cell types, including osteoblasts. There are two classes of P2 nucleotide receptors, P2X (ligand-gated ion channels) and P2Y (G protein-coupled receptors). P2X7 receptor knockout mice exhibit decreased periosteal bone formation. Using molecular and functional approaches, we have identified the expression of P2X7 nucleotide receptors on a subpopulation of murine osteoblasts. The purpose of this study was to investigate the response of osteoblasts to activation of P2X7 receptors. Osteoblast-enriched cultures were obtained by sequential collagenase digestion of calvariae from neonatal wild-type (WT) and P2X7 receptor knockout (KO) mice. In other cell types, activation of P2X7 receptors leads to cytoskeletal rearrangements. Time-lapse video microscopy was used to monitor morphological changes of osteoblasts bathed in divalent cation-free buffer at 37°C. Benzoylbenzoyl-ATP (BzATP, a relatively potent P2X7 agonist) induced dynamic membrane blebbing in a subpopulation of cells from WT, but not KO mice. Blebbing began within 5 min of addition of BzATP and was sustained for at least 30 min in the continued presence of agonist. The effects of BzATP were reversible upon washout, indicating cell viability. In contrast to the effects of BzATP, blebbing was not induced by UTP, which activates P2Y but not P2X7 receptors on osteoblasts. BzATP-induced blebbing was suppressed by the nonspecific phospholipase A_2 (PLA_2) inhibitor, arachidonyl trifluoromethyl ketone ($AACOCF_3$, 100 μM). Blebbing was observed in 16 ± 1% of cells pretreated with $AACOCF_3$ vs. 46 ± 2% of cells pretreated with an inactive analog ($P < 0.05$). Moreover, bromoenol lactone (BEL, 10 μM), a specific inhibitor of Ca^{2+}-independent PLA_2, reduced the percentage of blebbing cells from 43 ± 2% to 11 ± 4% of total ($P < 0.05$). Chelation of extracellular Ca^{2+} using EGTA, or cytosolic Ca^{2+} using BAPTA had little effect on the percentage of cells exhibiting blebbing, consistent with involvement of Ca^{2+}-independent PLA_2. In conclusion, P2X7 receptor activation induces dynamic membrane blebbing in a subpopulation of osteoblasts, a process dependent on PLA_2. Activation of PLA_2 and induction of cytoskeletal changes may contribute to the stimulatory effect of P2X7 receptors on periosteal bone formation.

Extracellular Inorganic Phosphate Regulates Glvr-2 Phosphate Transporter/Retrovirus Receptor mRNA Expression in Rat Bone Marrow Stromal Cells. K. Wada*[1], M. Mizuno*[1], T. Komori*[2], M. Tamura[1]. [1]Oral Health Science, Hokkaido University Graduate School of Dental Medicine, Sapporo, Japan, [2]1Division of Oral and Maxillofacial Surgery, Department of Organ Therapeutics, Kobe University Graduate School of Medicine, Kobe, Japan.

In mammalian cells, several observations indicate not only that phosphate transport probably regulates local inorganic phosphate (Pi) concentration, but also that Pi affects normal cellular metabolism, which in turn regulates apoptosis and the process of mineralization. To elucidate how extracellular Pi regulates cellular functions of pre-osteoblastic cells, we investigated the expression of type III sodium-dependent Pi transporters in rat bone marrow stromal cells and ROB-C26 pre-osteoblastic cells. The mRNA expression level of Glvr-2 was increased by the addition of Pi in rat bone marrow stromal cells, but not in ROB-C26 cells or in normal rat kidney (NRK) cells. In contrast, the level of Glvr-1 mRNA was not altered by the addition of extracellular Pi in these cells. The induction of Glvr-2 mRNA by Pi was inhibited in the presence of cycloheximide. Moreover, mitogen-activated protein kinase (MEK) /extracellular-signal-regulated kinase (ERK) pathway inhibitors; U0126 and PD98059 inhibited inducible Glvr-2 mRNA expression, but p38 mitogen-activated protein kinase inhibitor SB203580 did not inhibit the induction of Glvr-2 mRNA expression, suggesting that extracellular Pi regulates *de novo* protein synthesis and MEK/ERK activity in rat bone marrow stromal cells and through these, induction of Glvr-2 mRNA. Although Pi also induced osteopontin mRNA expression in rat bone marrow stromal cells but not in ROB-C26 cells and NRK cells, changes in cell viability with the addition of Pi were similar in both cell types. These data indicate that extracellular Pi regulates Glvr-2 mRNA expression, provide insights into possible mechanisms whereby Pi may regulate protein phosphorylation, and suggest a potential role for the Pi transporter in rat bone marrow stromal cells.

Isolation and Characterization of a Bone Marrow Stromal Side Population (SP). S. Uchida, S. Zhang, J. E. Aubin. Molecular and Medical Genetics, University of Toronto, Toronto, ON, Canada.

Cells characterized as mesenchymal stem cells (MSCs) reside within bone marrow stroma, however, significant enrichment and rapid isolation of these cells remain elusive. Recently, flow cytometric analysis of freshly isolated hematopoietic and muscle-derived cells has uncovered that efficient Hoechst 33342 dye exclusion via the ABC transporter family defines a side population (SP) enriched in multipotent stem cells leading to the hypothesis that adult stem cells may also reside in SPs of other tissues. We asked whether a SP exists in young adult rat bone marrow stromal cell populations and, if so, is enriched in osteoprogenitors and other precursor populations. RT-PCR analysis of precultured stromal cells revealed the expression of multiple members of the ABC transporter family, including multidrug resistance-associated protein 1 (Mdr1) and breast cancer resistance protein 1 (Bcrp1). Freshly isolated total bone marrow or the stromal fraction precultured for 7 days were therefore stained with Hoechst 33342, analyzed and sorted on a FACStarPlus (Becton Dickinson; BD Bioscience). Cells in the SP, non-SP and total/unfractionated population were re-plated in 96-well plates under osteogenic differentiation conditions. 0.05-0.2% of total marrow or 0.2-0.5% of stromal cells formed a distinct SP. The stromal SP cells gave rise to colony forming units (CFU) of different phenotypes. The percentage of wells with CFU-fibroblast (CFU-F) growth in the SP (63%) was much higher than that in either the non-SP (5%) or the total population (14%). Similarly, the percentage of wells with CFU-alkaline phosphatase (CFU-ALP) growth in the SP (45%) was significantly higher than that in non-SP (2%) or total population (3%). These data demonstrate that rat bone marrow stromal cell populations contain a SP enriched in CFU-F and osteoprogenitors compared to non-SP and total stromal populations. Sorting on the basis of Hoechst 33342 exclusion may be a useful enrichment stratagy for primitive osteoprogenitors and other precursor cell pools including MSCs.

A Distant Cis-Acting Element Is Responsible for Hormonal Regulation and Cell Type-Specific Expression of the Murine RANKL Gene. Q. Fu, I. P. Foote*, S. C. Manolagas, C. A. O'Brien. Div. Endo/Metab, Center for Osteoporsis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, Univ. of Arkansas for Med. Sciences, Little Rock, AR, USA.

PTH stimulates osteoclastogenesis and bone resorption in part by stimulating expression of RANKL. Previous studies demonstrate that PTH stimulates RANKL transcription via a protein kinase A (PKA)-CREB pathway in stromal/osteoblastic cells but not other cell types in vitro. Further, basal RANKL expression in vivo is limited primarily to bone and lymphocyte-containing tissues. The mechanisms responsible for this cell type- and tissue-specific expression remain unknown. To determine whether differential PTH receptor expression is responsible for tissue-specificity in vivo, mice were injected with dibutyryl-cAMP (db-cAMP) to broadly activate PKA in many tissues, independent of PTH receptor expression. Db-cAMP stimulated RANKL mRNA by 4-fold in bone tissue, as measured by RNAse protection assay, but did not significantly alter expression in kidney, spleen, liver, or lung. However, db-cAMP elevated IL-6 mRNA in all tissues. These results indicate that cAMP regulation of RANKL is tissue-specific and that mechanisms responsible for this specificity lie downstream of PKA activation. To determine whether cis-acting gene regulatory elements mediate the hormonal responsiveness and cell type-specificity of RANKL expression, we stably transfected murine RANKL promoter reporter constructs into a stromal/osteoblastic cell line that expresses endogenous RANKL (UAMS-32P) and a hepatoma cell line (Hepa), which does not express RANKL. A reporter construct containing 2.1 kb of 5'-flanking region had similar basal activity in UAMS-32P and Hepa cells and was not responsive to PTH or db-cAMP in either cell line. Both cell lines were capable of responding to db-cAMP, as an IL-6 promoter-reporter construct was stimulated by this agent in both lines. UAMS-32P and Hepa cells were then stably transfected with a reporter construct derived from a bacterial artificial chromosome (BAC) containing the entire murine RANKL gene as well as 120 kb of 5'-flanking region. This construct was generated by insertion of an internal ribosome entry site-luciferase cDNA cassette into exon 5 of the RANKL gene by homologous recombination. Expression of this construct was stimulated 5- and 11-fold by PTH and db-cAMP, respectively, in UAMS-32P cells. However, these agents did not stimulate the BAC construct in Hepa cells and the basal activity was also significantly lower in these cells. We conclude that distant elements, residing outside the proximal 2.1 kb 5'-flanking region, mediate both cAMP-responsiveness and cell type-specific expression of the murine RANKL gene.

Differential Osteogenic Potential in Bone Marrow and Soft Tissue Stromal Cells Mediated by the *Gnas/GNAS1* Gene. R. J. Pignolo[1], S. Blythe*[2], J. Gilmore*[2], F. S. Kaplan[2], E. M. Shore[2]. [1]Department of Medicine, University of Pennsylvania, Philadelphia, PA, USA, [2]Department of Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, USA.

The *Gnas* gene, encoding the murine alpha subunit of the stimulatory G-protein of adenylyl cyclase (Gsα), may function as a regulator of osteoblast differentiation in target cells that are, as yet, unidentified. Heterozygous inactivating mutations of the human *GNAS1* gene have been identified in patients with progressive osseous heteroplasia (POH), a disorder in which ectopic osteoblast differentiation and bone formation occurs within soft connective tissues. We have examined osteoblast differentiation in bone marrow and soft tissue stromal cells derived from wild-type mice and mice that are heterozygous for a *Gnas* null allele. Bone marrow derived mesenchymal stem cells (MSCs) were isolated by aspiration of femoral cavities after removal of the metaphyses. Soft tissue stem cells were partially purified from subcutaneous fat tissue. In both cases, cells were placed into osteogenic media and assayed for their ability to form bony nodules. Bone marrow stromal cells from *Gnas* heterozygous mice were found to have a reduced ability to differentiate into osteoblasts. However, soft tissue stromal cells from *Gnas* heterozygous mice appeared to have greater osteogenic potential compared to wild-type cells. These findings suggest that *Gnas* differentially influences cellular differentiation and bone formation based on the type and location of target cells. Thus, inactivating mutations in human *GNAS1* that cause developmental disorders of heterotopic bone formation may depend on the differential response of specific precursor cells to G-protein mediated stimulation as well as their location in soft tissue.

Bmp-2 Induced Osteogenesis Of Human Marrow Stromal Cells Involves Balancing Smad And Kinase Pathways. A. M. Osyczka*, G. A. Bhargave*, E. B. Golden*, D. L. Diefenderfer, P. S. Leboy. Biochemistry, University of Pennsylvania, Dental Medicine, Philadelphia, PA, USA.

Analyses of marrow stromal cells (MSC) isolated from femurs of over 25 patients undergoing hip arthroplasty have shown that the majority of isolates do not up-regulate alkaline phosphatase (ALP) mRNA and enzyme activity in response to BMP in vitro, although BMP-2 does stimulate transcription of genes for BMP-2, noggin, Id-1 and bone sialoprotein (Diefenderfer, Osyczka, Reilly and Leboy, Conn Tissue Res. 44(S1):305-311; 2003). Human MSC cultured with BMP-2 also show unexpectedly high levels of the transcription factor Msx2 mRNA, but no increase in total Runx2 mRNA.

To examine mechanisms modulating BMP-2 regulation of ALP expression, human MSC were cultured for 4 days in media containing 15% FBS and then were either treated with kinase inhibitors or transferred to serum-free media for an additional 1-3 days. Transfer to serum-free media containing insulin or IGF-1 permits BMP-2 to induce transcription of ALP and to increase expression of osteopontin mRNA. Insulin or IGF-1, alone or in combination with BMP-2, neither stimulates proliferation nor significantly affects ALP expression in the presence of serum. Studies with the p38 inhibitor SB203580 and the PI3K inhibitor Ly294002 indicate that activation of both of these protein kinases is required for BMP-2 stimulation of ALP. In contrast, when human MSC are cultured in serum with the ERK inhibitor PD98059, BMP-2 stimulates ALP to the same extent as dexamethasone, indicating that ERK activity suppresses BMP-2 induction of ALP. These results, along with Western blot analyses imply that the ability of BMP-2 to stimulate ALP in human MSC under serum-free conditions with insulin or IGF-1 is correlated with decreased ERK signaling in the absence of serum. Western blot analyses also indicate that the BMP-regulated Smad pathway is active in human MSC, both with and without ERK inhibition. We suggest that, while several BMP-responsive genes seem to be unaffected by MAP kinase activity, a proper balance between Smad and MAPK pathways is required for BMP-2 to activate ALP transcription in human marrow stromal cell cultures.

The Receptor Activator of Nuclear Factor (NF)kB Ligand (RANKL) Is a New Chemotactic Factor for Human Monocytes. V. Breuil[1], H. Schmid-Antomarchi*[1], A. Schmid-Alliana*[1], L. Euller-Ziegler[2], B. Rossi*[1]. [1]Inserm u 364, IFR50, Nice, France, [2]Rheumatology Department, Hopital l'Archet, Nice, France.

Aim of the study : Due to the role of RANKL in recruitment and fusion of monocyte-derived osteoclasts, we hypothesized that soluble RANKL (sRANKL) could exert chemotactic properties toward monocytic cells.

Methods : Chemotactic responses of MonoMac-6 cells were evaluated using 24-well chemotaxis chambers and polyethylene terephtalate inserts coated with fibronectin. MonoMac-6 cells, incubated for 16 hours with [3H]-methyl thymidine, were placed in the upper well and MCP-1, OPG or sRANKL, at various concentrations, were added to the lower well. After incubation at 37°C, migrated cells were collected at different time points in the lower well, and evaluated by measuring [3H]-methyl thymidine incorporation by scintillation counting. Peripheral blood mononuclear cells (PBMC) were obtained from buffy coats of blood from normal donors, and, for CD14+ experiments, a positive selection was performed using MACS colloidal superparamagnetic microbeads. Cells were seeded in the upper well of a

chemotaxis chambers and, after a 90 mn incubation, filters s were fixed and stained for 30 s with hematoxyline. Five fields were counted on each filter 's lower side.
Results : sRANKL induces the migration of MonoMac-6 monocytic cells as well as human freshly isolated total peripheral blood mononuclear cells (PBMC) and CD14+ purified PBMC. sRANKL induces the migration of MonoMac-6 cells in a dose-dependent manner and with an efficacy similar to MCP-1, the reference chemokine for monocyte. After a 8 hour incubation, sRANKL started to exhibit a chemoattractive effect on MonoMac-6 cells, with an increased effect observed for up to 24 hours. sRANKL elicits an additive chemotactic effect to MCP-1. Furthermore, addition of the sRANKL decoy receptor osteoprotegerin in the lower well or sRANKL in the upper well abrogates the sRANKL-induced migration of MonoMac-6 cells, hallmarking a true specific activity. RNAse protection assay experiments indicate that exposure of MonoMac-6 cells to sRANKL was without any significant effect on the expression of a variety of chemokines, known to attract monocytes.
Conclusion : This study provides the first evidence that RANKL behaves as a chemotactic factor for monocytic cells, emphazing the cross-talk between bone and immune system.

Podosomes and the Internalization of Vacuolar H+-ATPase from the Ruffled Membranes of Osteoclasts. I. R. Hurst*[1], S. Chen*[1], J. Zuo*[1], J. Jiang*[2], B. S. Lee*[3], M. Lu*[4], S. L. Gluck*[4], L. S. Holliday[1]. [1]Orthodontics, University of Florida College of Dentistry, Gainesville, FL, USA, [2]Endodontics, University of Florida College of Dentistry, Gainesville, FL, USA, [3]Physiology and Cell Biology, Ohio State University, Columbus, OH, USA, [4]Medicine/Nephrology, University of Florida College of Medicine, Gainesville, FL, USA.

Inhibition of phosphatidylinositol 3-kinase activity with 100 nM wortmannin triggers internalization of V-ATPase from the ruffled membranes of resorbing osteoclasts into cytosolic vesicles. This process is completed in about 40 min. In resorbing osteoclasts, podosomes are concentrated in the actin ring that surrounds the ruffled membrane and are present at much lower levels in the ruffled membrane area. Podosomes were detected by phalloidin-staining and confocal microscopy of osteoclasts fixed at time points after wortmannin treatment. During the first 10 min podosomes invaded the ruffled membrane area and were found increasingly intercalated within the spaces between membrane ruffles. By 10 minutes intercalation of podosomes and ruffled membranes had progressed to extensive co-localization between microfilaments and V-ATPase. Concurrent with the increasing co-localization between V-ATPase and F-actin increasing amounts of actin was recovered in immunoprecipitations using anti-V-ATPase antibodies. Wortmannin triggered both relocation of podosomes and a 30% reduction in the number of podosomes per osteoclast. Experiments with semi-permeabilized cells suggested wortmannin-treatment did not have profound effects on the dynamics of individual podosomes. Exogenous fluorescent-actin was incorporated into podosomes with or without wortmannin, and treatment with latrunculin A, which sequesters actin monomers, completely disrupted podosomes in the semi-permeabilized cells. Blocking actin turnover in intact wortmannin-treated osteoclasts using latrunculin A or jasplakinolide, which stabilizes filaments, inhibited the formation of cytosolic, V-ATPase containing vesicles. Taken together, these data suggest a role for podosomes, and podosomal dynamics, in the internalization of V-ATPase.

Actin-Related Protein 2/3 Complex Is Required for Osteoclast Differentiation and Actin Ring Formation. I. R. Hurst*[1], J. Zuo*[1], J. Jiang*[2], L. S. Holliday[1]. [1]Orthodontics, University of Florida College of Dentistry, Gainesville, FL, USA, [2]Endodontics, University of Florida College of Dentistry, Gainesville, FL, USA.

Actin-related 2/3 (Arp2/3) complex is associated with most dynamic microfilament-based structures and is found in the podosomes of src-transformed cells. In osteoclasts, podosomes that resemble those from transformed cells form actin ring structures that are required for bone resorption. Two components of the Arp2/3 complex (Arp2 and Arp3) were upregulated 3 fold in Raw 264.7 cells in response to stimulation with osteoprotegerin-ligand. Immunocytochemistry demonstrated that Arp2/3 complex was present in the actin rings of mouse marrow osteoclasts fixed in the process of resorbing bone and in the podosomes of the actin rings of Raw 264.7 cells on coverslips. Arp2/3 complex was found to co-localize in podosomes with F-actin and cortactin, a known regulator of Arp2/3 complex activity, but not with vinculin. Five small interfering RNAs (siRNAs) were designed against Arp2 and one effectively knocked down expression of the target protein. Raw 264.7 cells could be transfected either early (Day 3 after OPGL-stimulation) or late (Day 5) in the differentiation process with efficiencies of 50-80% as judged by a fluorescent oligos. When transfected early with the effective siRNA, the cells were rendered unable to form mature osteoclasts. Thirty hours after late transfection with the effective siRNA, levels of Arp2 were reduced 70% in whole cell lysates when standardized to actin levels and compared with ineffective controls. Many well spread giant cells were evident in cultures late transfected with the effective siRNA after 30 hours of culture; but when F-actin was stained using fluorescent-phalloidin, actin rings were not detected. In control cells transfected by ineffective siRNAs, podosomes and actin rings were normal. In summary, our results suggest that the Arp2/3 complex is vital to osteoclast differentiation and is required for the formation of actin rings.

A Specific Inhibitor of Atypical PKCs Blocks Formation of the Sealing Zone in Bone-Resorbing Osteoclasts. H. Zhao[1], S. Ohno*[2], S. L. Teitelbaum[1], F. P. Ross[1]. [1]Department of Pathology, Washington University School of Medicine, St. Louis, MO, USA, [2]Department of Molecular Biology, Yokohama City University School of Medicine, Yokohama, Japan.

Osteoclasts (OCs) are multinucleated bone resorbing cells of hematopoietic origin. Attachment to bone matrix stimulates OC polarization, thus initiating the resorptive process. Bone degradation involves formation of a tight sealing zone and the ruffled border in the plasma membrane juxtaposed to bone, followed by vectorial secretion of protons and proteases into the resorption lacuna. Little is known about the molecular mechanisms underlying these fundamental polarity events. Recent studies have shown that a ternary complex composed of the cell polarity proteins, par-3, par-6 and atypical PKCs (aPKCs), functions as an evolutionarily conserved protein machinery which is essential for establishing cell polarity in a variety of biological contexts. Given these facts, we explored the expression and function of par-3, par-6 and (aPKCs) in OCs and their myeloid precursors. Using the standard culture system of M-CSF dependent bone marrow macrophages cultured with M-CSF and RANKL, total RNA and cell lysates were prepared at different time points representing precursors, pre-OCs and mature cells. RT-PCR and western blot results showed that par-3, par-6 and both aPKC isoforms, PKC-ζ and PKC-λ , are expressed in mature OCs. Importantly, the expression level of par-3 increases during OC differentiation, with maximal expression found in the fully resorptive cells. Immunofluorescence and laser scanning confocal microscopy studies demonstrate that par-3 and aPKCs colocalize with F-actin at the sealing zone of OCs cultured on dentin slices. Together, our results suggest that par-3, par-6 and aPKCs may form a complex and function in the formation and maintenance of tight sealing zone in OCs. To test this hypothesis, we treated mature OCs cultured on dentin slices with specific inhibitors of PKC isoforms. While inhibitors of the classical PKCs, namely PKC-α and -β , and novel PKCs, such as PKC-θ and -ε, fail to alter actin ring formation, an aPKC specific inhibitor decreases this index of OC polarization in a dose- and time-dependent manner. Furthermore, the PI-3K inhibitor, LY294002, which also prevent OC actin ring formation, decreases phosphorylation of aPKCs. In conclusion, 1). Our results have localized components of a cell polarity protein complex containing aPKCs/par-3/par-6 at the OC sealing zone; 2) inhibition of aPKC activity blocks formation of actin rings, suggests a role for the polarity complex in OC polarization. 3). This complex may function as an important downstream effector of PI-3K signaling in regulating osteoclast function.

Actin Ring Formation Stimulated By RANKL Involves a Unique Actin Remodeling Mechanism Distinct from Osteoclast Podosomes and Mediated by CapG. B. D. Bennett[1], P. McAtee*[1], K. Tustison*[1], F. S. Southwick*[2], K. A. Hruska[1]. [1]Pediatrics, Washington University School of Medicine, St. Louis, MO, USA, [2]Department of Medicine, University of Florida College of Medicine, Gainesville, FL, USA.

A quantitative 2Dgel-mass spectrometry based proteome screen of rapidly tyrosine-phosphorylated proteins in osteoclasts detected CapG as the most prominent RANKL target. CapG was shown to cap actin filaments during assembly of the RANKL-stimulated actin ring, a process that was distinct from the gelsolin capped cytoskeleton (podosomes). CapG function was also regulated by ECM, polyphosphoinositides and calcium. CapG mediated organization of actin ring assembly was critical because its deficiency produced a mild osteopetrosis, similar to gelsolin deficiency, in CapG null mice. CapG deficiency was complemented by capping protein (CapZ), preventing the osteopetrosis from being severe. Gelsolin did not associate with the actin ring until disassembly during motility, demonstrating its role in actin severing (CapG does not sever actin filaments). The gelsolin capped cytoskeleton was morphologically separate from actin ring assembly and was focused at the cell periphery, lamellopodia and leading edges of osteoclasts. CapG associated with other actin barbed end regulators such as Scar and Arp2/3 and a specific intracellular calcium pool during assembly of the actin ring. RANKL stimulated calcium sensitization through src, phospholipase C gamma, and PYK2 leading to CapG activation and ring assembly. Calcium stimulated CapG capping activity and gelsolin translocation to the ring leading to its dissassembly. We conclude that CapG is a prominent RANKL effector protein mediating the unique process of osteoclast actin ring assembly during bone resorption. The CapG actin pool is a newly identified actin pool distinct from the podosome, responsible along with CapZ for the unique organization of the actin ring.

Activated T Cell Factors Inhibit Bone Formation *In Vitro*. S. Varghese[1], N. Wyzga*[2], F. A. Sylvester[2]. [1]Research, Saint Francis Hospital & Medical Center, Hartford, CT, USA, [2]Pediatric Gastroenterology, Connecticut Children's Medical Center, Hartford, CT, USA.

T cell activation is a hallmark of chronic inflammatory diseases associated with bone loss. We tested the hypothesis that factors produced by activated T cells inhibit osteoblast development from bone marrow stromal cells *in vitro*. We isolated T cells by magnetic cell sorting from spleen of 5-week-old C57BL/6J mice, which yielded T cell fractions that were >95% pure as judged by flow cytometry. The conditioned medium from resting and activated T cell cultures was used as a source of T cell-derived factors. We activated T cells with concanavalin A (Con A), phytohemagglutinin (PHA), *Staphylococcal* enterotoxin A (SEA, a superantigen), or anti-CD3ε and -CD28 (Abs). Bone marrow stromal cells were

harvested from femurs of C57BL/6J mice and grown in culture for 10 to 12 days to allow for stromal cells to settle and form colonies. Stromal cells were then exposed to 0.1 to 10% conditioned medium from resting and activated T cells for 3 weeks. Cultures were stained for calcium nodules with alizarin red and for alkaline phosphatase. Exposure of bone marrow cultures to different doses of conditioned medium from activated T cells reduced bone nodule formation and alkaline phosphatase activity in a dose-dependent manner, especially from T cells treated with either Abs or SEA. Medium from resting T cells had no effect. The decrease in nodule formation in the stromal cell cultures was accompanied by a decrease in cell number, as suggested by hematoxylin staining. We observed that the concentration of IFN-γ was highest in the medium from T cells activated with Abs (279-472 ng/mL) or SEA (2-6 ng/mL) (n=4). We tested if IFN-γ mediated the inhibitory effects of conditioned medium. IFN-γ by itself reduced nodule formation in a dose-dependent manner, with maximum inhibition at 5 ng/mL. However, reduced nodule formation persisted in bone marrow cultures exposed to activated T cell conditioned medium in the presence of an IFN-γ neutralizing antibody. In addition, inhibition of nodule formation occurred in bone marrow cultures from IFN-γ receptor null mice, indicating that other factors produced by activated T cells also contribute to the suppression of bone formation in bone marrow stromal cell cultures. Our studies suggest that soluble factors produced by activated T cells may play a role in inhibiting bone formation. Although IFN-γ present in the medium is inhibitory, it probably works together with other factors to inhibit osteoblast development from bone marrow stromal cells *in vitro*.

TNFα Induces RANKL and Inhibits OPG Gene Expression in Primary Bone Marrow Stromal Cells. S. Wei, F. P. Ross, S. L. Teitelbaum. Pathology, Washington University School of Medicine, St. Louis, MO, USA.

Enhanced osteoclastogenesis is a hallmark of various forms of bone disease, including the osteopenia involving chronic inflammation of bone or periosseous tissues. These events, which are accompanied by prolonged or excessive release of cytokines, are central to the pathogenesis of inflammatory bone joint destruction. TNFα is among the most potent of the osteoclastogenic cytokines produced in inflammation. While this molecule potently induces macrophages to assume the osteoclast phenotype, it does so only in the context of at least permissive levels of the essential osteoclastogenic molecule, RANK ligand (RANKL), expressed by bone marrow cells of the mesenchymal lineage. The present study was designed to investigate the molecular mechanism(s) by which TNFα regulates RANKL gene expression by marrow stromal cells. We first document, by semi-quantative RT-PCR analysis, that TNFα dose-dependently induces RANKL gene expression in primary murine bone marrow cells purified with an antibody against VCAM-1, a marker constitutively expressed on bone marrow stromal cells and myeloid cells. We next turned to define the molecular mechanism(s) underlying stimulation of RANKL expression by TNFα. We find that TNF enhances expression of IL-1α, another inflammatory cytokine known to induce osteoclast activation. While IL-1α alone does not increase the level of RANKL mRNA, the capacity of TNFα to stimulate this effect is abolished by the addition of excess IL-1 receptor antagonist (IL-1Ra). These data suggest that a synergy may exist between TNFα and IL-1α in the regulation of RANKL gene. This hypothesis is supported by the observation that the combination of a minuscule concentration of TNFα (1 ng/ml) and IL-1α (10 ng/ml) prompts robust upregulation of the RANKL gene. We also find that, within the same mesenchymal cell population, both TNFα and IL-1α inhibit expression of OPG, the decoy receptor for RANKL, thereby further augmenting the osteoclastogenic activity of RANKL. TNFα inhibition of OPG is not attenuated by IL-1Ra, indicating that the mechanism of this effect differs from that which regulates RANKL. Attesting to function, TNF-induced osteoclastogenesis in a coculture of wild-type VCAM-1 positive cells and bone marrow macrophages from TNF receptor double knockout mice, which is about 40% of that induced by 1,25-dihydroxyvitamin D, is inhibited by addition of IL-1Ra by approximate 60%. Thus, excess TNFα associated with states of chronic inflammation acts on the stromal environment to enhance expression of RANKL in synergy with IL-1α, and to inhibit expression of OPG, both leading to accelerated osteoclastogenesis.

The Stage Dependent Effects of Interleukin-6 on Osteoclastogenesis. R. K. Rahman*, S. V. Bukata, J. Gelinas*, W. Huang*, R. J. O'Keefe, J. E. Puzas, R. N. Rosier, E. M. Schwarz. Orthopaedics, University of Rochester School of Medicine, Rochester, NY, USA.

Interleukin-6 (IL-6) is a pleotropic cytokine previously recognized as having both osteoclastogenic and anti-osteoclastogenic properties. A number of studies have proposed IL-6 as a potent stimulator of bone-resorbing cells (osteoclasts), which are formed as a result of monocyte differentiation. As such, they have concluded that anti-IL-6 therapy is advocated for bone loss seen in post-menopausal osteoporosis, erosive arthritis, and wear debris-induced osteolysis. However, others have found that IL-6 inhibits osteoclastogenesis and bone resorption. To resolve this controversy, we evaluated the stage specific effects of IL-6 on the differentiation of osteoclast precursors using cells derived from IL-6 knock out, TNF-transgenic, and wild-type mice. Using murine splenocyte cultures, we found that IL-6 inhibited early precursors, had no effect on mature osteoclast precursors, and stimulated osteoclastogenesis of late precursors into osteoclasts. Flow cytometry for the osteoclast precursor marker CD11b on splenocytes from wild-type and IL-6 k/o mice revealed that IL-6 does not regulate the precursor frequency in vivo. Further studies, employing the murine calvarial model, were undertaken to investigate the effects of IL-6 on bone resorption and in vivo osteoclast formation. IL-6 knock out mice showed increased osteoclast formation and increased bone loss compare to wild-type control. Taken together these results show that the effects of IL-6 are dependent on the stage of differentiation of the osteoclast precursor, and support a model whereby IL-6 inhibits the differentiation of immature pre-osteoclasts, while synergizing with other osteoclastic factors to mediate the differentiation of mature pre-osteoclasts.

Tartrate-Resistant Acid Phosphatase (TRACP) in the Rat Bone, Serum and Osteoclast. Y. Igarashi[1], S. Shimizu*[1], K. Manaka*[2], T. Miura*[3], S. Matsuzaki*[1]. [1]Biochemistry, Dokkyo University School of Medicine, Mibu, Japan, [2]Institute for Medical Science, Dokkyo University School of Medicine, Mibu, Japan, [3]Biochemical Laboratry, Nitto Bouseki Co., Ltd., Koriyama, Japan.

Tartrate-resistant acid phosphatase (TRACP) is well-known as a marker of the osteoclast. However, its physiological significance in the osteoclast still remains unclear. In the human serum, Lam (1981) found that there were two types of TRACP 5 i.e. 5a and 5b, separated by native electrophoresis, and that the 5b was derived mostly from the osteoclast. We have shown that these two isoforms were identified by using heparin column chromatography [Igarashi Y. J Chromatogr B Biomed Sci Appl. 2001; 757:269-76]. The objective of our study is to specify the type of TRACP isoforms of rat bone by analyzing various monocytic tissues and cultured osteoclasts. Tibiae were homogenized using a Polytoron homogenizer with 50 mM Tris buffer pH7.5 containing PMS, Triton X-100 and EDTA at 4°C. The osteoclast progenitor cells, purchased from Hokudo (Sapporo, Japan), were cultured with M-CSF (20 ng/ml) and RANKL (20 ng/ml) for 4 days and refreshed with medium every day. Macrophage-rich dish-attached cell fractions were collected from the spleen, alveolus and peripheral blood and incubated with PBS for 1 hour. Each sample was dialyzed against 20 mM Tris-HCl pH 7.2 0.1 M NaCl and absorbed to the heparin column (Amachambiosciences Hitrap heparin HP 1ml). TRACP was eluted with NaCl linear gradient from 0.1 M to 1.335 M. The activities of fractionated TRACPs were photometrically analyzed with 50 mM pNPP, 100 mM citrate buffer pH 5.5. Three TRACP activity peaks were detected in the fractions of the samples from serum, bone, osteoclast and other macrophages. The peripheral blood and spleen macrophages were characterized by higher proportion of the first peak. The serum of 3 week-old rats showed the second peak the highest, but one of the 10 day-old showed the last one the highest. The figure indicated below shows the TRACP pattern of mature bone, which had a prominent third peak and that it was similar to that of alveolar macrophages. Rat osteoclasts expressed three peaks and both the second and the third peak were increased by the stimulation of M-CSF and RANKL. In conclusion, the rat osteoclasts have at least two isoforms of TRACP while human osteoclasts have only one TRACP 5b.

TNFr1 Regulates RANKL Expression and Osteoclastogenesis. Y. Abu-Amer. Orthopedics and Cell Biol. & Physiol., Washington Univ. Sch. of Medicine, St. Louis, MO, USA.

TNF stimulates basal osteoclastogenesis via its type 1 receptor. This is supported by the findings that, 1) TNF accelerates RANKL-primed osteoclastogenesis, and 2) marrow

derived from TNFr1-null mice generates far less osteoclasts compared to wild type (WT). Thus, TNF/TNFr1 might regulate RANKL and possibly RANK expression on osteoclast precursors (OCPs) and stromal cells, respectively. To test this hypothesis, we evaluated osteoclastogenesis using RANKL-primed OCPs, whole marrow cultures and OCP/stromal cell mix and match experiments. We find that RANKL-induced osteoclastogenesis using TNFr1-null OCPs is approximately 64% of the WT. Whole bone marrow cultures from knockout mice generated far less osteoclasts (23%) compared to WT cultures indicating that TNFr1-null OCPs and stromal cells have reduced osteoclastogenic potential.
To examine possible mechanisms for this retarded osteoclastogenesis, we measured mRNA expression of RANK and RANKL in OCP and stromal cells, respectively. RT-PCR revealed that levels of RANKL message in WT stromal cells are markedly increased following vitamin D treatment compared to low levels in TNFr1-null cells. Expression levels of OPG that regulates RANKL were largely unchanged. Thus, the positive ratio of RANKL/OPG, which supports osteoclasts, was overwhelmingly in favor of WT rather than TNFr1-null cultures. Changes in RANK expression on OCPs, that could regulate osteoclastogenesis, were subtle and unlikely to represent the significant changes in osteoclastogenesis. As a result, we reasoned that WT stromal cells might recapitulate retarded osteoclastogenesis by TNFr1-null OCPs. We find that WT stromal cells cocultured with TNFr1-null OCPs induced osteoclastogenesis by knockout OCPs up to 75% compared to WT OCPs. Asserting a direct role for RANKL in this process, OPG was sufficient to block osteoclastogenesis by these cultures. Next, we examined the direct effect of TNFr1 by reintroducing the receptor into TNFr1-null stromal cells. Viral reintroduction of TNFr1 to TNFR1-null stromal cells resumed expression of RANKL mRNA to normal levels which was increased in response to vitamin D. More importantly, osteoclast formation by OCPs resumed in a normal pattern when co-cultured with TNFr1-restored knockout stromal cells. Because exogenous RANKL was not sufficient to induce optimal osteoclastogenesis by TNFr1-null OCPs compared to WT cells, we reintroduced TNFr1 into these cells as well. TNFr1-null OCPs with the newly introduced TNFr1 underwent near optimal osteoclastogenesis (90%) when treated with RANKL or co-cultured with wild type stromal cells (106%). Thus, expression of intact TNFr1 on OCPs and stromal cells is required for optimal induction of basal osteoclastogenesis.

Development and Characterization of a Novel Human *In Vitro* Bone Resorption Assay Useful for Preclinical Testing of Osteoporosis Drug Candidates. J. P. Rissanen*[1], T. A. Hentunen[2], J. M. Halleen[1]. [1]Pharmatest Services Ltd, Turku, Finland, [2]Institute of Biomedicine, University of Turku, Turku, Finland.

The purpose of this study was to develop a rapid and reliable *in vitro* bone resorption assay that would be a useful tool in preclinical phases of antiresorptive drug development. We cultured commercially available CD34-positive osteoclast precursor cells in the presence of M-CSF, RANKL and TGF-beta1 to allow their differentiation into bone-resorbing osteoclasts. After the differentiation period at day 7, the medium was replaced and the formed mature osteoclasts were allowed to resorb bone for an additional 2-day culture period. Tartrate-resistant acid phosphatase (TRACP) isoform 5b (TRACP 5b) and C-terminal crosslinked telopeptides of type I collagen (CTX) were determined from the culture medium with commercially available methods. Resorption pits were visualized with peroxidase-conjugated Wheat Germ Agglutinin lectin, and the total resorbed area was quantitated. The number of TRACP-positive multinuclear osteoclasts was counted under a microscope. The amount of lactate dehydrogenase released into the culture medium was determined as an index of cell death. After the 9-day culture period, medium CTX showed a highly significant correlation with the total resorbed area ($r > 0.9$, $p < 0.0001$). Medium TRACP 5b correlated with medium CTX ($r > 0.7$, $p < 0.0001$), but not as well as with osteoclast number ($r > 0.9$, $p < 0.0001$), suggesting that TRACP 5b is a marker of osteoclast number rather than their activity. The cathepsin inhibitor E64 proved to be a useful control inhibitor of resorbing activity of mature osteoclasts, osteoprotegerin a useful control inhibitor of osteoclastogenesis, and sodium azide a useful control inducer of cell death. We conclude that with this assay, it is possible to test rapidly the effects of drug candidates on cell death, osteoclastogenesis and resorbing activity of mature osteoclasts from the same osteoclast cultures. Medium CTX values divided by medium TRACP 5b values can be used as a reliable index of the amount of bone resorption per osteoclast. These results show that this novel human *in vitro* bone resorption assay is a fast, convenient and reliable large scale method for screening and optimization of new antiresorptive lead compounds targeted for osteoporosis and related bone disorders.

Effect of Carboxyl (C) Terminal Fragments of PTH on Osteoclastogenesis. O. Lotz, P. Divieti, H. Jüppner, F. R. Bringhurst. Endocrine Unit, MGH, Boston, MA, USA.

Intact parathyroid hormone, PTH (1-84), is one of the major regulators of cellular differentiation and function in bone metabolism. It acts on cells of the osteoblastic lineage via the G protein-coupled type-1 PTH/PTHrP receptor. Moreover, osteoblasts and osteocytes derived from PTHR-null mice express additional receptors for PTH which specifically recognize the carboxyl-terminal region of the hormone. Unlike the PTHR-1 receptors, these C-terminal PTH receptors (CPTHRs) bind various carboxyl-terminal fragments of PTH (CPTH). These truncating fragments are either generated by the peripheral metabolism of intact PTH or directly secreted, in a calcium-dependent manner, by the parathyroid glands. It has been reported that synthetic PTH C-fragments of PTH (7-84) block the calcemic action of PTH (1-84) and PTH (1-34) in parathyroidectomized rats. We have previously shown that PTH (7-84) reduces the formation of osteoclasts in murine whole bone marrow cultures, treated with M-CSF and RANKL or with $1.25(OH)_2D_3$. To address a direct effect of PTH (7-84) on osteoclastogenesis, we utilized purified marrow macrophages (BMM). As expected, addition of RANKL and M-CSF induced osteoclast formation, as assessed by TRAP staining and TRAP solution assay. BMM cultures exposed additionally to PTH (7-84) (300nM) generated 10-20% fewer osteoclasts. We then performed CPTHR radioligand binding analysis using ^{125}I-(Tyr) hPTH (19-84) as tracer, and observed that BMMs express CPTHRs. The expression in the receptor is reduced by treatment with RANKL. These findings suggest that CPTHR expression might decrease during osteoclast maturation. When BMM cells were cultured for an additional 7 days in medium containing high doses of M-CSF produced by fibroblastic cell line L929, the inhibitory effect of PTH (7-84) was enhanced by 30-40%.
Using this population of BMMs the treatment with (1-84) PTH and PTH (1-34) had no effect on the formation of osteoclasts. Moreover, neither PTH (1-84) nor PTH (1-34) were unable to diminish the inhibition by PTH (7-84). Shorter fragments of CPTH such as 11-84, 19-84, 23-84 and 39-83 had no effect on the formation of osteoclasts. In contrast to these CPTH fragments, we found that a shorter CPTH fragment (53-84) can enhance osteoclastogenesis.
These findings demonstrate that CPTH fragments act on osteoclast precursors cells and that these effects are dependent on the size of the CPTH fragments.

Two Chloride Channel Genes Required for Human Osteoclasts: CLIC-5 Defects Suppress Early Differentiation and Vacuolar Acidification; ClC-7 Defects Restrict Lacunar Resorption, but Permit Expression of Osteoclast Markers. H. Blair[1], s. Kalla*[1], m. Saito*[2], P. Orchard[3], P. H. Schlesinger[2]. [1]Pathology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Cell Biology and Physiology, Washington University, St. Louis, MO, USA, [3]Medicine, University of Minnesota, Minneapolis, MN, USA.

It is established that an avian intracellular chloride channel $Cl_{or,62}$, the homolog of the human intracellular Cl^--channel CLIC-5, is expressed at high levels at the osteoclasts ruffled border and mediates HCl transport. However, transgenic studies and examination of osteopetrotic families shows that a Cl^--channel homolog, CLC-7 is required for osteoclast formation. We studied the relative roles of these two genes, which are in different intracellular chloride channel families, using CD14 selected human osteoclast precursors differentiated in vitro with RANKL and Csf-1. CLIC-5 expression was modified using an siRNA targeting nt 331-351 of GB AK075163, 30 b upstream of the translation initiation. Results were compared to normal controls and CD14 cells from a natural compound heterozygote with P249R and S744F mutations in each copy of CLC7, which causes severe osteopetrosis. Targeting of the siRNA was confirmed by cy3 labeling of the siRNA within target cells. CLIC-5 suppressed cells showed zero vacuolar acidification using lysotracker labeling. Cell attachment to cell culture substrate or bone was unaffected, but in these cells there was no evidence of osteoclastic maturation including lack of multinucleation and absence of osteoclast markers including MMP9. In contrast, CD14 selected CLC7 double heterozygotes did show vacuolar acidification and cells expressing osteoclast markers including TRAP and cathepsin K were formed, although the amount of lacunar resorption and number of resorbing cells was greatly reduced, typically << 10 % of lacunar resorption in controls, and the lacunae that were formed were atypical, comprising single highly localized deep pits and chains of broad lacunae, common in normal control osteoclasts, were not seen. We conclude that at least two chloride-channel family genes are required for human osteoclastogenesis, CLIC-5, which is required for vacuolar acidification, affects early differentiation and mutants are probably not compatible with life. CLC7 defects are compatible with vacuolar acidification and permit limited survival, but prevent normal lacunar resorption.

Osteoclasts from Patients with Autosomal Dominant Osteopetrosis II (ADOII) Have Defective Acidification and Resorption, but Normal Proteolytic Activity In Vitro. K. Henriksen*[1], J. Gram*[2], S. Schaller*[1], J. Delaissé[1], J. Bollerslev*[3], M. A. Karsdal[1]. [1]Nordic Bioscience, Herlev, Denmark, [2]Ribe County Hospital, Ribe, Denmark, [3]Medical Endocrinology, National University Hospital, Oslo, Norway.

Autosomal Dominant Osteopetrosis II (ADOII) is a relatively benign disorder caused by a missense mutation in the *ClCN-7* chloride channel gene that seems to have a dominant-negative effect, with some residual activity.

The osteoclasts from ADOII patients have never been characterized. Here we present an *in vitro* study of the resorptive activity of osteoclasts from the ADOII patients.

Isolated CD14+ monocytes from ADOII patients, harboring a G215R mutation, and from healthy age and sex-matched controls, were cultured in the presence of RANK-L and M-CSF to generate osteoclastic cells and evaluate parameters, such as cell fusion, TRAP activity, ion channel and resorptive activity.

By histological investigations, ADOII osteoclasts have been found to have increased number and size *in vivo*. However, we did not observe any significant changes in the osteoclast formation rate, size or morphology in this study.

When mature ADOII osteoclasts were investigated on fully mineralized bone they formed actin rings, but the resorption level was reduced by 95% when compared to controls. Interestingly, the secretion of TRAP, which is known to depend on acidification, was also significantly reduced in the ADOII osteoclasts. The small residual resorption activity in the ADOII osteoclasts was sensitive to both chloride channel and Cathepsin K inhibitors, showing some acidification, albeit at lower levels than controls.

To prove that the defect is linked to acidification, we tested osteoclasts from ADOII patients and controls for their ability to degrade demineralized bone matrix, and found no significant differences under these conditions. Thus, these observations imply that only processes involved in the dissolution of the inorganic phase, and not the proteolysis of the organic phase, are attenuated by the mutation in the C*lCN-7* gene.

In conclusion, this is the first functional study of human ADOII osteoclasts. We show that the major osteoclastic defect is impaired resorption, likely caused by reduced acidification. We also show that osteoclastogenesis is normal in ADOII osteoclasts, resulting in fully mature actin ring forming osteoclasts. The larger osteoclasts observed *in vivo* , but not *in vitro*, could be a consequence of the absence of signals normally generated during dissolution of the matrix, rather than a consequence of the absence of ClC-7 activity.

Targeting Osteoclasts with Zoledronic Acid Prevents Bone Destruction in Collagen-Induced Arthritis. N. A. Sims[1], J. R. Green[2], T. J. Martin[3], M. T. Gillespie[3], E. Romas[1]. [1]Department of Medicine at St. Vincent's Hospital, The University of Melbourne, Melbourne, Australia, [2]Bone Biology Unit, Novartis Pharma, Basel, Switzerland, [3]St. Vincent's Institute of Medical Research, Melbourne, Australia.

Bone destruction is a characteristic feature of rheumatoid arthritis (RA) and constitutes a major cause of progressive disability. Bone loss involves osteoclasts, which are responsible for periarticular joint destruction. Osteoclasts are also evident in animal models of RA such as collagen-induced arthritis (CIA). It has been shown previously that synovial cells in CIA and RA express high levels of receptor activator of NFκB ligand (RANKL), and that treatment of CIA with Fc-OPG blocks osteoclastogenesis thereby preventing focal bone destruction, suggesting the potential of osteoclast inhibitors to prevent structural joint damage in arthritis.

In the present study, we investigated the effects of Zoledronic acid (ZOL), a potent third generation bisphosphonate, in the effector phase of CIA. At the onset of CIA, rats were treated with single doses of ZOL (50 or 100 μg/kg S.C.) and monitored daily for paw swelling. At 2 weeks after onset, joints in the hindpaws were evaluated using histology and radiography. Paraffin-embedded joints were analysed and scored for inflammation, pannus formation, and cartilage and bone destruction using semi-quantitative grading scales.

Histopathologic and radiographic analyses indicated that ZOL prevented structural joint damage, even though it had no impact on inflammatory synovitis. ZOL treatment did not prevent paw swelling, and arthritic scores were mildly increased in rats treated with 100 μg/kg ZOL compared to controls. However, treatment with a single dose of 50 or 100 μg/kg ZOL reduced bone erosion scores (by 65% and 80% respectively) compared to untreated controls. ZOL treatment strikingly diminished radiographic bone erosions in the ankle joints. In contrast, synovial inflammation and cartilage destruction scores were not altered in either untreated or ZOL treated rats.

These findings demonstrate that ZOL has powerful bone protective effects in arthritis that are independent of synovial inflammation. Targeting osteoclasts with potent bisphosphonates like ZOL may be an effective strategy for preventing structural joint damage in RA.

Inhibition of Osteoclast Bone Resorption by Newly Synthesized NMDA-receptor Modulators. O. Hoffmann[1], T. Pöhler*[2], U. Maurer*[1], M. L. Berger*[3], C. Noe*[2]. [1]Pharmacology and Toxicology, University of Vienna, Vienna, Austria, [2]Pharmaceutical Chemistry, University of Vienna, Vienna, Austria, [3]Brain Research Institute, University of Vienna, Vienna, Austria.

Glutamate is the predominant excitatory transmitter in the central nervous system. It is involved in neuronal functions through the action of two types of membrane receptors, ionotropic receptors and metabotropic receptors. N-Methyl-D-aspartate (NMDA) receptors constitute a family of glutamate receptors that which are crucial for synaptic-like intercellular signaling. Recently, glutamate transporters, receptors, and components of synaptic signaling have been identified in bone. Osteoblasts and osteoclasts (OC) express distinct glutamate receptors and clustering proteins necessary for receptor localization. In vitro incubation of OC with MK-801, a specific NMDA glutamate receptor antagonist inhibits bone resorption. To further elucidate the role of NMDA-receptors in bone, we synthesized novel polyamine inverse agonists based on the structure of aryl-substituted dialkanediamines and tested the capacity of these ligands (IC50 between 120 and 300 nM) to inhibit OC function in vitro. OC derived from rabbit long bones were incubated for 24 hours on bovine bone slices in αMEM + 10% FCS. Contaminating bone cells were then removed and resorption lacunae on bone slices were measured. The known antagonist, MK-801 (1 μM) inhibited bone resorption by 50%. TP266 (1 μM), the most potent synthesized polyamine inverse agonist, completely inhibited bone resorption. The other less potent 8 compounds inhibited OC bone resorption in a concentration dependent manner (100 μM to 10 nM). Inhibition of OC resorption with each compound tested was associated with impaired OC adherence at concentrations higher than 10 μM. To test whether reduced OC resorption was due to cytotoxicity, we measured cell toxicity using a MTS cell toxicity assay. We observed OC toxicity at concentrations of inverse agonists higher than 10 μM, which correlated with impaired OC adherence. DAPI staining at both the low (1 μM) and high (100 μM) compound concentrations did not induce OC apoptosis. Taken together, these data illustrate that low doses of these novel NMDA-receptor blockers inhibit OC resorption 100 times more effectively than the known receptor antagonist, MK-801 and at higher concentrations appear to be cytotoxic. Understanding the role of NMDA receptors in OC is important for further understanding of the mechanisms operating in bone metabolism and may provide new targets for the treatment of osteoporosis. Specific inhibition of NMDA receptor OC resorption may offer a novel therapeutic approach for osteoporosis.

Nox and Osteoclasts. S. Yang, Y. Zhang*, W. Ries, L. Key. Pediatrics, Medical University of SC, Charleston, SC, USA.

A new superoxide-generating enzyme (Nox4) is present in osteoclasts and contributes to osteoclastic superoxide production. In this study, we demonstrate that among the Nox family members, only Nox4 has a higher level of expression in osteoclasts than that in precursor cells, suggesting Nox4 is associated with osteoclast differentiation and development. Cotransfection of Nox4/P22 DNA constructs results in 80% increase of osteoclastic superoxide production, indicating that P22 is required for Nox4 to function. Using a real time PCR, we show that expression of cathepsin K and TRAP is increased dramatically in osteoclasts transfected with Nox4/P22, while c-fms remains unchanged. Such increase is correlated with enhanced superoxide generation in osteoclasts transfected with Nox4/p22. Further study reveals that JNK, not NF-κB, is the signaling pathway involved in superoxide-mediated expression of cathepsin K and TRAP in osteoclasts. More interestedly, we found a negative regulation between JNK and NF-κB pathways in osteoclasts, because decreased NF-κB activity correlates with enhanced the JNK activation in osteoclasts.

Superoxide has been shown to directly participate in the process of bone resorption by facilitating matrix protein degradation. In addition to the direct contribution to bone resorption, we show that appropriate amount of superoxide might be needed for osteoclast development and maturation, and superoxide might be involved in triggering the signal transduction pathways necessary for osteoclasts to function.

Annexin II Stimulates RANKL Expression through a MAPK-dependent Pathway in Human Bone Marrow Cells. F. H. Li[1], S. V. Reddy[1], G. D. Roodman[2]. [1]Medicine-Hematology/Oncology, University of Pittsburgh, Pittsburgh, PA, USA, [2]Medicine-Hematology/Oncology, University of Pittsburgh and Department of Veterans Affairs Medical Center, Pittsburgh, PA, USA.

We previously identified Annexin II (AX-II) as an autocrine/paracrine factor secreted by osteoclasts (OCL), that induces OCL formation and bone resorption *in vitro*. AX-II induced GM-CSF production by bone marrow stromal cells and activated T-cells, which increases OCL precursor proliferation, and further enhanced OCL formation. We have identified a receptor for AX-II on marrow stromal cells that preferentially bound the P11 subunit of the AX-II ($(P_{36})_2P_{(11)})_2$). However, induction of GM-CSF by AX-II did not fully explain its effects on OCL formation. In this study, we tested the capacity of AX-II to induce expression of receptor activator of nuclear factor (NF-κB) ligand (RANKL), and

osteoprotegerin (OPG) as well as the corresponding molecular signaling pathways in human marrow stromal cells (SAKA-T). Western blot assays showed that AX-II significantly increases membrane-bound RANKL (4 folds) compared to control human bone marrow cells. ELISA analysis identified soluble RANKL in the stromal cell conditioned media treated with AXII. Real time PCR analysis further demonstrated a dose dependent decrease in OPG mRNA expression in the human marrow stromal cell line, SAKA-T cells, stimulated with AX-II. Treatment of SAKA-T cells with AX-II activated MAP-kinase (ERKs). PD89059, a specific inhibitor of MEK, abolished the effects of Annexin II on membrane-bound RANKL expression in the SAKA-T cells and human bone marrow cells. These data suggest that the stimulation of OCL formation by AXII is due in part to modulation of the ratio of RANKL and OPG synthesis by marrow stromal cells through a MAPK-dependent pathway. Therefore, AXII is an important physiologic regulator of osteoclastogenesis that can stimulate the proliferation of OCL precursors by GM-CSF, and their differentiation to mature OCL via RANKL.

Osteoclast Differentiation In the Presence of TGFβ Elevates NFκB Activation and Down Regulates PTEN Expression. A. Gingery[1], M. K. Karst*[2], M. J. Oursler[3]. [1]Biochemistry, University of MN, Duluth, MN, USA, [2]Biology, University of MN, Duluth, MN, USA, [3]Biology and Medical Microbiology and Immunology, University of MN, Duluth, MN, USA.

Understanding the regulation of osteoclast survival is pivotal to understanding osteoclast actions during normal and pathological bone degradation. In our studies we examined the mechanisms of second messenger signaling using osteoclasts generated from murine co-cultures. TGFβ regulates survival of many cells and is released from bone during bone resorption. Thus, there is more active TGFβ present when bone resorption is elevated. Considering these physiological conditions in the normal and pathological bone microenvironment, it is important to discover the impact of differentiation in the presence of TGFβ on osteoclast survival. We investigated the survival signals involved in TGFβ -induced osteoclasts (differentiated in the presence of TGFβ) and compared these with osteoclast that have been differentiated in the absence of TGFβ (naïve osteoclasts). Once mature, stromal cells were removed to study osteoclast survival mechanisms. TGFβ -induced osteoclasts that were further cultured with TGFβ have both increased survival and activation of survival second messengers compared to both naïve osteoclasts and TGFβ -induced osteoclasts withdrawn from TGFβ when further cultured. Since NFκB is known to promote survival we looked at levels of NFκB using EMSA analysis. We found higher levels of NFκB activation in TGFβ -induced osteoclasts compared with naïve osteoclasts. When NFκB activation was inhibited there was reduced osteoclast survival within 90 minutes of further culture. IKK activation results in the phosphorylation of IκB and the subsequent release of NFκB, allowing NFκB to translocate to the nucleus. Activation of IKK was evident within 30 minutes of further culture. TGFβ -induced osteoclasts also have increased levels of active Akt, an upstream activator of NFκB, within in 30 minutes of further culture. Chemical blocking of Akt results in decreased survival within 90 minutes of further culture. Osteoclast survival involves PI3K-mediated activation of Akt/NFκB and MEK/ERK pathways. Chemically blocking PI3K significantly decreases osteoclast survival within 90 minutes of further culture. Since PTEN acts as a repressor of PI3K pathway, we have examined PTEN levels. Interestingly, mature TGFβ -induced osteoclasts have lower levels of PTEN compared to naïve osteoclasts. These data support that signals from PI3K are important components of osteoclast survival and that these survival signals include NFκB activation and may hinge on PTEN regulation. In conclusion we have identified a novel regulator of PI3K survival signaling in osteoclasts, PTEN.

Genomic Structure and Regulation of Expression of the Microphthalmia Transcription Factor (Mitf) in Osteoclasts. C. L. Hershey, D. E. Fisher. Pediatric Oncology, Dana-Farber Cancer Institute, Harvard Medical School, Boston, MA, USA.

Microphthalmia transcription factor (Mitf) is a basic/helix-loop-helix/leucine zipper transcription factor key to the development and function of melanocytes and osteoclasts. The murine *mitf*-mutant (*mitf^{mi}/mitf^{mi}*) osteoclasts are predominantly mononuclear, lack a ruffled border and fail to resorb bone matrix resulting in osteopetrosis. Mitf is expressed as multiple isoforms each containing unique first exons, which variably contain open reading frames. At present eight isoforms have been published (Mitf-A, C, Mc, E, H, D, B and M). The expression of the different isoforms is governed by split promoter regulation, with each isoform having its own promoter. To understand how Mitf is regulated within osteoclasts, we wished to obtain a detailed characterization of its genomic structure, including potential transcriptional regulatory elements that may modify Mitf expression *in vivo*. RT-PCR analysis revealed that the A, H and B isoforms are expressed in osteoclasts, whereas the M isoform was not detected. We used genome sequence databases to map the location of the various isoforms and found the human *MITF* locus is ~229kb and the mouse *mitf* locus is ~208kb stretching from the most 5' isoform to the end of the 3'UTR. Previously we have shown that expression of Mitf in melanocytes is responsive to cAMP induction, however, expression in macrophages is not responsive to cAMP, suggesting differential promoter regulation. We used the MatInspector software to analyze the various promoters for potential transcription factor binding sites, including those that are conserved across species. Analysis of ESTs corresponding to the *MITF/mitf* gene has shown that Mitf is transcribed in many tissue types, yet some isoforms are tissue restricted in their expression (e.g. Mitf-M in melanocytes and melanoma). We have also identified a new isoform of Mitf, Mitf-J, from the analysis of ESTs corresponding to the *MITF* gene. By RT-PCR analysis this new isoform is expressed in various cell types including primary osteoclasts and ARPE-19 (retinal pigment epithelium) cells. This study provides a detailed analysis of the human and mouse 200kb Mitf gene. The identification of multiple transcriptional regulatory motifs in Mitf promoters highlights mechanistic links between this functionally important transcription factor and signaling pathways that may regulate its expression in osteoclasts. Efforts are underway to investigate the mechanism of regulation of Mitf expression in osteoclasts, focusing on the isoforms we have shown are expressed in these cells, namely Mitf-A, H, B and J.

Importance of the Calcineurin/NFAT Pathway for Osteoclastogenesis in RAW 264.7 Cells. H. Hirotani*[1], N. A. Tuohy*[1], J. T. Woo[1], P. H. Stern[1], N. A. Clipstone*[2]. [1]Molecular Pharmacology and Biological Chemistry, Northwestern University Feinberg School of Medicine, Chicago, IL, USA, [2]Microbiology-Immunology, Northwestern University Feinberg School of Medicine, Chicago, IL, USA.

Although best known for its role in T lymphocyte activation, the calcineurin/nuclear factor of activated T cells (NFAT) signaling pathway is also known to be involved in a wide range of other biological responses in a variety of cell types. We investigated the role of the calcineurin/NFAT signaling pathway in the regulation of osteoclast differentiation. RAW 264.7 monocyte-macrophage precursor cells were cultured for 5 days in 96-well plates in alpha-MEM/10% fetal bovine serum/penicillin/streptomycin with or without human soluble RANKL (3-100 ng/ml). Inhibition of calcineurin with either the immunosuppressant drugs cyclosporin A (CsA) and FK506 or the retrovirally-mediated ectopic expression of a specific calcineurin inhibitory peptide, VIVIT, all potently inhibited the RANKL-induced differentiation of the RAW264.7 cells, as indicated by decreases in tartrate-resistant acid phosphatase (TRAP) activity, in the number of TRAP-positive multinucleated cells, and in the ability of the cells to resorb a mineralized matrix substrate. In addition, we found that the NFAT family members NFATc1, NFATc2 and NFATc3 are expressed in RAW264.7 cells and that their expression is upregulated in response to RANKL stimulation. Most importantly, we found ectopic expression of a constitutively active, calcineurin-independent NFATc1 mutant in RAW264.7 cells is sufficient to induce these cells to differentiate into large mature multinucleated osteoclasts capable of resorbing the mineralized substrate. The results demonstrate that calcineurin is an essential downstream effector of the RANKL-induced signal transduction pathway leading towards osteoclast differentiation and furthermore indicate that activation of the NFATc1 transcription factor is sufficient to initiate a genetic program that results in the specification of the mature osteoclast cell fate.

The Structurally Unique Osteoclastic Protein-Tyrosine Phosphatase Is Driven by an Intronic Promoter that Is Cell Type-Specific by Virtue of Repressor Elements. K. H. W. Lau, M. Amoui*, J. B. Tillman*, D. J. Baylink. Musculoskeletal Disease Center, Jerry L. Pettis Mem VAMC, Loma Linda, CA, USA.

A structurally unique osteoclastic protein-tyrosine phosphatase (PTP-oc), which is essential for osteoclast activity, shows sequence identity with the intracellular domain of a renal receptor-like transmembrane PTP, termed GLEPP1. Because PTP-oc and GLEPP1 share the same gene, it has been assumed that PTP-oc is a truncated variant of GLEPP1, resulting from alternative splicing. However, the 5'UTR sequence of PTP-oc mRNA contains 217 bp from an intron of GLEPP1. There are no splicing acceptor sites at the PTP-oc transcription site. The intronic sequence flanking the 5'end of the PTP-oc transcription start site also contains potential promoter elements (e.g., TATA and CAT boxes) essential for transcriptional initiation. Accordingly, this study sought to test the hypothesis that the PTP-oc gene has its own intronic, tissue-specific promoter. To test this hypothesis, the basal promoter activity of a 1.3-kb PCR fragment covering the 5'-flanking proximal region of the PTP-oc gene was measured with the luciferase-based assay system. The putative PTP-oc promoter fragment showed relatively strong basal promoter activity in U937 cells, which was approximately 30% of that of SV40 promoter. Mutation of the putative TATA box within the PTP-oc promoter abolished 60% to 90% of its basal promoter activity. The 1.3-kb PTP-oc promoter fragment showed strong promoter activity in cells that express PTP-oc

(i.e., U937 cells and RAW264.7) but not in cells that do not express the enzyme (i.e., skin fibroblasts, TE85 cells, and HEK293 cells). These findings together strongly support the conclusion that the 1.3-kb intronic fragment contains the tissue-specific, PTP-oc proximal promoter. Deletion analysis of the putative PTP-oc promoter revealed that removal of the 5' sequence flanking the putative TATA box enhanced the basal promoter activity by 4- to 5-fold, suggesting that the 5' sequence contains repressor elements. The removal of the putative repressor elements led to the loss of tissue specificity since the truncated promoter showed high promoter activity in all test cell types. In conclusion, this study demonstrates for the first time that 1) there is an intronic promoter within the GLEPP1 gene that drives the expression of the PTP-oc in a cell type-specific manner, 2) the cell type-specificity is conferred by repressive elements, and 3) this GLEPP1/PTP-oc gene system is one of the very few, if not the only system, in which two important tissue-specific enzymes are derived from the same gene through the use of intronic promoters.

The GTPase Activity of Dynamin in Osteoclasts Is Involved in the Regulation of Bone Resorption. A. Bruzzaniti, L. Neff, A. Sanjay, R. Baron. Yale University, New Haven, CT, USA.

Dynamin is a large GTPase that plays an essential role in receptor-mediated endocytosis. Dynamin is also a substrate of Src, and phosphorylation by Src increases the GTPase activity of dynamin. Recent findings have shown that dynamin also associates with actin and is involved in actin remodeling, a function essential for cell migration. Given that osteoclast (OC) function is dependent both on endocytosis and cell migration, we have explored the possibility that dynamin plays a role in bone resorption. We found that dynamin is expressed in OCs within individual podosomes at early time points following attachment, coincident with the expression of the podosome markers, actin and vinculin. At steady state, i.e. when the actin ring has expanded to the periphery of the cell, dynamin expression was more restricted to the inner edge of the actin ring, suggesting it may have a role in podosome disassembly. The distribution of dynamin to the actin ring was Src-dependent and was disrupted in OCs derived from Src -/- mice, which fail to form an actin ring. Immunoprecipitation studies showed that dynamin constitutively associates with c-Cbl in OCs, independent of its GTPase activity. Interestingly, the dynamin-Cbl association was destabilized by Src kinase activity and conversely, stabilized by inhibition of Src activity or by expression of a Cbl mutant that cannot bind Src, suggesting that binding and subsequent phosphorylation of Cbl by Src were necessary to dissociate dynamin from Cbl. To further examine the functional role of dynamin, we over-expressed dynamin and GTPase-inactive dynamin DynK44A in OCs with adenovirus and characterized their effects on podosome formation, actin remodeling and bone resorption. Osteoclasts over-expressing dynamin exhibited morphological changes including increased membrane ruffling and spreading. In contrast, OCs infected with GTPase-inactive DynK44A were retracted, contained fewer podosomes and exhibited decreased resorption on dentin. Since dynamin-Cbl binding is regulated by Src activity, we then co-expressed dynamin with kinase-inactive SrcK295M in OCs. While SrcK295M-infected cells contained actin patches instead of rings and failed to resorb bone, cells co-infected with dynamin and SrcK295M contained small actin rings. These studies suggest that dynamin, Cbl and Src coordinately participate in signaling events that regulate podosome assembly and disassembly and thereby, osteoclast motility and bone resorption.

Just How Cellular is Woven Bone? C. J. Hernandez, R. J. Majeska, M. B. Schaffler. Leni and Peter W. May Department of Orthopaedics, Mt. Sinai School of Medicine, New York, NY, USA.

Woven bone tissue forms in cases of rapid bone proliferation. In addition to displaying a more random collagen orientation than other cortical bone tissue, woven bone has been estimated to contain 4 to 8 times more osteocytes per unit volume than cortical tissue. Quantitative data for osteocyte number in woven bone have not been reported, but are of great interest in light of recent studies that have linked osteocyte number to the targeting of bone remodeling and the regulation of bone volume. In this study we evaluate the osteocyte density (Ot.N, cells/mm2 bone tissue) of woven bone and cortical bone of the rat. Adult (400g) male Sprague-Dawley rats (n=5) experienced a controlled femoral fracture using the Bonnarens-Einhorn method in order to induce woven bone; animals were sacrificed 21 days later. Osteocyte density was evaluated on longitudinal sections using light microscopy. Ot.N was measured in woven bone at three sites: 1) in the center of the fracture callus, 2) in buttressing callus on the periosteum adjacent to the fracture and 3) primary spongiosa near the growth plate of the distal femur. These values were compared to osteocyte density measurements in cortical bone far from the fracture. Osteocyte density of woven bone in the center of the fracture callus (1699 ± 291, Mean ± S.D.) and in the primary spongiosa (1403 ± 233) was significantly greater than the osteocyte density in cortical bone (968 ± 120, $p < 0.001$). Osteocyte density in the buttressing callus (1111 ± 300) was not significantly different from that in cortical bone. These findings contradict the widely held notion that woven bone is much more cellular than cortical bone tissue. Rather than the expected 400-800% greater osteocyte density estimated in the literature, woven bone in the rat has, at the most, only 40-80% more osteocytes than cortical tissue. Moreover, osteocyte density was not uniform. Osteocyte density in woven bone of the buttressing callus was similar to that of cortical bone but was less than that near the center of the fracture callus and in the primary spongiosa. A possible explanation is that woven bone in the buttressing callus forms from the periosteum through intramembranous ossification, while woven bone in the center of the callus and at the primary spongiosa are endochondrally derived. Thus, the process through which woven bone tissue is formed determines its cellularity and may influence its bioactive properties.

Do Osteocyte Lacunae Initiate Microdamage Under Physiological Conditions? S. Qiu[1], D. Rao[1], S. Palnitkar*[1], A. Parfitt[2]. [1]Bone & Mineral Research Laboratory, Henry Ford Hospital, Detroit, MI, USA, [2]Division of Endocrinology and Center for Osteoporosis and Metabolic Bone Disease, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

It has been suggested that the osteocyte lacuna is the stress concentrator in bone which is responsible for the initiation of microdamage. However, this scenario may only occur when the skeleton sustains pathological high loading. There is no evidence that osteocyte lacunae initiate microdamage under physiological conditions.
Rib sections from 9 white men aged 50-59 years were stained with basic fuchsin and examined using bright-field and fluorescent microscopy. We have developed a special method to measure lacunar densities (Lc.N/B.Ar) in the areas adjacent to and remote from linear crack(s) in interstitial bone. In addition, osteocyte lacunae within 50 µm of linear cracks were examined using confocal microscopy.
Lacunar density was 16% lower in the area adjacent to crack(s) than in the area remote from crack(s) ($p < 0.01$)(Fig 1). Damaged osteocyte lacunae were enclosed by clustered tiny cracks or fuzzy stain (arrow heads, Fig 2). The lengths of cracks or the thickness of fuzzy stain were about 10-20 µm, and the cracks around different lacunae rarely connected with each other. Only about 7% of the osteocyte lacunae were encircled by submicroscopic cracks or fuzzy stain ($p < 0.001$).
Confocal microscopy showed that very few of the osteocyte lacunae in normal bone were associated with submicroscopic damage, suggesting that osteocyte lacunae in living bone do not contribute to the initiation of microdamage. This is probably because the maximum strain surrounding the lacunae does not exceed the peak physiological strain. In contrast, microdamage occurs preferentially in bone with impaired osteocyte lacunar-canalicular network.

MLO-Y4 Cells Produce an Unknown Chemoattrantant for Osteoclast Precursors. S. Ko, S. E. Harris, M. Dallas*, L. F. Bonewald. Oral Biology, University of Missouri at Kansas City, Kansas City, MO, USA.

The osteocyte most likely plays a role in bone remodeling by instructing osteoclasts to remove bone at specific sites. This entire process includes recruitment through chemotaxis of osteoclast precursors and proliferation of these precursors followed by fusion and activation of mature osteoclasts. Osteoblasts/stromal cells have been shown to support osteoclast formation and activation upon treatment with bone resorbing cytokines. The two major components necessary for this process are M-CSF and RANKLigand. The osteocyte-like cell line MLO-Y4 supports osteoclast formation and activation in the absence of any resorbing factor through the constitutive production of M-CSF and expression of RANKLigand on their dendritic processes.
To determine if MLO-Y4 cells will also support chemotaxis and proliferation of osteoclast precursors, two cell lines RAW 264.7 and MOCP-5 were utilized and migration was assayed using transwells. These cells form TRAP positive multinucleated cells upon the addition of soluble RANKLigand. Conditioned media alone from MLO-Y4 cells was sufficient to support proliferation and chemotaxis of both osteoclast precursor cell lines, unlike the support of osteoclast formation by bone marrow cells which required cell to cell contact. The MLO-Y4 cells produced much greater amounts of the proliferation activity and chemotactic activity than 2T3 osteoblasts or NIH3T3 fibroblasts. Proliferation was completely inhibited by neutralizing antibody to M-CSF whereas chemotaxis was not. This was surprising as M-CSF is a well-known chemotactic factor. The capacity of recombinant M-CSF to provoke chemotaxis in RAW 264.7 and MOCP-5 cells was determined, but the maximal response did not reach the maximal response of the conditioned media. Gene array analysis was used to identify potential chemoattractants. MLO-Y4 cells express much greater amounts of mRNA for MIP-2α, VEGF, MCP-3 and TGFβ1 compared to 2T3

osteoblast cells. MIP-2α and VEGF did not stimulate transmigration of the osteoclast precursor cells. MCP-3 stimulated RAW 264.7, but not MOCP-5 chemotaxis. The effects of TGFβ1 were modest compared to the conditioned media or to M-CSF. Sufficient neutralizing antibody to TGFβ1 and MCP-3 had no effect. M-CSF does not appear to synergize with either TGFβ or MCP-3. SDF-1, a potent chemoattractant is not made by MLO-Y4 cells. To date, an unknown factor exists that has the potential to synergize with M-CSF to stimulate osteoclast precursor chemotaxis. Identification of this factor should aid in the identification of chemotactic factors for osteoclast precursors made by primary osteocytes.

Characterization of a Monoclonal Antibody Specific for Osteocytes by Immunostaining but Not Specific by Western Blot Analysis. K. Zhang*, L. Ye*, Z. Li*, J. Rosser*, L. F. Bonewald. Oral Biology, Dental school, UMKC, Kansas city, MO, USA.

A monoclonal antibody called E11 that reacted specifically with rat osteocytes *in vivo* was generated by Wetterwald and coworkers (Bone 18:125-132, 1996). Previously, we too had generated a mouse osteocyte specific monoclonal antibody called 9C11. These antibodies reacted specifically with osteocytes and not with osteoblasts or other tissues. However, the gene encoding for this antigen was found to be expressed in a number of tissues, but mainly in cell types with cellular projections such as podocytes in kidney, Type 1 alveolar lung cells, and thymic epithelial cells. Keratinocytes stably transfected with this gene develop processes suggesting that the function of the gene product is the generation of cellular extensions. However, the rational for the specificity of E11 and 9C11 antibodies for osteocytes was not clear with such wide-spread gene expression in other tissues. To address this issue, we obtained a hamster monoclonal antibody, 8.1.1, to thymic epithelial cells from Dr. Andrew Farr (J Histochem Cytochem 40:651-664,1992). This antibody recognizes the same gene product as E11 and 9C11. By western blotting, this antibody recognized 40kD bands of similar intensity in MLO-Y4 osteocyte-like cells, MLO-A5 mineralizing cells, 2T3 and MC3T3 osteoblasts, NIH 3T3 fibroblasts and murine calvarial cells. The immunoreactive bands were of slightly different sizes with the MLO-Y4 band the smallest, 40 kD versus 42 kD in the other cells. These same cells express similar amount of mRNA as determined by RT-PCR. However, when immunohistochemical staining was performed on 19-day old mouse long bone sections, only osteocytes were stained by this antibody, not osteoblasts. There was no reactivity with growth plate, bone marrow, nor muscle. These results suggest that the E11 protein is expressed in osteoblasts, but that the epitope in osteoblasts for 8.1.1 antibody is masked or hidden. The data also suggest that the epitope in osteocytes in bone is exposed, perhaps due to post-translational modifications. Comparisons of the antigen from osteoblasts and from osteocytes is underway using 2-dimensional gel electrophoresis and mass spectrometry.

Precision of Height Measurement in Osteoporotic Subjects. K. Siminoski[1], T. Johnson*[2], G. Cline*[2]. [1]Radiology and Diagnostic Imaging, and Internal Medicine, University of Alberta, Edmonton, AB, Canada, [2]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

Serial measurement of total body height is a fundamental tool in the assessment of osteoporotic patients, with the primary goal being the detection of vertebral fractures. Given that the average height loss due to vertebral fracture is about 1 cm per fracture, precision error of height measurements has a direct bearing on the use of height monitoring in individual patients.

In this investigation, we have analyzed the long-term precision error of repeated height determinations. Subjects were women from 190 research centers in the placebo arms of the VERT MN/NA risedronate studies (average age 69.0 years; range: 38-85 years) who had data for height and vertebral morphometry. Height was measured with a stadiometer to the closest millimeter. Lateral vertebral radiographs were performed at the same times and were analyzed by digital morphometry from T4 to L4. Vertebral fractures were determined using both quantitative and semiquantitative methods. Only women who did not sustain a new vertebral fracture were studied. Precision errors over one-year intervals were calculated as root-mean-square standard deviations and coefficients of variation. These values were used to derive the amount of change necessary to detect a statistically significant difference on repeat measurement (at a 95% level of confidence). The least significant changes (LSC) for single replicates (LSC-1) and triplicate replicates (LSC-3) were determined.

The numbers of subjects with complete data over the three one-year intervals ranged from 573 to 713. The coefficents of variation ranged from 0.64% to 1.20%. The corresponding LSC-1 (for single measurements) at each time point were 2.8 cm to 5.2 cm, and LSC-3 (for triplicate measurements) ranged from 1.6 cm to 3.0 cm.

These results show that precision variability in height measurement is substantial in comparison to the amount of height loss that occurs due to vertebral fractures, even using a stadiometer. Triplicate measurements at each clinical evaluation reduce the LSC.

Height Measurement Precision

Time Interval (start yr-end yr)	n	CV	LSC-1	LSC-3
0-1	713	0.69	3.0	1.7
1-2	601	0.64	2.8	1.6
2-3	573	1.20	5.2	3.0

CV = coefficient of variation. LSC-1 = least significant change (95% confidence) for single measures at each time. LSC-3 = least significant change for triplicate measures at each time.

Predictive Value of Low Bone Mass for One Year Fracture Outcomes in NORA: Comparison of Results in Women Age 50-64 and Age 65 and Over. E. S. Siris[1], S. K. Brenneman[2], T. W. Weiss*[2], C. Ya-Ting[2]. [1]Department of Medicine, Columbia University College of Physicians and Surgeons, New York, NY, USA, [2]Outcomes Research, Merck & Co., Inc., West Point, PA, USA.

Low bone mass and fractures are prevalent in older postmenopausal women. Little information is available about the frequency of low bone mass and its association with fracture in early postmenopausal women. We evaluated the frequency of and association between low bone mass and fracture in women age 50-64 in comparison to their counterparts age 65 and over. NORA enrolled 200,160 postmenopausal women age 50 and older that had no prior diagnosis of osteoporosis. Baseline bone mineral density (BMD) was measured at the heel, forearm, or finger. A one-year follow-up survey requesting incident fractures since baseline was completed by 163,935 women. The association between BMD and fracture was assessed using logistic regression, adjusted for important covariates. In women age 50-64, 31% had low bone mass (T-scores <= -1.0) whereas 62% of women age 65 over had low bone mass. Fracture occurrence and association with BMD is shown in Table below.

	50-64	65 and over
N	87,594	76,341
No. (%) Osteoporotic Fractures	905 (37%)	1535 (63%)
Fracture Rate / 1000 person-years (95% CI)	8.4 (7.9, 9.0)	16.5 (15.6, 17.3)
RR of Fracture / 1 SD decrease in T-score (95% CI)*	1.5 (1.4, 1.6)	1.5 (1.4, 1.5)
RR of fracture per T-score category (95% CI; reference category > -1.0)		
-1.0 to -2.0	1.8 (1.5, 2.0)	1.6 (1.4, 1.8)
≤ -2.0	2.6 (2.1, 3.2)	2.6 (2.2, 2.9)

*RR: Relative Risk based on logistic regression model adjusting for BMD, prior fracture, health status, HRT usage maternal prior fracture, race, cortisone use, and densitometry device.

We conclude that about one third of postmenopausal women in NORA aged 50-64 had low bone mass. Although the absolute fracture rate was lower in these younger women, their relative risk for fracture within one year of the BMD measurement was similar to that in older women in NORA (age 65 and over) for each standard deviation decrease in T-score and by T-score category.

Comparison of BMD and Fracture Prediction Across Skeletal Sites: Evidence from National Osteoporosis Risk Assessment (NORA). P. D. Miller[1], S. K. Brenneman[2], S. Barlas*[2], T. A. Abbott[2]. [1]Colorado Center for Bone Research, Lakewood, CO, USA, [2]Outcomes Research & Management, Merck & Co., Inc., West Point, PA, USA.

Bone mineral density (BMD) measurements at both peripheral and central skeletal sites have been shown to predict risk of fracture. However, discordance of BMD measurements across sites exists within the same individual. It is not known whether BMD at the central sites is more predictive of fracture than those at the peripheral sites. We compared BMD measurements at 3 skeletal sites, hip, spine, and forearm, to determine the extent to which they concur and their ability to identify women with incident osteoporotic fractures within two years of measurement. Data from the Specialist Arm of NORA were used for this analysis. BMD T-scores were calculated using young adult reference database provided by the manufacturer. Fractures occurring in the subsequent two years were identified by self-report. The current analysis included women who had BMD measured at baseline at all 3 sites: hip (femoral neck), spine (total spine) and forearm (distal radius), and responded to the follow-up surveys. 685 women, mean age 63.7 (SD 8.5) years, reported 45 osteoporosis-related fractures (hip, rib, wrist/forearm and spine). Of the 685 women, 133, 163, and 201 had T-scores ≤ -2.5 at the femoral neck, total spine, and distal radius, respectively. Of the 306 women who were osteoporotic at any site, 51 (17%) were osteoporotic at all 3 sites, 89 (29%) at 2 of 3 sites and 166 (54%) at only one site. Of the 45 osteoporotic fractures, 29 (64%) were identified by T-score ≤ -2.5 at any site. There were no meaningful differences in the proportion of the fractures detected in women with BMD T-scores ≤ -2.5 using single site measures at the femoral neck, total spine and distal radius: 16 (36%), 14 (31%), and 15 (33%) fractures identified, respectively. We conclude that both central and peripheral BMD T-scores of ≤ -2.5 identify women at risk for fracture. However, a single BMD measurement resulting in a T-score > -2.5 does not necessarily rule-out osteoporosis at another site.

Native Canadian (First Nations) Status is a Marker for High Fracture Risk. W. D. Leslie[1], S. Derksen*[2], C. Metge*[2], L. Lix*[2], E. Salamon*[3], P. Wood Steiman*[4], L. L. Roos*[2]. [1]Dept. of Medicine, St. Boniface General Hospital, Winnipeg, MB, Canada, [2]Manitoba Centre for Health Policy, Winnipeg, MB, Canada, [3]Medicine, St. Boniface General Hospital, Winnipeg, MB, Canada, [4]Island Lake Tribal Council, Island Lake, MB, Canada.

Fracture rates are one index for the prevalence of osteoporosis in a population. Ethnicity is one of many factors that have shown to be determinants of fracture risk and bone density. Native Canadian (First Nations) status in Manitoba defines an ethnic population with unique cultural, socioeconomic and health related factors that could affect fracture rates. We performed a retrospective, population-based matched (1:3) cohort study using the Manitoba administrative data repository from 1987 to 1999. The cohort contained 32,692 First Nations (384,012 person-years follow-up) and 98,076 controls (1,085,778 person-years). Age- and sex-adjusted standardized incidence rate ratios (SIR) are produced for First-Nations and non-First Nations cohorts, and Poisson regression is used to model the incidence fracture data with demographic, socioeconomic, health, and geographic predictors. First Nations had significantly higher rates of any fracture (SIR 2.06, 95 percent CI 2.00 to 2.11). A similar age-related and female-predominant pattern was seen for wrist fractures (SIR 2.96, CI 2.61 to 3.35), spine fractures (SIR 1.93, CI 1.74 to 2.14) and hip fractures (SIR 1.92, CI 1.69 to 2.21). In contrast, craniofacial fractures (SIR 4.96, CI 4.65 to 5.30) were predominant in males and younger adults. Income class (P<.0001), geographic residence area (P<.0001), and diagnosis of diabetes mellitus (P<.0001) were also associated with fracture rates, but adjustment for these factors did not appreciably reduce the marked excess fracture risk seen in First Nations. We conclude that Manitoba First Nations are a previously unidentified group at high risk for fractures.

SIR for fractures: First Nations vs age-matched controls (95% CI).

	Males	Females	Combined
Any site	2.19 (2.12-2.67)	2.26 (2.20-2.36)	2.23 (2.18-2.29
Hip	2.10 (1.68-2.63)	1.70 (1.41-2.05)	1.85 (1.61-2.14)
Wrist	2.78 (2.29-3.39)	3.18 (2.68-3.79)	3.00 (2.63-3.42)
Spine	1.79 (1.54-2.08)	2.18 (1.88-2.51)	2.18 (1.88-2.51)
Craniofacial	4.89 (4.51-5.29)	5.48 (4.88-6.19)	5.07 (4.74-5.42)

Fractures, Bone Mass and Falls in Older Women with Parkinson's Disease. J. L. Schneider*[1], H. A. Fink*[2], K. Yaffe*[1], K. L. Stone[1], S. R. Cummings[3]. [1]University of California, San Francisco, CA, USA, [2]Veterans Administration Medical Center, Minneapolis, MN, USA, [3]University of California and California Pacific Research Institute, San Francisco, CA, USA.

A few studies have suggested that women with Parkinson's Disease (PD) have an increased risk of falling and hip fracture. No studies have examined the relationship between PD and BMD or PD and other types of fractures.

In the Study of Osteoporotic Fractures (SOF), a prospective study of older women, we analyzed the relationship between PD, and BMD, hip and other types of fractures, and falls in 8412 women. Seventy-three women reported a physician diagnosis of PD. Incident falls and fractures were ascertained during a mean 7.3 years of complete follow-up. All fractures were confirmed by radiology reports.

Women with PD had on average 7.2% lower age adjusted total hip BMD (p=0.01) and this was attenuated by adjustment for weight (p=0.22) and 3.7-fold increased risk of multiple falls (2+per year) (Relative Hazard=3.7, 95% CI 1.9-7.1). Women with PD had significantly increased risks of hip and other fractures (table). We estimated that women with PD have 30% risk of hip fracture over 5 years, compared to 5% for women without PD. The increased risk of hip fracture was independent of BMD.

Hazard Ratios for Hip and non-spine, fx associated with PD

	Hip fx HR (95% CI)	Non-spine fx RR (95% CI)
Age adj	2.89 (1.59, 5.25)	1.96 (1.30, 2.95)
Age, weight adj	2.57 (1.27, 5.17)	1.65 (0.99, 2.75)
Age, weight , BMD adj	2.88 (1.36, 6.09)	1.64 (0.95, 2.84)

We conclude that older women with PD have lower BMD, and an increased risk for falls and all types of fractures, including hip fractures. All older women with PD should be evaluated and, perhaps, treated to reduce their high risk of fractures.

Risk Factors for Fractures of Women Aged 48-67 Years. The 10-year Follow-up of OSTPRE Study. R. J. Honkanen. Research Institute of Public Health, University of Kuopio, 70280 Kuopio, Finland.

The Osteoporosis Risk Factor and Prevention (OSTPRE) study cohort was established in 1989 by selecting all women (N=14220) born in 1932-41 and resident in Kuopio Province, Finland. A total of 13100 women responded to baseline postal enquiry in 1989. The study population of the present study consists of those 11074 women who responded also to the 5-year and 10-year enquiries in 1994 and 1999. At baseline, 1865 women reported a fracture since the age of 15 (wrist fracture by 567 women). A total of 1915 women reported a follow-up fracture (ANY) during 1989-99 which could be verified by patient record perusal: 736 women had sustained a distal forearm fracture (DFF) and 381 women an ankle fracture (ANK).

Following variables increased the risk of fracture in multivariate logistic models: fracture history 1.8-fold for ANY fracture (p<0.001), 1.7 for DFF (p<0.001) and 1.4 for ANK (p=0.01); age for ANY (p=0.003) and DFF (p<0.001); use of prescribed drugs by 15 %/drug for ANK (p<0.001) and by 10 %/drug% for ANY (p<0.001); height 4 %/cm for ANY and DFF (p<0.001); smoking by 55 %/10 cigarettes for ANK (p<0.001); weight by 2 %/kg for ANK (p<0.001); physical activity for ANK (p=0.01) and menopause age by 2 % of ANK/year (p=0.02). Following factors were preventive: 100 mg of nutritional calcium prevented 5 % of DFF (p<0.001), 3 % of ANY (p<0.001) and 4 % of ANK (p=0.005); HRT (per one year use) prevented 7 % of DFF (p<0.001), 5 % of ANY (p<0.001) and 4 % of ANK (p=0.04); weight prevented 2 % of DFF/kg (p<0.001) and 1 % of ANY/kg (p=0.001). Following variables were not related to any of these three fracture groups, menarche age, parity, number of self-reported health disorders or work disability. In addition, fracture history predicted tibia, spine, hip and rib fracture.

Fracture history was a potent predictor, while HRT and nutritional calcium had a preventive effect for fractures of these women aged 48-67 years. Smoking and the use of drugs increased the risk of ankle fracture. The effects of putative risk/preventive factors vary by site of fracture.

Heredity for Breast Cancer and Hip Fracture in Relation to Bone Density and Fractures. The Nordos Sudy. E. B. Waern*[1], O. Johnell[2], K. Åkesson*[2], D. Mellström[1]. [1]Dept of Geriatric Medicin, Center for Bone research, Göteborg, Sweden, [2]Dept of Orthopaedics, Malmö University Hospital, Malmö, Sweden.

Heredity for hip fracture is an independent predictor for fractures in women and high bone densiy is a predictor of breast cancer.

The question is if there are differences in bone density and fracture risk among daughters to women with hip fracture and breast cancer respectively. 772 70 year old women from a random sample of the population in Göteborg and Malmö participated in the study. Bone density was measured with Hologic 4500 A. General health was measured in a health questionaire.

91 women, or 12,5 percent, had heredity for hip fracture and 43 women, or 5,9 percent, had heredity for breast cancer. Only 0,6 percent had heredity for both breast cancer and hip fracture.

There were no differences in body weight or body height between women with heredity for breast cancer compared to women with heredity for hip fracture. Women with heredity for breast cancer had higher hip BMD 0.840 (0.140) compared to women with heredity for hip fracture, BMD 0.784 (0.129) p<0.005. The risk for prevalent fractures in women with heredity for breast cancer compared to women with heredity for hip fracture OR 0.221 (0.079-0.615).

A multivariate model showed that BMD hip, OR 1.54 per SD, heredity for hip fracture, OR 1.8 and body height, OR 1.2 per SD, were independant predictors for previous fractures between 50-70 years of age.

We conclude that heredity for hip fracture and breast cancer have important impact on fracture risk. Women with heredity for breast cancer had a higher hip BMD compared to women with heredity for hip fracture.

Reduced Mechanosensitivity Is Associated with Fractures in the Old Order Amish. B. D. Mitchell[1], T. J. Beck[2], E. A. Streeten[1], D. J. McBride[1], A. L. Lodge*[1], K. Uusi-Rasi[2], A. R. Shuldiner*[1]. [1]Medicine, University of Maryland School of Medicine, Baltimore, MD, USA, [2]Radiology, Johns Hopkins University, Baltimore, MD, USA.

The sensitivity of bones to mechanical stimuli should be evident in the relationship between bone strength and skeletal load. Reduced mechanosensitivity should cause relatively weaker bones for equivalent skeletal loads and increase susceptibility to traumatic fracture. Underlying geometric differences in weaker bones should also lead to increased osteoporotic fragility in old age. The purpose of this study was to determine whether mechanosensitivity is related to fracture history. As an index of mechanosensitivity we analyzed the ratio of section modulus (index of bending strength) to lean body mass, the latter being a crude measure of muscle load. Total body and hip scans were obtained by DXA in participants of the Amish Family Osteoporosis Study. Section moduli were derived by Hip Structure Analysis (HSA) from hip DXA scans. Mechanosensitivity indexes (MSI) were created using total body lean mass and section moduli measured at three different hip sites: narrow neck (NN), intertrochanter (IT), and shaft (S).

The study population included 682 subjects (263 men, 419 women) ranging in age from 20-88 yrs. A total of 248 subjects (129 men, 119 women) reported having had one or more fractures during their lifetime. This total included 206 subjects reporting fractures resulting from moderate-to-severe trauma ("traumatic" fractures) and 57 reporting fractures resulting from low trauma, such as a fall from a standing height ("fragility" fractures). We compared mean bone mineral density (BMD) and mechanosensitivity between subjects with and without a history of fracture, accounting for correlations among family members. All analyses were adjusted for the effects of age, sex, height, and weight. MSI at the NN and IT were significantly lower in subjects reporting any fracture compared to those with no previous history of fracture ($p = 0.004$ and $p = 0.02$, respectively). In addition, subjects reporting "fragility" fractures had significantly lower MSI at the S ($p = 0.003$), while subjects reporting "traumatic" fractures had significantly lower MSI at the NN ($p = 0.004$). However, BMD was also uniformly lower in those reporting fractures; after simultaneously adjusting for differences in BMD between those with and without a fracture history, MSI at the S remained significantly associated with "fragility" fractures ($p = 0.003$), and MSI at the NN remained borderline associated with "traumatic" fractures ($p = 0.07$). We conclude that differences in mechanosensitivity may alter susceptibility to both "traumatic" and "fragility" fractures.

Vertebral Deformities Prevalence in Postmenopausal Women: a Population-based National Study. R. Nuti[1], G. Guglielmi[2], G. Capelli*[3], D. de Feo*[4], G. Giuda*[5], U. Senin*[6], S. Adami[7]. [1]Internal Medicine, University of Siena, Siena, Italy, [2]Radiology, Scientific Institute Hospital, Foggia, Italy, [3]Public Health, University of Cassino, Frosinone, Italy, [4]Procter & Gamble, Rome, Italy, [5]Orthopaedics, University of Napoli, Napoli, Italy, [6]Internal Medicine, University of Perugia, Perugia, Italy, [7]Rheumatology, Valeggio Hospital, Verona, Italy.

FEDRO (Fracture Evaluation by Digital Radiography Observational study) is a national study aimed at measuring the prevalence of vertebral fractures (VFs) in a sample of Italian postmenopausal women. Fifty-eight University and Hospital centers in Italy participated in the study. Each center was asked to consecutively enrol ambulatory patients who met inclusion criteria (aged 60+ yrs, 5+ yrs postmenopausal, BMD t-score < -2) over a 6-month period.

A total of 2750 subjects were enrolled in the study. All subjects had undergone an X-ray evaluation of thoracic and lumbar spine. Each film was centrally digitized: T4-L4 vertebral heights ratio were measured by a radiologist using a morphometry software (Spine-X Analyzer; CAM Diagnostics, Milan, Italy). The deformities were defined as: mild, moderate or severe, based on a height ratio decrease of 20%-25%, 25%-35% and more than 35% respectively. Currently data on roughly 1500 women are under revision due to low quality radiographs. The table below shows the prevalence (%) by age and grading of VFs in those 885 subjects with data currently available.

60-64 (n=267)		**65-69 (n=262)**	**70-74 (n=187)**	**75-79 (n=115)**	**80+ (n=54)**	**ALL (n=885)**
1+VFs T4-L4	18.0	22.5	23.0	30.4	35.3	23.1
Mild	9.4	11.8	11.8	13.9	13.0	11.4
Moderate	7.1	9.5	7.5	13.9	16.7	9.4
Severe	1.5	1.2	3.7	2.6	5.6	2.3
2+VFs T4-L4	3.8	9.9	7.5	7.8	20.4	7.9
1+VFs T4-T12	15.7	19.9	19.8	27.0	26.0	19.9
Mild	9.0	12.6	10.7	14.8	13.0	11.4
Moderate	5.6	6.9	5.9	10.5	9.3	6.9
Severe	1.1	0.4	3.2	1.7	3.7	1.6
1+VFs L1-L4	7.1	11.1	7.0	9.6	13.0	9.0
Mild	5.2	6.1	4.3	4.4	3.7	5.1
Moderate	1.5	4.2	2.1	3.5	7.4	3.1
Severe	0.4	0.8	0.6	1.7	1.9	0.8

Preliminary results of this study confirm the high prevalence of undiagnosed VFs in elderly women (at least one VF in 23.1% in population with BMD t-score < -2), showing a strong age-effect trend. Physicians and health authorities should strongly consider the importance of raising awareness at national level on osteoporosis and fractures as a real "social disease".

Incident Rates of Hip Fractures in Mexicans Over 50 Years. P. Clark[1], P. Lavielle*[2], J. Salmeron*[3], S. R. Cummings[4]. [1]Clinical Epidemiology Unit, Centro Medico Nacional, IMSS-Faculty of Medicine UNAM, Mexico City, Mexico, [2]Clinical Epidemiology Unit, Centro Medico Nacional, IMSS, Mexico City, Mexico, [3]Epidemiology & Health Systems Unit, IMSS, Morelos, Mexico, [4]SF Coordinating Center, San Francisco, CA, USA.

We have recently shown that the rate of vertebral fractures is similar in Mexico and Whites in the US. The rates of hip fracture in Mexico have never been determined in a population-based study. To describe rates in urban Mexico, cases in individuals over 50 years of age were identified from institutional registers of all hospitals with hip surgery facilities from the two largest Health Systems in Mexico City. Cases were verified against surgical and x rays logs. Age, sex, type of fracture, ICD-10 coding and place of residence were obtain. Age stratified incident rates were developed using the CENSUS 2000 population data.

The rates of hip fracture increase exponentially with age in both genders. Age-standardized rates in Mexico (206 for women and 108 for men) were 2.5 lower than the rates in US non Hispanics for women and 1.6 times lower for men (510 and 174/100 000 for women and men respectably) but similar to rates found in urban Chinese and US Hispanics. This first population based study in Mexicans shows that the risk of hip fracture in Mexican women and men are lower than the US and Europe and similar to several other developing countries.

Age group	Total No. Cases		Population (per thousands)		Annual rate x 100,000 (IC)	
	Men	Women	Men	Women	Men	Women
50-59	29	38	145.99	192.51	20 (13-30)	20(14-28)
60-69	52	105	99.70	138.61	52 (36-73)	76 (58-98)
70-79	95	236	58.62	79.92	162(115-227)	295 (228-385)

Design and Methods for a Community-Based Study of Bone Health in Men: BACH Bone. S. S. Harris[1], A. B. Araujo*[1], M. F. Holick[2], J. B. McKinlay*[1]. [1]New England Research Institutes, Watertown, MA, USA, [2]School of Medicine, Boston University, Boston, MA, USA.

The distribution and determinants of osteoporosis have been far less studied in men and in ethnic and racial minorities than in Caucasian women. The purpose of the BACH Bone Study is to estimate the prevalence of low bone mineral density (BMD) and to examine its medical, hormonal, and behavioral correlates in a diverse, community-based, random sample of adult men. In addition, the study has been designed to facilitate anticipated follow-up measurements.

BACH Bone is a substudy in 900 men from the 6000 men and women now being enrolled in the Boston Area Community Health Survey (BACH). BACH is a survey of uro-gynecologic conditions and related measures in a random sample of Hispanic, African-American, and Caucasian urban adults aged 30-79. Men who complete an in-home BACH visit are invited to participate in BACH Bone by visiting a clinical research center. The BACH visit provides much of the data for BACH Bone, but the clinic visit adds DXA BMD and other bone-related measurements. This approach is efficient because it uses an existing cohort that can only be assembled with costly methods that include extensive field tracing of selected households, and field or telephone eligibility screening. In addition, this approach permits potential participants who might otherwise be wary of clinic-based research to have positive interview experiences in their homes and to receive study stipends before being approached for BACH Bone. As further incentive, the study provides free transportation, bone scan results, and a second stipend.

Data obtained at the BACH visit include demographics, physical measurements, gonadal and pituitary hormone measurements, and medical and lifestyle information. Data obtained at the clinic visit include DXA scans of the hip, spine, whole body, and forearm, and measurements of grip strength, physical and cognitive function, calcium-regulating hormones, and markers of bone turnover. Both studies collect and archive blood samples for future measurements.

Cohort maintenance activities are conducted in anticipation of future follow-up measurements. These include obtaining contact information for a person who will always know how to reach the participant, annual mailings to participants (birthday cards), use of postal service change-of-address notification, and continual updates to our computerized participant information database.

In conclusion, the BACH Bone study combines information from an in-home survey and a clinical site visit in an efficient approach to collecting comprehensive information about skeletal health in a random, multi-ethnic sample of urban men.

Men with Idiopathic Vertebral Osteoporosis Have Low Lean (but not Fat) Mass and No Abnormality of COL1A1-Sp1 Genotype. M. W. J. Davie, S. Evans*, H. Davies*, C. Sharp*. Charles Salt Centre, Robt Jones and Agnes Hunt Hospital, Oswestry, United Kingdom.

Osteoporosis in men has been associated with small body size and low serum concentrations of IGF-I. Smaller frame size relates to low bone mass in normal men. We have investigated whether lean body mass and total bone mineral mass (BMC) are low in men with idiopathic vertebral fracture. We have also investigated whether the G>T mutation in the Sp1 binding site of the COLIA1 promoter region is associated with these variables in men.

We have determined COLIA1-Sp1 genotype, body composition, bone density (BMD) and stature in 33 consecutively referred consenting men (mean age 64±10, range 50 –78 yrs) with idiopathic vertebral fracture (IVO) and in 73 healthy (H) volunteers (61±8, 50-78yrs).Indices of body composition were measured using an Hologic QDR4500 densitometer. COLIA1-Sp1 genotypes were determined using a microtitre plate based method with a colorimetric end-point (Axis-Shield, Scotland, UK). Group comparisons were made using the Students t-Test and relationships by simple linear correlation.

Men with IVO were significantly lighter (73±9 vs 82±12 Kg) and shorter (169.5± 8 vs 174.3± 6 cm) than H (both p>0.001). Total body (tb-) BMC (2.1±0.3 vs 2.69±0.4 Kg) and tb-Lean mass (53.6±6 vs 59.3±7 Kg) were also lower in IVO (both p>0.0001). tb-Fat mass was not significantly different. Men with IVO had significantly lower BMD at the lumbar spine (0.880±0.2 vs 1.048±0.2 gcm^2), proximal femur (0.831±0.1 vs 1.017±0.1 gcm^2) and femoral neck (0.682±0.1 vs 0.831±0.1 gcm^2) (all p>0.0001). In both IVO and H men tb-BMC correlated with tb-Lean (r^2=0.3 and r^2=0.49, both p>0.001 respectively) but not with tb-Fat mass.COLIA1-Sp1 alleles were in Hardy-Weinberg equilibrium. Genotype frequencies were GG=72.7 / 68.5; GT=27.3 / 30.1; TT= 0 / 1.4 in IVO and H respectively, and their distributions were not significantly different. Classification of IVO and H groups into GG and GT/TT genotypes revealed no significant differences in any of the measured variables. However, men with the T allele in both IVO and H groups tended to have greater tb-Mass than those with the GG genotype (75±11 vs 72±8 and 83±14 vs 81±11 Kg respectively).

Conclusion: men with IVO are lighter than age-matched healthy men. tb-BMC is low and related to the low tb-Lean mass. Lean body mass, not COLIA1-Sp1, is more closely associated with IVO in men.

Long-term Physical Activity Increases Bone Bending Strength despite No Change of Areal Bone Mineral Density - the MINOS Study. P. Szulc[1], T. J. Beck[2], P. D. Delmas[1]. [1]INSERM 403 Research Unit, Lyon, France, [2]The Johns Hopkins Outpatient Center, Baltimore, MD, USA.

The long-term effect of physical activity on areal bone mineral density (aBMD) and biomechanical properties of bone is not fully understood. We evaluated the effect of professional physical activity on aBMD as well as on morphological and biomechanical parameters of radius, ulna and femoral neck in 824 men aged 45 to 85 years belonging to the MINOS cohort. The intensity of physical activity was evaluated using a self-reported four level score (low, medium, high, very high) based on the work performed by each participant during the largest part of their professional career. Analyses were adjusted for age, body weight, body height, tobacco smoking, levels of free testosterone and 17β-estradiol, leisure sport activity as well as for lower limb muscular mass for femoral neck and upper limb muscular mass for radius and ulna. aBMD of the three bones did not differ between levels of physical activity. At the radius and ulna, external diameters were 7 and 9 % wider (p<0.0001) and endocortical diameter was 8 and 11 % higher (p<0.0001) in men with the very high physical activity compared with those with the low one. In all three bones, men with the highest physical activity had higher cross-sectional moments of inertia (7.5 to 34 %, p<0.05-0.0001) and higher section moduli (6 to 23 %, p<0.03-0.0001) compared with men with the lowest physical activity. Average buckling ratio was slightly higher at the radius and ulna (7 and 8 %, p<0.05-0.01) but not at the femoral neck.

Our data indicate that the long-lasting high physical activity can modify the morphological and biomechanical parameters of bones in ways that are not apparent in aBMD.

Prevalent Clinical Fractures and Hip Fractures are Associated with Stiffness Index Measurement in Men: Results from the Population Based ESOPO Study. L. Sinigaglia*[1], M. Varenna*[1], G. Isaia[2], S. Adami[3], S. Giannini[4], S. Maggi*[5], P. Filipponi[6], O. Di Munno*[7], D. de Feo*[8], G. Crepaldi[4]. [1]Rheumatology, Gaetano Pini, Milano, Italy, [2]Internal Medicine, Torino University, Torino, Italy, [3]Rheumatology, Valeggio Hospital, Verona, Italy, [4]Internal Medicine, Padova University, Padova, Italy, [5]CNR Agin Center, Padova, Italy, [6]Internal Medicine, Umbertide Hospital, Perugia, Italy, [7]Rheumatology, University of Pisa, Pisa, Italy, [8]Procter & Gamble, Roma, Italy.

A multicenter population based study was conducted to relate the prevalence of Osteopenia and Osteoporosis with personal fracture history in the Italian general male population. Eighty-three University and Hospital Centers performed the study. Subjects were randomly invited to participate from 1,536 GPs by a specific randomization protocol with 4,981 men aged 60-79 yrs enrolled. Each subject underwent a bone quantitative ultrasound measurement (QUS) on a Lunar Achilles Express. Personal history for clinical fractures (vertebral, hip, rib, wrist and other low-trauma fractures occurred after the age of 50) was recorded together with several life-style and anthropometric variables. In the sample we found 798 men with prevalent fractures after the age of 50. Age, BMI and calcium intake were similar in fractured and non-fractured counterparts whereas patients with fractures had a significantly higher alcohol consumption and a longer history of tabagism (p<0.03). Stiffness Index (SI) was significantly lower in men with prevalent fractures (p=0.0001) after adjustment for the main co-variates such as age, BMI and Calcium intake. Similarly, adjusted means for SI were significantly lower in hip-fractured men as compared to non hip-fractured counterparts (p=0.0001). A logistic model in which the dependent variable was the existence of any prevalent clinical fracture for a total of 4,365 observations showed an OR of 1.2 (95 % CI: 1.1-1.3) for 1 SD decrease of SI. A second model in which a prevalent hip fracture was the dependent variable (3,823 observations) showed an OR of 2.1 (95 % CI:1.5-3.1) for 1 SD decrease in SI.

Logistic procedure. Dependent variable: Prevalent Fractures. N. 4,365 observations

Variable	Unit	Odds Ratio	Lower	Upper
BMI	1unit	1.002	0.991	1.011
Age	1 yrs	1.037*	1.022	1.052
Smoking	Yes / no	1.222*	1.002	1.485
Use of OP drugs	Yes / no	0.869	0.765	2.119
Antihypertensives	Yes / no	0.869	0.738	1.023
Alcohol abuse	Yes / no	1.003*	1.001	1.006
Calcium intake	1 score	1.000*	1. 000	1. 001
Stiffness	- 1 SD	1.272*	1.173	1.381

*p<0.05

This large population-based retrospective study shows that SI ultrasound measurement is strongly related to prevalent clinical fractures and to hip fractures in men older than 60.

Applying the Osteoporosis Self-Assessment Tool (OST) in Primary Care Practices Uncovers Osteoporosis in Men: Preliminary Report. M. I. Williams*, V. I. Petkov*, S. L. Johnson*, S. Wright*, M. T. Tran*, R. A. Adler. Endocrinology, McGuire Veterans Affairs Medical Center, Richmond, VA, USA.

Despite the availability of reliable diagnostic tests and treatment, osteoporosis (OP) is still under-diagnosed, particularly in men. OST, a simple screening tool for stratifying osteoporosis risk, is calculated by the formula {[weight (kg)-age]*0.2} and correlates well with axial bone mineral density (BMD by DXA) in men and women. We hypothesized that introducing OST as a screening aid in primary care clinics will increase the diagnosis and treatment of OP in men.

Providers in 3 primary care group practices at a single Veterans Affairs Medical Center were randomly assigned to one of the following interventions: 1. Education about OST and an OST pocket nomogram; 2. Education/nomogram plus a computer desktop OST-index calculator; 3. Education/nomogram plus an automatic clinical reminder in the electronic patient record for patients with high and moderate risk of OP according to OST. The 3 practices had similar provider number and patient mix. Outcomes were percent change in DXAs ordered, metabolic bone clinic consults requested, and osteoporosis specific prescriptions issued as compared to a baseline period.

We report preliminary results from a half-year intervention. The distribution of patients according to their OST values was very similar in the 3 group practices during baseline and intervention periods: 4.3% had high risk for OP, 31.8% were at moderate risk and the rest were low risk, similar to other OST studies. At baseline, the practices did not differ significantly in DXAs ordered, bone clinic consults, and OP specific prescriptions ordered. Comparing each practice to its baseline, no significant differences were observed in the practices randomized to education only or to education plus the desktop OST calculator. In contrast, the practice using the electronic BMD reminder ordered many more DXAs (526% increase). During the intervention period 100 DXAs were performed as a result of OST (3% from the practice with education only, 6% from the practice with education plus desktop OST calculator and 91% from the practice with electronic reminder). The prevalence of OP was high: 30% had at least one DXA site (spine, femoral neck, or total hip T-score) $\leq$ -2.5, and 79% had at least one T-score $\leq$ -1. At this preliminary assessment, bone clinic consult and OP medication changes were insignificant because of the time lag between DXA and follow-up.Applying OST as a screening tool for OP, particularly using electronic reminders, can increase the number of DXAs ordered and number of men diagnosed with OP.

Factors Associated with Low BMD Among Middle-Aged Canadian Chinese Immigrants. A. M. Cheung[1], R. Chaudhry*[1], C. Chan*[1], K. Milstead*[1], N. Diaz-Granados*[1], D. Lui-Yee*[1], O. Gajic-Veljanoski*[1], M. Hamidi*[1], N. Carnide*[1], G. Chan*[2], L. Thompson*[1]. [1]Department of Medicine, University Health Network, Toronto, ON, Canada, [2]Yee Hong Centre, Toronto, ON, Canada.

We conducted a community-based cross-sectional study to explore the relationship between risk factors for osteoporosis and BMD among Chinese-Canadian immigrants aged 45 and older. We recruited through media announcements, health fairs, and community outreach through centres, churches and libraries which predominantly serve the Chinese community in the Greater Toronto Area. Heel BMD was measured using Sahara Quantitative Ultrasound (Hologic, Inc). Data were also collected on height, weight, demographics, diet, physical activity, medication use, co-morbid conditions, fall and fracture history, and health care utilization.

In total, we recruited 1087 participants over a 3 year period (June 2000-March 2003). This analysis includes 650 women and 270 men for whom the data were complete. Participants were primarily immigrants from Hong Kong (64%) & China (18%). The mean duration in Canada was 14.2 years (Range <1 to 53 years). Population characteristics included: mean age 61:64 yrs (Female:Male); height 154:167 cm (F:M); weight 55.5:66.5 kgs (F:M). Overall 39% rated their health as good or very good and 11% as poor or very poor. Mean heel BMD was 0.49:0.51g/cm2 (F:M); mean t-score using a female Caucasian reference population was -0.812:-0.615 (F:M); 3.7:1.5% (F:M) had t-score less than or equal to -2.5 and 41.7:35.2% (F:M) had t-scores between -1 & -2.5. Dietary assessment showed a mean calcium intake of 763 mg/day for women and 722 mg/day for men.

There was a significant inverse relationship between age and BMD. Lower BMD was also significantly associated with smoking and late menarche. BMD was not significantly associated with height, weight, age at menopause, or dietary intake of calcium or vitamin D. Mean BMD for those in the highest tertile for calcium intake was 0.496:0.503 g/cm2 (F:M) as compared to 0.483:0.498 g/cm2 (F:M) in the lowest tertile but the trend was not significant. There was no clear relationship between years since immigration and dietary intake of calcium or vitamin D.

Our preliminary analyses showed that older age, smoking, and late menarche are associated with lower heel BMD among Chinese-Canadian immigrants. These risk factors are similar to those identified in other epidemiologic studies. Calcium intake for our population is similar to that of Asian immigrants in the Ontario Health Survey, which found intake to be lower than that of the general population. Multivariate analysis is being performed to examine the relationship between risk factors, diet and BMD in our study.

Race may not Protect Against Low Bone Mineral Density (BMD) in Women with Lupus. A. B. Chadha[1], E. Shamiyeh*[1], S. Manzi*[2], S. Spies*[1], R. Ramsey-Goldman[1]. [1]Feinberg School of Medicine, Chicago, IL, USA, [2]University of Pittsburgh, Pittsburgh, PA, USA.

Women (W) with Lupus are at risk for BMD but it is not clear whether differences in risk exist based on race. The primary aim of this study was to assess risk factors for low BMD at the spine, hip, and distal forearm in both African American (AA) and Caucasian (C) W with lupus. 300 W with lupus completed this cross sectional study (225 C and 75 AA). BMD was measured at the hip, spine, and distal forearm by dual x-ray absorptiometry. All W completed a self-administered risk factor questionnaire and a physician completed the Systemic Lupus International Collaborating Clinics (SLICC, excluding osteoporosis) damage index (DI). Univariate analyses were done on all risk factor variables and BMD scores. The mean age of AA and C W was 39.6 yrs and 42.5 yrs respectively (p= 0.02). These traditional risk factors for low BMD differed significantly between AA and C W: body mass index, BMI (28.7 vs. 26.3 kg/m^2, p= 0.02), daily calcium intake (956 vs. 1285 mg/day, p= 0.0006, mean daily caffeine intake (70 vs. 111 mg/day, p= 0.001), mean daily alcohol intake (0.77 vs. 2.62 g/day, p= < 0.0001), and mean age at menopause (38.5 vs. 42.4 yrs, p= 0.03). These Lupus-related risk factors differed significantly in AA vs. C W: mean age at lupus diagnosis (29.3 vs. 33.7 yrs, p= 0.005), current dose of corticosteroids (8.0 vs. 5.1 mg/day, p= 0.02), duration of corticosteroid use in yrs (8.7 vs. 5.9 yrs, p= 0.02), and the SLICC/DI (1.82 vs. 1.12, p= 0.004). AA W compared to C W had higher BMD raw scores at the hip (0.928 g/cm^2 vs. 0.887 g/cm^2, p= 0.04) and distal forearm (0.689 g/cm2 vs. 0.668 g/cm2, p= 0.04). However, spine BMD raw scores (0.989 g/cm2 vs. 0.981 g/cm2) were similar in AA and C W, but when comparing T scores AA W had significantly lower BMD at the spine than C W (-1.394 vs. -0.599, p= <0.0001) and lower T-scores at the hip (AA vs. C, -0.596 vs. -0.497), but higher T-scores at the distal forearm (0.135 vs. -0.181). Higher BMD raw scores were associated with higher BMI at hip (r= 0.348, p= <0.0001) and spine (r= 0.282, p= <0.0001) only in C W. Lower BMD raw scores at all 3 sites were associated with higher SLICC/DI scores and longer disease duration regardless of race (P<0.05). AA compared to C W with lupus have significantly higher BMD at the hip and distal forearm. However, spine and hip T-scores were lower in AA compared to C W suggesting race may not be protective against low BMD at these sites. In part, this may be due to AA W having lupus at an earlier age, undergoing menopause at an earlier age, having greater disease burden (as measured by SLICC/DI), higher daily use of corticosteroids, and/or longer duration of corticosteroid burden. Measures to prevent osteoporosis need to be implemented early in all lupus W regardless of race.

A Membranous Bone, Parietal, Shows the Same High MAR and BFR as Endochondral Bone in the C3H (High Bone Density) Mice Compared to B6 (Low Bone Density) Mice. M. H. C. Sheng[1], D. J. Baylink[1], K. H. W. Lau[1], W. G. Beamer[2], J. E. Wergedal[1]. [1]Musculoskeletal Disease Center, J.L. Pettis VAMC, Loma Linda, CA, USA, [2]The Jackson Laboratory, Bar Harbor, MI, USA.

We have previously demonstrated that two inbred mouse strains, the C3H/HeJ (C3H) and C57Bl/6J (B6), displayed a profound difference in femur peak bone density. The higher bone density in C3H mice compared to B6 mice was, in part, due to a greater BFR that was due exclusively to an increase in the mineral apposition rate (MAR), rather than in tetracycline-labeled surface (TLS) per bone surface (BS). To investigate whether membranous bone had a similar phenotype to endochondral bone, 6-week old mice were injected with demeclocycline (25 mg/kg) and tetracycline (30 mg/kg) with a 6-day interval in between and histomorphometric measurements were made on the parietal bone. The results are listed in the table:

Table 1

	B6 (n=6)	C3H (n=5)	% Difference	P
Bone width (μm)	125±2	172±8	38	0.003
TLS/BS (mm/mm)	.963±.049	.956±.013	1	N.S.
MAR (μm/d)	1.42±0.09	1.88±0.11	32	0.01
BFR/BS (mmx10^{-3}/d)	1.02±0.10	1.34±0.06	31	0.03

To further investigate whether differences in MAR and BFR were due to differences in osteoblasts themselves, we isolated osteoblasts from the calvarias of the newborns (n=5, 4 pups per sample) and 6 week old mice (n=6-7, 2 females per sample) by collagenase digestion and established cell cultures. ALP activities were greater by 208% at newborns (P=0.012) and 267% at 6 weeks (P=0.015) in the C3H osteoblasts than those in the B6 osteoblasts. Cell doubling time was similar in the two strains at both ages, consistent with the lack of difference in TLS *in vivo*. In cells from newborn mice, mineralized nodule formation was greater in the C3H osteoblast cultures than that in the B6 osteoblast cultures

(13.4±0.2 % vs. 4.0±0.8 %, P<0.001). In addition, preliminary data indicated that insoluble collagen production was greater by104% in the C3H than B6 osteoblasts. Because the phenotype appears to be present in neonates, the difference between C3H and B6 is not dependent on hormonal differences and is unlikely to be due to a serum factor. We concluded that: 1) the phenotypes of high MAR and BFR in C3H mice were expressed in membranous bone as well as endochondral bone; and 2) greater MAR in the C3H was due to a higher degree of differentiation and greater activity of osteoblasts.

Increased Release of Substance P and TNFa Underlie Osteoporosis Induced by Mg Restriction in the Rat. R. K. Rude[1], H. E. Gruber[2], H. J. Norton*[2], L. Y. Wei*[1], A. Frausto*[1], B. G. Mills[1]. [1]Medicine, University of Southern California, Los Angeles, CA, USA, [2]Carolinas Medical Center, Charlotte, NC, USA.

Previous studies have demonstrated that severe Mg deficiency results in osteoporosis in rodent models. Here we assess the effects of more moderate dietary Mg restriction (10% of nutrient requirement (NR)) on bone and mineral metabolism over a 6 month experimental period in the rat. At 2, 4, and 6 months, serum Mg, Ca, PTH, and 1,25(OH)2D were measured. Femurs and tibias were collected for mineral content, histomorphometry, and immunocytochemical staining. Data for month 4 and 6 are shown in the Table. Serum and bone (data not shown) Mg were significantly reduced by 2 months and continued so through 6 months. sCa was slightly, but significantly, higher than control at all time points. At 2 months sPTH was elevated in Mg depleted animals but was significantly decreased at 6 months. Serum 1,25-D was significantly reduced at 4 and 6 months of study. Histomorphometry demonstrated decreased bone volume and trabecular thickness, and increased osteoclast (Ocl) numbers over time compared to control. This was confirmed by micro-CT which also showed that trabecular volume, thickness, and number were significantly lowered.

	4 month control	4 month Mg def	6 month control	6 month Mg def
sMg, mg/dl	1.9 +/- 0.2	0.6 +/- 0.1*	1.9 +/- 0.2	0.6 +/- 0.1*
sCa, mg/dl	8.9 +/- 0.5	9.9 +/- 0.7*	8.6 +/- 0.5	9.9 +/- 0.4*
sPTH, pg/ml	152 +/- 93	180 +/- 140	361 +/- 228	141 +/- 56#
1,25-D, pg/ml	46 +/- 31	8 +/- 6*	19 +/- 17	3 +/- 0.5#
BV/TV (%)	24 +/- 3	14 +/- 5	20 +/- 4	9 +/- 4#
TTh (um)	45 +/- 7	35 +/- 5	38+/- 6	32 +/- 3#
NOc/BPm	2.7 +/- 0.4	3.0 +/- 0.5	2.3 +/- 0.8	3.9 +/- 3#

Data are means + SD. *p<.001, #p<.01

TNFa immunocytochemical localization in Ocls was 199% of controls at 2 months, 75% at 4 months and 194% at 6 months. Increased TNFa may be due to increased substance P which was increased to 250% of control at 2 months and 266% at 4 months; however no difference was seen at 6 months. These data demonstrate that Mg intake of 10% NR in the rat causes bone loss which may be secondary to increased release of substance P and TNFa

Disclosures: ***R.K. Rude****, None.*

Dietary Iron and Calcium Interact to Affect Iron Status and Bone Health in a Response Surface Study of Growing Female Rats. Z. K. Roughead[1], L. K. Johnson*[1], J. L. Wagner*[2]. [1]Grand Forks Human Nutrition Research Center, USDA-ARS, Grand Forks, ND, USA, [2]Department of Physics, University of North Dakota, Grand Forks, ND, USA.

The concerns about inadequate intakes of calcium (Ca) and iron (Fe) have led to extensive fortification of both minerals in the US food supply. The objective of this study was to test the interaction of Ca and Fe over a wide range of intakes using a two-factor central composite response surface design. Weanling female Sprague-Dawley rats (n= 44) were randomly assigned to 9 groups fed AIN-93G basal diets with varying amounts of Fe (3, 5, 17, 60, or 100 ug/g diet), and Ca (1000, 1330, 2646, 5264, or 7000 ug/g diet) for 7 weeks. Semi-partial correlation coefficients (R^2_p) were obtained by stepwise regression analysis and reported at a significant level of p<0.02. Iron status (hemoglobin, hematocrit, red cell distribution, liver nonheme Fe) was primarily determined by dietary Fe (R^2_p = 0.92, 0.93, 0.81, and 0.78, respectively). However, increased Ca intake had an antagonistic effect on Fe status such that, based on the regression model, the predicted maximum hemoglobin of 16.8 g/dL occurred when Fe intake was moderate (43.5 ug/g diet) and Ca intake was minimal (1000 ug/g diet). Although Ca intake was the primary determinant of femur density, accounting for 79% of its variability, Fe intake also affected femur density (R^2_p = 0.10). Femur density was maximal at moderate intakes of Fe and Ca (38 and 4963 ug/g diet, respectively) and decreased slightly with higher intakes of both minerals. Variability in femur breaking strength (N/mm^2) was determined only by Ca intake (R^2_p = 0.70), was maximal with moderate Ca intake of 4120 ug/g diet, and decreased with further increases in Ca intake. While the main constituents of bone matrix (Ca and collagen) were only affected by dietary Ca (R^2_p = 0.42, 0.28, respectively), certain noncollagenous components in bone (osteocalcin, hexosamines) responded to changes in both Ca and Fe intakes. Serum concentrations of insulin-like growth factor-1 (IGF-1) did not respond to either dietary Ca or Fe, but bone IGF-1 concentration was weakly associated with dietary Ca (R^2 = 0.26). In summary, in growing female rats, high Ca intake reduced Fe status. While adequate intakes of both Ca and Fe were essential for maximal bone density, excessive intakes of these minerals reduced bone density and strength. In conclusion, the effects of high Ca intake on Fe status were more pronounced than the effects of Fe nutriture on bone health. These findings indicate that Ca intakes above the adequate amount do not offer additional benefits and may even be detrimental to bone. Additionally, indiscriminate fortification of foods with Ca may compromise the Fe status of vulnerable segments of the population.

The Effects of Long-Chain Polyunsaturated Fatty Acids on Bone Mass and Bone Metabolism in the Piglet Model. R. C. Mollard*, H. R. Kovacs*, H. A. Weiler*. Human Nutritional Sciences, University of Manitoba, Winnipeg, MB, Canada.

The dietary long chain polyunsaturated fatty acids (LCPUFAs) arachidonic acid (AA, 20:4n-6) and docosahexaenoic acid (DHA, 22:6n-3) have been shown to elevate bone mass, however, the optimal amount requires clarification. This study was designed to determine the amount of AA plus DHA that influences bone cell metabolism and mass. Forty male piglets were randomized to receive one of four isocaloric formula: control or LCPUFA supplemented (0.5% AA & 0.1% DHA, 1.0% AA & 0.2% DHA or 2.0% AA & 0.4% DHA wt/wt total fat). After 15 days of study measurements included: bone mineral density (BMD) of whole body, lumbar spine and excised femurs using dual energy x-ray absorptiometry; bone cell metabolism assessed by plasma osteocalcin, urinary N-telopeptide and ex vivo prostaglandin E_2 (PGE_2); and liver fatty acids using gas chromatography. Main effects were identified using a two-factor ANOVA and differences among groups identified using the Bonferroni t-test

. Liver AA and DHA increased in proportion to dietary supplementation. Whole body and lumbar spine BMD was significantly higher (p<0.05) in the group supplemented with 0.5% AA and 0.1% DHA. The group supplemented with 1% AA and 0.2% DHA had significantly lower urinary N-telopeptide (p=0.039), suggesting reduced bone resorption. PGE_2 (p=0.723) and osteocalcin levels (p=0.077) were not significantly different among the groups. Supplementation of AA and DHA at 0.5% and 0.1% wt/wt total fat lead to elevated bone mass, but higher amounts provided no additional benefit.

Biochemical Markers of Bone Turnover in Glucocorticoid-Treated Patients Are Altered by Calcium Supplementation: Preliminary Results from ACTIVATE Trial. N. Lane[1], S. Goldring[2], J. Stewart*[3], S. Morris[3]. [1]Department of Medicine, UCSF, San Francisco, CA, USA, [2]Chief of Rheumatology, Beth Israel Deaconess Medical Center, Boston, MA, USA, [3]Medical Research, Aventis, Bridgewater, NJ, USA.

Glucocorticoids (GC) create an uncoupling of bone turnover related to reduced bone formation and increased bone resorption. The ACTIVATE Trial was undertaken to determine whether providing information on bone turnover and vertebral fractures affected compliance with daily risedronate therapy in patients on oral GC. Initial data from this study have provided insights into the effects of oral calcium supplement on biochemical markers of bone turnover in patients on GC. Currently, 139 subjects on GC (≥7.5 mg/d) have been enrolled (40% of total): 106 in chronic treatment category (TREAT; >6 mos GC therapy) and 33 initiating GC treatment (PREV). Baseline serum osteocalcin (OST), osteoprotegerin (OPG), parathyroid hormone (PTH), creatinine and urine N-telopeptide (NTX) were obtained. Mean age of patients in TREAT group was 61.4 years and 67.7 years in PREV. Mean GC doses were 13 mg and 17 mg prednisone in TREAT and PREV, respectively, with a mean duration of usage for 73 months for the TREAT and 0.8 months for the PREV. Oral calcium supplement (defined as at least 500 mg daily) was determined by questionnaire. When biochemical marker values were represented as median and range for each group, calcium supplementation was associated with the following effects (NTXR represents the ratio of the urine NTX/serum creatinine).

Feature	Calcium	TREAT	PRE
NTRX	No	32.3 (10.75-272.6)	42.7(15.9-91.2)
	Yes	29.8(6.3-122.5)	33.6(12.1-86.6)
OST	No	10.7(1.9-31.6)	10.0(4.5-35.0)
	Yes	10.4(3.7-31.5)	8.9(1.1-14.9)

	Yes	2.85(1.30-7.30)	2.70(1.60-6.60)

These results indicate that initiation of GC treatment is associated with an increase in bone resorption (elevated NTXR) and that oral calcium supplementation diminishes this effect. In the TREAT group, median NTXRs were lower than in the PREV group. Nevertheless, oral calcium supplement also produced reductions in this index of bone resorption in this group. Although suggestive, more data are required to confirm whether this effect of oral calcium supplement is related to suppression of endogenous PTH and increase in OPG.

Bone Loss in Multiple Sclerosis Patients Treated with Corticosteroids. J. J. Stepan[1], E. Havrdová*[2], M. Týblová*[2], D. Horáková*[2], V. Tichá*[2], I. Nováková*[2], V. Zikán*[1]. [1]3rd Department of Internal Medicine, Charles University Faculty of Medicine, Prague, Czech Republic, [2]Department of Neurology, Charles University Faculty of Medicine, Prague, Czech Republic.

Background. Patients with multiple sclerosis (MS) may be at greater risk of fracture because the glucocorticoid (GC) induced bone loss is superimposed on detrimental effects of physical inactivity. The aim of this study was to evaluate the relative contribution of GC treatment, immobilization, and other factors, to decrease in bone mineral density (BMD), in patients with MS. ***Patients and Methods*.** From the out-patient clinic, 515 patents were randomly chosen. The study population involved 404 females (mean ± SD, age, 43 ± 10 yr, weight, 65 ± 13 kg, height, 165 ± 8 cm, duration of MS 14 ± 9 yr) and 111 males (age, 42 ± 11 yr, weight, 76 ± 12 kg, height, 178 ± 7 cm, duration of MS, 14 ± 8 yr). The mean dose of GC was 6.5 ± 2.5 mg/day, 45% of the patients received > 7.5 mg/day. The patients were advised to take the daily recommended dose of calcium and vitamin D. Motor function of the patients was evaluated using the Kurtzke EDSS, a scale useful in measuring the ability to walk that is decisive for normal remodeling of bone. The total amount of used GC was calculated based on documented treatment. All fractures since the start of GC therapy ware counted. BMD was measured using the Delphi A bone densitometer (Hologic, MA) at the lumbar spine, and proximal femur. ***Results*.** BMD > -1 T-score was found in 43% of the patients (age, 42 ± 9 yr, weight, 71 ± 14 kg, total dose of GC, 29 ± 23 g, duration of treatment, 5.9 ± 4.5 yr, KEDDS, 3.9 ± 1.8, fractures in 13% of the patients). Osteopenia (BMD T-score of -1 to -2.5) was found in 40% of the patients (age, 43 ± 11 yr, weight, 66 ± 12 kg, total dose of GC, 36 ± 24 g, duration of treatment, 15 ± 9 yr, KEDDS, 4.6 ± 1.8, fractures in 21% of the patients). Osteoporosis (BMD < 2.5 T-score) was found in 17% of the patients (age, 44 ± 11 yr, weight, 63 ± 15 kg, total dose of GC, 43 ± 25 g, duration of treatment, 8.9 ± 6 yr, fractures in 31% of the patients). In the stepwise regression analysis, the BMD at the lumbar spine, and femoral neck was significantly inversely related to the KEDDS, smoking, and duration of GC treatment, and positively related to weight (Rsqr = 0.21, and 0.33, respectively, $p < 0.001$). The other variables, age, height, sex hormone deficiency, duration of MS, and the cumulative dose of GC did not enter the equation. After controlling for the other factors, prevalence of fractures was determined by the femoral T-score, estrogen deficiency, and duration of GC treatment. ***Conclusion***. In MS treated with low dose GC, immobilization was the main determinant of the low bone mass, which was the main fracture risk factor in these patients.

Bone Density and Bone Metabolism in Healthy Men Are Unaffected by the Marked DHT Suppression Produced by the Dual 5α-Reductase Inhibitor Dutasteride. R. V. Clark[1], C. S. Huffman*[1], A. M. Matsumoto*[2], R. S. Swerdloff*[3], C. Wang*[3], W. J. Bremner*[2]. [1]GSK Research and Development, Research Triangle Park, NC, USA, [2]Department of Medicine, University of Washington School of Medicine, Seattle, WA, USA, [3]Department of Medicine, Harbor-UCLA Medical Center, Torrance, CA, USA.

The novel dual 5α-reductase inhibitor, dutasteride, has been shown to be effective and well tolerated in patients with benign prostatic hyperplasia (BPH). The objective of this study was to determine whether marked dihydrotestosterone (DHT) suppression observed with dutasteride has an effect on bone mineral density (BMD) and bone metabolism.

In this randomized, double-blind, placebo-controlled study healthy men aged 18–55 were randomized to receive 0.5 mg dutasteride, 5.0 mg finasteride or placebo for 52 weeks, with a further 24 week follow-up after cessation of study medication. Bone density by x-ray absorptiometry was determined at screening, weeks 48–52 and follow-up weeks 20–24. Markers of bone metabolism, serum osteocalcin, serum bone alkaline phosphatase, and urinary n-telopeptide (osteomark) were measured at baseline, weeks 8, 16, 24, and 52, and follow-up weeks 8, 12 and 24.

Ninety-nine subjects were included in the intent-to-treat analysis. The mean reductions in serum DHT concentration in the dutasteride group were >90% at each treatment phase visit compared with 70% for finasteride ($p<0.001$). There were no clinically, nor statistically, significant changes in BMD from baseline, or between groups at weeks 48-52 or follow-up weeks 20-24 (see table).

	Week	Mean % change in BMD		
		Placebo	Dutasteride	Finasteride
Lumbar spine	48-52	0.573	-0.077	0.003
	FU 20-24	0.866	0.094	-0.816
Proximal femur	48-52	-1.823	-0.367	-0.378
	FU 20-24	-0.104	-0.366	0.521

There were no consistent changes or trends seen in any of the bone markers in any treatment group during the treatment period. At follow-up week 24, mean urinary osteomark values were significantly greater in the finasteride group compared with the placebo and dutasteride groups (2-sided p-values=0.017 and 0.003, respectively). However, all parameters remained within normal ranges.

In conclusion, the marked suppression of DHT observed with dutasteride compared with other 5ARIs, had no clinically or statistically significant effect on BMD or bone metabolism.

Changes of Nail Ca and Mg Concentrations with Reference to Age, Gender and Bone Mineral Density. Implications for the Detection and Screening of Osteoporosis. S. Ohgitani*[1], Y. Fujii[2], C. Hayashi*[3], H. Nishio*[3], T. Fujita[4]. [1]Division of Clinical Laboratory, Minami-Kyoto National Hospital, Kyoto, Japan, [2]Calcium Research Institute, Kishiwada, Osaka, Japan, [3]Public Health, Kobe University School of Medicine, Hyogo, Japan, [4]Katsuragi Hospital, Kishiwada, Osaka, Japan.

Nails in contact with periosteum are readily sampled and their mineral content may reflect some aspect of mineral metabolism and bone status. Ca and Mg concentrations in the finger and toe nails were therefore measured by using Atomic Absorption Spectrophotometer, Perkin- Elmer Type 408, in 119 males and 175 female between ages of 10 and 90 years without diseases primarily affecting mineral metabolism. In another group of subjects with a mean age of 62 years, lumbar bone mineral density (LBMD) was measured by dual energy X-ray absorptiometry using XR-26 in addition. Fingernail Ca concentration decreased from 927±52 ppm (SD) in the 20s to 529±83 in the 80s with a significant negative correlation with age ($r=-0.288$, $p<0.0001$) and toenail Ca concentration similarly fell with age in males. Decreases in females were less distinct. Fingernail Mg concentrations, on the contrary, increased from 78±14 to 140±6 in corresponding age groups with a significant positive correlation ($r=0.315$, $p<0.0001$) and toenail Mg showed a similar tendency in males, but changes in females were less distinct. In a group with similar age, a significant positive correlation was noted between fingernail Ca concentration and LBMD ($r=0.528$, $p=0.0016$) and a negative correlation between fingernail Mg concentration and LBMD ($r=-0.377$, $p=0.0272$). No significant correlation was noted between toenail Ca or Mg concentration and LBMD. Significant correlation was found between Ca and Mg concentrations at the same site and either Ca or Mg concentrations between finger and toenails. Inverse relationship between Ca and Mg concentrations in males may reflect some kind of antagonism between these two elements, though the mechanism remains to be elucidated. Decrease of Ca concentration and increase of Mg concentration in fingernails in males may be utilized to detect a low LBMD in osteoporosis.

Decreased Vitamin D-Dependent Intestinal Calcium Absorption in Immobilized Rats. T. Sato*[1], K. Morita[2], Y. Kado*[2], H. Yamamoto[2], Y. Taketani[2], Y. Nii*[3], E. Takeda[2]. [1]Clinical Nutrition, University of Tokushima, Tokushima, Japan, [2]Clinical nutrition, University of Tokushima, Tokushima, Japan, [3]Food Technology Division, Tokushima Prefectural Industrial Technology Center, Tokushima, Japan.

Skeletal unloading caused by bed rest or immobilization result in a loss of bone. Previous studies have demonstrated negative calcium balance with increased urinary and fecal excretion during bed rest and space flight. Understanding the molecular mechanism of altered intestinal calcium absorption in the development of disuse bone loss is important for the prevention and treatment. Therefore, various parameters affecting calcium and bone metabolism were investigated in immobilized rats. Each rat of the immobilized group (Wistar male rats), which imitated human bed rest, was kept in Ballman cage III for 2 weeks. Each rat of control group was kept in ordinary cage and fed the food (AIN-93G, 0.6% calcium and 0.6% phosphorus) intake of the immobilized rats. In the second experi-

ment, immobilized rats received a high calcium diet (1.2% calcium and 0.6% phosphorus), a high calcium and high vitamin D diet (20,000IU/100g cholecalciferol, 1.2% calcium and 0.6% phosphorus) or onion diet (7% onion, 0.6% calcium and 0.6% phosphorus) for 2 weeks. In immobilized rats, intestinal net calcium absorption, bone mineral density (BMD) in femur and lumbar vertebrae measured by pQCT, serum level of 1,25(OH)2D, and mRNA levels of renal 1 alpha hydroxylase, duodenal calcium transport protein 1 (CaT1) and calbindin-D9k were decreased and renal 24 hydroxylase mRNA level increased, but colonic CaT1 mRNA level was not decreased. Administration of etidronate (20mg/Kg/day) prevented the reduction of BMD, but did not recover net calcium absorption in immobilized rats. These findings suggest that immobilization stimulated catabolism and depressed production of 1,25(OH)2D and consequently decreased the duodenal 1,25(OH)2D dependent calcium transport activity that is not related with bone resorption. In addition, immobilized rats fed calcium, vitamin D or onion enriched diet interestingly resulted in increased intestinal calcium absorption and BMD without increment of CaT1 or calbindin D9k mRNA levels. Therefore, it might be concluded from present study that those diets are effective to prevent disuse osteoporosis.

Oral Daily and Intermittent Ibandronate Significantly Reduce Height Loss in Postmenopausal Osteoporosis. C. H. Chesnut[1], A. Skag*[2], A. Hoiseth*[3], J. Gilbride*[4], R. C. Schimmer[4]. [1]University of Washington, Seattle, WA, USA, [2]Bergen Osteoporosesenter, Bergen, Norway, [3]Sentrum Rontgeninstitutt, Oslo, Norway, [4]F. Hoffmann-La Roche Ltd, Basel, Switzerland.

Ibandronate, a highly potent, nitrogen-containing bisphosphonate, is the subject of an ongoing clinical development program that aims to maximize the potential of simplified, less frequent dosing in postmenopausal osteoporosis (PMO). A recent multicenter, double-blind, randomized study (oral iBandronate Osteoporosis vertebral fracture study in North America and Europe: BONE) investigated the fracture efficacy and safety of ibandronate when administered as an oral daily and intermittent regimen with a between-dose interval of >2 months. A total of 2,946 women (aged 55–80 years, time since menopause ≥5 years) with low bone mineral density (BMD; T-score <–2) in ≥1 vertebra of the lumbar spine (L1–L4) and 1–4 prevalent vertebral fractures (VF) were enrolled into the study. Participants received either oral daily ibandronate (2.5mg; n=982), oral intermittent ibandronate (20mg every other day for 12 doses every 3 months; n=982) or placebo (n=982) for 3 years with daily calcium (500mg) and vitamin D (400IU) supplementation. The primary endpoint was the rate of patients with new incident VF after 3 years. Secondary endpoints included height, BMD, biochemical markers of bone turnover and safety. After 3 years, oral daily and intermittent ibandronate significantly reduced the risk of radiologically confirmed VF (62% [p=0.0001] and 50% [p=0.0006], respectively) relative to placebo. A mean height loss of 5.6mm was observed in the placebo arm. This loss was significantly greater than the loss observed in the oral daily (3.9mm; p=0.0005 vs placebo) and intermittent (4.7mm; p=0.0144 vs placebo) ibandronate arms. The average annual height loss in the oral daily and intermittent ibandronate groups was also significantly less than that observed with placebo (using ANOVA p<0.0001 and p=0.0115, respectively). Significant increases in lumbar spine and hip BMD and sustained decreases in biochemical markers of bone turnover were also observed. Ibandronate was well tolerated, with no significant safety concerns. In summary, oral daily and intermittent ibandronate significantly reduce the risk of VF in women with PMO. This finding is corroborated by the significant and sustained reductions in height loss observed in the active treatment groups compared with placebo. Ongoing studies of ibandronate are evaluating alternative intermittent dosing regimens, such as oral monthly, that aim to provide enhanced treatment outcomes in PMO.

Relative Contributions of the Early Changes in Bone Resorption and Later Changes in Hip Bone Mineral Density to the Reduction in Vertebral Fracture Risk with Risedronate. A. Blumsohn[1], I. P. Barton*[2], A. Chines[3], R. Eastell[1]. [1]University of Sheffield, Sheffield, United Kingdom, [2]Procter & Gamble Pharmaceuticals, Egham, United Kingdom, [3]Procter & Gamble Pharmaceuticals, Mason, OH, USA.

Anti-fracture efficacy of antiresorptive therapies is partially explained by increases in bone mineral density (BMD) and partially by decreases in bone resorption markers. The relative importance of these two factors and whether or not their effects are independent is not known. We examined this by measuring N-telopeptide of type I collagen (NTX) in osteoporotic patients in the risedronate VERT and HIP (Group 1, low BMD) fracture trials. We studied 1245 women (mean age 72 years, SD 6) with either a femoral neck BMD T-score less than -3, or a vertebral fracture who received calcium (and vitamin D if required) and placebo or risedronate 5 mg daily for 3 years. A method based on the Cox-regression model proposed by Li et al. (Statistics in Medicine, 2001) was used to estimate the overall treatment effect in reducing the risk of incident fracture and the effect explained by both NTX and BMD within a single model. The changes in femoral neck BMD at follow-up (mean, -1.1 and +2.0%) and the reductions in urinary NTX (median, 22 and 54%) at 3 to 6 months of placebo or risedronate 5 mg, respectively, were significantly associated (P<0.05) with the reduction in vertebral fracture risk (54% over 3 years). The changes in BMD accounted for 17 and 26% (at one and three years) and those in NTX accounted for 44 and 33% (at one and three years) of risedronate's effect in reducing the risk of vertebral fractures over 3 years, compared with placebo. The estimate of the percent of fracture risk reduction accounted for by NTX was not altered after adjusting for the changes in BMD. In conclusion, the increase in BMD and the decrease in bone resorption in patients taking risedronate each account for some but not all of the reduction in vertebral fracture risk and these effects are independent.

Comparative Efficacy of Hormone Replacement Therapy, Bisphosphonates, Calcitonin, Vitamin D and Vitamin K in Postmenopausal Women with Osteoporosis. Y. Ishida, S. Kawai*. Department of Orthopaedic Surgery, Yamaguchi University School of Medicine, Ube-City, Yamaguchi, Japan.

This randomized controlled trial was conducted at 3 university hospitals to assess the comparative effectiveness of several medications on bone mineral density (BMD), biochemical bone markers, and a new vertebral fracture incidence in postmenopausal women with osteoporosis. A total of 455 postmenopausal women aged 50-75 with osteoporosis were randomly allocated into six groups: 1) hormone replacement therapy (HRT, conjugated estrogen 0.625 mg/day plus medroxyprogesterone 2.5 mg/day); 2) bisphosphonates (alendronate, 5 mg/day or etidronate, 200 mgx14d q3m); 3) eel calcitonin (CT, 20 IU/week); 4) vitamin D3 (alfacalcidol 1 micro g/day); 5) vitamin K2 (45 mg/day); and 6) control (no treatment). Thoracic and lumbar spine radiographs and BMD at distal 1/3 radius were assessed at baseline and at every 3 months, along with markers of bone turnover [serum bone specific alkaline phosphatase, serum osteocalcin, urinary N-telopeptide of type I collagen (NTX), and urinary deoxypyridinoline (DPD)]. Mean changes in BMD relative to baseline after the 2-year treatment in HRT, alendronate, etidronate, CT, vitamin D, vitamin K and control was 2.0%, 2.3%, -1.0%, 1.6%, -3.6%, -1.9% and -3.3%, respectively. In control, the incidence of new vertebral fractures after the 2-year treatment was 25.8%. In HRT, alendronate, etidronate, CT, vitamin D and vitamin K, the fracture incidence was reduced by 63%, 64%, 53%, 58%, 34% and 45%, respectively, compared to control (P=0.02, P=0.01, P=0.01, P=0.04, P=0.27, and P=0.04, respectively, Log-rank test). Logistic regression analysis revealed that changes in BMD relative to baseline at month 3 significantly predicted changes in BMD after 2 years (odds ratio: 4.63 in HRT; 10.54 in alendronate; 8.54 in etidronate; 9.80 in CT; 5.38 in vitamin D; and 2.60 in vitamin K; P<0.01) and the new vertebral fracture risk (odds ratio: 2.17 in HRT; 2.64 in alendronate; 2.54 in etidronate; and 3.53 in CT; P<0.05). Changes in NTX and DPD relative to baseline after 3 months were significant predictors of the incidence of new vertebral fractures (odds ratio: 1.83 and 2.02 in HRT, respectively; 3.04 and 3.87 in alendronate; 2.04 and 1.87 in etidronate; 3.07 and 2.07 in CT; P<0.05). Vitamin K appears to reduce the risk of vertebral fractures without improvement in BMD or reduction of markers of bone resorption, indicating that other mechanisms, not measured by BMD, may also play an important role in vertebral fracture. In conclusion, our results demonstrate the importance of measurements of BMD and markers of bone resorption at month 3 in identifying women for whom drug therapy to prevent vertebral fracture is appropriate.

Safety and Tolerability of Risedronate in the Treatment of Osteoporosis in Patients with Renal Insufficiency. M. F. Delaney[1], S. Hurwitz*[2], J. J. Carey[3]. [1]Endocrinology, Diabetes, and Hypertension Division, Brigham and Women's Hospital, Boston, MA, USA, [2]Endocrinology, Diabetes, and Hypertension Division, Brigham and Women' Hospital, Boston, MA, USA, [3]Rheumatology, Cleveland Clinic Foundation, Cleveland, OH, USA.

Osteoporosis is a common disorder effecting more than 10 million Americans. With increasing age, renal insufficiency is more prevalent. The risk of fracture increases with age, so too does the need for safe and effective anti-resorptive therapy for these patients. Risedronate is an oral bisphosphonate approved for the treatment of osteoporosis in patients with a creatinine clearance >30ml/min and is approved to treat steroid-induced bone loss. Often an oral bisphosphonate is the treatment of choice, particularly in patients with a low hip BMD. The safety profile and efficacy of Risedronate is unknown in patients with impaired renal function.

In this retrospective study, we examined patients with mild to moderate renal insufficiency (serum creatinine >1.1 mg/dl) treated with Risedronate for osteoporosis. Patients identified were treated between 1999 and 2003 in Osteoporosis Clinic and were identified from a clinic chart review. All patients had a serum chemistry panel measured prior to starting Risedronate and a follow up at 3-6 months. BMD was performed to establish the diagnosis of osteoporosis using a DEXA QDR 4500A, Hologic, or a Lunar DPX-IQ. Baseline BMD scans were performed in all patients and follow up BMD was available in a subset. All patients were treated with Risedronate, but dosing regimens varied, 5mg daily, and 30mg or 35mg weekly.

We identified 12 patients for this study, 4 men and 8 women, and the mean age is 74 years (range 37-94). Baseline creatinine levels ranged from 1.1 to 1.7 mg/dl (mean 1.4), BUN

ranged from 18 to 45 and calcium ranged from 8.7 to 10 mg/dl. Patients with secondary causes of bone loss were not excluded. Active medical problems included Inflammatory Bowel Disease, Renal Transplant, Hypertension, Diabetes, etc. And concomitant medications included prednisone, hydrochlorthiazide, androderm, prilosec, etc. All received adequate calcium and vitamin D supplementation.
Follow up creatinine levels show a mean value of 1.37mg/dl, that is no significant change since baseline creatinine pre-treatment. No patients were withdrawn from treatment with Risedronate. Baseline BMD T scores ranged from LS –1.2 to –3.5, FN –1 to –4, TR –1.13 to –3.6 and TH –1.07 to –2.9. Follow up BMD scans are not yet available in all patients.
In summary, Risedronate is well tolerated in patients with mild to moderate renal insufficiency. There is no observed nephrotoxicty with FDA-approved doses. Further studies of bisphosphonate therapy in renal insufficiency is recommended.

SA343

Oral Daily and Intermittent Ibandronate have a Similar Safety Profile in Elderly and Younger Patients: Results from the BONE Study. M. P. Ettinger[1], A. Skag*[2], A. Hoiseth*[3], B. Leishman*[4], R. C. Schimmer[4]. [1]Radiant Research and the Regional Osteoporosis Center of South Florida, Stuart, FL, USA, [2]Bergen Osteoporosesenter, Bergen, Norway, [3]Sentrum Rontgeninstitutt, Oslo, Norway, [4]F. Hoffmann-La Roche Ltd, Basel, Switzerland.

Owing to a decline in functional status and the presence of comorbidities, there is a concern that elderly women with osteoporosis may be more vulnerable to bisphosphonate-related adverse events (AEs) than younger women. As such, the safety profile of a bisphosphonate in this patient population is of particular importance. Ibandronate is a highly potent, nitrogen-containing bisphosphonate with proven efficacy when administered with extended between-dose intervals. Most notably, a recent study (oral iBandronate Osteoporosis vertebral fracture trial in North America and Europe: BONE) demonstrated that oral daily (2.5mg) and intermittent (20mg every other day for 12 doses every 3 months) ibandronate regimens significantly reduce the risk of vertebral fracture by 62% (p=0.0001) and 50% (p=0.0006), respectively.[1] Of the 2,946 women enrolled, 1,416 (48%) were aged ≥70 years and 1,530 (52%) were aged <70 years (mean age 74.0 and 63.8 years, respectively). Patients receiving medications likely to irritate the gastrointestinal (GI) tract or with existing upper GI disorders were not excluded. Both ibandronate regimens were well tolerated, with an overall safety profile similar to placebo. The overall incidence of AEs, drug-related AEs and upper GI AEs was comparable among the treatment groups. There was no general effect of age on tolerability: elderly patients (aged ≥70 years) receiving ibandronate therapy did not appear to be at greater risk of experiencing AEs than elderly patients receiving placebo or younger patients receiving ibandronate therapy or placebo. In particular, elderly patients were shown to be at no greater risk of dyspepsia or esophagitis. In summary, oral daily and intermittent ibandronate are well tolerated in postmenopausal osteoporosis, regardless of age. These findings highlight a strong potential for ibandronate therapy in both older and younger patients with PMO.

Early Changes in Serum Osteoprotegerin (OPG) Correlates with Changes in Bone Mineral density following treatment with Risedronate in Post-Menopausal Women with Osteoporosis. S. Sankaralingam*[1], M. Frost[2], I. Fogelman[2], G. Hampson[1]. [1]Chemical Pathology, St Thomas Hospital, London, United Kingdom, [2]Osteoporosis Screening Unit, Guy's Hospital, London, United Kingdom.

Serum osteoprotegerin(OPG) concentration has been shown to increase with age and is higher in post-menopausal women compared to pre-menopausal women. There are few studies of the effects of anti-resorptive treatment on serum OPG in post menopausal osteoporosis. We investigated changes in bone turnover and serum OPG following Risedronate treatment in a group of post menopausal women with osteoporosis. The study group comprised of 18 post menopausal women with newly diagnosed osteoporosis(mean age[SEM]) 67 yrs [1.3]. They were started on 5mg/day of Risedronate for 12 months.Bone mineral density (BMD) was measured at baseline and at 6 and 12 months. Serum levels of bone specific alkaline phosphatase (bsALP), and urinary deoxypyridinoline (DPD) were measured at baseline and at 3, 6 months. Serum OPG and C-terminal telopeptide (CTX) were measured at baseline, 3,6 and 12 months. A significant increase in BMD was observed at the lumbar spine at 6 and 12 months of treatment (mean [SEM]) ***6 months*** 1.74%[0.833]*** p<0.05** and ***12 months*** 4.31% [1.06] * **p<0.005**). There was no significant change in BMD at the femoral neck and total hip. Significant decreases in serum bone specific alkaline phosphatase, serum CTX and urinary DPD were seen at 3 and 6 months (***3 months*** bsALP –28.4% [1.34]* **p<0.0005**, CTX –14.1% [7.28]* **p<0.05**, DPD –22.9% [2.32]* **p<0.005**, ***6 months*** bsALP –22.65%[2.44]*** p< 0.005,** CTX –25.1%[6.08]* **p<0.0005,** DPD –18.1%[3.92]***p<0.005**). Serum OPG concentration did not change significantly at 3 and 6 months. However a significant decrease was seen at the later time point,12 months (–31.6 %[5.8]* **p<0.0005) .** No significant correlations were seen between changes in BMD at 12 month and changes in serum CTX at any time point. However a positive correlation was seen between the changes in BMD at the lumbar spine and % change in serum OPG at 3 month (r = 0.62, p = 0.02). In those patients (38%) where the change in BMD was less than 2% (-0.4 %[1.07]), a significant reduction in serum OPG was observed at 3 month (-26.4%[5.78], p = 0.01) compared to the rest of the study population (BMD : 7.6%[1.15] p =0.0003) where a small increase in serum OPG was seen (8.8%[4.0] p = 0.06).
Early reduction in serum OPG leads to a smaller BMD response at 12 months in patients on Risedronate. Measurement of serum OPG may help in the early assessment of treatment responsitivity.

The Effect of Risedronate on Bone Mineral Density After Total Hip Arthroplasty. D. F. Scott*, J. N. Woltz*. Orthopaedic Specialty Clinic of Spokane, Spokane, WA, USA.

The purpose of this study is to evaluate the effect of risedronate, an antiresorptive medication, on proximal femoral bone loss after total hip arthroplasty (THA).
Significant proximal femoral remodeling after THA has been observed and characterized by subjective roentgenographic analysis, with regions of relative bone resorption and regions of hypertrophy. Risedronate is an antiresorptive agent effective in increasing bone mineral density (BMD) in postmenopausal women with low bone mass. We hypothesize patients who take risedronate post THA will have less bone loss than patients not taking risedronate.
This prospective, open-label study consists of two statistically similar groups, the control group and the study group. All patients underwent uncemented THA with the same implant and postop protocol. Patients in the study group take 5 mg of risedronate daily beginning 5 to 7 days preoperatively, continuing for 24 months after surgery. Dual energy X-ray absorptiometry (DEXA) scans of the operated proximal femur are performed on all patients preoperatively, 3 to 7 days postop, 6 weeks postop, 6 months postop, 1 year postop, and 2 years postop. Dexa scans are analyzed using Lunar (Lunar Corp., Madison, WI) software and longitudinal changes in BMD compared within and between the two groups.
Using the first postop scan as the baseline, we found the mean decrease in BMD for the control group at latest follow-up to be 7.39 percent and for the study group to be 4.23 percent. Analyzing data of female subjects showed the mean decrease in BMD at latest follow-up to be 11.93 percent in the control group and 4.55 percent in the study group. This was found to be statistically significant (p=.027) using repeated measures analysis.
This short-term data reveals that risedronate significantly reduces bone loss in females after uncemented total hip arthroplasty.

Offset of the Action of Clodronate (Bonefos®) After 3 Years of Treatment in Women with Osteoporosis. S. Bal[1], E. McCloskey[1], P. Selby[2], M. Davies[2], J. Robinson*[3], R. M. Francis[4], J. Adams[5], A. Dey*[1], R. Ashford*[1], D. deTakats*[1], M. Beneton*[1], D. Charlesworth*[1], J. Rosnell*[6], J. Kanis[1]. [1]University of Sheffield, Sheffield, United Kingdom, [2]Manchester Royal Infirmary, Manchester, United Kingdom, [3]Crosby Clinical Research Centre, Liverpool, United Kingdom, [4]University of Newcastle, Newcastle, United Kingdom, [5]University of Manchester, Manchester, United Kingdom, [6]Schering Oy, Helsinki, Finland.

In a 3 year double blind placebo controlled study, clodronate 800mg daily (Bonefos®) by mouth increased BMD and reduced the incidence of vertebral fracture in osteoporotic women. During a 2 years blinded extension to the original study, we have examined the reversibility (offset) of the effect of oral clodronate on bone metabolism.
Of 140 women treated with clodronate for 3 years, 72 were randomly assigned to continue therapy while 68 were randomised to an identical placebo. All of the women continued to receive calcium 500mg daily by mouth.
Continuation of clodronate during the 2 years extension was associated with a further 3.3% increase (P<0.0001) in spine BMD (mean increase from study start +7.5%, p<0.0001). Total hip and forearm BMD remained stable over the whole 5 years of therapy (+0.54% and +0.93% respectively from study start, p=NS). In contrast, discontinuation of clodronate after 3 years was associated with a significant decrease in spine and hip BMD by the end of the first year off therapy (-1.19%, p=0.014 and -1.74%, p=0.0038 respectively) but only the changes at the spine were significantly different between the clodronate and placebo groups (p=0.019). A similar pattern was observed at the distal forearm where BMD decreased significantly by the end of the second year off treatment (-2.64 %, p<0.0001). The rates of decrease at the various skeletal sites in the women changing from clodronate to placebo were similar to those observed in women receiving placebo in the original 3

year study. In line with BMD, discontinuation of clodronate resulted in significant increases in all bone turnover markers (fasting urinary calcium/creatinine, hydroxyproline/creatinine, serum CTX and bone specific alkaline phosphatase) within 6-12 months.
We conclude that the offset of effect of clodronate commences within the first post-treatment year after 3 years of treatment. The effect of treatment to decrease bone turnover is rapidly reversible.

Intravenous Pamidronate Increases Bone Density in Postmenopausal Women Previously Treated with Oral Bisphosphonates. A. Rastelli, N. Napoli, R. Civitelli. Div. of Bone and Mineral Diseases, Washington University in St Louis, St Louis, MO, USA.

Pamidronate, an aminobisphosphonate approved in the United States for the treatment of hypercalcemia of malignancy as intravenous (IV) formulation, is also commonly used for osteoporosis treatment in select patients. To evaluate the effectiveness of IV pamidronate on bone density, we retrospectively analyzed 17 patients (mean age 66.8±3.1) who attended our Bone Health clinic and received pamidronate (30 mg IV) at 3-month intervals up to 2 years. All patients had been previously treated with oral bisphosphonates (1 to 4 years) , but developed gastroesophageal discomfort. They were also on 1000-1500 mg of calcium and 400-800 IU of Vitamin D daily. Ten patients had a history of vertebral fractures and five had a hip fracture. All these subjects had one or more DEXA bone mineral density (BMD) measurements of the lumbar spine and proximal femur before starting IV pamidronate, and at least two repeat BMD 6 to 18 months thereafter. A group of 32 postmenopausal women (mean age 61.1±1.9), who were only on calcium and vitamin D supplements, were used as control. Data were expressed as annualized percent changes in BMD calculated by linear regression across all available data points for both groups, starting from the BMD just before initiation of pamidronate therapy (baseline). BMD at the lumbar spine increased during pamidronate therapy (+4.12±1.19 %/yr) compared to the changes that had occurred during the pre-treatment period (+0.10±0.47%/yr). This difference was statistically significant ($p = 0.02$; paired t-test). More to the point, the BMD increase observed during pamidronate therapy was significantly higher than the changes detected in the control group (-0.24 ± 0.44 %/yr; $p< .001$; unpaired t-test). Likewise, BMD of the proximal femur also increased in patients undergoing IV pamidronate (neck: +0.92 ± 0.88 %/yr; total: +5.14 ± 3.7 %/yr) relative to control subjects (neck: -0.04 ± 1.18 %/yr; total: +0.52 ± 0.66 %/yr), although the changes did not reach statistical significance. No adverse side effects or new clinical fractures were reported during IV pamidronate therapy. These data are consistent with a positive effect of pamidronate on BMD in osteoporotic subjects who had already been treated with other bisphosphonates. Larger prospective studies could further evaluate the long-term efficacy and fracture reduction properties of IV pamidronate.

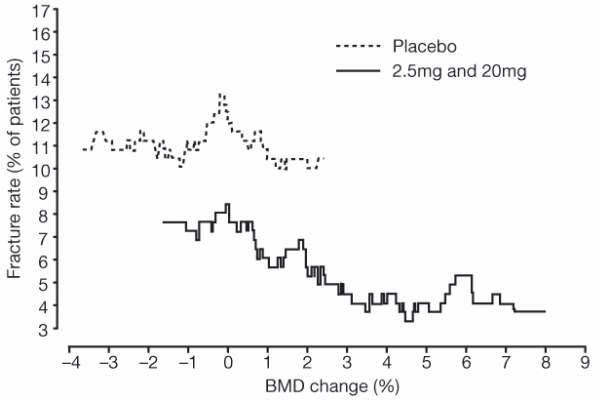
Changes in Bone Mineral Density as a Predictor of Vertebral Fracture Efficacy with Ibandronate: Results from a Phase III Fracture Study. R. Wasnich[1], P. D. Miller[2], C. H. Chesnut[3], H. Huss*[4], K. Wilson*[5], R. C. Schimmer[5]. [1]Radiant Research, Honolulu, HI, USA, [2]Colorado Center for Bone Research, Lakewood, CO, USA, [3]University of Washington, Seattle, VA, USA, [4]tbc, Leverkusen, Germany, [5]F. Hoffmann-La Roche Ltd, Basel, Switzerland.

The fracture efficacy of antiresorptive agents is thought to be related to their ability to increase bone mineral density (BMD). A recent study (oral iBandronate Osteoporosis vertebral fracture trial in North America and Europe: BONE) of oral daily and intermittent ibandronate demonstrated significant increases in BMD and substantial reductions in vertebral fracture (VF) risk (62% [p=0.0001] and 50% [p=0.0006], respectively). A moving average procedure was used to explore the relationship between BMD change and VF rate with ibandronate. Increased BMD was associated with reduced VF rate. Most notably, analysis of total hip BMD change at 3 years revealed a decrease in the percentage of patients with VFs from approximately 7% in patients with no increase in BMD to approximately 4% in patients with ≥4% increase in BMD (Figure). Change in total hip BMD was also compared with the number of VFs per 100 patients. VF rate decreased from approximately 12 per 100 patients to 4–5 per 100 patients in patients with >5% increase in BMD. A similar pattern was observed for total hip BMD change at 2 years and lumbar spine (L2–L4) BMD change at 2 and 3 years. To further evaluate the relationship between BMD change and VF rate, a logistic regression model, which included BMD change as a linear term and considered the predictive value of number of prevalent VFs, was employed. Total hip BMD change at year 3 was found to be a significant predictor of VF risk reduction: a 1% increase in total hip BMD was estimated to account for a 7.9% (p=0.0084) reduction in risk. This finding was supported by subsequent analyses without adjustment for the number of prevalent VFs (7.1%; p=0.0165). Similar findings were reported for the change in total hip BMD at 2 years and lumbar spine (L2–L4) BMD at 2 and 3 years, although overall risk reductions were smaller than those at the total hip. Although BMD change does not provide a complete explanation for fracture risk reduction, these findings support the strong relationship between BMD change and VF efficacy with ibandronate.



Relative change in hip BMD vs vertebral fracture rate after 3 years

Risedronate Reduces Vertebral Fractures in Men with Osteoporosis. J. D. Ringe*, A. Dorst*, H. Faber*. Department of Internal Medicine IV, Hospital Leverkusen, Teaching Hospital University of Cologne, D-51375 Leverkusen, Germany.

The incidence of vertebral fractures in men is lower than in women, but has recently been approximated to 6/1000 patient years. Causes of male osteoporosis include excess of glucocorticoids, hypogonadism, and other systemic conditions, medications, and lifestyle factors, but often there is no obvious cause. In women with postmenopausal osteoporosis Risedronate has been shown to significantly reduce vertebral and nonvertebral fracture risk as early as 6 months with sustained fracture reduction demonstrated for up to 5 years.
The purpose of this study is to determine the effects of Risedronate on vertebral fractures, spine and hip BMD in men with primary and secondary osteoporosis. In the single center, open label, prospective clinical trial 280 male patients (mean age: 57 years, range 33-77 years) with T-score values of lower than -2.5 SD at lumbar spine (LS) and lower than -2.0 SD at the total hip with or without prevalent vertebral fractures (vert.-fx) were included. The patients were allocated in pair-wise fashion into two treatment groups: Patients in group A (n=140) received Risedronate 5 mg daily plus Calcium 1000 mg and 800 IU Vit. D. In this group 69 patients had prevalent vert.-fx and 71 did not. Of 140 patients in group B, those with a prevalent vert-fx (subgroup B1 n=70) were treated with Alfacalcidol 1 g plus Calcium 500 mg daily, whereas patients without prevalent vert.-fx (subgroup B2, n=70) were treated with Calcium 1000 mg plus 800 IU plain Vitamin D daily. In group A 55 of 140 patients (39%) and in group B 56 of 140 patients (40%) had evidence of secondary osteoporosis. BMD, body height as well as x-rays were obtained at baseline and after 12 months, back pain was recorded on a scale from 0 (no pain) to 3 (severe pain).
After one year of treatment Risedronate increased mean lumbar spine LS-BMD by 4.5% compared to 0.8% in group B ($p<0.0001$). Significant increases of BMD were also observed for total hip and femoral neck BMD. Within one year the risk of new vertebral fractures was significantly reduced by 58% in men on Risedronate (7/140 (Ris) vs. 17/140 (Control), p=0.033, Chi^2-Test). Reduction of back pain after one year was significantly more pronounced in Risedronate versus control patients ($p<0.0001$), and mean height loss in men receiving Risedronate (-0.11cm) was less than in controls (-0.51 cm, $p<0.0001$, Wilcoxon-Test).
In men with primary or secondary osteoporosis, Risedronate reduces the risk of vertebral fractures within one year and increases BMD, consistent with the results from phase III trials in postmenopausal osteoporosis. In addition Risedronate treatment in men reduces height loss and back pain within one year.

Health-Economic Analysis of the Treatment of Osteoporosis with Risedronate. J. G. Brecht*[1], H. Kruse[2], D. Felsenberg*[3], W. Möhrke*[4], A. Oestreich*[4], E. Huppertz*[5]. [1]InForMed GmbH, Ingolstadt, Germany, [2]Abteilung für Nephrologie/Osteologie, Universitätsklinikum Hamburg-Eppendorf, Hamburg, Germany, [3]Zentrum für Muskel- und Knochenforschung, Universitätsklinikum Benjamin Franklin, Berlin, Berlin, Germany, [4]Procter & Gamble Pharmaceuticals - Germany, Weiterstadt, Germany, [5]Aventis Pharma Deutschland GmbH, Bad Soden am Taunus, Germany.

Hip fracture is an important and costly problem. The therapy with the bisphosphonate Risedronate effectively prevents hip and other fractures among women with established osteoporosis (McClung, 2001). Risedronate is a first choice therapy option in the German Guidelines of the Dachverband Osteologie for Osteoporosis according to evidence-based medicine criteria for treatment of postmenopausal osteoporosis, osteoporosis of the elderly (women > 75 years) and gluco-corticoid induced osteoporosis (Leitlinie DVO, 2003).

Few economic evaluations of bisphosphonates have been published in Germany. So an assessment of the cost-effectiveness of Risedronate utilizing a Markov model of established post-menopausal osteoporosis based upon randomised clinical trial data was developed. Uncertainty underlying model parameters and outcomes was dealt with using traditional sensitivity analysis and stochastic sensitivity analysis to produce quasi-95%CIs. Baseline model was a cohort of 1000 70-year-old women, who received Risedronate for 3 years and were followed up for an overall observation period of 10 years, modelling transitions through estimated health states and evaluating outcomes.

Over the 3 year period of treatment and 10 year observation Risedronate dominated the current average basic treatment in Germany. In the Risedronate group 33 hip fractures were averted and 32 quality adjusted life years were gained (discounted values).

Treatment with Risedronate is cost saving for the German Social Insurance: The net present value of the associated costs from the perspective of the German Social Insurance is 10.66 million Euro if treated with Risedronate versus 11.00 million Euro in the case of basic treatment, thus net savings of €340 000 for the treatment group per 1000 treated women were calculated.

Furthermore treatment with Risedronate is cost-effective from the perspective of the Statutory Health Insurance with costs per averted hip fracture in the analysed population of €33,856 and cost per QALY gained of €35,690. Both results demonstrate cost effectiveness and are far below the accepted threshold level of €50.000.

Based on this analysis Risedronate is a cost-effective treatment for postmenopausal osteoporosis within the German health care system offering benefits for osteoporotic patients and for budget decision makers.

Alendronate Effects on Material Properties and Pre- and Post-Yield Behavior of Rat Cortical Bone may not Entirely Depend upon Bone Mass and Mineralization. M. A. Chiappe*[1], G. R. Cointry*[2], R. F. Capozza*[2], G. Iorio*[1], E. Alvarez*[1], J. R. Zanchetta[2], E. J. Roldán[2], J. L. Ferretti[2]. [1]Dept. of Physiology, Faculty of Veterinary Sciences, UBA, Buenos Aires, Argentina, [2]Centro de Estudios de Metabolismo Fosfocálcico, Faculty of Medicine, UNR, Rosario, Argentina.

In order to describe Alendronate (AL) effects on cortical bone, 40 3-month-old rats were ovariectomized (OX) and immediately given sc doses of 0 (OX ctrl, n=13), 5 (OX+5, 13), and 25 ug/kg (OX+25, 14) of AL 2/wk during 6 months, while further 15 remained as sham controls. Their femur diaphyses were studied by DEXA and pQCT and tested in bending.

Despite that no differences in bone mineralization ("areal" or volumetric BMD) and geometry (cortical cross-sectional diameters, area, and bending moment of inertia, CSMI) were observed, the OX reduced all bone tissue stiffness (elastic modulus, E), diaphyseal stiffness, load supported at the yield point, and ultimate load. The post-yield behavior of the bones (difference between ultimate and yield loads) was strikingly improved by OX, presumably as a consequence of the inverse relationship usually observed between effects on crack generation (facilitated in this case) and progression. AL treatment prevented all negative OX effects and improved the bones' ultimate strength over sham values at the highest dose. Despite that the load at the yield point was normal in AL-treated groups (no effects on crack generation), their bones showed the same improvement in the post-yield strength as those from OX rats (resistance to crack progress). The negative correlations observed between bone architecture (CSMI, y) and material quality indicators (E, x) showed significant "anti-anabolic" shifts for the OX group and "anti-catabolic" displacements for the OX+AL groups with respect to controls. This should have reflected negative and positive interactions of OX and AL, respectively, with the feedback control of bone geometry as a function of bone material stiffness according to the mechanical usage of the skeleton (bone "mechanostat" theory). Lack of effects on mineralization and geometry and the effects on post-yield bone behavior suggest that both OX and AL treatment would have affected the microstructural determinants of bone material stiffness / strength which are unrelated to bone mineralization. Data suggest that the improvement induced in the post-yield behavior of bones by both OX and AL treatment should have reflected different effects on those factors. These interesting aspects of bisphosphonate effects, perhaps related to the observed dissociation between bisphosphonate effects on BMD and fracture incidence in clinical studies, deserve further attention.

Femoral Neck Mechanical Quality and MR Microscopic Imaging of a Postmenopausal Osteoporosis Model in Ewes Treated with Calcitonin. Y. Jiang[1], J. J. Zhao[1], J. A. Lynch*[1], X. Ouyang*[1], P. Geusens[2], P. Adriaensens*[2], J. Gelan*[2], M. Azria*[3], H. K. Genant[1]. [1]Osteoporosis and Arthritis Research Group, University of California, San Francisco, CA, USA, [2]Limburgs Universitair Centrum, Diepenbeek, Belgium, [3]Novartis, Basel, Switzerland.

To evaluate an ovariectomy (OVX)-induced osteoporotic model and effects of salmon calcitonin (sCT), an osteclast inhibitor, 28 middle aged (5–8 years old) ewes were randomly and equally allocated into 4 groups: sham (Sham) or OVX injected with vehicle, OVX injected with sCT at 50 U or 100 U. It was a double-blind study with 3 subcutaneous injections a week. They were euthanized 6 months post-OVX. The femoral neck was examined with an MR imager at 9.4 Tesla in axial, coronal, and saggital planes, using a spin echo multislice pulse sequence with TR 1 s, TE 1.8 ms, inplane resolution 78 μ, and slice thickness 1 mm. An internal calibration procedure standardizing image analysis was used to adjust the segmentation threshold. Data from all 3 axial, coronal, and saggital planes were averaged. The operators were blinded to animal codes. The femoral neck BMD was measured by both dual energy QCT and DXA. Compressive testing was performed on trabecular (Tb) cylinder cores of 8 mm in diameter and 10 mm in length aligned with the axis of the neck. Compared with Sham, OVX induced statistically significant changes in the femoral neck micro structure: Tb bone volume fraction –18%, Tb separation +23%, number of free ends +28%, number of nodes –39%, number of Tb branches –23%, and mean length of Tb branches –19%. There was a dose response of sCT effect on the Tb structure. Compared with OVX, treatment of sCT at 100 U statistically significantly improved all the Tb structural parameters to the Sham level, while at 50 U significantly increased the mean length of the Tb branches. OVX significantly decreased Tb biomechanical competence (compressive strain -28%). Treatment with sCT resulted in a significant dose-dependent preservation of compressive stress. Tb bone volume fraction explained 74% of compressive stress. Combination of all structural parameters in a multivariate regression analysis significantly improved the explanation to 84%, and combination of BMD further increased the explanation to 92%. Thus, OVX induces deterioration of the MRI-drived Tb microstructure and of the biomechanical properties in the femoral neck of ewes. sCT treatment prevents OVX induced changes in a dose-dependent manner. The femoral neck Tb microstructure significantly correlates with biomechanical properties, and its combination with BMD further improves the prediction of bone quality. The effects of sCT on the OVX ewes may help explain reduced fracture risk in postmenopausal osteoporotic women treated with sCT.

Hip and Spine BMD Increases Following Six Months of Daily Treatment with Fortical® Salmon Calcitonin Nasal Spray. N. Mehta, W. Stern*, A. Sturmer*, A. Malootian*, S. Philip*, S. Mitta*, J. P. Gilligan. Unigene Laboratories Inc, Fairfield, NJ, USA.

A novel nasal spray formulation (Fortical®) has been developed that contains recombinant sCT (rsCT) produced using a direct expression technology in *E. coli.* The pharmacodynamic response of Fortical® was determined in a multi-dose, double blind, parallel design tolerability and pharmacology study using a commercially available nasal spray product as a positive control. One hundred and thirty four osteoporotic women received 6 months of daily dosing of 200 IU per day of Fortical® nasal spray or the positive control, with calcium and vitamin D supplementation. Several markers of bone resorption and bone formation were measured throughout the first 3 months of the study. Spine and hip BMD were measured at baseline and at the end of the six-month dosing period. The key findings from the study were as follows: 1) Fortical® treatment resulted in a modest but statistically significant increase in BMD of 1.3 % at the AP spine and 1.1% at the hip at 6 months, compared to baseline. 2) Plasma levels of the primary end-point β-CTx, were decreased by approximately 40% after the first month, and this decrease persisted through 3 months of Fortical® treatment. 3) Statistically significant decreases in NTx and urinary DPD were also seen throughout the 3 months of measurement. 4) Fortical® significantly decreased the bone formation markers osteocalcin and BSAP at the 3 month time-point compared to baseline. Overall, there was no statistically significant difference in bone markers or BMD between Fortical® and the positive control. Fortical® nasal spray is an alternate sCT nasal spray therapy that achieves equivalent clinical results and has a comparable systemic safety profile to that of a currently marketed sCT nasal spray product, with a formulation that does not contain benzalkonium chloride.

Soy Isoflavones: Increased Bone Turnover and Less Bone Loss at the Hip in Postmenopausal Women. L. A. Fitzpatrick[1], A. Vincent[1], A. Oberg*[2]. [1]Endocrinology, Diabetes, Metabolism, Nutrtion & Internal Medicine, Mayo Clinic, Rochester, MN, USA, [2]Biostatistics, Mayo Clinic, Rochester, MN, USA.

Soy phytoestrogens are SERM-like compounds that have lower affinity for binding estrogen receptors alpha and beta compared to estradiol, however, in vivo work has suggested that they have more potent transcriptional activity than 17-β-estradiol. These soy isoflavones exhibit both antiresorptive and anabolic actions on the skeleton in vitro. Genistein, one of the soy isoflavones, stimulates DNA synthesis and markers of differentiation in osteoblast-like cells. Few studies have examined the effect of isolated isoflavones on bone markers and BMD long term to determine the magnitude of their effects and whether isoflavones are antiresorptive or anabolic to bone. We tested the effects of 110 mg of isolated soy isoflavones (1:1 genistein:daidzein) on bone markers and BMD in postmenopausal women over 1 year. Seventy-one healthy postmenopausal women, mean age 58.3 years, were randomly assigned to placebo or 2 isolated isoflavone tablets (ISO) for 6 months; 43 subjects agreed to extend and completed the study for 1 year. The isoflavones were commercially available as "Healthy Woman Soy Menopause" a proprietary, standardized tablet made from highly concentrated soy isoflavones and containing 320 mg of soy extract and 55 mg of isoflavones per tablet. Bone markers (N-telopeptide (NTx), pyridinoline (Pyd), deoxypyridinoline (Dypd), osteocalcin (OC), bone-specific alkaline phosphatase (BSAP)) and DEXA BMD at hip and spine were measured at baseline, 6 and 12 months.

There were significant increases in Dypd and Pyd in both groups, however, the increases were greater in the ISO group at 12 months ($p=0.04$ and $p=0.034$, respectively). BSAP ($p<0.01$) was significantly increased in the ISO group at 12 months compared to baseline levels. Serum NTx decreased in the ISO group ($p=0.045$) and OC increased ($p=0.009$) compared to placebo. However, urine NTx increased in both groups at 12 months ($p<0.02$ for ISO; $p<0.05$ for placebo) but there was no significant difference between groups. Hip BMD fell in the placebo group ($p<0.01$) over 12 months, with no decrease noted in the ISO-treated group. No differences were noted in spine BMD over 12 months in either group.

The changes in the bone markers in the ISO group (with the exception of serum NTx) are suggestive of increased bone turnover that is consistent with the anabolic action of other agents. These minimal changes are reflected in less bone loss at the hip in the ISO-treated group. These data suggest that isolated soy isoflavones may have a small benefit in terms of preventing postmenopausal bone loss, but long-term studies are needed to assess any reduction in fracture risk.

Soy Protein-Based Diet Improves Bone Mineral Density in Osteopenic Female Rats. D. A. Khalil[1], L. Devareddy*[1], L. J. Hammond*[1], D. Y. Soung[1], D. Bellmer*[2], B. H. Arjmandi[1]. [1]Nutritional Sciences, Oklahoma State University, Stillwater, OK, USA, [2]Food and Agricultural Products Research and Technology, Oklahoma State University, Stillwater, OK, USA.

The objective of this study was to determine if soy protein with graded dose of isoflavones reverses bone loss in an ovariectomized (ovx) osteopenic rat model. Seventy-seven 9 mo old Sprague-Dawley rats were either sham-operated (sham; 1 group) or ovx (5 groups) and fed a semi-purified casein-based diet. After 90 days the occurrence of bone loss was confirmed using dual energy x-ray absorptiometry. Thereafter, rats were assigned to following treatments: sham, ovx (control), ovx + 17β-estradiol (E_2; 10 μg E_2/kg body wt. twice per wk), ovx + soy protein depleted of isoflavones (Soy-; 1.1 mg isoflavones/g protein), ovx + soy protein with normal isoflavone content (Soy; 2.2 mg isoflavones/g protein)), and ovx + soy protein enriched isoflavones (Soy+; 4.4 mg isoflavones/g protein). After 125 days rats were sacrificed and tissues were collected.

	Left tibia		Fourth lumbar	
Group	BMC	BMD	BMC	BMD
Sham	0.3584^{a}	0.1993^{a}	0.1465^{a}	0.2342^{a}
Ovx	0.3103^{c}	0.1825^{c}	0.1189^{b}	0.2055^{b}
Soy-	0.3272^{bc}	0.1882^{bc}	0.1245^{b}	0.2088^{b}
Soy	0.3423^{ab}	0.1908^{b}	0.1273^{b}	0.2124^{b}
Soy+	0.3296^{bc}	0.1899^{b}	0.1243^{b}	0.2097^{b}
Estrogen	0.3273^{bc}	0.1892^{b}	0.1270^{b}	0.2132^{b}

Values in a column not sharing a superscript letter are different from each other ($P<0.05$; $n=12$ per treatment group).

Data analysis indicated that Soy had significantly increased tibial bone mineral content (BMC) but Soy- and Soy+ did not significantly increase tibial BMC. These observations confirm the notion that soy isoflavones may have a biphasic effect on bone. Furthermore, this increase in BMC may be due to the ability of soy in enhancing insulin-like growth factor-I which is known to positively influence BMC. Tibial bone mineral density (BMD) was equally increased by Soy, Soy+, and E_2 but not Soy- indicating the importance of isoflavones in reversal of bone loss. Although 4th lumbar BMC and BMD were slightly improved by soy and E_2 treatments, the values were not significantly different from the ovx control group. Perhaps a longer treatment period would have shown a more pronounced effects on 4th lumbar BMC and BMD.

Clinical Outcomes in Osteoporotic Patients with Acute Vertebral Fractures Treated by Percutaneous Vertebroplasty or Conservative Measures: An Interim Analysis. T. H. Diamond, W. A. Clark*. Endocrinology, University of New South Wales, St George Hospital Campus, Sydney, Australia.

Acute osteoporotic vertebral fractures often cause severe back pain, resulting in hospitalisation and an increased morbidity. Percutaneous vertebroplasty (PV) has been a major breakthrough in the management of this syndrome. In an interim analysis, we compare the role of PV to conservative therapy (CT).

126 consecutive osteoporotic patients presenting to St George Hospital with severe back pain due to acute vertebral fractures were enrolled over a 24 month period. 88 patients were treated by PV and 38 by CT alone. All patients received anti-osteoporotic therapies in addition to analgesia. Their osteoporotic risk factors and bone densitometry was measured at baseline, while the patients' pain score and level of function was recorded on presentation, at 24 hours, 6 weeks, 12 and 24 months post therapy. All data was compared using a student t-test or analysis of variance and analysed on an intention to treat analysis.

There were 39 men and 87 women, aged 51-95 years, followed for 362 days (range 32-764). Patients treated by PV did not differ from those treated by CT, with respect to their biochemistry, bone densitometry and radiological evidence of multiple pre-existing vertebral fractures. A significant decrease in the patients' pain score from 20 to 8 (-60%, P=0.0001) and an improvement in their physical functioning from 13 to 18 (+34%, P=0.0001) was noted at 24 hours after PV. Twenty-six patients (30%) were able to cease their analgesia and a further 54 patients (61%) were able to reduce their analgesia by more than 50% after the procedure. By contrast symptomatic improvement in the patients treated by CT was delayed. A decrease in their pain score from 19 to 7 (-63%, P=0.0001) and an improvement in their physical functioning from 14 to 17 (+21%, P=0.01) was only evident at 6 weeks post therapy, with 32 patients (84%) still requiring some form of ongoing analgesia. No significant differences were noted between the two groups at 12 and 24 months of follow up.

Early complications related to PV included a psoas haemorrhage in 1 patient (1.1%) and fractured transverse process in 3 patients (3.4%). There were 11 patients (13%) in the PV and 6 patients (16%) in the CT group who died from non-procedural related diseases. New clinical apparent vertebral fractures occurred in 7 patients (8%) treated by PV and in 2 patients (5%) treated by CT.

In experienced hands, PV is safe and allows for the prompt relief of pain and rapid rehabilitation of patients presenting with acute osteoporotic vertebral fractures. In the interim analysis, PV did not appear to result in an increase in mortality or clinical apparent fractures.

Discrepancy in Follow-Up Absorptiometry Measurements of Lumbar Spine and Proximal Femur. S. Di Gregorio*, L. del-Rio, P. Bassa*, J. Rosales*. Bone densitometry, CETIR.Centre Medic, Barcelona, Spain.

Bone mineral density (BMD) measurement by DXA of at least two skeletal regions (lumbar spine and proximal femur) has shown its utility for assessment of risk fracture as well as a method to evaluate bone mass changes due to metabolic bone diseases or their treatment. Trend in bone changes, however, is not always alike for both regions, irrespective of technical differences and this arises some clinical concern with regard to patient follow-up. In order to investigate the impact of these differences and their origin, a longitudinal study with 3,310 patients who attended our service for evolution of BMD by DXA was undertaken. BMD of lumbar spine and proximal femur were evaluated in every patient with the same DXA device as the previous scan (mean time between scans was 2.9±1.8 years). A "discordant evolution" was established when differences greater and with opposite sign to three times the variation coefficient adjusted for the device used were found between lumbar spine and proximal femur measurements.

In order to avoid confusing factors we furthermore selected a group of patients with the following inclusion criteria: postmenopausal women with no treatment nor diseases that affected BMD including osteoarthritic changes. In this group, changes in BMD, weight, body mass index, calcium intake, physical activity were statistically treated by bivariate correlation, linear regression and multinomial logistic regression.

From the total of patients analyzed, (n= 3310) a discordant evolution was found in 8.5% (n=282). The mean age for the patients with no treatment or diseases (n=107) was 62 years (range 46-83 years). In these patients the most common discordant evolution model (76%) was a BMD increment in lumbar spine and decrease in femoral region (Type I). The loss in spine density and femoral increase (Type II) was only detected in 24% of patients. In both discordant models a consistent statistical positive correlation ($p< 0.0001$) was found between femoral BMD and weight gain and a similar but negative order correlated with the spine density ($p< 0.001$). The relationship was most powerful in the following cases: women aged 65 years or older; early menopausal; calcium intake above 1,000 mg/day, 3 kg or greater weight gain.

The treated group (mostly anti-resorptive) (n= 175; mean age 63 years, range 35-84) showed a similar discordance pattern with a 70% Type I and 30% Type II.
A small but significant discordant trend was found in follow-up BMD measurements in our population. Some factors like changes in anthropometric parameters and especially the body weight could, at least partially, make up for these differences in BMD evolution in the non-treated patient.

Screening Heel Ultrasound from Primary Care Settings Effectively Guides Treatment. D. J. Brown*, R. J. Quinet, W. E. Davis*, L. H. Serebro*, J. M. Zakem*, M. Krousel-Wood*, S. Ishaq*. Rheumatology, Ochsner, New Orleans, LA, USA.

Heel Ultrasound has been found to effectively predict fracture risk. We studied the association between heel ultrasound results and effect on subsequent therapy. **Methods:** 94 female patients who had screening heel ultrasound in the year 2000 at Ochsner Clinic Foundation who were referred from primary care clinics were enrolled. Heel ultrasound was performed using Hologic Sahara heel ultrasound machine. Osteoporosis/osteopenia was defined as T score less than or equal to –1.0. Follow up by the primary care physician and subsequent prescription of estrogen therapy, calcium, raloxifene, bisphosphonates, and calcitonin was observed through chart review. Pearson chi-square test was used for statistical analysis. **Results:** Mean patient age was 66.27 (range 39 – 82 years). Of the 94 patients, 86 were Caucasian, 6 were Hispanic, and 2 were African American. 47.9% of the patients had an abnormal bone density test. Abnormal heel ultrasound was found to be significantly associates with smoking (p=0.016), and weight less than 124 lbs (p=0.022). Prescription of osteoporosis medication was significantly associated with the heel ultrasound result. Patients who had an abnormal result were more likely to have osteoporosis medications prescribed than those who had normal results (X2 = 22.88, p=0.001). Of the individual medications screened for, bisphosphonates were more likely to be prescribed if the heel ultrasound was abnormal (p=0.001). The other medications screened for approached but did not reach statistical significance. **Conclusion:** We concluded that heel ultrasound is an effective instrument in identification of osteoporosis and results guide treatment in primary care clinics.

The Changes of Circulating Osteoprotegerin after Hormone Replacement Therapy in Postmenopausal Women and their Relationship with Estrogen Responsiveness on Bone. Y. Kang*[1], K. Han[2], J. Kim*[1], S. Kim*[1], C. Hwang*[1], I. Moon*[1], C. Yim*[2], H. Chung[2], W. Park*[2], H. Yoon[2], I. Han*[2]. [1]Laboratory of Endocrinology, Samsungcheil Hospital, School of Medicine, Sungkyunkwan University, Seoul, Republic of Korea, [2]Internal Medicine, Samsungcheil Hospital, School of Medicine, Sungkyunkwan University, Seoul, Republic of Korea.

Estrogen replacement reduces the increased rate of bone remodeling after menopause. Osteoprotegerin (OPG) is a negative regulator of osteoclast-mediated bone resorption. The studies in vitro have shown that estrogen stimulates OPG production. We, therefore, analyzed serum for OPG levels and assessed their association with estrogen responsiveness on bone before and after hormone replacement therapy (HRT) in 99 postmenopausal women aged 52.3 ± 4.9 yr. This is the first study conducted under conditions of estrogen replacement in healthy postmenopausal women. The mean circulating level of OPG before HRT was 3.54 ± 1.13 ng/ml. Baseline levels of OPG were correlated neither with bone formation marker, serum osteocalcin (BGP) nor with bone resorption marker, serum carboxyterminal telopeptides (CTx). No significant association of baseline OPG level was found with baseline bone mineral densities (BMDs) measured at lumbar spine and femoral neck. Serum OPG levels measured after 3 months and 1 yr of HRT decreased significantly compared to baseline (p<0.001 in both). The median decrements of circulating OPG were 14.7% (-22.4~ -2.8%, IQR) and 11.8% (-27.0~-2.9%, IQR) at 3 months of HRT and at 1 year of HRT, respectively. The changes in circulating OPG at 3 months of HRT were correlated with the changes in both serum BGP (r=0.226, p=0.029) and serum CTx (r=0.214, p=0.038) at 3 months after HRT. We, however, could not find any association between changes in circulating OPG at 3 months of HRT and changes in BMDs at 1 yr of HRT measured at either lumbar spine or femoral neck. These results suggest that baseline OPG levels do not reflect the bone turnover status and that the serial measurement of serum OPG after HRT is not a useful predictor for the long-term effects of estrogen on bone. The decreased serum concentrations of OPG after HRT seem to be caused by the compensation to suppress the bone resorption by estrogen.

PSK 3471, a New Designer Estrogen, Prevents Ovariectomy-induced Bone Loss in Mice and Keeps a Safe Profile on Uterus. P. Clément-Lacroix[1], R. Galien[1], F. Marsais*[1], M. Roux*[1], F. Nique*[1], C. Belleville*[1], D. Minet*[1], L. Lepescheux[1], M. Gaillard-Kelly*[2], M. Resche-Rigon[1], R. Baron[1]. [1]ProSkelia Pharmaceuticals, Romainville, France, [2]Oncology, Aventis Pharma, Vitry, France.

Estrogen replacement therapy (ERT) after menopause prevents the development of osteoporosis and reduces the risk of fracture. ERT, however, increases the risk of endometrial and breast cancer. Selective Estrogen Receptor Modulators (SERMs) display antiestrogenic activity in breast and uterus, while triggering estrogenic effects in bone. However increased risk in endometrial cancer is still associated with Tamoxifen (TAM), a first generation SERM. PSK3471 is a new steroidal designer estrogen, which behaves in vitro as an AF2 antagonist like TAM and Raloxifen (RAL). In contrast to TAM, but similarly to RAL, PSK3471 has limited if any, ability to stimulate the AF1 function of ERα. In addition, PSK3471 *per se* does not stimulate proliferation of MCF7 cells and inhibits the E2-induced proliferation of these cells. In the present study, PSK3471 has been evaluated in ovariectomized (OVX) mice. Twelve week-old OVX mice were orally administrated PSK3471 (0.01, 0.03, 0.1, 0.3, 1mg/kg/d), TAM (0.03, 0.1, 0.3mg/kg/d), or RAL (0.1, 0.3, 1, 3mg/kg/d) immediately after surgery, for 4 weeks. MicroCT analysis of proximal tibial metaphysis demonstrated full prevention of OVX-induced trabecular bone loss in mice dosed with PSK3471 (0.1mg/kg/d), a dose equipotent to TAM 0.3mg/kg/d or RAL 3mg/kg/d. Ranking of compounds in this model on the basis of their activity on bone tissue was PSK3471>TAM>RAL. In order to assess possible adverse effects on genital tract, morphometry of uterus and proliferation index (PI) of luminal epithelial cells were evaluated. As expected, ovariectomy induced a dramatic atrophy of the uterus, which was partially prevented in mice treated with either compound. Most importantly, PI of epithelial cells was highly stimulated in mice treated with lower doses of TAM. At higher doses several kystic glands appeared within the endometrium of these mice. In sharp contrast, neither RAL, nor PSK3471 significantly stimulated proliferation of epithelial cells or induced formation of kystic glands at any tested doses. These data indicate that PSK3471 is a promising compound for the prevention and/or treatment of postmenopausal osteoporosis.

Molecular Action of Phytoestrogens in Human Breast Cancer (MCF-7) Cells. W. Chen*[1], R. Y. K. Chan*[1], D. Guo*[2], M. Wong[1]. [1]Central Laboratory of the Institute of Molecular Technology for Drug Discovery and Synthesis, The Hong Kong Polytechnic University, Hong Kong, Hong Kong Special Administrative Region of China, [2]School of Pharmaceutical Sciences, Peking University, Beijing, China.

Estrogen replacement has been an important therapy for the prevention and treatment of osteoporosis in postmenopausal women. However, its undesirable side effects have limited its long-term use. Phytoestrogens are currently receiving considerable attention as potential alternative therapy for reducing the incidence of cancer and for protection against osteoporosis. Elucidating their mechanism of actions can help us to understand the potentially benefit and risk of phytoestrogens consumption. Recent studies demonstrated that cross talk exists between estrogen receptor (ER)-dependent and Insulin-like growth factor I receptor (IGFIR)-dependent pathways in ER-positive breast cancer cells. In the present study, we hypothesize that ginsenoside Rg1 and isoflavone genistein will act like estrogen and mediate their actions via the cross-talk with IGF-I receptor mediated pathway.
MCF-7 cells were routinely cultured in phenol-red free DMEM supplemented with 1% charcoal-stripped fetal bovine serum for 5 days. Then cells were exposed to 1pM Rg1, 1μM genistein or 10nM 17β-estradiol, their effect on cell proliferation were determined by flow cytometry. Protein expression of IGF-IR, IRS-1 and Shc were measured by western blotting analysis and mRNA expression of IGF-IR and IRS-1 were determined by RT-PCR**.** Our results show that Rg1 and genistein significantly increased the proliferative phase (S-phase) and decreased the resting phase (G0/G1 phase) (p<0.05) of MCF-7 cells after 24h treatment. Both Rg1 and genistein increased the expression of IGF-IR and its downstream signaling molecule IRS-1 in a time dependent manner. But no apparent change was found on Shc protein level. And these effects could be blocked by estrogen antagonist ICI 180,782. Cycloheximide, a protein synthesis inhibitor could block the induction of IGF-IR and IRS-1 by both Rg1 and genistein. These data provide the first evidence that the IGF-IR pathway is involved in the proliferative effect of phytoestrogen, Rg1 and genistein, in MCF-7 cells.

No Effect of Estrogen Receptor Gene Polymorphisms on Bone Mineral Density, Bone Loss and Treatment Response to Estrogen. P. B. Rapuri[1], J. C. Gallagher[1], V. Haynatzka*[2]. [1]Bone Metabolism Unit, Creighton University, Omaha, NE, USA, [2]Department of Preventive Medicine, Creighton University, Omaha, NE, USA.

The genetic basis of osteoporosis has been known for several years. Several candidate genes which contribute to bone mineral density (BMD) and bone turnover have been implicated in the pathogenesis of osteoporosis. As estrogen deficiency is a major determinant of bone loss after menopause, association studies have been carried out between estrogen receptor (ER) gene polymorphisms and BMD and the results have been inconsistent. The aim of the present study was to investigate the influence of ER gene polymorphisms on baseline BMD, bone loss rates and response in BMD to estrogen/hormone therapy (ET/HT) in elderly postmenopausal women. The association between ER genotypes and baseline BMD was tested in 489 elderly women (mean age 71± 3 years) recruited for an osteoporosis intervention study. The association between ER genotypes and the rate of bone loss after 3 y was studied in 96 women assigned to the placebo arm and the relation between ER genotypes and response to ET/HT was studied in 79 women receiving the ET/HT for 3 y. The ER gene was genotyped for restriction enzymes PvuII and XBaI. BMD measurements for spine, proximal femur, total body and radius were performed by DEXA and the percent change in BMD over baseline after 3 y of treatment was calculated. The baseline BMD, rate of change in BMD after 3 y in placebo and ET/HT groups were compared between the ER genotypes. The data were analyzed by procedure Mixed from SAS statistical package. Adjustments were made for appropriate covariates like age, weight etc. The observed frequency distribution was PP 21.3%, Pp 51.2% and pp 27.1% for PvuII and XX 14.1%, Xx 48.9% and xx 37.1% for XbaI ER gene polymorphisms. Neither the PuvII nor the XbaI ER gene polymorphisms were associated with baseline BMD. There was no significant association between ER gene polymorphisms and the rate of bone loss after 3 y in women of the placebo group. Also the ER gene polymorphims did not influence the response in BMD to ET/HTafter 3 y. In conclusion, we could not demonstrate any major effect of the ER gene polymorphisms on BMD, rate of bone loss or on the response in BMD to ET/HT in elderly postmenopausal women.

Association Study of Estrogen Receptor Thymine-Adenine Repeat Polymorphism with Estrogen Responsiveness after HRT on Bone Density and Serum Lipid in Postmenopausal Women. C. Yim*[1], K. Han[1], Y. Kang*[2], J. Kim*[2], S. Kim*[2], C. Hwang*[2], I. Moon*[2], H. Chung[1], W. Park*[1], H. Yoon[1], I. Han*[1]. [1]Internal Medicine, Samsungcheil Hospital, School of Medicine, Sungkyunkwan University, Seoul, Republic of Korea, [2]Laboratory of Endocrinology, Samsungcheil Hospital, School of Medicine, Sungkyunkwan University, Seoul, Republic of Korea.

Several biologically plausible mechanisms have been proposed for estrogen-associated changes in lipid and bone metabolism. These effects are thought to be mediated via estrogen receptor (ER). Several polymorphisms in the gene encoding estrogen receptor alpha may modify the effects of hormone-replacement therapy on lipid and bone density in postmenopausal women. We examined 284 postmenopausal women for thymine-adenine (TA) repeat polymorphism at the ER gene locus and its relationship to bone density and lipid. Their mean age was 52.2 ± 5.0 years. We assessed the association of ER TA repeat polymorphism with either BMD or bone turnover markers. We also analyzed the association between ER TA repeat polymorphism and changes in BMD, bone turnover markers and lipid until 1 year after hormone replacement therapy. The women were stratified by the mean number of TA repeats and assigned to one of two groups : group H, with higher number of repeats (TA>16)(n=110); group L, with lower number of repeats (TA≤16)(n=174). No significant genotypic differences were found in BMD and bone markers. Group L showed significantly greater changes in total and LDL cholesterol levels after 3 month of estrogen replacement therapy than in group H (changes in total cholesterol: -8.4 ± 11.3% vs. -4.2 ± 12.5%, p=0.019), (changes in LDL cholesterol: -18.7 ± 18.4% vs -8.8 ± 30.1%, p=0.006). There was no significant relationship between TA repeat polymorphism and changes in HDL cholesterol, and triglyceride levels after 1 year of estrogen replacement therapy. These data suggest that ER TA repeat polymorphism may predict the response of lipid profile to estrogen replacement therapy, but this ER polymorphism is not associated with changes in BMD or bone turnover markers in Korean women.

Meta-Analysis of the Efficacy of Raloxifene on Reduction of Vertebral Fracture Risk. E. Seeman[1], G. Crans*[2], A. Diez-Perez[2], S. R. Cummings[3]. [1]University of Melbourne, Melbourne, Australia, [2]Lilly Research Laboratories, Eli Lilly and Company, Indianapolis, IN, USA, [3]San Francisco Coordinating Center, San Francisco, CA, USA.

Raloxifene (RLX) has been reported to reduce vertebral fractures (VFx) in the Multiple Outcomes of Raloxifene Evaluation (MORE) trial, but no systematic analysis of the vertebral fracture reduction efficacy has been reported examining the results of several other studies in which vertebral fracture data have been collected. In an attempt to determine whether there is internal consistency of the results, and to more accurately define the point estimate for fracture risk reduction, a meta-analysis was undertaken using all randomized, double-blind, placebo-controlled trials in postmenopausal women in which fracture data was available from prospectively scheduled spinal radiographs. Three prevention studies (GGGF, GGGG, GGGH), two arms of the MORE trial, and two additional treatment studies were included in the analysis. A systematic review of the literature (MedLine, EMBASE) confirmed that all appropriate RLX studies had been identified for this analysis. The effects of raloxifene 60 mg/d (RLX60) and120 mg/d pooled with 150 mg/d (RLX120/150) were analyzed. Intention-to-treat data were used in the analysis, and tests of heterogeneity were performed. If the results of the different studies were not heterogeneous, the weighted relative risk (RR) estimates with 95% CI were calculated. The data from each study are summarized in the table.

Study	Duration	Therapy	VFx#/patients	RR (95% CI)
MORE Non-prevalent VFx	3 years	PL	62/1457	
		RLX60	27/1401	0.45 (0.29, 0.71)
		RLX120	37/1414	0.61 (0.41, 0.92)
MORE Prevalent VFx	3 years	PL	169/835	
		RLX60	121/858	0.70 (0.56, 0.86)
		RLX120	87/863	0.50 (0.39, 0.63)
Prevention studies (GGGF, GGGG, GGGH)	3 years	PL	6/287	
		RLX60	3/281	0.51 (0.13, 2.02)
		RLX150	2/267	0.36 (0.07, 1.76)
Japan Trial	1 year	PL	2/97	
		RLX60	0/90	N/A
		RLX120	1/93	0.52 (0.05, 5.65)
Osteoporosis Trial (GGGN)	1 year	PL	18/45	
		RLX60	21/43	1.22 (0.76, 1.96)
		RLX120	20/45	1.11 (0.68, 1.80)

There was no statistically significant heterogeneity in studies of vertebral fractures for either RLX60 or RLX120/150. Weighted relative risk values (95% CI) were 0.53 (0.39, 0.78) for RLX60 and 0.57 (0.39, 0.80) for RLX120/150. These results show a consistent effect of raloxifene on the reduction of vertebral fracture risk across studies in several populations of postmenopausal women. A significant 47% reduction in vertebral fracture risk has been observed for RLX60. These results confirm that raloxifene substantially reduces the risk of vertebral fracture.

Raloxifene and Estrogen Do Not Affect Microdamage Accumulation or State of Mineralization in Monkey Vertebra. J. Li*[1], D. Burr[1], Z. Fan*[2], J. Y. Rho[2], C. Jerome[3], M. Sato[4], C. Turner[1]. [1]Indiana University School of Medicine, Indianapolis, IN, USA, [2]University of Memphis, Memphis, TN, USA, [3]Skeletech, Inc., Bothell, WA, USA, [4]Eli Lilly & Company, Indianapolis, IN, USA.

Previously, alendronate was shown to increase the degree of mineralization and accumulation of microdamage in animal bones. In an effort to ascertain if long-term suppression of bone turnover with other inhibitors of bone resorption can also affect mineralization and microdamage accumulation, we evaluated bones from cynomolgus macaques treated with raloxifene (R) or conjugated equine estrogens (CEE). Cynomolgus monkeys (Macaca fascicularis) were randomized, ovariectomized (except for Sham controls), and treated orally with vehicle (Sham and Ovx controls), 1 mg/kg raloxifene (R1), 5 mg/kg raloxifene (R5), or 0.04 mg/kg CEE. The functional quality of the mineralized matrix was analyzed post-necropsy by biomechanical testing, histomorphometry, and nanoindentation. A beam of pure cortical bone was machined out of the femoral diaphysis and subjected to materials analysis by biomechanical failure testing. No differences in material strength (ultimate stress) were observed between groups; however the Young's modulus (E) of Sham, CEE and R5 were significantly greater than Ovx. R1 had E that was between Ovx and Sham, but not significantly different from either. Histomorphometry of the lumbar vertebra showed that ovariectomy increased the rate of endocortical bone turnover (BFR/TV) with Ovx BFR/TV 301% of Sham. Relative to Sham, endocortical BFR/BV was 81% for CEE, 129% for R1 and 142% for R5. Trabecular bone turnover (Cn BFR/TV) was 106% for CEE, 138% for R1 and 158% for R5, retative to Sham, but these effects were not significantly different from Ovx. Analysis of microcrack surface density showed a 40% reduction for Ovx relative to Sham. CEE increased microcrack surface density to Sham levels, while the

R5 density was less than Sham. R1 microcrack surface density was not significantly different from Sham and Ovx. No significant differences in crack length were observed between groups. Hardness, which is a measure of the state of mineralization, and Young's modulus were measured for both trabecular bone and the cortex on a micron scale by nanoindentation. No significant differences between groups were observed for either parameter in trabecular or cortical bone. In summary, differences in functional quality of the cortical or trabecular bone were not observed between Sham, Ovx or treated monkeys. CEE increased microcracks from Ovx to Sham levels, whereas raloxifene had no effect on microdamage accumulation. Therefore, neither raloxifene nor CEE adversely affected bone material properties beyond normal levels in nonhuman primates.

The Release Profiles and Bioactivity of Parathyroid Hormone from Poly(lactic-co-glycolic acid) Microspheres. G. Wei*, G. J. Pettway*, L. K. McCauley, P. X. Ma. The University of Michigan, Ann Arbor, MI, USA.

Human parathyroid hormone (PTH) has recently been approved for systemic administration to treat osteoporosis, and although it has shown promise for applications of local bone regeneration, the methods for local delivery of PTH are not well established. The purpose of this study was to develop and characterize a local delivery system for PTH that provides reliable release of biologically active peptide. Poly(lactic-co-glycolic acid) (PLGA) microspheres containing bovine serum albumin (BSA) or PTH(1-34) were prepared using a double emulsion method with high encapsulation efficiency and controlled particle sizes. The microspheres were characterized with regard to their surface morphology, size, protein loading, degradation and release kinetics, and in vitro and in vivo assessments of biological activity of the released PTH. It was showed that PLGA5050 microspheres degraded rapidly after a 3-week lag time and could be degraded completely within 4 months. In vitro BSA release kinetics from PLGA5050 microspheres was characterized by a burst effect followed by a slow release phase within 1 to 7 weeks and a second burst release at 8 weeks, which was consistent with the degradation study. The PTH incorporated PLGA5050 microspheres released biologically active PTH in the initial 24 hours, and the released PTH stimulated the release of cAMP levels from ROS cells as well as increased serum calcium levels when injected into hypocalcemic mice subcutaneously. Both in vitro and in vivo assays demonstrated that the bioactivity of PTH was maintained largely during the fabrication of PLGA microspheres and upon release. These studies illustrated the feasibility in achieving local delivery of PTH to induce anabolic responses in bone cells by a microsphere encapsulation technique.

Skeletal Effects of PTH Are Superior to Alendronate in Senile Intact and Severely Osteopenic Ovariectomized Rats, Especially in the Femoral Neck. Y. L. Ma, A. Schmidt*, R. Cain*, Q. Q. Zeng*, J. Hoover*, H. U. Bryant, M. Sato. Lilly Research Laboratories, Indianapolis, IN, USA.

Skeletal effects of parathyroid hormone (PTH) and alendronate (ABP) were compared in intact and osteopenic ovariectomized (Ovx) rats, during the last 4 months of life. The lifetime of female rats was confirmed to be about 24 months, as half of the intact vehicle controls failed to survive during the last two months (23-24 months of age). Interestingly, all Ovx animals survived until study termination regardless of treatment, as tumor (mammary, uterine, vaginal) incidence was lower post-ovariectomy. Intact or osteopenic, Ovx animals at about 19 months old were treated with human PTH (1-38)10 (Ovx only) or 30ug/kg/d s.c, or ABP (28µg/kg twice weekly s.c) for 4 months. The Ovx animals were ovariectomized at 6 month age and permitted to lose bone for 13 months before treating for the last 4 months. Skeletal efficacy was evaluated by biomechanical, QCT and histomorphometric analyses postnecropsy. Alendronate had no effect on femoral neck strength in either intact or Ovx rats. By comparison, PTH strengthened the femoral neck by 25% at the low dose of Ovx rats and by 15% at the high dose in intact animals. ABP had no effect on the strength of lumbar vertebra in intact animals, but increased strength of Ovx vertebra by 48%. Also in intact animals, ABP increased vertebral BMD by 7%, but had no effect on vertebral BMC, or femoral midshaft BMD. In Ovx rats, ABP also increased vertebral BMD by 16%, vertebral BMC by 16%, compared to Ovx vehicle controls. By comparison, PTH increased vertebral strength by 60%, vertebral BMD by 23%, vertebral BMC by 22% and femoral midshaft BMD by 11% over intact controls. In Ovx rats, PTH dose dependently increased vertebral BMD (37% and 43%, low and high dose, respectively), vertebral BMC (27% and 42%), femoral midshaft BMD (13% and 21%), midshaft BMC (10% and 22%), and midshaft strength (20% and 34%) over controls. Treatment group comparisons showed that PTH is significantly superior to ABP in increasing bone mass, improving the spatial architecture, and enhancing quality of the axial and appendicular skeleton of senile as well as severely osteopenic, ovariectomized rats. Finally, ovariectomy was observed to confer a survival advantage to rats by reducing the incidence of mammary, uterine and vaginal tumors, which was not affected by either PTH or alendronate treatment during the last 4 months of life.

A Single Dose of Sustained-Duration PTH(1-34)-Fc Increases Serum Markers of Bone Formation for 28 Days in Cynomolgus Monkeys. B. J. Stouch*[1], P. Kostenuik[2], H. Gunn*[1], S. Baughman*[1], A. DePaoli*[3], C. R. Dunstan[4], S. W. Martin[1]. [1]Pharmacokinetics and Drug Metabolism, Amgen, Thousand Oaks, CA, USA, [2]Metabolic Disorders, Amgen, Thousand Oaks, CA, USA, [3]Clinical Research, Amgen, Thousand Oaks, CA, USA, [4]ANZAC Research Institute, Concord, Australia.

Daily injection of PTH is a strong anabolic stimulus for bone. Because continuous infusion of PTH is not anabolic, investigators have considered that the short half-life of PTH is essential for this anabolism. We challenged this assumption by engineering a long-acting form of PTH-(1-34), the half-life of which was increased substantially by its fusion to the Fc portion of human IgG1. This PTH-Fc fusion molecule has optimal anabolic effects with less frequent injections relative to PTH-(1-34) in rats. The objective of the current study was to determine the pharmacokinetics and pharmacodynamic response to IV or SC administration of PTH-Fc in female cynomolgus monkeys. Thirty-three monkeys were separated into 11 dosing groups (3/group) and received either a single SC or IV dose of PTH-Fc or a single SC dose of Placebo. Whole blood samples were collected from each animal and analyzed for drug levels, ionized calcium (Ca^{++}) and serum markers of bone formation [osteocalcin (OC) and bone specific alkaline phosphatase (BSALP)]. Urinary N-Telopeptide (NTx) and C-Telopeptide (CTx) (urinary markers of bone resorption) were determined serially from each animal. IV and SC treatments with PTH-Fc led to rapid and transient increases in NTx, CTx and ionized calcium levels during the first 3 days, indicating an increase in bone resorption. Bone formation indices such as BSALP and OC transiently declined during the first week, followed by dose-dependent and sustained increases for up to 28 days. PTH-Fc serum concentration-time profiles (IV 300 µg/kg) declined in a triphasic manner with a terminal half-life of 37.8 hours. At the highest dose (both IV and SC) PTH-Fc serum levels were still greater than 100 pg/mL between 7 and 10 days postdose. PTH-Fc underwent limited extravascular distribution (Vss = 93.3 to 187 mL/kg). Clearance of PTH-Fc decreased 2 to 3 fold as dose increased 30-fold (10 to 300 µg/kg). Following SC administration, maximum concentration occurred 6 to 12 hours post dose and then declined in a similar fashion to that observed following IV administration. The changes in biochemical markers of bone turnover are consistent with the recently reported ability of PTH-Fc to increase BMD in cynomolgus monkeys. A single injection of PTH-Fc resulted in pharmacologic exposure to PTH that persisted for 7-10 days. This finding calls into question the perception that rapid clearance of PTH is essential for bone anabolic effects.

Delivery of Osteoprotegerin (OPG)Using an Adeno-Associated Virus (AAV) Gene Therapy Vector Reverse Established Osteopenia in Ovariectomized (OVX) Mice. S. Morony[1], B. Bolon*[2], C. Carter*[3], Z. Geng*[1], M. Daris*[3], P. J. Kostenuik[1], J. Sheng*[3]. [1]Metabolic Disorders Research, Amgen Inc., Thousand Oaks, CA, USA, [2]Pathology, Amgen Inc., Thousand Oaks, CA, USA, [3]Protein Science, Amgen Inc., Thousand Oaks, CA, USA.

We previously demonstrated that recombinant OPG gene therapy using an adenoviral (Ad) vector prevents acute osteopenia in OVX mice when given at the time of OVX (Mol Ther 3: 197, 2001). However, the Ad vector induced mild liver toxicity as indicated by increased liver weight and elevated serum activities of hepatocyte cytosolic enzymes. In the present study, we performed OPG gene therapy in an OVX mouse model of established osteopenia to simultaneously examine (1) the safety and efficacy of an AAV vector and (2) the capacity of AAV-OPG to reverse established osteopenia. Basal bone mineral density (BMD) was assessed by pQCT in 12-week-old CDF1 females (n = 6 – 9/group). Ovaries of all mice were exposed and either touched (sham) or removed (OVX), after which animals were allowed to lose bone mass for 6 weeks. At this time, OVX mice exhibited significant osteopenia by pQCT in the tibia relative to the sham or pre-surgery controls. Animals with established osteopenia were injected once IV with an AAV vector bearing cDNA of human OPG (AAV-OPG) or B-galactosidase (AAV-BGal), after which mice were maintained for 10 weeks. Ten weeks after a single treatment, OVX mice given AAV-OPG had significantly greater tibial BMD compared to age-matched OVX animals given AAV-BGal. Sham-operated mice treated with AAV-OPG also had significantly higher tibial BMD than those that received AAV-BGal. The enhanced BMD in AAV-OPG animals occurred in conjunction with significant increases in bone volume and significant reductions in osteoclast surfaces in the proximal tibial metaphysis. In a separate study, a single IV injection of 4 week old mice with AAV-OPG resulted in systemic exposure to pharmacologic levels of OPG for the lifespan of the mice (>16 months). In contrast to the hepatic lesions induced by Ad, the AAV vector elicited no systemic toxicity as revealed by normal architecture in liver and peripheral lymphoid organs and the absence of AAV-related increases in circulating activities of hepatocellular enzymes. These data demonstrate that a single inoculation with AAV-OPG can reverse established osteopenia in OVX mice without evidence of systemic toxicity. Thus, AAV delivery appears to be a safe and effective method to produce sustained systemic exposure to OPG.

Bioactive Compounds of Denshen Prevent Bone Loss in Rat Models of Osteoporosis. L. Cui[1], T. Wu*[1], L. Y. Zou*[1], Y. Y. Liu*[1], Y. F. Deng*[2]. [1]Department of Pharmacology, Guangdong Medical College, Zhanjiang, China, [2]Guangdong Key Laboratory for Research and Development of Natural Drugs, Guangdong Medical College, Zhanjiang, China.

Danshen (*Salvia miltiorrhiza* Bunge), a traditional herbal medicine, has been widely used in clinical practice in China for the prevention of cardiac diseases, arthritis and other inflammation-related diseases. Tens of individual compounds have been extracted from danshen and their chemical structures have been demonstrated. The purpose of current studies was to determine whether the ethanol extract (EEX) and water extract (WEX) of danshen could prevent bone loss in rat models of osteopenia. The known bioactive individual compounds in EEX are tanshinone IIA and cryptotanshione while known bioactive individual compound in WEX is danshensu. In the first study, EEX at 100 mg/kg (equals to 17.2 mg/kg of tanshinone IIA, 8 mg/kg of cryptotanshione) or vehicle were given by daily oral gavage to 4-month-old ovariectomized (OVX) rats starting one day post-surgery for 10 weeks. Trabecular bone histomorphometric analysis of proximal tibial metaphysis and fourth lumbar vertebral body showed that a significant decrease in trabecular bone volume (TBV) and trabecular number (TBN) and a significant increase in osteoclast surface (OCS/BS) and mineralizing surface (MS/BS) were found in OVX controls compared with sham controls. EEX significantly prevented the decreases in TBV and TBN and the increase in OCS/BS. However, EEX had no effect on MS/BS and uterine weight compared with vehicle-treated OVX controls. In the second study, 4-month-old Spragus-Dawley male rats were received either 2.7 mg/kg/day of prednisone oral gavage or prednisone plus WEX of danshen at dose of 128 mg/kg/day (equals to 25mg/kg/day of Danshensu) for 10 weeks. Treatment with prednisone significantly decreased body weight, bone calcium content, bone hydroxyproline content, and significantly increased serum calcium compared with vehicle controls. Further, decreased TBV and TBN and increased OCS/BS were found in proximal tibial metaphysis in rats treated with prednisone compared with vehicle controls. Treatment with WEX completely prevented the above changes induced by prednisone. Our data illustrate that ethanol extract (EEX) of danshen prevents OVX-induced bone loss and water extract (WEX) of danshen prevents glucocorticoid-induced bone loss in rats. Inhibition of elevated bone resorption is likely the mechanism for their bone protective effects of these extracts. These results demonstrate that the ethanol extract (EEX) and the water extract (WEX) of danshen may have potentials for prevention and treatment of skeletal disorders such as osteoporosis in human.

2-Methoxyestradiol Induces Cell Death in Osteoclasts. A. Maran[1], M. J. Oursler[2], G. Gorny*[2], M. Zhang*[1], R. T. Turner[1]. [1]Orthopedic Research, Mayo Clinic, Rochester, MN, USA, [2]Dept. of Biology, University of Minnesota, Duluth, Duluth, MN, USA.

The effects of 2-Methoxyestradiol (2-ME), a naturally occurring metabolite of 17β-estradiol on cultured osteoclast cells were investigated. 2-ME at 5 μM concentrations decreased cell survival by more than 95% in 3 osteoclast model systems (RAW 264.7 cells cultured with RANKL, mouse marrow ST2 cells co-cultured with stromal support cells and spleen cultured without support cells in media supplemented with RANKL and M-CSF) that were examined. 2-ME treatment resulted in the induction of osteoclast apoptosis in RAW 264.7 cells, mouse marrow co-culture system and in spleen cells by 65%, 39% and 55% respectively. Also, 2-ME treatment resulted in the inhibition of osteoclast differentiation in RAW 264.7 cells and mouse marrow co-culture system. 2-ME was ligand specific, its immediate precursor (2-hydroxyestradiol) and the equivalent metabolite of estrone (2-methoxyestrone) did not reduce cell number or induce osteoclast apoptosis. Co-treatment with ICI 182,780 did not block the 2-ME mediated decrease in cell number, suggesting that the cytotoxic effect of 2-ME is not estrogen receptor mediated. Also the 2-ME mediated induction of cell death in RAW 264.7 cells coincided with an increase in gene expression of the proapoptotic cytokines tumor necrosis factor (TNF)-α, interferon-β and transforming growth factor (TGF)-β. TNF-α mRNA levels showed a time-dependent increase with 2-ME treatment and increased by 3-fold at 12 hrs and by 8-fold at the end of 72 hrs. Interferon-β and TGF–1 mRNA levels increased by 7-fold and 2.5-fold respectively at the end of 72 hrs of treatment. These findings suggest that 2-ME could be useful for treating skeletal diseases, such as postmenopausal osteoporosis in which bone resorption is increased. This conclusion is supported by recent *in vivo* studies demonstrating that 2-ME prevents bone loss by inhibiting bone resorption in ovariectomized rats by a non-estrogen receptor mediated pathway.

AMG 162 Maintains Serum Concentrations for up to 9 Months Following a Single Subcutaneous Dose in Healthy Postmenopausal Women. M. C. Peterson[1], B. J. Stouch*[1], D. Chen*[1], S. Baughman*[1], D. L. Holloway[2], A. Rasmussen*[2], P. Leese*[3], L. Galitz*[3], C. R. Dunstan[4], P. J. Bekker[2], A. DePaoli*[2], S. W. Martin[1]. [1]Pharmacokinetics and Drug Metabolism, Amgen Inc., Thousand Oaks, CA, USA, [2]Clinical Research, Amgen Inc., Thousand Oaks, CA, USA, [3]Quintiles, Lenexa, KS, USA, [4]ANZAC Research Institute, Concord, Australia.

RANKL (Receptor Activator of NF kappa B Ligand) is an essential osteoclastic differentiation and activation factor. The pharmacokinetics of AMG 162, a fully human monoclonal antibody to RANKL, was evaluated in postmenopausal women in this randomized, double-blind, placebo-controlled, single-dose, dose escalation study. Six cohorts of 8 to 9 women randomly received a single subcutaneous (SC) injection of either AMG 162 or placebo (3:1 ratio). AMG 162 doses were 0.01, 0.03, 0.1, 0.3, 1.0, and 3.0 mg/kg. Serum levels of AMG 162 were measured by a validated enzyme-linked immunosorbent assay. The pharmacokinetics of AMG 162 following single dose SC administration to postmenopausal women is summarized in the table below.

Following SC administration, AMG 162 serum levels rose rapidly reaching maximum average concentrations of 50 ng/mL (0.01 mg/kg) to 36,400 ng/mL (3.0 mg/kg) at 5.8 to 21 days post-dose. As the dose increased from 0.1 to 3.0 mg/kg, a plateau in serum levels (>2000 ng/mL) was observed which lasted for 14 days at 0.1 mg/kg to 6-months at 3.0 mg/kg. Thereafter, when concentrations dropped below approximately 1000 ng/mL, a more rapid terminal elimination phase was observed that was dose-dependent, with slower rates of elimination at higher doses.

Subcutaneous Pharmacokinetics Parameter Estimates for AMG 162 in Postmenopausal Women

Parameter	Units	AMG 162 SC Dose (mg/kg)					
		0.01 (n=6)	0.03 (n=6)	0.1 (n=6)	0.3 (n=6)	1.0 (n=6)	3.0 (n=7)
Tmax	days	5.8	8	6.8	21	19.2	13.7
Cmax	ng/mL	50	547	721	2230	8990	36400
Plateau Half-life	days	N/A	N/A	N/A	32.4	32	28
Terminal Half-life	days	5.6	5.0	4.9	7.7	11.3	12.6
MRT	days	11.3	16.1	20.5	33.9	43.6	45.1

N/A = Not able to determine

In conclusion, AMG 162 maintained serum levels for a prolonged period (up to 9 months) following a single SC dose of 3.0 mg/kg and potentially allows for infrequent SC dosing in the treatment of bone disorders, such as osteoporosis and cancer related bone diseases.

Rapid, Profound, and Sustained Suppression of N-Telopeptide Following Administration of AMG 162, a Fully Human Monoclonal Antibody Against RANKL, in Cynomolgus Monkey. M. C. Peterson[1], B. J. Stouch*[1], D. Chen*[1], S. Baughman*[1], A. DePaoli*[2], C. R. Dunstan[3], S. W. Martin[1]. [1]Pharmacokinetics and Drug Metabolism, Amgen Inc., Thousand Oaks, CA, USA, [2]Clinical Research, Amgen Inc., Thousand Oaks, CA, USA, [3]ANZAC Research Institute, Concord, Australia.

AMG 162 is a fully human monoclonal antibody that binds with high affinity and specificity to RANKL (Receptor Activator of NF kappa B Ligand). A pharmacokinetic (PK) and pharmacodynamic (PD) study of AMG 162 in cynomolgus monkeys following single dose intravenous (IV) and subcutaneous (SC) administration of 0.005 to 3.0 mg/kg has been performed. Thirty-three monkeys were separated into 11 dosing groups: five SC groups, five IV groups, and 1 SC placebo group (n = 3/dose/route). Serum levels of AMG 162 were measured by a validated enzyme-linked immunosorbent assay. Serum N-Telopeptide (sNTx) was used as the PD marker of bone resorption measured by competitive ELISA (Ostex; Bothel, WA). Within 24 hours of dosing, AMG 162 caused a rapid suppression of sNTx. Maximum suppression of sNTx occurred between 1 and 10 days post dose. Average maximum suppression (SD) increased from 14% (9.8) to 71% (4.4) and from 7.7% (7.2) to 75% (3.4) as IV and SC doses increased, respectively. Duration of sNTx suppression increased with dose to a maximum of 56 days (3.0 mg/kg SC). Both extent and duration of effect were similar following IV and SC administration. Following IV administration, AMG 162 demonstrated non-linear PK with a 16-fold decrease in clearance (4.40 to 0.277 mL/hr/kg) as doses increased. Serum IV profiles were generally tri-phasic, exhibiting a rapid distribution phase (t1/2=3.9 hrs), a slower secondary phase (t1/2=96 hrs), and a rapid terminal phase (t1/2=8.4 to 37 hrs). Volume of distribution ranged from 30 to 50 mL/kg, indicating limited distribution outside the systemic circulation. Following SC administration, AMG 162 peak concentrations were observed 10.7 to 96 hours post-dose. In general, as serum levels of AMG 162 decreased below 2000 ng/mL placebo-normalized sNTx levels started to return towards baseline. A PK/PD model was developed and will be presented, in which AMG 162 inhibited the synthesis of sNTx. In conclusion, AMG 162 was a highly effective bone antiresorptive agent, producing rapid and profound suppression of sNTx, and has demonstrated favorable PD and PK profiles following single dose administration to cynomolgus monkeys. These results suggest that AMG 162 may allow for infrequent SC dosing in the treatment of bone disorders, such as osteoporosis and cancer related bone diseases.

An Orally-Bioavailable Cathepsin K Antagonist with Anti-Resorptive Activity In Vivo. D. B. Kimmel[1], B. Pennypacker[1], S. B. Rodan[1], G. Wesolowski[1], L. T. Duong[1], S. Venkatraman*[2], E. Setti*[2], Z. Q. Tian*[2], J. Palmer*[2], R. M. Oballa*[3], J. Robichaud*[3], P. Prasit*[3], J. P. Falgueyret*[3], D. Riendeau*[3], M. D. Percival*[3], G. A. Rodan*[1]. [1]Bone Biology and Osteoporosis, Merck Research Laboratories, West Point, PA, USA, [2]Medicinal Chemistry, Celera, South San Francisco, CA, USA, [3]Medicinal Chemistry, Merck-Frosst Canada, Kirkland, PQ, Canada.

Cathepsin K (CatK), a cysteine protease, cleaves Type I collagen at acidic and neutral pH and is highly and selectively expressed in osteoclasts. The object was to identify orally bioavailable Cat K inhibitors as potential anti-resorptive agents.
Compound A (*N*-(1-{[(cyanomethyl)amino]carbonyl} cyclo-hexyl)-4-[2-(4-methylpiperazin-1-yl)-1,3-thiazol-4-yl] benzamide) is a fully reversible inhibitor of human, rabbit, and rat CatK (Ki's of 0.2, 0.5, and 5nM, respectively). Compound A inhibits human Cathepsins B, L, and S with Ki's of 1, 6, and 47µM, respectively. Compound A is a potent inhibitor of bone resorption *in vitro* (rabbit osteoclasts on bovine bone assay) with an IC_{50} of 5nM.
When given orally once daily for 27 weeks to adult (7mo, 3.9kg) newly-ovariectomized (OVX) rabbits, Compound A partially (2mg/kg/d, P<.05) or fully (10mg/kg/d, P<.001) prevented bone loss and preserved bone strength in the second lumbar vertebra.
When given orally once daily for 8-11 days to 15-year-old OVX rhesus monkeys at four years post-OVX (0.6, 3, or 15mg/kg/d), A decreased urinary NTx/Cre (n-telopeptides) by 31% (P<.01), 68% (P<.0001), or 76% (P<.0001), respectively. UNTx/Cre returned to control (vehicle monkeys) levels ten days post-treatment cessation.
We conclude that an orally-bioavailable small molecule that selectively (vs. CatB, CatL, and CatS) inhibits rabbit and human CatK with sub nanomolar potency: 1) blocks bone resorption in vitro; 2) fully blocks estrogen deficiency bone loss in adult rabbits; and 3) suppresses bone resorption in estrogen deficient non-human primates in a reversible fashion. Small molecule, selective CatK inhibitors have the potential to prevent and/or treat post-menopausal osteoporosis.

HIV Protease Inhibitor Ritonavir Disrupts Osteoclast Cytoskeleton through Preventing RANKL Induced Membrane Recruitment of TRAF6. M. W. Wang, R. Faccio, S. Takeshita, S. L. Teitelbaum, F. P. Ross. Pathology, Washington University School of Medicine, St. Louis, MO, USA.

We previously reported that HIV infected patients treated with protease inhibitors (PIs) have diminished bone mineral density relative to similarly infected individuals not receiving these drugs. Surprising, one of the HIV PIs, ritonavir, was found to be a potentially bone sparing agent based on its ability to abrogate in vitro and in vivo osteoclastogenesis, without affecting osteoblast function. Also, we showed that ritonavir disrupts the osteoclast cytoskeleton with resultant elimination of bone resorption. A specific signaling pathway induced by RANKL that is known to be important in maintaining cytoskeleton integrity, namely PI3 kinase – Akt pathway, was also inhibited by ritonavir.
To elucidate the molecular basis of ritonavir induced osteoclast cytoskeletal disruption, we constructed constitutively active (CA) PI3 kinase (PI3K-CA) and Akt (Akt-CA) containing retroviruses. Osteoclasts transduced with PI3K-CA do not manifest cytoskeletal disruption when treated with ritonavir. In contrast, Akt-CA and control vector transduced cells exhibit cytoskeletal disruption in response to ritonavir. Furthermore, when monitored by phospho-Akt immunoblots, PI3K-CA transduced osteoclasts show enhancement in both the baseline and RANKL stimulated Akt activation, with the enhancement not inhibited by ritonavir. In contrast, the constitutively phosphorylated Akt in Akt-CA transduced osteoclasts is dephosphorylated upon ritonavir exposure. These results indicate that ritonavir inhibition of cytoskeletal disruption acts at or upstream of PI3 kinase activation. The activation of PI3 kinase pathway by RANKL has been shown to require the recruitment of TRAF6-Src-PI3 kinase complex to the membrane surface by ligand activated oligomerization of RANK. Isolation of a lipid raft membrane fraction from pre-osteoclasts demonstrates that ritonavir inhibits RANKL induced recruitment of TRAF6 and Src to the membrane fraction. Establishing specificity, the RANKL induced recruitment of TRAF2 to the lipid raft fraction is enhanced with ritonavir treatment. Thus, the potentially bone sparing HIV PI, ritonavir, inhibits osteoclast function by preventing RANKL induced membrane recruitment of TRAF6 and the subsequent activation of PI3 kinase.

Potent Inhibition of Cathepsin K Results in Inhibition of Bone Resorption in vitro and in vivo in Non-human Primates. G. B. Stroup[1], M. W. Lark*[1], D. F. Veber*[2], S. M. Blake*[1], L. C. Dare*[1], L. A. Day*[1], K. F. Erhard*[1], S. M. Hwang*[1], I. E. James[1], J. U. Jeong*[1], S. J. Hoffman*[1], R. W. Marquis*[1], M. Mcqueney*[1], H. J. Oh*[1], C. R. Person*[1], J. A. Vasko-Moser*[1], T. Tomaszek*[1], D. S. Yamashita*[1], S. Kumar*[1]. [1]GlaxoSmithKline Pharmaceuticals, King of Prussia, PA, USA, [2]none, None, PA, USA.

Cathepsin K (EC 3.4.22.38) has been shown to play an important role in bone matrix degradation during osteoclastic bone resorption. In the current studies we test the ability of a novel compound to inhibit cathepsin K activity and bone resorption *in vitro* and *in vivo,* following oral delivery, using estrogen deficient cynomolgus monkeys with elevated bone turnover. Monkeys were used because, unlike other preclinical species, the mature form of the enzyme is identical to human.
Compound A is a potent inhibitor of cathepsin K (Ki = 0.041nM) that is selective versus cathepsins –B (Ki = 15nM), and –S (Ki = 1.6nM). The compound is not selective versus cathepsins -L (Ki = 0.068nM) and –V (Ki = 0.053nM). We have previously shown that cathepsin L inhibition does not prevent human osteoclastic bone resorption and no effect of cathepsin V on bone turnover has been described. Compound A inhibited resorption by human osteoclasts cultured on bone with an IC_{50} of 20nM. In sections of human osteoclastoma tissue this compound also inhibited native cathepsin K activity with an IC_{50} of 45nM. For *in vivo* assessment, cynomolgus macaques were rendered medically ovariectomized (ovx) by depot administration of a gonadotropin releasing hormone agonist (GnRHa) every 28 days. Six weeks after the first dose, estrogen deficiency was verified and bone turnover markers were significantly higher than baseline. Compound A was administered to eight animals at four dose levels (0, 3, 10 and 30 mg/kg) by oral gavage using a Latin Square experimental design. In this design, animals received each treatment over a series of four study days separated by at least one week. Serum and urine markers of bone turnover were evaluated in timed samples collected over 48 hours from the time of dosing. Treatment with compound A resulted in a significant (p<.05) reduction of serum N-telopeptide of type I collagen (NTX) 1.5, 4, 8 and 24 hours after gavage. At 24 h the levels of reduction were 26%, 40% and 43% at 3, 10 and 30 mg/kg respectively. Urinary NTX corrected for creatinine showed significant reductions from 0-24 hours of 20%, 54% and 49%. Results were similar 24- 48 hours after dosing, showing a sustained impact of the compound. These data strongly suggest that inhibition of cathepsin K by compound A is a viable approach to the treatment of osteoporosis and other metabolic bone diseases.

Bioavailability and Effects of Vitamin D Fortified Cheese on Vitamin D Status in the Elderly. J. L. Johnson*[1], V. V. Mistry*[1], B. L. Specker[2]. [1]Dairy Science, South Dakota State University, Brookings, SD, USA, [2]Martin Endowed Human Nutrition Program, South Dakota State University, Brookings, SD, USA.

Due to changes in the consumption patterns of milk and Process cheese, and to the availability of new methods for the vitamin D fortification of Process cheese, the objective of this study was to determine the effect of 2 months of daily vitamin D3 fortified Process cheese consumption, delivering 600 IU/ vitamin D3 per day, on changes in serum 25-OHD, PTH, and osteocalcin (OC) among the elderly (>60y). In addition, a crossover absorption trial in 4 elderly (>70y) and 4 mid-age adults (18-50y) also was conducted to determine vitamin D2 bioavailability in cheese vs. water. Individuals (N=100) were enrolled in the feeding study and randomly assigned to cheese+vitamin D3, cheese, or no cheese. Cheese (no vit D3, mean vit D intake=529(+/- 69) IU) had an increase in 25-OHD of 1.4 ng/ml (change different from 0, p=0.01), a decrease in PTH of 3.3 pg/ml (p=0.05) and showed no change in OC. The group that consumed the vitamin D3 fortified Process cheese (vit D intake=1034(+/- 54) IU) exhibited a decrease in 25-OHD of –2.4 ng/ml (p=0.0004), with no change in PTH or OC. The control group (mean intake=340(+/-38) IU) showed 25-OHD, PTH and OC concentrations that remained constant. There were differences among the groups in 25-OHD change due to a higher baseline 25-OHD concentration among the cheese+vitamin D3 group at baseline (p<0.001). There were no differences in 25-OHD, PTH, or OC among the groups at study's completion. These results differ from what was hypothesized, so an additional study was conducted to determine whether vitamin D2 was bioavailable from cheese and whether absorption differed by age. The results of this study showed that the elderly individuals absorbed the vitamin D2 from both the water (32750 IU/250ml) dilution and from the Process cheese (5880 IU/2 oz) just as efficiently as the younger individuals. Peak serum vitamin D2 concentration and area under the curve were similar between the elderly and mid-age adults. Vitamin D2 was absorbed more efficiently from Process cheese than from water. Peak serum vitamin D2 concentrations were 14.7 (+/- 1.0) ng/ml per 10,000 IU and 1.7 (+/- 0.4) ng/ml per 10,000 IU (p<0.001) in Process cheese and water respectively, and the area under the curve was 89(+/- 6.6) and 63(+/- 1.5) (p=0.03). In conclusion, we found that vitamin D in fortified cheese is bioavailable and that among elderly 2 months of consuming cheese fortified with 600 IU/vit D was insufficient to maintain serum 25OHD concentrations.

Oral Vitamin D Supplementation Among 12-14 year Old Black Girls. S. Arunabh*, J. Yeh*, S. Pollack*, J. F. Aloia*. Bone Mineral Research Center, Winthrop University Hospital, Mineola, NY, USA.

Vitamin D insufficiency is a major problem among black women living at higher latitudes and may influence bone mass gain during early years of life. Serum 25-OHD levels >70 nmol/L are now considered optimal. AIM: To assess the relationship between serum 25-OHD, PTH and bone mass in adolescent black girls and determine safety and efficacy of supplementation of 50µg/day (=2000 IU/d) of oral vitamin D3. METHOD:We recruited 21 black girls, 12-14 years of age, during late winter. Height and weight were recorded and diet assessed. Fasting blood sample was drawn for serum 25-OHD and PTH. We performed bone densitometry by DXA (Hologic QDR 4500). 14 girls were randomized to 50 µg/d vitamin D_3 and 7 to a matching placebo in a double-masked study for 12 weeks. All participants were asked to optimize their dietary calcium intake to 1200 mg/d. Serum 25-OHD, PTH, fasting urine calcium and 24 hour urine calcium excretion was assessed at study end. RESULTS: Mean BMI was 22.1Kg/m^2 and pubertal development ranged from Tanner stage 2-5. Mean dietary calcium intake was 573 (±279) mg/d and vitamin D intake of 67IU/d (0-284 IU/d). Mean serum 25-OHD level and PTH levels at baseline were 24.7 (±10.7) nmol/L and 44.0 (±17.9) pg/ml respectively. Serum 25-OHD and PTH levels were inversely related, r= -0.43, p= 0.04.

DXA	serum PTH	
	r	p
Total Body BMC	-0.44	0.04
BMC spine L1-4	-0.39	0.08
BMD Total Femur	-0.60	0.004

The mean serum 25-OHD increased by 27.9 (±14.2) nmol/L in vitamin D3 group as compared to an increase of 11.8 (± 6.7) nmol/L in the placebo ($p<0.04$). All participants, except one, attained a serum 25-OHD level of <70 nmol/L. The PTH levels declined to 39.5 (±15.8) pg/ml in the active group and increased to 54.6 (±28.8) pg/ml in the placebo group. Fasting urinary calcium excretion increased from 6.0±3.1 mg/dl to 10.3±7.7 mg/dl (p=ns). There was no hypercalcemia (>10.6 mg/dl) or hypercalciuria (>5mg/kg/day) seen with vitamin D3 supplementation. CONCLUSION: PTH is inversely related to Total body BMC among the adolescent black girls. This suggests that vitamin D-PTH axis could influence achievement of peak bone mass. In addition, we conclude that daily supplementation with vitamin D3 is an effective strategy to enhance vitamin D nutrition. 50µg per day of vitamin D3 is safe but may not be enough to optimize the serum 25-OHD levels (>70 nmol/L).

Comparative Effects of Vitamin K and Vitamin D Supplementation on Prevention of Osteopenia in Calcium-Deficient Young Rats. J. Iwamoto[1], J. K. Yeh[2], T. Takeda*[1], S. Ichimura[3]. [1]Department of Sports Medicine, Keio University School of Medicine, Tokyo, Japan, [2]Department of Medicine, Winthrop-University Hospital, Mineola, NY, USA, [3]Department of Orthopaedic Surgery, Kyorin University School of Medicine, Tokyo, Japan.

The aim of this study was to clarify the difference in the effects of vitamin K and vitamin D supplementation on the development of osteopenia in young rats under mild calcium deficiency. Sixty female Sprague-Dawley rats, 6 weeks of age, were randomized by stratified weight method into six groups with 10 rats in each group: baseline control, 0.5% (normal) calcium diet, 0.1% (low) calcium diet, 0.1% calcium diet + vitamin K (30 mg/100 g), 0.1% calcium diet + vitamin D (25 µg/100 g), and 0.1% calcium diet + K + D. After 10 weeks of feeding, serum, urine, and feces were analyzed, and bone histomorphometric analyses were performed on cortical bone of the tibial shaft and cancellous bone of the proximal tibia. Calcium deficiency induced hypocalcemia, increased serum parathyroid hormone (PTH) and 1,25 (OH)2 D3 levels with decreased serum 25 (OH) D3 level, stimulated intestinal calcium absorption and renal calcium reabsorption, and reduced maturation-related cortical bone gain as a result of decreased periosteal bone gain and enlarged marrow cavity, but did not significantly influence maturation-related cancellous bone gain. Vitamin K supplementation in calcium-deficient rats stimulated renal calcium reabsorption, retarded the abnormal elevation of serum PTH level, increased maturation-related cancellous bone gain, and retarded the reduction in maturation-related cortical bone gain. On the other hand, vitamin D supplementation in calcium-deficient rats stimulated intestinal calcium absorption via increased serum 1,25 (OH)2 D3 level with prevention of the abnormal elevation of serum PTH level, prevented hypocalcemia, reduced the maturation-related cancellous bone gain, and prevented the reduction in periosteal bone gain and enhanced enlargement of the marrow cavity with no significant effect on the reduction in maturation-related cortical bone gain. However, no synergistic effect of vitamin K and vitamin D on intestinal calcium absorption, renal calcium reabsorption, and cancellous and cortical bone mass was found. This study shows that vitamin K supplementation stimulates renal calcium reabsorption, increases maturation-related cancellous bone gain, and retards the reduction in maturation-related cortical bone gain, while vitamin D supplementation stimulates intestinal calcium absorption, and prevents the reduction in maturation-related periosteal bone gain by inducing accumulation of calcium from cancellous and endocortical bone.

Effect of Calcitriol on Serum and Urine Calcium. J. C. Gallagher, R. Satpathy, P. B. Rapuri. Bone Metabolism, Creighton University Medical Center, Omaha, NE, USA.

Hypercalcaemia and hypercalciuria are well known side effects associated with the use of larger doses of vitamin D, active metabolites of vitamin D and calcium supplements. Hypercalcaemia due to vitamin D lasts for weeks whereas with Calcitriol it lasts 24-48 hours. The aim of this analysis was to see if there was any relationship between the development of hypercalcaemia and hypercalciuria. We monitored serum and urine calcium in 489 elderly women randomized to treatment with placebo, calcitriol 0.25 mcg bid (C), conjugated equine estrogen 0.625 mg/d or medroxyprogesterone acetate 2.5 mg/d (ET/HT) and a combination group (C+ET/HT). Serum total and ionized calcium, 24 hour urinary calcium (Nova Nucleus) were measured at baseline, 6th week, 12th week and then every 6 months for 3 years. Hypercalcaemia was defined as serum calcium> 10.0 mg/dl for total calcium and >5.28 mg/dl for ionized calcium, hypercalciuria was 24-hour urine calcium > 400 mg. The protocol allowed a continuation of treatment with a repeat test after 1 week in these cases. Over 3 years mean 24-hour urine calcium increased by 19 mg in the placebo group, 7 mg on ET/HT, 72 mg on calcitriol ($p<0.001$) and 79 mg on the combination ($p<0.001$). As a percentage of tests done over 3 years, hypercalciuria > 400 mg/d occurred in 1.2% on placebo, 4% on calcitriol, 0.6% on ET/HT and 2.8% on C+ET/HT. On calcitriol there were 58 cases of hypercalciuria, 76% returned to normal on the second test and 21% on the third test. On C+ET/HT there were 25 cases of hypercalciuria, 80% returned to normal on the second test and 16% returned to normal on the third test. If 300 mg/d was used as the cut-off, the incidence of hypercalciuria was 7% on placebo, 29% on calcitriol, 6% on ET/HT and 18% on the C+ET/HT. Over 3 years mean serum ionized calcium showed no significant change on placebo, ET/HT or C+ET/HT, but increased 0.04 mg/dl on calcitriol ($p<0.001$). Hypercalcaemia occurred in 6% of patients on placebo, 12% on calcitriol, 5% on ET/HT and 5% on C+ET/HT. In all cases, it was mild and ionized calcium rarely exceeded 5.48 mg/dl. Serum calcium returned to normal in 66% of the cases after 1 week and in 98% after 2 weeks, indicating that the episodes were transient. There was no correlation between serum calcium and urine calcium values during 3 years. Only about a quarter of the hypercalcaemic cases were found to have hypercalciuria. In conclusion, hypercalcaemia and hypercalciuria appear to be independent events during treatment with calcitriol and the episodes are less when calcitriol is combined with estrogen.

Effects of a Long-term Alfacalcidol or Calcitnin Administration on Body Sway in Japanese Elderly Women. T. Koike[1], T. Okawa*[2], M. Wada*[1], T. Kita*[2], K. Takaoka[1]. [1]Orthopaedic Surgery, Osaka City University Medical School, Osaka, Japan, [2]Orthopaedic Surgery, Osaka City Municipal Kosaiin Hospital, Osaka, Japan.

Long-term vitamin D and calcium supplementation are effective in reducing non-vertebral fractures in elderly people. In Japan, alfacalcidol (1 alpha-hydroxycholecalciferol) is very popular as a therapeutic agent for senile osteoporosis. Few studies, however, have demonstrated the increase in bone mineral density (BMD) in the patients who had received alfacalcidol. An alternative explanation for the discrepancy between small increase in BMD and significant reduction in the incidence of non-vertebral fractures might be that alfacalcidol affects factors directly related to fall risk. In this cross-sectional study we investigated the effect of long-term administration with alfacalcidol or elcatonin on BMD, anthropometric measurement and body sway in Japanese healthy old women.
One hundred and forty three women in a nursing home were divided into three groups: group D (n=37) who had received alfacalcidol for over 10 years, group E (n=22) who had received elcatonin for over 10 years and 81 controls (group C). There was no significant differences in age (D: 80.2±7.9, E: 82.4±7.1, C: 79.9±6.7 yrs), body height (D: 144.4±5.9, E: 143.5±6.2, C: 143.2±6.9 cm), body weight (D: 44.0±4.2, E: 46.4±10.0, C: 47.3±9.7 Kg) and lean body mass (D: 32.4±2.4, E: 34.1±5.3, C: 33.9±4.7 Kg) among groups. Lumbar BMD (QDR-2000, Hologic) also did not differ among groups (D: 0.751±0.134, E: 0.788±0.178, C: 0.785±0.175 g/cm2). Body sway was assessed with gravicorder GS-10 (Anima, Japan). Group D showed the significant ($p<0.05$) lower recording area (3.4±2.1 cm2) compared to group E (5.0±3.6 cm2). However, there was no significant difference between group D and controls (Rec. Area 3.9±2.1 cm2). As a performance, those who had received alfacalcidol could stand stably than other groups (mean one-legged standing time; D: 8.7, E: 5.4, C: 4.6 sec, not significant). Although some reports suggested the direct effect of vitamin D on muscle strength, we could not find any differences in grip strength (D: 10.8±4.2, E: 11.0±4.8, C: 11.2±5.3 Kg) or the strength of other skeletal muscles. Our results suggest that long-term administration of alfacalcidol improves body sway and the agent affects coordinative muscle function more than strength. Alfacalcidol therapy should be considered as an approach for fall prevention as well as exercise.

Vitamin D Deficiency and Functional Parameters in Community Dwelling Subjects with Hip Fractures. M. S. LeBoff[1], W. Hawkes*[2], S. Hurwitz*[3], J. Yu Yahiro*[4], J. Magaziner[2]. [1]Endocrine, Diabetes,and Hypertension, Brigham and Women's Hospital, Boston, MA, USA, [2]Epidemiology and Preventive Medicine, University of Maryland, Baltimore, MD, USA, [3]Endocrinology, Diabetes and Hypertension, Brigham and Women's Hospital, Boston, MA, USA, [4]Union Memorial Hospital, Baltimore, MD, USA.

Hip fractures rise exponentially with age and are associated with a high morbidity and progressive loss of muscle mass and function. Most hip fracture subjects lose the capacity to function independently. Available data show that, ≤26 % of patients with hip fractures are treated with calcium and vitamin D (J T Harrington et al. Arth. and Rheum 2002). To evaluate the prevalence of vitamin D and the association of baseline vitamin D levels with functional capacity after a hip fracture, we measured 25-hydroxyvitamin D levels and longitudinal performance measures after a hip fracture in 115 community-dwelling subjects with hip fractures from Boston, MA (n=30) and the Baltimore Hip studies, Baltimore MD (n= 85). 25-hydroxyvitamin D (25OHD) levels were measured by RIA. At 2, 6, and 12 months post fracture, grip strength, leg strength, chair rise, and walking were measured in a subset of 44 to 55 subjects from Baltimore cohort. The age (mean ±SD) for the 2 cohorts were 77.9±9.2 and 79.7 ±8 years, respectively. The median 25-OHD levels were 12.96 and 10.20 ng/ml, for patients enrolled from Boston and Baltimore, respectively. Vitamin D deficiency was defined as a 25-hydroxyvitamin D level of <15 ng/ml.

Vitamin D Deficiency in subjects with Hip fracture (N=115)

	25OHD<5 ng/ml		25OHD<15ng/ml	
	N	(%)	**N**	(%)
Combined Groups	14	12%	78	68%
Boston, MA	4	13%	17	57%
Baltimore, MD	10	12%	61	72.9%

A number of performance measures of functioning were evaluated longitudinally post-fracture, but were not significantly associated ($P<0.05$) with baseline vitamin D levels. In sum-

mary, vitamin D deficiency is very prevalent in community-dwelling American women with hip fractures. There were no significant differences in the change in functional parameters in those subjects with or without vitamin D deficiency at baseline, although, the small number of subjects and those with normal vitamin D levels at the time of hip fractures limited the analyses. Vitamin D deficiency should be identified and treated with pharmacological doses of vitamin D in subjects with hip fractures. Vitamin D deficiency can be prevented and correction of vitamin D deficiency may improve hip fracture repair and reduce future fracture risk.

New Bone Formation Is Impaired in a Model of Type 1 Diabetes Mellitus. K. M. Thrailkill, L. Liu, E. C. Wahl*, Z. Liu*, R. C. Bunn*, W. Hogue*, L. J. Suva, D. S. Perrien, J. L. Fowlkes, J. Aronson*, C. K. Lumpkin. Pediatrics, Orthopedics and Physiology, University of Arkansas for Medical Sciences, Little Rock, AR, USA.

In humans, the presence of type 1 diabetes mellitus (T1DM) imparts several deleterious consequences for skeletal health, including diminished peak height velocity during the pubertal growth spurt, decreased adult bone density, an increased risk for osteoporosis and fracture, poor bone healing and diabetes-induced skeletal embryopathy, processes which rely on *de novo* bone formation. Mechanisms by which T1DM may impede new bone formation (NBF) are unclear, but may involve metabolic derangements and/or autoimmune-mediated events characteristic of the pathogenesis of this disease. To study the effect of T1DM on NBF, we utilized a model of tibial distraction osteogenesis, uniquely modified for use in the non-obese diabetic (NOD) mouse, a model of T-cell mediated autoimmune DM. Nine week old female NOD mice were monitored weekly for glucosuria as confirmation of diabetic conversion. Seven diabetic (urine glucose 1000-2000 mg/dl) and 11 comparably aged non-diabetic mice (negative urine glucose) were studied. Anesthetized animals underwent application of a two-ring external fixator to the left tibia, using four transosseous pins and a mid-diaphyseal, low-energy osteotomy (day 1). Daily manual distraction was initiated on day 4, at 0.075 mm BID, for 14 days. At sacrifice, the lengthened and the contralateral tibiae were surgically removed and plasma was obtained. Distracted tibiae were analyzed radiographically and histologically. Contralateral tibiae were analyzed using pQCT. Plasma glucoses in diabetic vs. control animals were 457.6 ± 70.4 (mean ± SEM) vs. 176.3 ± 9.9 mg/dl ($p \leq 0.001$). A significant reduction in radiographic total NBF in the distraction gap in diabetic animals compared with controls (27.1 ± 9.9 % vs. 61.0 ± 6.5 %, $p \leq 0.01$) was observed. Impairment in NBF was confirmed using μCT on a representative pair of distraction gaps. At sacrifice, 3 of 7 diabetic animals were ketotic; a further disparity was noted in NBF between ketotic and non-ketotic mice (7.4 ± 5.3% vs. 41.9 ± 12.5%; $p = 0.7$). Histological analysis is in progress. Analysis of contralateral tibias by pQCT, showed no significant differences between diabetic and control groups in trabecular, cortical or total bone density; strength strain indices, reflective of 3-point bending strength, were also equivalent. This study demonstrated marked inhibition of rapid intramembraneous NBF in a model of relatively short term T1DM (max. duration of 4 wks), despite an insufficient duration of disease to effect overall bone remodeling.

Increased Length of Long Bones but Decreased Trabecular and Cortical Bone Mineral Density in SOCS2 Deficient Mice. M. Lorentzon[1], C. Greenhalgh*[2], W. S. Alexander*[2], A. L. Eriksson[1], C. Ohlsson[1]. [1]Centre for Bone Research at the Sahlgrenska Academy (CBS), Department of Internal Medicine, Göteborg University, Göteborg, Sweden, [2]Division of Cancer and Haematology, The Walter and Eliza Hall Institute of Medical Research, Royal Melbourne Hospital, Melbourne, Australia.

Growth hormone (GH) is the most important regulator of postnatal body growth. A large part of the growth promoting effect is mediated by GH-stimulated expression of insulin-like growth factor (IGF) 1 in the liver, but also in peripheral tissues. Suppressor of cytokine signaling-2 (SOCS2) is a member of the suppressor of cytokine signalling family. These related proteins have been shown to inhibit cytokine action by interfering with the Janus kinase (JAK) signal transducers and activators of transcription (STAT) signalling pathway. It has been reported that SOCS2 inhibits signalling by GH and that mice lacking SOCS2 (SOCS2 -/-) have increased length of long bones but unchanged levels of IGF-I in serum and in bone (Metcalf, D. 2000, *Nature*: 405: pp1069-1073). In the present study, we show that the longitudinal growth of tibia and femur is unchanged during the early postnatal growth period while it is increased during the later GH-dependent growth period in SOCS2 (-/-) mice, compared to wt mice. Using peripheral quantitative computerized tomography, trabecular bone mineral density (BMD) in the distal metaphyseal area of the femur was found to be decreased by 10 % at 4 weeks of age and by 32 % at 15 weeks of age in SOCS2 -/- mice, compared to wt mice. Cortical BMD, cross sectional bone area, and bone mineral content (BMC), of the femur, was also reduced in 4-week-old SOCS2 -/- mice, but only cortical BMD remained lower in 15-week-old SOCS2 -/-, compared to wt. In conclusion, SOCS2 inactivation results in increased GH-dependent longitudinal bone growth but decreased trabecular and cortical BMD. The effect of SOCS2 inactivation on longitudinal bone growth could be explained by a loss of inhibition of GH-signalling while the mechanism behind the decreased cortical and trabecular BMD remains to be elucidated.

Nail Patella Syndrome: A Potential Model for Altered Architecture with a High Prevalence of Fractures and Mildly Decreased Bone Mineral Density. C. A. Clay, A. Towers*, P. S. Coates, S. M. Sereika*, I. McIntosh*, K. Desai*, S. L. Greenspan. Univ. of Pittsburgh, Pittsburgh, PA, USA.

Nail Patella Syndrome (NPS) is a rare autosomal dominant disorder characterized by hypoplastic or absent patella, dystrophic fingernails and toenails, dysplasia of elbows and iliac horns, and frequently glaucoma and progressive nephropathy. The underlying defect in NPS is caused by loss of function mutations in the transcription factor LMX1B on chromosome 9, which results in an abnormality of collagen type IV. We hypothesized that these patients would have a reduced bone mineral density (BMD). To examine differences in BMD, fracture risk, and scoliosis in patients with NPS, we performed dual x-ray absorptiometry (DXA) in NPS patients [NPS(+), confirmed by genotyping] and their unaffected relatives [NPS(-)]. All participants completed a questionnaire on history of fractures and scoliosis. Results expressed as mean +/- SD.

BMD Z-scores and Percent Fractures

	NPS(+) All (n=43)	NPS(+) Adults (n=34)	NPS(+) Children (n=9)	NPS(-) Controls (n=12)
Age	35±17	41±15	11±2	39±11
Spine Z-score	-0.35±1.30	-0.27±1.36	-0.63±1.07	0.12±0.90
Femoral neck Z-score	-0.55±0.90*	-0.46±0.91*	-0.88±0.79*	0.18±1.08
Trochanter Z-score	-0.84±0.84*	-0.87±0.85*	-0.71±0.83*	0.29±1.01
Intertrochanter Z-score	-0.75±0.91*	-0.90±0.84*	-0.17±0.96	-0.06±0.94
Total hip Z-score	-0.86±0.85*	-0.96±0.82*	-0.47±0.93	0.03±1.02
% Fracture	48.8	52.9	33.3	16.7

Compared to age-matched controls from the Hologic database, NPS(+) patients (6 men, 28 women, 9 children) had BMD at all hip sites that was significantly lower than expected (Z-score=0, *p<0.05) with a similar trend for the spine (p=0.080). Nearly half (48.8%) of the NPS(+) subjects had experienced a fracture, compared to 16.7% of NPS(-) subjects (p=0.055). The odds of fracture for NPS(+) individuals was 4.7 times greater than that of controls (95% CI 0.93 to 24.4). Moreover, the number of fractures per patient was significantly higher than controls, where NPS(+) patients had a mean 1.07 fractures (range 0-5) compared to a mean 0.17 fractures for controls (range 0-1, p=0.035). The number of patients with scoliosis was not significantly different than that observed in the control group (p=0.150). We conclude that NPS(+) patients may be at an increased risk for fracture despite a minimal, yet significant decrease in BMD. Further studies are needed to examine the structural composition, bone architecture, and bone turnover that may account for an increased risk of fractures in NPS(+) patients.

Vitamin D Supplementation in Coeliac Disease Patients on a Gluten-free Diet - a Randomised Controlled Trial. S. Venkatachalam*[1], W. Fickling*[2], D. A. Robertson*[2], A. K. Bhalla[1]. [1]Rheumatology, Royal National Hospital for Rheumatic Diseases, Bath, United Kingdom, [2]Gastroenterology, Royal United Hospital, Bath, United Kingdom.

Osteopaenia which is seen in over 50% coeliac disease patients, improves on a gluten-free diet alone. Our objective was to find if Vitamin D supplementation accelerates the bone density change.

Fifty newly diagnosed coeliac disease patients on a strict gluten-free diet were randomized to either 300,000 IU parenteral Vitamin D or normal saline at baseline and 12 months. Duodenal biopsy confirmed the initial diagnosis and was repeated after 3 months to assess response. Patients with osteomalacia and renal disease and those on steroids and bone active medication were excluded. The recruitment was between July 1996 and March 2000. Bone mineral density (BMD) assessment, bone profile and biochemical markers of bone turnover were done at baseline, 6, 12 and 24 months.

Sixteen men and 34 women were recruited and had a mean age of 53.8 years. Twenty- two patients received Vitamin D and 28, normal saline. Mean age was 49.2 years in the active group and 58.4 years in the placebo. Two patients did not complete the 2 years while another died due to an unrelated cause. Spine BMD g /sq cm increased from 0.917 (0.16-Standard Deviation) to 0.929 (0.16) in the active group and from 0.901 (0.18) to 0.935 (0.2) in the placebo group after 2 years. Total hip BMD increased from 0.863(0.2) to 0.888(0.19) in the active and from 0.829 (0.15) to 0.854 (0.16) in the placebo group.

The active group was younger than the placebo group by 9.2 years on average, which could partly explain the baseline BMD differences. Spine BMD could increase spuriously due to osteoarthritis in older age.

Vitamin D supplementation did not significantly influence bone density increase in coeliac disease patients on a gluten-free diet.

Early Lethality in *Hyp* Mice with Targeted Deletion of the *Pth* Gene. X. Y. Bai*[1], D. S. Miao[2], J. R. Li*[2], D. Goltzman[2], A. C. Karaplis[1]. [1]Medicine, SMBD-Jewish General Hospital, McGill University, Montreal, PQ, Canada, [2]Medicine, MUHC, McGill University, Montreal, PQ, Canada.

Inactivating mutations and/or deletions of *PHEX/Phex* are responsible for *XLH* in humans and for the murine homologue, *Hyp*. Although increased circulating levels of PTH with normocalcemia has been reported in *Hyp* mice, hyperparathyroidism in *XLH* is postulated to arise from the standard use of phosphate salts, which induce chronic stimulation of PTH secretion. In this study, we sought to examine the putative role of PTH in the metabolic derangements associated with *XLH*/*Hyp* by generating hemizygous hypophosphatemic (*Hyp/Y*) mice homozygous for the *Pth*-null allele.

Matings between female *Hyp* and male *Pth*-null mice were conducted to initially obtain *Hyp/Pth*$^{+/-}$ progeny and subsequent intercrossings were used to derive *Hyp/Y-Pth*$^{-/-}$ animals. This genotype was not observed in any of the 639 mice examined following weaning. However, immediately after birth, *Hyp/Y-/Pth*$^{-/-}$ mice were present but only very few of them were alive longer than 72 hr after birth.

To investigate the early lethality of the *Hyp/Y-Pth*$^{-/-}$ mice, analysis of serum biochemistry was performed in the four genotypes (wild-type, *Hyp*, *Pth*$^{-/-}$, *Hyp/Y-Pth*$^{-/-}$) at 0, 6, 12, 24, 36, and 48 hrs after birth. In the *Hyp/Y-Pth*$^{-/-}$ mice, serum phosphate levels increased within the first six hours to levels comparable to those in the *Pth*$^{-/-}$ mice, while in *Hyp* mice, the serum concentration had dropped significantly during the first 48 hr after birth. Serum calcium levels started low after birth and remained reduced in both *Pth*$^{-/-}$ and *Hyp/Y-Pth*$^{-/-}$ mice, although more profoundly so in the latter group (5.5 mg/dL vs. 3.8 mg/dL), while in *Hyp* mice, the levels were initially lower than but reached wild-type levels by 24 hr. Circulating PTH levels in *Hyp* mice were significantly higher than wild-type levels throughout the first 48 hr and continued to be so well into adulthood (2.5-fold). Histological analysis of tissues from the compound mutants failed to identify any cause for their early lethality, although minor alterations were evident in the long bones of these animals.

The present findings indicate that the likely cause of death in the *Hyp/Y-Pth*$^{-/-}$ mice is severe hypocalcemia. A potential role for FGF23 in promoting secondary hyperparathyroidism by suppressing renal 1-α hydroxylase activity is proposed. Hence, the combined effect of low 1,25-dihydroxyvitamin D_3 levels and absence of circulating PTH would then lead to severe hypocalcemia and early lethality of the *Hyp/Y-Pth*$^{-/-}$ mice. Hyperparathyroidism, therefore, is an integral component of the pathophysiology of *Hyp/XLH* that may also contribute to the renal phosphate transport defect in this disorder.

Subcellular Localization and PTH-Dependent Translocation of NaPi-IIa in Renal Proximal Tubular Cells. Y. Taketani, K. Nashiki*, N. Sawada*, H. Yamamoto, M. Ichikawa*, K. Morita, H. Arai, E. Takeda. Department of Clinical Nutrition, University of Tokushima, Tokushima, Japan.

Parathroid hormone (PTH) is most potent and important regulator for the type IIa sodium-dependent phosphate transporter (NaPi-IIa) that plays a key role in the renal phosphate reabsorption to determine Pi homeostasis. PTH inhibits NaPi-IIa activity by leading translocation from apical plasma membrane to intracellular organelle. In this study, we investigated the mechanism of translocation of NaPi-IIa from apical plasma membrane. Our results demonstrated that NaPi-IIa was mostly localized in caveolae of the plasma membrane in OK-N2 cells that stably express human NaPi-IIa or rat kidney by means of both cell fractionation analysis and immunofluorescence analysis. Caveola is a flask-shaped membrane microstructure and a lipid-ordered microdomain enriched in cholesterol and sphingolipids. Caveolae can associate with regulation of many signal transducing molecules as well as endocytosis or potocytosis. We examined whether caveolae can be related to the translocation of NaPi-IIa by PTH. PTH decreased immunoreactive NaPi-IIa in caveolar membrane and Pi transport activity in OK-N2 cells. Methyl-beta-cyclodextrin, which is an inhibitor of caveolae-dependent endocytosis, clearly inhibited the PTH-dependent NaPi-IIa disapperance from caveolae and down-regulation of NaPi-IIa activity. While chrolpromazine that is an inhibitor of clathrin-dependent endocytosis slightly inhibited the PTH action. These data suggest that caveolae would play a key role in the translocation of NaPi-IIa by PTH.

The Response of MEPE to Long-Term and Short-Term Phosphate Supplementation in Healthy Volunteers. H. C. Allen[1], N. S. Fedarko*[2], A. Jain*[2], A. Whybro*[1], M. E. Barker*[1], R. Eastell[1], A. Blumsohn[1]. [1]Bone Metabolism Group, University of Sheffield, Sheffield, United Kingdom, [2]Department of Medicine, Johns Hopkins University, Baltimore, MD, USA.

Matrix extracellular phosphoglycoprotein (MEPE) is one of several putative humoral mediators of phosphaturia in oncogenic osteomalacia and X-linked hypophosphatemia. The hypophosphatemia and hyperphosphaturia associated with these diseases may be partly regulated by MEPE, suggesting that MEPE may also have a role as a physiological 'phosphatonin'. It is uncertain whether serum MEPE responds to altered phosphate intake in healthy humans and whether it has a physiological role in phosphate metabolism

The aim of this study was to examine the effect of short-term and long-term phosphate supplementation on serum MEPE in healthy adults. To examine long-term phosphate supplementation, samples were collected from twelve healthy men (ages 19 – 38 years). Individuals were studied on their habitual diet for one week and then placed on a standardized diet containing 1000mg/d phosphate and 1000mg/d calcium for another four weeks. An escalating dose of supplemental phosphate was provided on consecutive weeks (phosphate intake 1000mg/d, 2000mg/d, 2500mg/d, 3000mg/d on successive weeks). Blood and urine samples were collected before breakfast at the end of each week. To assess the effect of short-term phosphate supplementation, samples were collected from 10 healthy men and women (ages 22-46, mean 30) after either oral placebo (1400mg sodium bicarbonate and 1260mg potassium bicarbonate) or an oral phosphate supplement (2000mg). Supplement or placebo was given in a single dose at 09:30 after an overnight fast in a randomised crossover design. Blood and urine samples were collected over the next four hours. Serum MEPE immunoreactivity was determined using a competitive ELISA which is not specific for full-length MEPE.

Fasting MEPE decreased significantly by 41%$\pm$11 in response to long-term phosphate supplementation. These findings are consistent with anecdodal evidence following phosphate supplementation in patients using this assay. Serum MEPE increased by to 474.86%$\pm$130.9 ($P<0.01$) following acute phosphate supplementation, but a similar increase was observed following placebo supplementation. It is possible that MEPE may show a circadian rhythm, and that this may contribute to the well described rhythm of renal phosphate handling. MEPE is a likely humoral contributor to pathological phosphaturia in XLH and OM. However, the direction of the MEPE response to chronic phosphate supplementation makes MEPE an unlikely candidate as a physiological phosphotonin.

In Vivo **Studies of Cyclooxygenase-2 Knockout Mice.** M. Xu*[1], D. Goltzman[2], G. A. Gronowicz[1], L. G. Raisz[1], C. C. Pilbeam[1]. [1]Medicine, University of Connecticut Health Center, Farmington, CT, USA, [2]McGill Univercity, Montreal, PQ, Canada.

Cyclooxygenase (COX)-2 expression markedly enhances both osteoclast and osteoblast differentiation *in vitro* but the role of COX-2 in bone turnover *in vivo* is unclear. To study COX-2 *in vivo*, we used COX-2 knockout (-/-) mice and their wild type (+/+) littermates bred in a C57Bl/6 x 129 background. Mice were sacrificed at 2, 4 and 10 mo of age. Body weights of COX-2-/- males were the same as COX-2+/+ males at all ages, but weights of 10 mo old COX-2-/- females (23.1 ± 0.8 g, n = 13) were significantly lower than 10 mo old COX-2+/+ females (26.2 ± 0.7 g, n = 19). Previous studies reported that COX-2-/- mice in this background were born with renal abnormalities that resulted in renal dysfunction and early death. As expected, serum creatinine (Cr) levels were significantly elevated in 2 mo old COX-2-/- mice (0.66 ± 0.04 mg/dl, n = 14) relative to 2 mo old COX-2+/+ mice (0.48 ± 0.05 mg/dl, n = 12). At 4 mo of age, Cr levels also tended to be higher in COX-2-/- mice (0.56 ± 0.06 mg/dl, n = 25) than in COX-2+/+ mice (0.45 ± 0.05 mg/dl, n = 31). However, at 10 mo of age, Cr levels in COX-2-/- mice (0.53 ± 0.03 mg/dl, n = 24) were no different from those in COX-2+/+ mice (0.51 ± 0.02 mg/dl, n = 37). Serum calcium (Ca^{++}) levels were significantly elevated in COX-2-/- mice (10.6 ± 0.4 mg/dl, n = 24) relative to COX-2+/+ mice (9.8 ± 0.2 mg/dl, n = 37) at 10 mo of age. Serum PTH levels measured by ELISA tended to be higher in COX-2-/- mice (93 ± 12 ng/dl, n = 23) compared to COX-2+/+ mice (72 ± 7 mg/dl, n = 37) at 10 mo age. $1,25(OH)_2$ vitamin D_3 levels measured by RIA were significantly elevated in COX-2-/- mice (179 ± 15 pg/dl, n = 12) relative to COX-2+/+ mice (123 ± 13 pg/dl, n = 15) at 10 mo age. The combination of elevated serum Ca^{++} and $1,25(OH)_2$ vitamin D_3, without PTH suppression, suggests mild primary hyperparathyroidism in the 10 mo COX-2-/- mice. To avoid the potential effects of renal dysfunction on bone metabolism that may be present in 2 - 4 mo old mice, we are using the10 mo old mice with normal serum Cr to study effects of COX-2 on bone density. Preliminary studies showed significantly lower femoral bone mineral density (BMD) by PIXImus in COX-2-/- females (0.066 ± 0.002 g/cm^2, n = 11) compared to COX-2+/+ females (0.071 ± 0.002 g/cm^2, n = 14). On calvariae histology in 10 mo old males, there was significantly decreased total bone area / total tissue area (TA/TTA) in COX-2-/- males (89.1% ± 2.5%, n = 9) compared to +/+ males (94.7% ± 1.2%, n = 12), with no difference in calvarial width. Our studies suggest that COX-2-/- mice at 10 mo of age have normal renal function, mild primary hyperparathyroidism, and small (6 - 8%) decreases in bone density relative to COX-2+/+ mice.

The Effects of Cinacalcet HCl (AMG 073) on Serum Calcium Levels in Patients with Parathyroid Carcinoma or Recurrent Primary HPT after PTX. S. J. Silverberg[1], C. Faiman*[2], J. P. Bilezikian*[1], D. M. Shoback[3], M. R. Rubin[1], L. C. McCary*[4], K. A. Olson*[4], S. A. Turner*[4], M. Peacock[5]. [1]Columbia Presbyterian Med Ctr, New York, NY, USA, [2]Cleveland Clinic Found, Cleveland, OH, USA, [3]Univ of California, San Francisco, Dept of Veterans Affairs Med Ctr, San Francisco, CA, USA, [4]Amgen Inc., Thousand Oaks, CA, USA, [5]Indiana Univ Sch of Med, Indianapolis, IN, USA.

Parathyroid carcinoma and recurrent primary hyperparathyroidism (HPT) post-parathyroidectomy (PTX) with severe hypercalcemia are rare, but patients are usually symptomatic with nephrolithiasis, nephrocalcinosis, renal insufficiency, bone pain, and osteopenia common. Medical management is challenging given the difficulties associated with PTX and the resistance of parathyroid carcinoma to anti-cancer therapy. The novel therapy, cinacalcet HCl, activates the calcium sensing receptor, resulting in decreased secretion of parathyroid hormone (PTH) and reduction in serum calcium. This open-label, dose-titration trial evaluated cinacalcet HCl in 8 patients with parathyroid carcinoma (n = 6) or recurrent primary HPT post PTX (n = 2) with serum calcium > 12.5 mg/dL. Cinacalcet HCl dose was adjusted sequentially (dose range 30 mg bid to 90 mg qid) throughout a titration phase to achieve a clinically relevant reduction in serum calcium of ≥ 1 mg/dL. The end of the titration phase occurred after 16 weeks or when serum calcium was ≤ 10.3 mg/dL.

Mean (range) serum calcium at baseline was 14.8 (11.8 to 17.9) mg/dL and was 11.2 (8.5 to 13.4) mg/dL at the end of titration phase. The proportion of patients who achieved a target reduction in serum calcium of ≥ 1 mg/dL was 75% (6/8). The baseline mean (range) intact PTH (iPTH) was 705 (137 to 1232) pg/mL. Pre-dose iPTH levels were not reduced, although modest reductions in iPTH were seen at 2 and 4 hours post-dose. Serum calcium and iPTH values at baseline and the end of the titration phase are presented below. Cinacalcet HCl was generally well-tolerated, with gastrointestinal side effects attributed to study drug in some patients.

	Normal	Baseline		End of Titration Phase	
	Range	n	Mean	Mean	Mean Change (SE)
Serum calcium (mg/dL)	8.4 - 10.3	8	14.8	11.2	-3.6 (0.97)
				End of Titration Phase	
				Pre-dose Mean	Hour 2 Mean	Hour 4 Mean
iPTH (pg/mL)	10 - 65	7	705	847	624	647

n = Number of subjects with non-missing baseline and end of titration phase lab values

In these patients, cinacalcet HCl was effective in reducing serum calcium levels. The study continues with serum calcium reductions maintained up to 18 months. Cinacalcet HCl is potentially an effective therapy for the treatment of hypercalcemia in patients with parathyroid carcinoma or recurrent primary HPT after PTX.

Cloning and Expression of Fourteen N-terminally Truncated PTH Fragments and their use for the Validation of Assay Specificities. P. Gao, S. Scheibel*, K. Hakim*, T. L. Cantor. Assay Development and Kit Manufacturing, Scantibodies Laboratory, Inc., Santee, CA, USA.

It was demonstrated that the third generation PTH assay measured human PTH(1-84) without any cross-reaction to the large non-(1-84)PTH fragment (P Gao, et al. J Bone Miner Res 1999;14:S446), which was believed to be N-terminally truncated peptide from the wild type hormone and directly secreted by the parathyroid glands (E Slatopolsky, et al. Kidney International 2000;58:753-761). However, the molecular form or forms of these N-truncated PTH fragments have not been elucidated. To subsequently elucidate which of these candidate N-truncated PTH fragment forms is secreted by the parathyroid gland and to presently demonstrate the specificities of PTH assays, we cloned wild type human PTH(1-84) into IPTG inducible vector pDZ-1; and further mutated and cloned PTH(2-84), (3-84), (4-84), (5-84), (6-84), (7-84), (8-84), (9-84), (10-84), (11-84), (12-84), (13-84), (14-84) and (15-84) into the same expression vector. cDNA sequence analysis revealed correct reading frame of each clone within the vector and also verified the fidelity of each PTH clone sequence. By utilizing appropriate codon optimization strategies in combination with a very strong promotor based pDZ-1 Escherichia coli expression system, we generated recombinant PTH peptides. Using all these recombinant PTH peptides we validated the detection specificities of two routinely used commercial PTH immunoradiometric assays (IRMA), a Whole PTH IRMA or CAP assay (P Gao, et al. J Bone Miner Res 2001;16:605-614) and a Total Intact PTH IRMA. Briefly, wild type recombinant PTH(1-84) as well as the above fourteen N-truncated PTH fragments were spiked and diluted into a PTH zero human plasma at increasing concentrations. These samples were, then, measured using the two PTH assays. The results showed that the Whole PTH IRMA measured the recombinant PTH(1-84) exclusively and did not detect any amount of any of the above N-truncated PTH fragments up to the very high level of 100,000 pg/ml. However, the Total Intact PTH IRMA detected not only the wild type PTH(-84) but also all of the above N-truncated PTH fragments.

In conclusion, we have successfully cloned fourteen N-terminally truncated human PTH fragments with amino acid sequences from 2-84, 3-84, up to 15-84 using a pDZ-1 vector E. coli expression system. It is also demonstrated that the third generation Whole PTH IRMA detects exclusively the wild type human PTH(1-84) without any cross-reaction to any of the N-terminally truncated PTH fragments from PTH(2-84) to PTH(15-84).

Correlation of ABC Transporter Gene Expression and Technetium-99-Sestamibi (99-MIBI) Uptake by Parathyroid Tissue. N. C. Greep, F. R. Singer, A. E. Giuliano*, N. M. Hansen*, H. Wang*, D. S. B. Hoon*, H. Takeuchi*. John Wayne Cancer Institute at Saint John's Health Center, Santa Monica, CA, USA.

Previous studies have suggested that p-glycoprotein (P-gp), a membrane pump belonging to the ATP-binding cassette (ABC) family of membrane transporters, is present in parathyroid tissue and capable of transporting 99-MIBI out of a parathyroid cell. We conducted a pilot study to investigate whether the amount of P-gp (also known as multiple drug resistance or MDR1 protein) and another ABC transporter, MDR-associated protein (MRP), correlates with imaging of parathyroid glands in patients with primary hyperparathyroidism. Paraffin-embedded tissues of normal (n=9) and adenomatous parathyroid tissue (n=14) were obtained from patients who previously had undergone parathyroidectomy for primary hyperparathyroidism at Saint John's Health Center. No normal parathyroid glands were detected by 99-MIBI imaging and 11/14 adenomas were detected. Messenger RNA (MDR1, MRP) was assessed using quantitative Real Time reverse transcriptase polymerase chain reaction (RT-PCR) technique. Glyceraldehyde 3 phosphate dehydrogenase mRNA expression was assessed as a house-keeping gene in all specimens to verify the integrity of the mRNA extracted. Protein expression of the transporters was assessed by IHC using polyclonal goat anti-human MDR1 and anti-human MRP antibodies. We found evidence for both MDR1 and MRP in parathyroid tissue using both RT-PCR and IHC. As assessed quantitatively by RT-PCR, levels of the two transporters were significantly correlated (Spearman correlation coefficient = 0.79, $p < 0.0001$). The expression of both genes was greater in normal parathyroid glands compared to adenomatous glands: median MDR1 was 71 vs. 22 ($p= 0.0018$), and median MRP was 877 vs. 248 ($p= 0.0012$). Although our sample size was small, the activity of the two transporter genes was equally low in eleven 99-MIBI positive adenomas and three 99-MIBI negative adenomas. However, the median weight of the excised abnormal glands which had been 99-MIBI negative was much smaller than those which had been 99-MIBI positive (182 mg vs. 489 mg, $p= 0.027$). We conclude that retention of 99-MIBI by parathyroid adenomas is associated with decreased expression of both the MDR1 and MRP membrane transporter proteins. In addition, failure to visualize a parathyroid adenoma by 99-MIBI imaging may reflect the small size of an adenoma. In such cases the resolution of the gamma camera detector is probably inadequate to localize the tumor, despite reduced ABC transporter activity. This study suggests that downregulation of MDR1 and MRP gene expression occurs in parathyroid adenomas and significantly influences 99-MIBI imaging.

Significance of Metaphyseal Radiolucent Changes Following Ischemic Necrosis of Capital Femoral Epiphysis. H. K. W. Kim, D. Skelton*, E. Quigley*. Shriners Hospitals for Children, Tampa, FL, USA.

Although metaphyseal radiolucent changes are often seen in children with Legg-Calve-Perthes disease, the pathogenesis and the clinical significance of these changes remain controversial. The purpose of this study was to determine the occurrence of metaphyseal radiolucent changes in a piglet model of ischemic necrosis of immature femoral head and to determine the histopathological nature of the metaphyseal changes. The study also investigated whether these lesions are associated with growth disturbance of the proximal femoral physis. The study was approved by the local institutional animal care and oversight committee. Ischemic necrosis was induced in 50 piglets by surgically placing a ligature tightly around the femoral neck. Radiographs and histologic sections of the femoral heads were assessed at 2 to 8 weeks following the induction of ischemia. The radiographs were used to measure the femoral neck lengths to assess for proximal femoral growth disturbance. Thirteen out of 50 femoral heads were found to have metaphyseal radiolucent changes. The metaphyseal radiolucent changes ranged from a focal “cystic” lesion to a diffuse area of radiolucency around the proximal femoral physis. Three distinct types of histological changes were observed. In type I change, a focal thickening of the growth plate was observed extending down to the metaphysis. Some lesions showed cystic degeneration of the thickened cartilage. In type II change, a central disruption of the growth plate and resorption of the metaphyseal bone around the region were observed. Type III change showed diffuse resorption of the growth plate and resorption of the adjacent metaphyseal and epiphyseal bone. The femoral heads with metaphyseal radiolucent changes had shorter femoral necks in comparison to those femoral heads without the metaphyseal radiolucent changes ($p=0.02$), indicating a greater degree of proximal femoral physeal growth disturbance. In conclusion, the metaphyseal radiolucent changes were due to histopathological lesions that involved the growth plate. The study validates the clinical observation that a presence of diffuse metaphyseal radiolucent changes may herald significant growth disturbance of the proximal femur in the patients with Perthes disease. The study provides histopathological basis for the proximal femoral physeal growth disturbance that has not been demonstrated in the past. Our findings may also provide histopathological basis for MRI findings of “metaphyseal cysts” in the patients with Perthes disease.

Bone Mineral Density (BMD) in Childhood Survivors of Acute Lymphoblastic Leukaemia (ALL) Treated without Cranial Irradiation (XRT). M. Z. Mughal, B. M. D. Brennan*, C. Beane*, A. Auld*, K. A. Ward, R. Ashby*, S. M. Shalet*, O. B. Eden*, R. F. Stevens*, A. Will*, S. A. Roberts*, J. E. Adams. Manchester Children's Hospitals, Christie Hospital & the University of Manchester, Manchester, United Kingdom.

We have previously shown that adult survivors of childhood ALL treated with multi-agent chemotherapy, steroids and cranial XRT had a significant reduction in volumetric spinal BMD. In this cross sectional study, we examined the BMD at distal radius, bone geometry at mid-radius and the lumbar spine BMD in 54, [23 males] childhood survivors of ALL who had completed their treatment without XRT at least one year previously, and in age & gender matched controls. Bone mineral content (BMC) and bone area (BA) of L1 to L4 vertebrae (LS) were measured using the Hologic QDR-4500 dual energy x-ray absorptiometer. The bone mineral apparent density (BMAD) of LS was calculated by dividing LS BMC by LS $BA^{1.5}$.The Stratec XCT 2000 peripheral quantitative computer tomography (pQCT) scanner was used to measure the volumetric total (cortical & trabecular) and trabecular BMD at the distal radius (4% site). The endosteal circumference, periosteal circumference, cortical thickness and the axial moment of inertia (related to bending strength) at the mid radius (50% site) were also measured using the pQCT. Data are presented as median (IQR) values. The growth and bone parameters in each ALL subject were compared with that of gender & age matched control using the Wilcoxcon test.

	Childhood Survivors of ALL	Age & Gender Matched Controls	P
Age (yrs)	11.0 (9.0 to13.7)	11.0 (9.0 to 13.8)	0.91
Height (cm)	146 (137 to 158)	147 (137 to 159)	0.81
Weight (kg)	44 (34 to 54)	40 (33 to 55)	0.44
LS BMAD (g/cm^3)	0.21 (0.19 to 0.23)	0.21 (0.20 to 0.23)	0.15
Distal radial total BMD (mg/cm^3)	302 (279 to 328)	294 (276 to 332)	0.66
Distal radial trab. BMD (mg/cm^3)	172 (157 to 188)	180 (162 to 214)	0.0035
Endosteal circumference (mm)	20.1 (18.0 to 22.4)	18.5 (16.4 to 20.6)	0.019
Periosteal circumference (mm)	33.8 (31.4 to 36.5)	32.5 (29.5 to 36.2)	0.36
Cortical thickness (mm)	2.0 (1.8 to 2.3)	2.2 1.9 to 2.5	0.022
Axial Moment of inertia (mm*4)	574 (419 to 749)	501 (348 to 779)	0.77

The distal radial trabecular but not total BMD was reduced in the ALL subjects. At the mid-radial site, we speculate that ALL or its treatment resulted in endosteal bone loss, cortical bone thinning but the axial moment of inertia was not different from controls, probably due to gain in bone at the periosteal surface.

Accelerated Skeletal Growth and Mineral Deposition During Maintenance Chemotherapy in Children with Standard Risk Acute Lymphoblastic Leukemia (ALL). L. J. Moyer-Mileur, J. L. Quick*, R. VanOrden*, C. Bruggers*. Pediatrics, University of Utah, Salt Lake City, UT, USA.

Background: Survival of children with acute lymphoblastic leukemia (ALL) has improved dramatically over the past two decades. Diminished bone mineral density (BMD) has been reported as long-term complication in ALL survivors. The investigation of skeletal growth and mineral acquisition during the early stages of cancer therapy, however, are limited. Objective: To track growth and changes in bone characteristics during maintenance chemotherapy in children with standard risk ALL. Design/Methods: A 12-month longitudinal study of 5 children ages 4-9 y (4F/1M) with standard risk ALL was performed. Subjects were recruited form the Hematology/Oncology Clinical, Primary Children's Medical Center, Salt Lake City, UT. Measurements were obtained at the initiation of maintenance chemotherapy (baseline) and repeated at 6 and 12 months. Cross-section measurements of the tibia by pQCT (XCT2000, Orthometrix) to assess cortical and trabecular bone compartments, bone size and strength; whole body, hip, and spine by dual energy x-ray (DXA, Hologic QDR4500A) for body composition and bone density were obtained. A regional reference (n=68, 38M/30F) was used for comparison. Anthropometrics and diet and physical activity histories were also collected. Average height and weight gains during the intensive and maintenance phases of therapy were calculated. ANCOVA controlling for age, gender, and body size was used for comparison of ALL to reference values. Wilcoxon-signed rank tests were used to examine changes in height, weight, and bone characteristics. Results: At baseline, tibia trabecular BMC (mg) and vBMD (mg/cm3) and cortical thickness (mm), total hip areal BMD (g/cm2) and BMAD (g/cm3/2), and whole body BMC adjusted for fat-free mass were significantly lower in ALL children ($p<0.01$). From baseline to 6 months, height, tibia cortical bone, total hip, spine, and whole body bone characteristic gains were accelerated ($p<0.04$) when compared to gains from 6 to 12months. Tibia trabecular BMC and vBMD values did not change. Dietary intake and physical activity met or exceeded advised levels. Conclusions: This preliminary data suggests that children with standard risk ALL experience accelerated linear growth and rapid recovery of compact bone mass once the intensive chemotherapy is stopped and the maintenance phase of chemotherapy is initiated. The chronic, diminished trabecular bone mass may reflect continued, albeit decreased exposure to chemotherapy agents.

Increased Vertebral Fracture Prevalence is Associated with Time on Dialysis. G. J. Elder, E. Edström-Elder*. Bone and Mineral Program, Garvan Institute of Medical Research, Sydney, Australia.

Patients with end stage renal disease (ESRD) are reported to be at increased risk of fracture, which has been associated with levels of iPTH and bone mineral density (BMD). However both gain and loss of BMD has been reported following commencement of dialysis. In this study prevalence of vertebral fracture was examined in relation to time on dialysis, BMD and biochemical parameters in 63 consecutive patients with ESRD about to undergo a renal or renal-pancreas transplant.

Patients (36 male and 27 female) with median age 42 years (range 22-65) were admitted for transplantation. Haemodialysis or peritoneal dialysis was used in 56 of these, with median time on dialysis 30 months (range 5-120). Insulin dependent diabetes mellitus (IDDM) was the cause of ESRD in 33% of patients. Biochemical parameters were assessed within the 24 hours prior to transplant. Spinal X-rays and BMD by DXA were assessed within 2 weeks of transplantation.

Time on dialysis was positively correlated with lumbar spine and femoral neck Z scores ($p<0.02$; $r^2=0.10$ and $p<0.001$; $r^2=0.19$ respectively). Mean lumbar spine and femoral neck Z scores were normal and as expected were higher at the lumbar spine than the femoral neck (0.12±1.25 vs -0.37±1.26; $p<0.001$). Femoral neck Z scores were lower for patients with IDDM (-1.14±0.85 vs 0.00±1.27; $p<0.001$; ANOVA). Intact PTH values were 4.4 times the assay upper range (median; range 0.4-35 times) and were not associated with time from commencement or mode of dialysis.

Vertebral fracture was detected in 30% of patients and these patients had been on dialysis for longer than those without fracture (46±30 vs 25±20 months; $p<0.003$). However fracture was not associated with BMD, age, gender, IDDM or iPTH levels. Time on dialysis was longer for males than females (38±28 vs 24±18 months; $p<0.05$) and time on dialysis was associated with fracture ($p<0.002$) in logistic regression analysis.

These relatively fit patients had a high prevalence of vertebral fracture associated with time from commencement of dialysis. This may reflect progressive architectural change due to renal osteodystrophy which may mask the influence of BMD in patients with ESRD.

Hyperphosphatemia Is Associated with Renal Osteodystrophy and Vascular Calcification in a Murine Model of Chronic Kidney Disease. R. J. Lund*, M. R. Davies*, K. A. Hruska. Renal Division, Washington University School of Medicine, St Louis, MO, USA.

Hyperphosphatemia and a high CaxP are associated with increased mortality and morbidity in ESRD patients. Increased mortality is primarily cardiovascular in nature and associated with increased vascular calcification (VC), even at a young age. We hypothesize that the increase in VC in Chronic Kidney Disease (CKD) may be in part due to altered bone remodeling and disturbances in serum Pi, and can be treated with BMP-7 by reversing the underlying Renal Osteodystrophy.

1)12 week week old C57Bl6 mice were subjected to electrocautery of the right kidney followed in two weeks by left nephrectomy to create CKD, then randomized into 3 Groups: Sham operated mice fed low Pi chow (0.2% Pi, 0.5% Ca) and calcitriol (20 ng/kg tiw sq); CKD mice fed low Pi chow and treated with calcitriol; CKD mice fed low Pi chow and treated with calcitriol and BMP-7 (10 mcg/kg q week). 2) 10-week old LDLR-/- mice (C57Bl6 background) were given CKD by the same procedure. These mice were fed a high cholesterol (15%) diet and developed hyperglycemia, hypercholesterolemia, intimal and medial aortic calcification. Three groups, sham/high fat, CKD/high fat and CKD/high fat + BMP-7 (10 mcg/kg q week) were evaluated. All groups were maintained on their regimens for 12 wks prior to calcein labeling of mineralization fronts, sacrifice and histomorphometry of distal femur metaphyses.

BUN levels were elevated equally in all of the CKD groups; iPTH levels were elevated only in the CKD high fat animals. In study 1 the iPTH suppression by the calcitriol and low Pi diet resulted in an Adynamic Bone Disorder (osteoid volume, osteoblast perimeters, mineralizing surfaces, bone formation rates, and activation frequency were all decreased). The changes were all reversed to normal or greater levels in the BMP-7 group ($p<.05$). Pi levels were higher in the CKD mice 6.1±0.6mg/dl vs 4.5±1.5mg/dl ($p<0.05$) for the mice treated with BMP-7. In study 2, despite high iPTH levels 176.3±186.6pg/ml in CKD vs 33±26.7pg/ml in sham ($p<0.05$), the underlying osteodystrophy in the LDLR-/- mice was consistent with an ABD (decreased OV/TV, ObN, MS/BS, BFR/TV, and Acf). BMP-7 treatment normalized the osteodystrophy, and there was a reduction in VC by histology staining. Pi levels were reduced from 16.4±0.4mg/dl to 10.1±0.4mg/dl with BMP-7 treatment ($p<0.01$) (Sham Pi 9.9±0.6). Serum Ca levels did not differ among the study groups, and the CaxP mirrored the serum Pi results. This study suggests hyperphosphatemia is a link between Renal Osteodystrophy and VC in a CKD diabetic, hypercholesterolemic murine model and can be successfully reversed by treating the Osteodystrophy and altered bone remodeling with BMP-7 therapy.

Mice Lacking the αvβ3 Integrin Develop Severe Inflammatory Osteolysis. K. Aya[1], C. Pham*[2], S. Wei[1], K. Roth*[3], F. P. Ross[1], S. L. Teitelbaum[1]. [1]Pathology and Immunology, Washington University School of Medicine, St. Louis, MO, USA, [2]Medicine, Washington University School of Medicine, St. Louis, MO, USA, [3]Pathology, University of Alabama at Birmingham, Birmingham, AL, USA.

Neo-angiogenesis and osteoclastogenesis are believed central to the pathogenesis of the periarticular bone loss attending inflammatory arthritis. Since the αvβ3 integrin is expressed on osteoclasts and inflamed endothelial cells, and is essential for optimal bone degradation, the heterodimer presents itself as a potential therapeutic target in inflammatory osteolysis. To test this hypothesis we assessed the impact of αvβ3 deletion on the natural history of experimental inflammatory arthritis. To this end we compared the severity of experimental arthritis and attendant bone loss in β3 integrin null (β3-/-) mice and their heterozygous litter mates (β3+/-), the latter being indistinguishable from wild type. These animals were injected with 250μL serum from spontaneously arthritic KRN/NOD mice. The procedure was repeated two days later and at this time was accompanied by administration of 50 μg LPS. The animals were sacrificed on day 14 at which time 100% of each genotype had developed clinically apparent arthritis. Paw swelling, bone erosions and histological scoring of inflammation were slightly but significantly ($p<.05$) reduced in β3-/- as compared to β3+/- arthritic mice but in each circumstance the magnitude of disease was substantial. In keeping with this conclusion,
angiogenesis was indistinguishable between the two strains as was the number of osteoclasts. (β3+/-24.9+/-9.7 vs. β3-/- 24.4+/-14.6/mm2). Furthermore, while increased M-CSF expression compensates for αvβ3 deletion in the osteoclastogenic process in the basal state, we find marrow M-CSF increased to similar levels in both strains of arthritic mice. These data suggest that while αvβ3 blockade holds promise as an anti-osteoporosis strategy, it will be ineffective in preventing the bone loss of inflammatory arthritis.

Bone Loss Due to Glucocorticoids; Update of a Systematic Review of Prospective Studies in Rheumatoid Arthritis and Other Diseases. M. C. Lodder*[1], W. F. Lems[1], P. J. Kostense*[2], A. C. Verhoeven*[2], B. A. C. Dijkmans[1], M. Boers*[2]. [1]Rheumatology, 4 A 42, VU University Medical Center, Amsterdam, Netherlands, [2]Clinical Epidemiology and Biostatistics, VU University Medical Center, Amsterdam, Netherlands.

Objective: To quantify glucocorticoid (GC)-induced bone loss through a meta-analysis of prospective cohorts.
Methods: A previous systematic review up to 1996 (ref) was extended by an exhaustive search of published studies in MEDLINE (1995 to 2002), web of science (2000 and 2001), Cochrane databases (1995 to 2002), and bibliographic references. Prospective studies of patients receiving systemic GC who underwent serial bone mineral density (BMD) measurements by dual energy X- ray absorptiometry were included. Only suppletion with calcium or vitamin D was allowed. The primary outcome was the change in lumbar spine BMD in one year. The overall estimates are weighted means of the individual study arm results (weight=inverse variance).
Results: Of 1727 abstracts, 34 studies (39 study arms) remained. Two transplantation studies with very high GC doses caused heterogeneity and were excluded from further analyses. In the remaining study arms, 20 studied GC starters (602 patients) and 16 patients on chronic GC (405 patients). One study investigated both GC starters and chronic users (142 patients). Mean GC dosis was 8.9 mg (range 3.3 to 16.4 mg) prednisone equivalents. Weighted BMD decrease was –1.61% (95% confidence interval –1.84 to –1.37) per year (n=1149) in the lumbar spine and –1.45% (–1.76 to –1.14) at the hip (n=991). In exploratory regression analyses, the start of GC use, higher mean daily dose of GC, and either no suppletion or suppletion with calcium alone, were independent predictors of high bone loss at the lumbar spine. At the hip, only the start of GC use was such a predictor. The best regression models yield an explained variance of 73% at the spine and 51% at the hip, respectively.
Conclusion: In GC doses up to 16.4 mg prednisone equivalents/day, this review yields strong evidence for a yearly loss of 1.5% BMD in both spine and hip, and reinforces the need for adequate preventive measures, especially in patients starting therapy.

Autocrine and Paracrine TNF-mediated Apoptosis in Human Osteoblasts. C. W. Borysenko*, Y. Li, R. Bu, L. J. Robinson*, H. C. Blair. Pathology and Physiology & Cell Biology, University of Pittsburgh and Pittsburgh VAMC, Pittsburgh, PA, USA.

TNF is critical to bone destruction and inflammation in hyper-resorptive pathologies, such as rheumatoid arthritis; however, the mechanisms linking TNF to such periarticular bone destruction are controversial. Net bone catabolism can be initiated either by osteoclast formation or by osteoblast apoptosis. There is evidence for TNF stimulation of osteoclast formation via indirect mechanisms. There is also evidence of direct TNF-mediated apoptosis in non-human osteoblasts, but in human osteoblasts TNF-mediated apoptosis is controversial. We studied the occurrence and functional activity of TNF-family ligands and receptors in nontransformed human osteoblasts and osteosarcoma cells. Findings included that TNFRI mRNA is consistently expressed. Typically, MG63 osteosarcoma cells express the cell-surface receptor at low density (~500 copies per cell), consistent with reports that human osteoblasts are insensitive to TNF-induced apoptosis. For comparison, we determined that the TNF-sensitive cell line U937 has an ~ 7-fold higher TNF-binding capacity. However, we found that osteoblast cell density and growth conditions can alter the expression levels of TNF-family members. In media containing fetal bovine serum, osteoblasts and osteosarcoma cells express not only TNFRI but also TNF, albeit with TNF and TNFRI expressed at highly variable levels. Flow cytometry using anti-TNF suggested that this is due to variable growth phases, where in MG63 cultures a 5-10% subpopulation of cells bound anti-TNF at levels consistent with ~ 10-fold higher receptor expression, similar to that of U937 cells. Further, the sub-population with enhanced TNF-binding was highly sensitive to apoptosis, as demonstrated by annexin V binding. Sensitive cells shared morphologic features with the population of nonsensitive cells in most respects but over half of the sensitive cells are less granular and have a smaller diameter, suggesting nonsecretory or inactive osteoblast phenotype. We found that the proportion of sensitive MG63 cells was increased by cytokine withdrawal, suggesting that the local environment of osteoblasts, including growth factors and probably also cell cycle and differentiation phase, regulate the sensitivity of osteoblasts to TNF-mediated apoptosis. Thus, in environments predominated by inflammatory cytokines, such as in rheumatoid arthritis, the proportion of osteoblasts possessing high TNF-binding capacity would be expected to be sensitive to apoptosis. Taken together, these results are consistent with a functional TNF-mediated apoptotic pathway in human osteoblasts, which may be regulated by autocrine, paracrine, or exocrine stimuli.

Combination Therapy with Rapamycin and Cyclosporine A or Prednisone Affects Chondrocyte Proliferation and Differentiation. C. P. Sanchez, Y. He*. Pediatrics, UW Medical School, Madison, WI, USA.

Rapamycin, an immunosuppressant, when administered alone considerably affects endochondral bone formation in young rats. It is unknown, however, if combination therapy with other immunosuppressive agents that are used to maintain the renal allograft has the same effects on growth and the growth plate. Thus, 52 male weanling rats, 48± 5 grams, were randomly divided into 4 groups: Control (N=13) received saline, Pred + Rapa (N=13) received Prednisone and Rapamycin, Rapa + CsA (N=13) received Rapamycin and Cyclosporine A, and Pred + CsA (N=13) received Prednisone and Cyclosporine A. Prednisone was given at 3 mg/kg/day, Rapamycin was given at 2.5 mg/kg/day, and Cyclosporine A was given at 7.5 mg/kg/dose by gavage route. The animals were sacrificed after 14 days (N=24) and after 28 days of treatment (N=28). Body weight and body length were obtained weekly. Blood was collected for serum calcium, phosphorus, intact PTH, and IGF-I. The proximal tibia was collected, decalcified and sections were obtained for growth plate morphometry, in-situ hybridization and immunohistochemistry experiments.
Gain in body weight was less in animals that received Rapa + CsA and Rapa + Pred, 52±10 grams and 50±14 grams, compared to Control, 73±8 grams after 14 days of therapy, $p<0.001$. Gain in body length was shorter in the Rapa+CsA and Rapa+Pred groups, 7±0.8 cm and 7±0.8 cm, compared to Control, 9±0.5 cm, $p<0.001$. Serum calcium, phosphorus and IGF-I levels were lower in the Rapa+Pred animals, 8.8±0.6 mg/dl, 10±0.4 mg/dl, 766±159 pg/ml, compared to Control 10±0.4 mg/dl, 11±0.4 mg/dl and 912±195 pg/ml. Serum PTH levels were lower and tibial length measurements were shorter in all treated animals compared to the Control group. The width of the growth plate and the area occupied by the hypertrophic zone were wider, whereas the area of the proliferative zone was less in the Rapa+CsA animals compared to the other groups. The expression of type II and type X collagen is considerably lower in the Rapa+CsA animals. Gelatinase B staining was much lower in all treated groups. Tartrate staining for acid phosphatase was increased in the Pred+CsA animals and expression for Indian hedgehog protein was less in Pred+CsA and Rapa+Pred animals. There was no difference in the expression of IGF-I protein, IGF-I receptor and PTH/PTHrP receptor in all groups. Thus, rapamycin either alone or in combination with Cyclosporine A or Prednisone affects growth, chondrocyte proliferation and chondrocyte differentiation in young rats.

Osteoporosis in Adult Survivors of Pediatric Cardiac Transplantation May Be Related to Hyperparathyroidism, Mild Renal Insufficiency and Increased Bone Turnover. A. Cohen*[1], L. J. Addonizio*[2], J. M. Lamour*[2], P. Gao*[3], E. Shane[1]. [1]Medicine, Columbia University College of Physicians and Surgeons, New York, NY, USA, [2]Pediatrics, Columbia University College of Physicians and Surgeons, New York, NY, USA, [3]Scantibodies Lab, Inc., Santee, CA, USA.

Adults who undergo cardiac transplantation (CTX) commonly develop bone loss and fractures. Hypothesizing that adults who have had a CTX during childhood would also develop osteoporosis, we studied adult survivors of pediatric CTX in a case-control, cross-sectional evaluation of bone mineral density (BMD), indices of mineral metabolism and bone turnover markers. Nine patients (2 women), who were transplanted between ages 12-16, were evaluated (ages 21-32) and compared to age, gender and race matched controls (C). Patients (P) had CTX at a mean of 12±4 years prior to BMD evaluation and were treated with prednisone (mean dose at evaluation: 6±3 mg/day), azathioprine, and cyclosporine or FK506. Mean BMD Z scores in P were -2.3±0.9 at the spine (LS), -1.4±0.6 at the total hip (TH), -1.6±0.7 at the femoral neck (FN), and -3.2±0.7 at the distal radius (DR). BMD Z scores were significantly higher in C (LS: -0.47±1.2, TH: 0.37±0.8, FN: 0.18±1.0, DR: 0.06±0.9; p<0.001 vs. P at all sites by paired t test). Osteoporosis (Z≤-2) was present at the LS, FN and DR in 56%, 33%, and 100% of P, respectively. Although body mass index was similar between P and C, current height compared to midparental height was significantly lower in P (-8.2±4 vs. 0.5±8 cm; p=0.03). Bone mineral apparent density (g/cm^3), which corrects for the effect of smaller bone size of P on BMD, remained significantly lower in P than C at the LS (p=0.007), FN (p=0.001) and DR (p=0.003). By paired t test, parathyroid hormone (PTH) was 3-fold higher in P when measured by the intact assay (P: 75±19, C: 25±7 pg/mL; p<0.001) and 2-fold higher by the "whole" (1-84) assay (P: 32±8, C: 15±4 pg/mL; p=0.001). Serum calcium, phosphorus, 25-OH vitamin D and 1,25 $(OH)_2$ vitamin D were not different between P and C. Bone specific alkaline phosphatase (P: 35±13, C: 26±10 U/L; p=0.007), osteocalcin (P: 12±7, C: 7±2 ng/mL; p=0.06) and serum N-telopeptide (P: 30±14, C: 16±2 nM BCE; p=0.03) were higher in P than C. BUN was higher in P (P: 30±12, C: 17±5 mg/dL; p=0.04) and creatinine clearance tended to be lower (P: 83±42, C: 114±26 ml/min; p=0.07). Testosterone did not differ between male P and C. In summary, BMD is significantly lower in adult survivors of pediatric CTX, particularly at the DR, a site sensitive to excessive PTH secretion. Low BMD in this population may be related to mild renal insufficiency, hyperparathyroidism and increased bone turnover. We conclude that adult survivors of pediatric CTX should be evaluated for osteoporosis.

Bone Density Is Stable After Discontinuing Antiresorptive Therapy During the Second Year after Cardiac Transplantation. V. Addesso[1], A. Cohen*[1], D. J. McMahon*[1], P. Namerow*[2], S. Maybaum*[1], D. Mancini*[1], E. Shane[1]. [1]Medicine, Columbia University, College of Physicians & Surgeons, New York, NY, USA, [2]Population & Family Health, Columbia University, Mailman School of Public Health, New York, NY, USA.

The first year after cardiac transplantation (CTX) is characterized by rapid bone loss. We reported, in a randomized clinical trial (RCT), that alendronate (ALN; 10 mg QD) and calcitriol (1,25D; .25 mcg BID) were comparably effective in preventing bone loss at the spine (LS), femoral neck (FN) and total hip (TH) in this setting. Although we had previously noted that rapid bone loss was confined to the first year (Y) after CTX, others have noted significant bone loss in Y2 after discontinuing 1,25D. To determine if ALN or 1,25D can be safely discontinued one year after CTX, we measured bone density (BMD), mineral metabolism and bone turnover at 12, 18 and 24 months (M) after CTX in subjects who completed the RCT on ALN or 1,25D and in control subjects (CON; n=16) who received no preventive therapy in Y1. Blinding of subjects and investigators was maintained in Y2. Because of the differing pharmacology of ALN and 1,25D, we hypothesized that the 1,25D (n= 25) group would sustain bone loss and the ALN (n=34) group would not.

At 12M after transplantation, before stopping ALN and calcitriol, the 1,25D group had higher serum calcium (SCa) (CON: 9.3+.1; ALN: 9.2+.1; 1,25D: 9.6+.1 mg/dl; p=.02); urine Ca (UCa) also tended to be higher in the 1,25D group (CON: 112+23; ALN: 140+16; 1,25D: 180+19 mg/24h; p=.06) and PTH tended to be lower (CON: 39+7; ALN: 41+5; 1,25D: 27+6 pg/ml; p=.16). CON had higher bone alkaline phosphatase (BAP) (CON: 24.3+2.3; ALN: 18.3+1.6; 1,25D: 18.1+1.8 U/l; p<.04) and serum NTX (CON: 21.4+1.9; ALN: 16.7+1.3; 1,25D: 15.9+1.5 nmol/l; p<.05).

Over the second year, UCa fell (180+19 to 119+19 mg/24h; p=.003) in the 1,25D group, as did serum Ca (9.6+ .1 to 9.3+ .1 mg/dl; p=.03); both remained stable in ALN and CON. Also in 1,25D, BAP increased by 57% (18.1+1.8 to 28.4+2.0 U/l; p=.0001) and serum NTX increased by 30% (15.9+1.5 to 20.5+1.6 nmol/l; p=.0001). Neither changed in ALN. During Y2, LS BMD (g/cm2) increased by 3.2% in CON (1.049+.04 to 1.083+.04; p =.04) and was stable in ALN (1.052+.03 to 1.063+.03) and 1,25D (1.059+.03 to 1.066+.03; p=ns). FN and TH BMD remained stable in all groups.

In summary, after discontinuing ALN and 1,25D, BMD remained stable during the second year after CTX, despite marked increases in bone turnover in the 1,25D subjects. The stability of BMD despite discontinuing these therapies at 12M suggests that patients with normal BMD by one year after CTX may safely be observed without risk of excessive bone loss.

Factors Determining the Prevalence of Osteoporosis and Fractures a Year after Successful Kidney Transplantation. N. A. T. Hamdy[1], M. J. K. Mallat*[2], N. Bravenboer[3], P. Lips[3], J. W. de Fijter*[2]. [1]Endocrinology & Metabolic Diseases, Leiden University Medical Center, Leiden, Netherlands, [2]Nephrology & Transplantation, Leiden University Medical Center, Leiden, Netherlands, [3]Endocrinology, Free University Medical Center, Amsterdam, Netherlands.

Successful renal transplantation (Tx) corrects many of the metabolic abnormalities leading to renal osteodystrophy. Bone disease is however prevalent post-Tx and persistent hyperparathyroidism and use of immunosuppressive agents are the main contributory factors. Data interpretation has been so far confounded by variables such as time elapsed, spanning months to years post-Tx, and variable graft function. We have examined the prevalence of osteoporosis, fractures and histologic bone disease in 33 kidney Tx recipients analysed between 12 and 18 months post-Tx. All patients were asymptomatic, had stable graft function (creatinine clearance > 50 ml/min) and agreed to have a transiliac bone biopsy. There were 19 men and 14 women, 9 of whom were post-menopausal not on HRT. Median age was 50, range 22-67 years. All patients had been on dialysis (CAPD, n= 20; HD, n=13) for a median of 3 years (range 3 month-14 years). Immunosuppression consisted of prednisone and cyclosporin or mycophenolate mofetil. Mean serum creatinine was 121± 5 µ mol/l. Serum calcium was mildly elevated in 8 patients (mean 2.47± 0.03mmol/l), although intact PTH concentration was increased in the majority (26/33 patients: mean 11.69± 0.94 pmol/l). Bone alkaline phosphatase activity was increased in 16 patients (mean: 21.62± 2.71µ g/l). Four patients had low serum 25-hydroxyvitamin D levels. Lumbar spine (LS) and femoral neck (FN) BMD were respectively 0.95± 0.02 and 0.76± 0.02. Ten patients had osteoporosis as defined by a T-score <-2.5 at LS and/or FN. 25 patients had osteopenia at the FN. There was no significant correlation, between age, sex, mode and years on dialysis or any biochemical parameter measured and the presence or absence of osteoporosis. Six osteoporotic patients, one postmenopausal woman and 5 men, had prevalent vertebral fractures. High bone turnover was the predominant histologic feature, and only one (vitamin D replete) patient had evidence for a mineralisation defect. Osteoporosis is prevalent in a 1/3 of patients a year after successful renal Tx and is associated with asymptomatic vertebral fractures in 2/3 of these. Bone turnover is not suppressed despite the use of glucocorticoids. Hyperparathyroidism which is prevalent does not predict the presence of osteoporosis, neither do other biochemical parameters of bone turnover.

PTH Anabolic Induced Gene in Bone (PAIGB), a Novel Gene which may Play an Important Role in Bone Formation. J. A. Robinson, V. Susulic*, W. Zhao, Y. Kharode, V. Gironda*, Y. B. Liu*, M. Wasko*, R. Murrills, F. Bex. Women's Health Research Institute, Wyeth Research, Collegeville, PA, USA.

While the role of Parathyroid hormone (PTH) in calcium regulation and bone metabolism is well known, its biological activity on bone is quite complex as demonstrated by its catabolic and anabolic activities. These conflicting activities may in part be attributed to the fact that PTH can signal through at least two different pathways. These pathways include the cAMP dependent protein kinase A (PKA) pathway and the phospholipase C dependent protein kinase C (PKC) pathway. We were particularly interested in the anabolic action of PTH in order to identify new bone anabolic targets. Therefore, studies utilizing rapid amplification of differentially expressed genes (RADE) were performed on tibia RNA samples obtained from PTH treated Sprague Dawley rats . Here we describe the identification of a novel gene designated PAIGB whose expression was induced selectively by a PTH anabolic treatment (40 ug/kg/day s.c. for 8 days) but not by a catabolic treatment with continuous infusion of the same daily dose. PAIGB is a 145 amino acid cytoplasmic protein which is highly conserved between human, mouse and rat species. Analysis of other tissues demonstrated PAIGB expression in the brain, heart and kidney, however, PAIGB expression was not regulated by PTH in these tissues. To localize the expression of PAIGB in bone, PTH 1-34 was administered subcutaneously to mouse calvariae in a regimen previously shown to be anabolic (20 ug/kg/day s.c. for 18 days). Subsequent immunohistochemical analysis of vehicle treated calvariae demonstrated minimal endogenous PAIGB protein expression whereas the PTH treated calvariae demonstrated selective expression in the osteoblasts adjacent to the bone surface within the periosteum and endosteum. In vitro studies demonstrated that PAIGB mRNA expression was maximally induced after 4hr of PTH treatment in rat and human osteoblastic cells. Although we found that other bone forming factors including PGE2, dexamethasone and Vit D3 can induce PAIGB expression modestly, PTH was by far the most potent inducer. Experiments with phosphodiesterase inhibitors (Rolipram), PKC inhibitors (19-27 peptide) and adenylate cyclase activators and inhibitors (Forskolin and SQ22536 respectively) suggest that PAIGB is regulated by PTH through the cAMP/PKA and not the PKC pathway. This conclusion was supported by the fact that PTH 3-34, which has a minimal effect on adenylate cyclase activation, was unable to induce PAIGB expression.

In summary, we describe a novel protein which is rapidly regulated by PTH in osteoblasts through the PKA pathway and which is selectively induced in bone by an anabolic treatment of PTH.

In Vitro and In Vivo Characterization Of PTH-Fc Constructs: C-Terminal Truncation of PTH-(1-34) Reduces Receptor Affinity and Pharmacologic Responses. V. Shalhoub[1], H. Tan*[1], M. Grisanti*[1], S. Morony[1], K. S. Warmington*[1], G. Biddlecome*[2], S. Simonet*[1], S. Adamu*[1], T. Boone*[3], D. L. Lacey[1], P. J. Kostenuik[1]. [1]Metabolic Disorders Research, Amgen Inc., Thousand Oaks, CA, USA, [2]HTS Molecular Pharmacology, Amgen Inc., Thousand Oaks, CA, USA, [3]Protein Science, Amgen Inc., Thousand Oaks, CA, USA.

Infrequent injections of a sustained duration PTH construct [PTH-(1-34)-Fc]increase BMD in mice, rats and monkeys. Despite their overall anabolic effect, PTH constructs including PTH-(1-34)-Fc cause increased bone resorption that can lead to hypercalcemia. We tested whether C-terminal truncations of PTH-(1-34) would reduce the calcemic effects of PTH-(1-34)-Fc while maintaining anabolic activity. Recombinant PTH-(1-34)-Fc includes human PTH-(1-34) fused to the Fc fragment of human IgG1. Stepwise C-terminal truncations of PTH-(1-34)-Fc were made down to PTH-(1-20)-Fc. A single SC injection of PTH-(1-34)-Fc caused transient hypercalcemia in young mice. C-terminal truncations had progressively diminished calcemic effects when injected at equimolar doses. Anabolic activity was assessed with semi-quantitative X-ray analysis of young mice treated SC with different PTH-Fcs. PTH-(1-34)-Fc and PTH-(1-31)-Fc were the most potent constructs in this assay, and C-terminal truncations were progressively less potent. In vitro studies revealed that PTH-(1-34) and PTH-(1-34)-Fc had similar binding affinities for the PTH1 receptor, while truncated fragments of PTH-(1-34)-Fc had progressively diminished affinity. Anabolic PTH fragments are typically active in cAMP and PKA assays, so we examined these responses in MC3T3 osteoblasts treated with PTH-Fc constructs. C-terminal truncation of PTH-(1-34)-Fc resulted in progressive decreases in potency in both of these assays. Treatment of MC3T3 cells with PTH-(1-34)-Fc dose-dependently increased IGF-I mRNA (a putative mediator of osteoblast stimulation by PTH), and this induction was significantly diminished with C-terminal truncations. PTH activates osteoclasts in part by decreasing osteoblast production of OPG, a natural inhibitor of bone resorption. PTH-(1-34)-Fc dose-dependently suppressed OPG mRNA in MC3T3 cells, and the truncated PTH-Fcs had progressively diminished potency in this assay. In summary, the stepwise truncation of PTH-(1-34)-Fc from the C-terminus resulted in fragments that have progressively diminished PTH1R binding affinity and decreased potency in assays of PTH1R activation, osteoblastic gene expression, hypercalcemia, and anabolic activity. These data suggest that the catabolic and anabolic effects of PTH constructs are tightly coupled and closely related to their binding affinity for PTH1R.

Hypocalcemia and Parathyroid Hormone Increase a Novel Secreted Phosphoprotein 24 kDa (Spp24) in Kidney and Bone Cells. M. J. Beckman[1], A. Bajwa*[1], R. L. Horst[2], R. Dalgleish*[3]. [1]Biochemistry, Virginia Commonwealth University, Richmond, VA, USA, [2]Natl. Animal Disease Center, Ames, IA, USA, [3]Genetics, University of Leicester, University Road, United Kingdom.

Osteodystrophy is a multifactorial disease of unknown etiology. In this disease, cortical kidney dystrophy leads to impaired renal handling of mineral homeostasis and increased blood levels of parathyroid hormone (PTH). Similar conditions can be generated by dietary calcium (Ca) restriction leading to secondary hyperparathyroidism. Using a dietary model of secondary hyperparathyroidism and a hypercalcemic model induced by $1,25(OH)_2D_3$, cortical kidney tissues from the two models were compared for differential gene expression by differential display RT-PCR (DD) and by oligonucleotide microarray (MA). In both techniques one common gene was preferentially regulated by the conditions of low serum calcium and high PTH, and its expression was suppressed by hypercalcemia. The transcript of this gene was isolated in DD. Sequencing identified the product as the 24 kDa secreted phosphoprotein (Spp24). The regulation pattern of Spp24 in kidney was opposite that of another secreted phosphoprotein, namely Spp1 or osteopontin. The tissue distribution of Spp24 was analyzed by Real-Time RT-PCR and found to have strong expression in liver, kidney and bone and weak expression in muscle, lung and parathyroid gland. Quantitative Real-Time RT-PCR in cortical kidney also confirmed a 3.5-fold increase in Spp24 transcript in hypocalcemic compared to control rat kidney, which was similar in magnitude to the differential expression of Spp24 observed between low and high blood Ca conditions that were observed in MA. This indicates that the increase in Spp24 under low Ca conditions is influenced by PTH. Treatment of human proximal kidney (HK-2) and fetal osteoblast (FOB) cells with PTH 1-34 increased Spp24 transcript 2-fold, whereas, PTH-1-34 treatment to these cell types in the absence of Ca in the medium increased Spp24 transcript levels by an additional 2-fold over the control. The few studies on Spp24 in the literature indicate that this molecule is secreted into the extracellular space and has some ability to combine with the futin-mineral complex that accumulates in serum and bone. In conclusion, Spp24 is a novel phosphoprotein produced in several calciotropic organs in response to changes in serum Ca and additionally in response to PTH. The exact role of Spp24 in Ca metabolism is now under study.

Vitamin D Status as a Major Factor Determining Circulating Levels of Parathyroid Hormone. J. Pepe*[1], E. Romagnoli*[1], I. Nofroni*[2], S. De Geronimo*[1], E. D'Erasmo*[1], S. Minisola[1]. [1]Department of Clinical Sciences, University of Rome, Rome, Italy, [2]Department of Experimental Medicine and Pathology, University of Rome, Rome, Italy.

The aim of the study was to investigate the relative contribution of the major factors regulating calcium homeostasis in determining the circulating levels of PTH. We studied a large group of healthy volunteers which included 137 males (mean age 48.0 ± 18.8 yr; range 17 - 90 yr) and 125 females (50.5 ± 19.9 yr; range 19 - 92 yr). The women's group was subdivided according to gonadal status in 55 fertile and 70 postmenopausal subjects.
Metabolic study included a fasting blood morning sample for the measurement of serum total Ca, Mg, P, albumin, creatinine, total ALP and 25(OH)D levels. Circulating PTH levels have been determined by 3 different IRMA. The first one (PTH S) measures serum hormone levels using two affinity-purified polyclonal antibodies, one specific for the 1-34 portion of PTH molecule and the second specific for the 39-84 sequence of the hormone (N-tact PTHSP, DiaSorin Inc., Stillwater, MN, USA). PTH plasma levels were also measured by two other IRMA (Duo PTH Scantibodies Lab. Inc.; Santee, CA, USA) sharing polyclonal anti-PTH (39-84) coated beds as universal solid phase. The first assay (PTH W) utilizes a second polyclonal antibody, directed against the N-terminal (1-4) aminoacid sequence. The second assay (PTH T) utilizes a second antibody specific for the 7-34 region. Concentrations of fragments lacking 1-6 aminoacid sequence (PTH N-truncated, PTH N-t) were determined by the difference of values between PTH T and PTH W. For each kind of PTH assay, multiple linear regression models of the numerous independent variables examined were constructed.
Vitamin D was the main explicative variable almost in every model both considering the group as a whole (PTH S: $R2 = 0.238$, $p < 0.0001$; PTH W = R2: 0.08, $p < 0.001$; PTH T R2: 0.145, $p < 0.0001$; PTH N-t: R2: 0.081, $p < 0.009$) and separately men and women, pre- and postmenopausal subjects.
In subjects with vitamin D insufficiency ($n = 53$) (serum 25(OH)D < 30 nmol/L), mean serum levels of PTH were significantly higher ($p < 0.001$) than those in subjects of similar age with normal vitamin status ($n = 209$) with all the assays employed (PTH S: 36.5 ± 12.8 ng/L vs 29.6 ± 11.8; PTH W: 23.9 ± 10.5 vs 18.4 ± 9.4; PTH T 39.3 ± 13.9 vs 31.4 ± 13.4) the only exception being represented by the N-t fragments.
This study provides information as regards the factors regulating PTH secretion in physiological conditions, that for the first time have been simultaneously considered; it demonstrates the central role of 25(OH)D. Vitamin D status represents a parameter to be taken into consideration in evaluating subjects with parathyroid hormone values above the normal range.

Sustained PTH-stimulated cAMP Signaling in Primary Osteoblasts from ßarrestin2 KO Mice Leads to Altered Skeletal Response to Intermittent PTH. D. D. Pierroz[1], V. Glatt[2], R. Rizzoli[1], S. L. Ferrari[1], M. L. Bouxsein[2]. [1]Division of Bone Diseases, University Hospital, Geneva, Switzerland, [2]Orthopedic Biomechanics, Beth Israel Deaconess Medical Center, Boston, MA, USA.

Cytoplasmic ß-arrestin2 (ßarr2) plays an important role in desensitization of PTH-stimulated cAMP signaling. We hypothesized that absence of ßarr2 would lead to sustained cAMP signaling in primary osteoblasts in vitro and altered skeletal response to PTH in vivo.
Thus, we investigated PTH-stimulated cAMP signaling in primary osteoblastic cells from neonatal calvariae of ßarr2 KO and WT mice and the skeletal response to intermittent PTH (20, 40, 80 µg/kg/d) or vehicle (VEH) for 4 wks in adult WT and KO females (n=6-11/group) using pDXA and µCT.
In presence of a phosphodiesterase (PDE) inhibitor, IBMX (1µM), PTH dose-dependent stimulation of cAMP was 50-70% higher in KO compared to WT cells ($p<0.0001$). Moreover, in cells pre-exposed to PTH, cAMP response to rechallenge with PTH (100nM) was significantly desensitized in WT (-34.5%, $p=0.0001$) but not in KO cells. In absence of IBMX, differences in PTH-stimulated cAMP levels between KO and WT cells were even more dramatic (54±1 vs 19±7 fold increase over baseline, respectively, $p<0.001$), and peak cAMP levels were maintained for up to 30 min. in KO cells, whereas at that time they had declined by 33% in WT cells ($p<0.0013$). These results are consistent with ß-arrestin-mediated inhibition of cAMP signaling through both receptor uncoupling from G protein and recruitment of PDE.
Compared to VEH, PTH significantly increased total body (TB) BMC, whole femur density (F. BV/TV), mid-femoral cortical thickness (C.Th), and vertebral trabecular density (V. BV/TV) ($p=0.0011$-0.0001). Significant interaction with genotype was found for C.Th ($p=0.02$) and F. BV/TV ($p=0.07$), indicating increased cortical bone response to PTH in KO, particularly at the lowest PTH dose (C.Th, PTH20 vs VEH, +10%, $p=0.0019$ and +0%, ns, in KO and WT, respectively). In contrast, V. BV/TV and the percent increase in TB BMC were, on average, 10% ($p=0.011$) and 25% ($p=0.06$) lower, respectively, in PTH-

treated KO compared to WT.
These data indicate that absence of ß-arr2 leads to sustained and prolonged cAMP signaling in primary osteoblasts, which is less desensitized in response to PTH. This increased PTH activity in vitro translates in vivo into increased net anabolic effects on cortical but not cancellous bone in KO mice. Consistent with our previous observations in male ßarr2 KO mice, these results suggest that, in absence of ßarr2, some downstream molecular mechanisms for PTH activity in cancellous bone/bone marrow may be dysregulated.

A High Calcium Intake Promotes Positive Bone Balance via a PTH-Dependent Mechanism. Y. Xue*[1], J. Li*[1], H. Su*[2], A. C. Karaplis[2], D. Goltzman[1], D. Miao[1]. [1]Department of Medicine, Calcium Research Lab, McGill University, Montreal, PQ, Canada, [2]Medicine, SMBD-Jewish General Hospital, McGill University, Montreal, PQ, Canada.

Increased dietary calcium intake reduces bone loss in aging individuals and may increase bone mass and reduce fracture risk. Although this has been ascribed in part to reduction of secondary hyperparathyroidism, the mechanism of calcium action on the skeleton is unclear. To investigate this issue we examined the effect of a high calcium diet on the skeleton of mice with targeted disruption of the PTH gene ($PTH^{-/-}$). $PTH^{-/-}$ mice and wild-type (WT) littermates were fed either a normal (1.0%) or high (2.0%) calcium diet. On a normal calcium diet, serum $1,25(OH)_2D_3$ levels were 113 ± 6 pg/ml in WT mice and 55 ± 9 pg/ml in $PTH^{-/-}$ mice but on the high calcium diet were reduced to 4.5 ± 0.5 pg/ml and 5.0 ± 0.6 pg/ml in WT and $PTH^{-/-}$ mice respectively. On the normal calcium diet serum calcium was 2.5 ± 0.1 mmol/L and 1.6 ± 0.1 mmol/L in WT and $PTH^{-/-}$ mice respectively but on the high calcium diet calcium levels in both groups were within the normal range (2.5 ± 0.1 mmol/L in WT and 2.3 ± 0.1 mmol/L in $PTH^{-/-}$). In the WT mice serum PTH levels fell from 44 ± 8 pg/ml on a normal calcium intake to 18 ± 4 pg/ml on the high calcium intake; PTH levels were undetectable in $PTH^{-/-}$ mice. Bone formation rates (assessed by double calcein-labeling) and alkaline phosphatase positive osteoblast numbers were increased in both mouse models on the high compared to the normal calcium intakes but both increases were greater in WT than in $PTH^{-/-}$ mice. On the high calcium intake TRAP-positive osteoclast size and numbers decreased and the ratio of OPG/RANKL bone mRNA increased in WT but not in $PTH^{-/-}$ mice. Overall, on the high calcium intake, trabecular bone volume rose in WT animals by 61-68% but fell by 7-21% in $PTH^{-/-}$ mice. The results indicate that (1) calcium may not directly alter osteoclastogenesis but may reduce PTH-dependent osteoclast production (2) calcium may enhance bone formation in the absence of PTH but this response in more robust in the presence of PTH. Increases in dietary calcium may therefore increase trabecular volume by enhancing the anabolic action of endogenous PTH.

Transcriptional Profiling of Embryonic Tibia after PTH Treatment in vivo Reveals Numerous Genes that Are Affected by PTHR Activation. J. Guo[1], G. Short*[2], A. Szczepanik*[1], N. Elmessadi*[3], F. R. Bringhurst[1], H. M. Kronenberg[1]. [1]Endocrine Unit, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA, [2]Microaaray Facility, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA, [3]Microarray Facility, Massachusetts General Hospital and Harvard Medical School, Boston, MA, USA.

The PTH/PTHrP receptor (PTHR) delays chondrocyte hypertrophy, and this process is accompanied by global changes in gene expression involving molecular events such as signal transduction and regulation of transcription. To identify genes involved in PTHR-modulated chondrocyte differentiation, we used cDNA oligonucleotide microarray analysis (13,000 murine genes –Operon set) to compare gene expression profiles of E14.5 embryonic tibial explants 6 hr after ex vivo treatment with rPTH(1-34) (100 nM) vs. vehicle alone. Thirty eight genes were significantly up-regulated (ratio > 2.0) and 61 genes were down-regulated (ratio < 0.5) in PTH-treated samples compared to control samples on four separate chips, using 4 independent RNA pools. To validate the potential downstream target genes identified in the arrays, we performed real-time PCR (RT-PCR) and in situ hybridization analysis on a subset of the genes identified as significantly regulated on DNA chips. Results from 14 out of the18 genes tested by RT-PCR confirmed the DNA chip data. Among up-regulated genes confirmed by RT- PCR were Wnt-7B, Wnt inhibitory factor 1 and secreted frizzled-related sequence protein 4. Interestingly, osteopontin, a marker for hypertrophic differentiation, was dramatically up-regulated by PTH and this increased expression of osteopontin in hypertrophic chondrocytes was further verified by in situ hybridization. Decreased expression of Hedgehog-interacting protein, bone sialoprotein and PTHR was confirmed by real-time PCR. In summary, these data could provide a new insight into the understanding of molecular events involved in PTHR-directed chondrocyte differentiation.

Effect of α-N-Methylation of Residues in the Receptor-Binding Region of hPTH(1-31)NH_2 on Structure and Adenylyl Cyclase Activation. G. E. Willick*, J. Barbier*, S. MacLean*, J. F. Whitfield. Biological Sciences, National Research Council, Ottawa, ON, Canada.

The functional recognition of a peptide hormone such as the potently anabolic hPTH-(1-31)NH_2 (Ostabolin™) for its receptor depends on both the side-chains of the amino acids and the carbonyl and amide groups of the peptide backbone. Although the effect of amino acid residue mutations is frequently studied, relatively little attention has been directed towards the CO and NH groups of the backbone. These groups frequently are important determinants of the specificity of the hormone-receptor interaction. For example, N-methylating the backbone NH functions of residues modulates the specificity of somatostatin for its receptor sub-types (Rajeswaren *et al* 2001 J Med Chem 44**:** 1305). The S17–V31 residues of hPTH-(1-31)NH_2 were selectively N-methylated and their adenylyl cyclase (AC)-stimulating activities measured in HKRK-B7 cells stably expressing the hPTHR1 receptor. In these cells, hPTH(1-31)NH_2 stimulates both the AC and phospholipase-Cβ signaling pathways. The effect of the methylations on the peptide's secondary structure was measured by circular dichroism (CD) spectroscopy. Methylation of the three C-terminal residues (QDV) had little effect on the α-helix content and did not diminish AC activity. Methylating the N-terminal residues (SME) reduced helix content by 25% and AC-stimulating activity by about 75%, but methylation of R20 resulted in little AC loss despite a similar 25% loss of α-helix. Methylation of residues E22-L28 (EWLRKKL) resulted in a loss of at least 50% of the helix content and an almost total loss of AC-stimulation with the exception of residues E22 and K26, that retained about 10% and 25%, respectively, of AC stimulation activity. These results point to a loss of some AC-stimulating activity associated with the loss of stability of the C-terminal amphiphilic α-helix, but also to the backbone nitrogens associated with V21, W23, L24, R25, K27, and L28 being critical for correct receptor-activating binding.

Development of PTH(1-14)-based Antagonist Analogs that Bind to the Juxtamembrane Portion of the PTH-1 Receptor. N. Shimizu*, J. C. Tsang*, A. Khatri*, T. J. Gardella. Endocrine Unit, Massachusetts General Hospital, Boston, MA, USA.

For GPCRs in general, ligands that function as antagonist and/or inverse agonists can be useful probes of ligand-binding and receptor activation mechanisms. For the PTH-1 receptor (P1R), most antagonists are N-terminally truncated analogs of PTH(1-34) or PTHrP(1-36), which are thought to bind predominantly to the receptor's amino-terminal extracellular ("N") domain. Here we sought to develop antagonists that bind exclusively to the portion of the P1R that contains the seven transmembrane helices and extracellular loops (the "J" domain). We started with the J domain-specific agonist, [Ac_5c(aminocyclopentane carboxylic acid)[1], Aib(aminoisobutyric acid)[3], Gln^{10}, Har^{11}, Ala^{12}, Trp^{14}]PTH(1-14)NH_2 {[M4]PTH(1-14)}, which functions as a potent agonist in cells (COS-7 or LLC-PK1) transfected with either the intact P1R or a P1R construct deleted for the N domain (EC_{50} for cAMP production ~ 2 nM; E_{max} ~ 50-fold basal; Shimizu et al. 2003, J. B. M. R. Vol 17, abstract # SU246). Based on the known importance of the N-terminal residues of PTH for inducing receptor signaling, we introduced single or multiple amino acid substitutions at positions 1-3 of [M4]PTH(1-14). The Analog [Bpa^2,M4]PTH(1-14), in which Val-2 was replaced by benzoylphenylalanine, exhibited adequate binding affinity {IC_{50} ~ 1 μM, vs. ~30 nM for [M4]PTH(1-14)} and very weak agonism (EC_{50} >> 10 μM; E_{max} ~ 5-fold basal). We then introduced Deg (diethylglycine) at positions 1 and 3, as these paired substitutions confer partial agonism to [M4]PTH(1-14) (*ibid*). The resulting analog [$Deg^{1,3}$,Bpa^2,M4]PTH(1-14) maintained adequate affinity (IC_{50} = ~0.8 μM), but was nearly devoid of agonism (E_{max} < 2-fold basal). On the intact P1R, [$Deg^{1,3}$,Bpa^2,M4]PTH(1-14) (10 μM) inhibited the agonist activity of [M4]PTH(1-14) (1 nM) by ~70% but was ineffective against PTH(1-34) (1 nM); PTHrP(5-36) (10 μM) inhibited [M4]PTH(1-14) by ~60% and PTH(1-34) by ~85%. On a P1R construct having the N domain replaced by PTH residues (1-9) (tethered to TM1) and which thus exhibits high "basal" activity, the basal activity was inhibited ~ 50% by [$Deg^{1,3}$, Bpa^2, M4]PTH(1-14) but only ~ 10% by PTHrP(5-36). Analogs [Bpa^2, M4]PTH(1-14) and [$Deg^{1,3}$, Bpa^2, M4]PTH(1-14) were selective inverse agonists, as they depressed the constitutive activity of P1R-H223R but not that of P1R-T410P or P1R-I458R. The results show that PTH analogs that bind only to J domain of the P1R can function as competitive antagonists and inverse agonists. The study thus opens new pathways for pharmacologically exploring ligand-receptor interactions that occur within the J domain of the P1R, particularly those involving the first three residues of PTH.

Vitamin D Represses the Herpes Simplex Virus Thymidine Kinase Promoter: Identification of a Repressor Element and Cell-type Specificity. N. J. Koszewski, A. P. Alimov, H. H. Malluche. Division of Nephrology, Bone & Mineral Metabolism, University of Kentucky Medical Center, Lexington, KY, USA.

The herpes simplex virus thymidine kinase (HSVtk) promoter has been widely used as a heterologous promoter in characterizing a variety of DNA response elements, including vitamin D response elements (VDREs). We noted the capacity of vitamin D to suppress reporter gene activity in opossum kidney (OK) cells from constructs lacking functional VDREs, including the parent HSVtk reporter itself. This was strictly dependent on co-expression of the heterodimer receptors, was not seen with an SV40-driven promoter and did not occur when estrogen receptors were co-expressed with the HSVtk reporter and exposed to estradiol. Mobility shift assays using recombinant heterodimer-containing extracts revealed multiple, specific DNA-binding complexes with an HSVtk promoter fragment (-105 to +57). Binding appeared to be restricted to the 3' portion of this fragment (–44 to +48), and interference footprinting confirmed that interactions were localized over four half-sites from ca.-12 to +25. Use of a series of oligonucleotide probes encompassing various half-site combinations resembling DR+3-like motifs revealed single, specific heterodimer binding complexes with each. Transient transfection analysis in OK cells using a mutant HSVtk promoter that incorporated changes to the 3' pair of half-sites continued to exhibit a repressive response when treated with calcitriol. Mutations made to the 5' pair of half-sites resulted in increased basal activity, but an inability to repress transcription in response to hormone, suggesting that these sites conveyed the repressive response. Finally, modest vitamin D-dependent gene activation could be observed in OK cells with an enhancer VDRE linked to the HSVtk-promoter, while strong suppression was observed from a repressor VDRE construct. In contrast, transfection of the same reporters in COS-7 kidney cells revealed robust activation from the enhancer VDRE, but no suppression of reporter activity from the repressor VDRE construct irrespective of the amounts of co-transfected heterodimer expression vectors. In summary, the vitamin D receptor heterodimer forms strong, multiple DNA-binding complexes with the HSVtk promoter that results in hormone-dependent suppression of gene activity. This repression is cell-type specific, however, suggesting that other factors are playing a role in this response.

A Mutation in the Ligand Binding Domain of the Vitamin D Receptor that Alters 1,25(OH)2D3 Binding, RXR Heterodimerization and Coactivator Binding thereby Causing Hereditary Vitamin D Resistant Rickets. P. J. Malloy*[1], R. Xu*[1], L. Peng*[1], S. Peleg[2], A. Ashwal*[3], D. Feldman[1]. [1]Department of Medicine, Stanford University, Stanford, CA, USA, [2]Department of Endocrine Neoplasia and Hormonal Disorders, University of Texas, M. D. Anderson Cancer Center, Houston, TX, USA, [3]Department of Pediatrics, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia.

Hereditary vitamin D resistant rickets (HVDRR) is an autosomal recessive disease caused by mutations in the vitamin D receptor (VDR). The patient in this study, a young Saudi Arabian girl, exhibited the typical clinical features of HVDRR but without alopecia. Analysis of her DNA revealed her to be homozygous for a unique T to C mutation in exon 7 of the VDR gene that changed the codon for isoleucine to threonine at amino acid 268 (I268T). Based on the crystallographic studies of the VDR ligand-binding domain (LBD), I268 directly interacts with $1,25(OH)_2D_3$ and is involved in the hydrophobic stabilization of helix H12. We recreated the I268T mutation in the VDR cDNA and analyzed its effects on VDR function. Several defects in $1,25(OH)_2D_3$ action were demonstrated. In ligand binding assays, the I268T mutant VDR exhibited a ~10-fold lower affinity for $[^3H]1,25(OH)_2D_3$ compared to the WT VDR consistent with I268 interaction with the ligand. However, in transactivation assays, the I268T mutant required ~100-fold higher concentrations of $1,25(OH)_2D_3$ to stimulate gene transcription compared to the WT VDR. Since I268 is involved in stabilizing helix H12 we examined coactivator binding using GST-pull down assays. The I268T mutant required ~100-fold more $1,25(OH)_2D_3$ to promote binding to the coactivators SRC-1 and DRIP205. We also examined RXR binding using the yeast two-hybrid system and GST-pull down. The I268T mutant showed a marked decrease in RXR binding compared to the WT VDR. However, the I268T mutant was able to form a complex on the osteopontin vitamin D response element as shown by gel shift assays. We re-tested the mutant in transactivation assays and showed that the responsiveness of the I268T mutant to $1,25(OH)_2D_3$ could be partially rescued by the addition of RXR. In conclusion, we describe a novel mutation in the VDR LBD, I268T that alters ligand binding, RXR heterodimerization, and coactivator binding. These cumulative defects cause resistance to $1,25(OH)_2D_3$ action and result in the syndrome of HVDRR.

Vitamin D Receptor-Mediated Transcription Is Enhanced by Calmodulin-dependent Kinase IV, Potential Interplays between Vitamin D and Calcium Signaling Pathways. T. I. Ellison*, D. R. Dowd*, P. N. MacDonald. Department of Pharmacology, Case Western Reserve University, Cleveland, OH, USA.

The major physiological role of 1,25-dihydroxyvitamin D3 [1,25(OH)2D3] is to maintain normal calcium homeostasis, primarily by ensuring adequate absorption of dietary calcium in the small intestine. The biological actions of 1,25(OH)2D3 are mediated through the vitamin D receptor (VDR), a member of the nuclear receptor superfamily of ligand-activated transcription factors. Despite critical roles for 1,25(OH)2D3 in calcium transport across enterocytes, little information exists on the effects of intracellular calcium on the transcriptional activity of liganded VDR. To explore potential interplays between VDR and intracellular calcium regulated pathways, initial studies focused on the calmodulin (CaM)-dependent kinase termed CaM kinase IV. A vitamin D responsive luciferase reporter gene (VDRE4TATA-luciferase) and a VDR expression vector (SG5-VDR) were transfected into COS7 cells or HeLa cells in the absence or presence of a vector encoding a constitutively active form of CaM kinase IV. A dramatic induction of 1,25(OH)2D3-activated reporter gene expression was observed in cells receiving the CaM kinase IV derivative. The response was dependent on the amount of transfected CaM kinase IV plasmid showing a maximal 12-fold induction in 1,25(OH)2D3 responsiveness compared to controls. No effects were observed on basal or unstimulated expression of the reporter gene. Moreover, 30 micromolar KN93, a relatively selective inhibitor of CaM kinase IV, inhibited vitamin D-activated reporter gene expression by 50 %. No effect of this compound was observed on basal or unstimulated reporter gene expression. Together, these data indicate that CaM kinase IV selectively augments VDR- and 1,25(OH)2D3-activated transcription in both HeLa cells and COS7 cells. We also observed potent activation by CaM kinase IV using a heterologous gal4-VDR(93-427) construct and a gal4-responsive luciferase reporter gene (gal4TATA-luciferase). These data suggest the effect of CaM kinase IV is mediated through the VDR ligand binding domain. A potential mechanism for this enhanced activity of VDR was suggested in western immunoblots which indicated an enhanced level (app 2-fold) of VDR protein in response to CaM kinase IV expression. However, it is likely that this does not account for the full stimulatory effect on VDR-activated transcription. To pursue additional mechanisms we are currently examining whether VDR or VDR associated comodulatory proteins are targets for CaM kinase IV phosphorylation using in vivo labeling and immunoprecipitation strategies.

Analysis of Mice Lacking both Vitamin D Receptor and Calbindin-D28k Reveals a Critical Role of Calbindin-D28k in Calcium Homeostasis. W. Zheng*[1], G. Li[2], Y. Jiang*[3], J. Kong*[1], Y. C. Li[1]. [1]Medicine, University of Chicago, Chicago, IL, USA, [2]Trauma and Orthopaedic Surgery, Queen's University Belfast, Belfast, United Kingdom, [3]Radiology, University of Chicago, Chicago, IL, USA.

The role of Calbindin(CaBP)-D28k, a cytosolic calcium-binding protein mainly expressed in the kidney and brain, in calcium homeostasis remains controversial. It has long been speculated that CaBP-D28k plays an important role in transcellular calcium transport in the kidney, largely based on its calcium-binding property and its abundant expression in distal tubules, which is reduced in vitamin D-deficient state. However, recent studies suggest that CaBP-D28k is not essential for calcium metabolism. In particular, genetic ablation of CaBP-D28k in mice has no effect on calcium homeostasis. Our recent studies show that genetic inactivation of the vitamin D receptor (VDR) results in a 90% reduction in CaBP-D9k, but has little effect on CaBP-D28k expression, in the kidney, which is associated with an increase in calcium excretion and development of hypocalcemia in VDR knockout (KO) mice. It is possible that the function of CaBP-D28k is compensated by CaBP-D9k in CaBP-D28kKO mice, whereas the reverse is not true in VDRKO mice. To further investigate the role of CaBP-D28k in calcium reabsorption, we have generated VDR/CaBP-D28k double KO mice, which express no CaBP-D28k and only 10% of CaBP-D9k in the kidney, and the double KO mice were examined in parallel with wild-type (WT), CaBP-D28kKO and VDRKO mice. As shown previously, CaBP-D28kKO mice appear grossly normal and show no calcemic abnormalities as compared with WT mice. While VDRKO mice have lower body weight than WT mice, the double KO mice are even smaller than VDRKO mice and usually die at about two months of age. The tibiae and femurs of the double KO mice are significantly shorter than those of WT, CaBP-D28kKO as well as VDRKO mice. Peripheral quantitative computer tomography demonstrates that the double KO mice have a much greater reduction in total, trabecular and cortical bone mineral density than VDRKO mice as compared to WT mice. Histological analyses reveal deformity in the growth plate region in both VDRKO and the double KO mice; however, the double KO mice show much more severe distortion and less ossification and bone formation than VDRKO mice. The trabecular bones in the metaphysis regions are predominately osteoid with numerous microvascular invasions, and no secondary ossification center is found. Our results indicate that VDR/CaBP-D28kKO mice show much more severe calcemic and bone abnormalities than VDRKO mice, which provides direct in vivo evidence that CaBP-D28k does play a critical role in maintaining normal bone development by regulating calcium homeostasis.

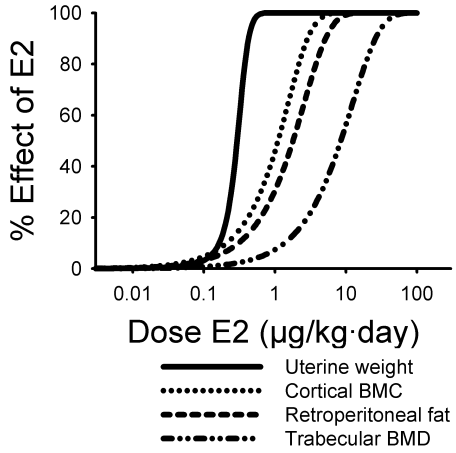
Tissue Specific Differences in Response to Estrogenic Stimulation in Ovariectomized Mice. N. Andersson[1], E. Egecioglu*[2], C. Ohlsson[1]. [1]Centre for Bone Research at the Sahlgrenska Academy (CBS), Department of Internal Medicine, Göteborg University, Göteborg, Sweden, [2]Department of Physiology, Göteborg University, Göteborg, Sweden.

Estrogen deficiency increases the risk for a wide variety of pathological conditions including osteoporosis, cardiovascular diseases, and neuro-degenerative diseases. Estrogen replacement therapy is associated with side effects such as breast cancer and deep venous thrombosis and agents that can maintain the benefit of estrogen but avoid the risks are therefore needed.

The aim of the present study is to in detail investigate the 17β-estradiol (E2) dose-response pattern in different estrogen sensitive tissues. 8-week-old female C57BL/6 mice were ovariectomized and then treated with E2 for two weeks. Different doses of E2 were administered (0, 0.01, 0.1, 1, 10 and 100 µg/kg·day) using subcutaneously implanted osmotic minipumps. The estrogenic response of peripherally administered E2 was determined in estrogen responsive target organs (E2 increased cortical and trabecular bone mass and uterus weight, while it decreased retroperitoneal fat weight). All organs responded dose-dependently to E2. ED_{50}-values were estimated to be 0.3, 1, 2 and 9 µg/kg·day for uterine weight, cortical bone mineral content (BMC), retroperitoneal fat weight and trabecular bone mineral density (BMD), respectively (see figure).



Regarding the mechanisms of action for estrogen, two major pathways need to be considered: an indirect action through the central nervous system and a direct peripheral action on target tissue. The effect of E2 on uterine hypertrophy is considered to be a direct peripheral effect while its effect on food intake and fat mass is regarded to be central effects. The effect on bone has been suggested to be mediated by peripheral E2 action directly on bone tissue. The present study clearly shows tissue specific differences in response to estrogenic stimulation which may be an indication of the underlying mechanism of action for estrogen. The dose response pattern for E2 in the regulation of cortical and trabecular bone are more similar to the pattern for fat than that for the uterus. Thus, further studies are needed to fully distinguish between the central and the peripheral actions of E2 on bone.

Differences in Bone Turnover in Subchondral (SC) vs. Epiphyseal/ Metaphyseal Cancellous (EMC) Bone in the Proximal Tibia of Monkeys Are Accentuated by Estrogen Deficiency. K. D. Ham*, C. S. Carlson*. Veterinary Diagnostic Medicine, University of Minnesota, St. Paul, MN, USA.

The purpose of this study was to evaluate the effect of estrogen deficiency on histomorphometry indices in the SC bone versus the EMC bone of the proximal tibia.

Adult female cynomolgus monkeys were ovariectomized (OVX), divided into 2 treatment groups (OVX and OVX estrogen (E2)-treated [Premarin®]) for a 3-year treatment period, and given calcein 14 and 7 days prior to euthanasia. At necropsy a mid coronal section of the right proximal tibia from 20 randomly selected animals/treatment group was embedded in Bioplastic, sectioned at 10µm, and mounted unstained.

Primary static (2X objective) and dynamic (10X objective) histomorphometry measurements were done. SC bone measurements were taken from the medial tibial plateau in a 3.5 mm wide field, beginning 2 mm medial to the central long axis. EMC bone measurements were taken in a 3.5 X 3.5 mm field 3 mm below the lower limit of the SC bone, centered on the central long axis. Derived indices included: MAR; MS/BS; dLS/BS; BFR/BS; BFR/BV; BS/BV; Tb.N; Tb.Sp; Tb.Th and BV/TV. SC bone widths and areas were also calculated. Data were compared using t-tests.

All dynamic indices (except MAR in EMC) in both sites were significantly higher in the OVX group than the OVX E2-treated group. Within each treatment group means for dynamic histomorphometry indices were higher for SC bone than for EMC bone, and many of these differences were significant (see Table). In addition, Tb.N ($p<0.01$) and BS/BV ($p<0.001$) were higher and Tb.Sp ($p<0.01$) and Tb.Th ($p<0.05$) were lower in the OVX E2- treated group than in the OVX group. There were no significant differences in SC bone width or area or in EMC bone volume between the two groups.

In summary, the bone turnover activity is higher in the SC bone than the EMC bone, and this site difference is accentuated by estrogen deficiency. These differences may have implications for the role of SC bone in the development of osteoarthritis in postmenopausal women.

Parameter	ovx SC bone	ovx EMC bone
MAR	1.51 (0.36)	0.91 (0.19)
MS/BS	15.68 (2.97) **	6.45 (1.32)
BFR/BS	120.2 (40.5) *	28.9 (5.94)
dLS/BS	9.25 (2.06) **	3.17 (0.69)
BFR/BV	66.11 (20.3)	69.76 (15.2)
Parameter	ovx-E2 SC bone	ovx-E2 EMC bone
MAR	0.49 (0.2)	0.47 (0.21)
MS/BS	4.96 (1.67)	2.48 (0.93)

Testosterone Regulates Skeletal Homeostasis During Puberty Independently of Growth Hormone Receptor Activation in Mice. K. Venken*[1], J. Kopchick*[2], K. Coschigano*[2], S. Boonen[3], R. Bouillon[1], C. Ohlsson[4], D. Vanderschueren[1]. [1]Laboratory for Experimental Medicine and Endocrinology, K.U.Leuven, Leuven, Belgium, [2]Edison Biotechnology Institute, Athens, OH, USA, [3]Center for Metabolic Bone Diseases, K.U.Leuven, Leuven, Belgium, [4]Division of Endocrinology, Department of Internal Medicine, Sahlgrenska University Hospital, Gothenburg, Sweden.

Growth hormone (GH) and androgens are both known to affect skeletal growth during puberty. The aim of the present study was to evaluate a possible interaction between GH and androgen action and, particularly, whether the ability of androgens to stimulate skeletal modeling requires the presence of a functional GH receptor (GHR). To this end, we evaluated the effects of testosterone (T) replacement (1.5 µg T daily via subcutaneous silastic implants) in orchidectomized (orch) male mice with disrupted GHR (GHRKO) and corresponding wild-type mice (WT) during late puberty (6-10 weeks). Results are expressed as % gain or loss compared to orch and analyzed via two-factor ANOVA. Both in GHRKO and WT, T enhanced recruitment of osteoblasts at the outer site of the femur and increased periosteal bone formation rates by 94% and 81% in GHRKO and WT, respectively, as measured by dynamic histomorphometry on femoral cross-sections. This increase of periosteal bone formation was associated with statistically similar increases in body weight (+ 26% and + 14%, resp.) and lean body mass (+ 24% and + 13%, resp.) in GHRKO and WT. At the inner site of the femur however, T reduced bone turnover at the endocortical (bone formation rates -51% and -56% in GHRKO and WT, resp.) and trabecular sites (osteoid perimeter -59% and -39%, resp.). This decrease in bone turnover was reflected by a significant reduction in serum osteocalcin in both models (-28% and -41%, resp.). In line with these findings, T significantly increased trabecular bone volume in GHRKO as well as WT. In these models, T did not affect femoral length and serum IGF-I. The end result of T action on appendicular skeleton was a similar thickening of the cortex and maintenance of trabecular bone in GHRKO and WT. We conclude that, in the context of the mice models studied, T action during puberty on trabecular and cortical bone is independent of GHR activation. These findings support the concept that T action on skeletal modeling does not involve activation of the GH axis.

ERα and ERβ Bind SRC1 with Different Affinities in Normal Human Osteoblast Extracts Using a Modified *in vitro* Assay. D. G. Monroe[1], F. J. Secreto*[1], B. J. Getz*[1], B. L. Riggs[2], S. Khosla[2], T. C. Spelsberg[1]. [1]Biochemistry and Molecular Biology, Mayo Clinic, Rochester, MN, USA, [2]Endocrine Unit, Mayo Clinic, Rochester, MN, USA.

Estrogen (i.e. 17β-estradiol; E2) has multiple functions in the maintenance and homeostasis of the skeleton, including important metabolic functions in the bone-forming osteo-

blasts (OB). The functions of E2 are largely mediated through two distinct estrogen receptor isoforms, ERα and ERβ, and both are found coexpressed in normal OBs. Following ligand binding, the ER dimerizes and binds either directly or indirectly to regulatory elements within the control regions of genes. The altered ER protein conformation induced by ligand binding causes recruitment of coactivator complexes that are involved in the activation of transcription. Additionally, it has been shown that binding of alternate ER ligands (i.e. genistein, tamoxifen, raloxifene; SERMs) induces novel, often suboptimal, ER conformations that can potentially have drastic effects on the recruitment of coactivators. The aim of this study is to identify the effect of various SERMs on the ability of ERα and ERβ to recruit SRC1, the founding member of the p160 family of coactivators. We have developed a modified version of the GST-pulldown assay. Glutathione-S transferase (GST) fusion proteins containing the ligand binding domain of either ERα and ERβ were generated and bound with ethanol control, E2, or one of the SERMs (genistein, tamoxifen, or 4-OH tamoxifen). The ligand bound fusions were incubated with hFOB nuclear extracts, a normal human osteoblast cell line developed in our laboratory. Western blot analysis was performed and bound SRC1 protein was detected using a specific antibody. Our analysis indicated that SRC1 was recruited to both ERα and ERβ when either receptor was bound E2 or genistein. However, in both cases, ERα recruited SRC1 more efficiently than ERβ, as indicated through densitometry. Other studies indicated that ER bound with tamoxifen, but not 4-OH tamoxifen, resulted in minor recruitment of SRC1 with ERα . We are currently involved in determining relative affinities for SRC1 binding to the ER isoforms by altering the GST binding and washing conditions. Furthermore, similar GST-pulldown assays to examine the association of other ER coactivators and corepressors (i.e. SRC2, REA, p300) with the ER isoforms are currently underway.

Changes in Gene Expression by Estrogen Receptor Ligands in the Femora of Hindlimb Unloaded Male Rats. M. Sajid*[1], C. Nolan*[1], M. R. Allen*[2], S. A. Bloomfield[2], C. L. Smith[1]. [1]Molecular and Cellular Biology, Baylor College of Medicine, Houston, TX, USA, [2]Health & Kinesiology, Texas A&M University, College Station, TX, USA.

Decreases in mechanical usage that occur during spaceflight, bedrest and hindlimb unloading (HU) induce loss of bone mass in weight bearing bones; this may be accompanied by reductions in serum testosterone. Bone loss in humans and rats with testosterone and/or aromatase deficiencies can be attenuated by 17β-estradiol (E2) treatment, and we have shown that treatment with E2 or the selective estrogen receptor modulator, raloxifene (Ral), attenuates bone loss in mature male rats subjected to 28 d HU. This study's objective was to investigate alterations in gene expression that accompany HU relative to cage control (CC) animals, and to determine the ability of either E2 or Ral to modulate gene expression in unloaded bones in comparison to placebo HU controls. Six-month-old Sprague-Dawley rats were implanted with time-release pellets containing vehicle (Veh), E2 (12 μg/d), or Ral (535 μg/d) and were assigned to one of 4 groups: CC+Veh, HU+Veh, HU+ E2, or HU+Ral (4 rats/group). Femora were obtained 28 d thereafter. Bone mineral densities and areas in the left distal femora were measured *ex vivo* by peripheral quantitative computed tomography scans. E2 and Ral increased total BMD by 13.1% and 7.6%, respectively, in comparison to HU+Veh values. They also attenuated loss of endocortical bone at the metaphysis, preventing the 8.8% increase in marrow area observed in HU+VEH in comparison to CC+Veh rats. Total RNA was isolated from the proximal femora for assessment of various cytokine, and growth and transcription factor mRNAs by quantitative, real-time RT-PCR; target gene expression was normalized to 18S rRNA. Hindlimb unloading resulted in increased transforming growth factor-β (TGFβ), stress activated protein kinase (SAPK) and c-jun mRNA expression; no changes in insulin-like growth factor-1 (IGF-1), interleukin-1α (IL-1α), IL-1β, IL-6 or IL-10 mRNA expression due to 28 days of mechanical unloading were detected. There were no significant effects of E2 or Ral treatment on IGF-1, IL-1α, IL-1β or IL-10 mRNA expression. However, E2 but not Ral repressed IL-6 and c-jun mRNA levels. In addition, both E2 and Ral inhibited SAPK mRNA expression and tended to reduce TGFβ expression in HU animals. These results indicate that E2 and Ral protection from bone loss induced by mechanical unloading is associated with changes in gene expression that may contribute to the mechanisms by which E2 and Ral treatment alleviates disuse-induced osteoporosis.

Body Fat Is Inversely Associated with 25-Hydroxyvitamin D Levels in Healthy Postmenopausal Women. J. M. Lappe, M. J. Barger-Lux, G. Haynatzki, R. P. Heaney, R. R. Recker, D. Travers-Gustafson. Osteoporosis Research Center, Creighton University, Omaha, NE, USA.

Optimal vitamin D nutrition is essential for skeletal health. However, low levels of serum 25(OH)D are extremely prevalent. Evidence suggests that percentage of body fat is inversely related to 25(OH)D. Considering the epidemic of obesity in the US, it is important to further explore this relationship. Thus, the purpose of this analysis is to determine the association between serum 25(OH)D levels and percentage body fat in healthy postmenopausal women.

The analysis was conducted on data from 1180 white women randomly selected from the population of healthy postmenopausal women over 55 years of age in a nine-county farming area of Nebraska. Participants were enrolled into an intervention study of calcium and vitamin D. This report includes only data collected at baseline before the intervention was begun.

Each participant underwent a total body scan using DXA (Hologic Inc. Waltham, MA). Percentage body fat (%BF) was calculated as (fat mass [g]/ fat mass + lean mass [g]) X 100. Blood samples were collected after a 3-hour fast. Serum 25(OH)D was measured by RIA. To evaluate seasonal variation, we divided the year into 4 seasons based on serum vitamin D levels in this cohort: Jan-Mar, Apr-June, July-Sept, and Oct- Dec.

Analysis indicated that %BF is inversely associated with 25(OH)D after adjusting for age, season of the year, and vitamin D supplementation ($P<0.0001$). Levels of 25(OH)D decrease in a stepwise manner as quartile of %BF increases. Our findings are congruent with other reports that serum 25-OHD levels vary with adiposity and underscore the importance of considering body fat when evaluating vitamin D requirements.

Baseline Characteristics

Variable	Mean	SD
Age (yrs)	66.7	7.3
Body fat (%)	40.0	5.5
Body mass index (wt/ht x ht)	29.0	5.6
Serum 25(OH)D (nmol/L)	71.8	20.1
Vitamin D supp (IU/d)	318	150
Calcium intake (mg/d)	683	398

Bone Status and All-*trans*-Retinoic Acid (atRA) Homeostasis in Mice Lacking Cellular Retinol-Binding Protein I (CRBPI-KO) Before and After Chemical Insult by TCDD. P. Hoegberg*[1], P. M. Lind[1], N. Stern*[1], C. Trossvik*[1], A. Thomassen*[2], R. Blomhoff*[2], T. Jämsä*[3], J. Tukkanen*[3], N. B. Ghyselinck*[4], C. Ohlsson[5], H. Håkansson*[1]. [1]Inst. of Environmental Medicine, Karolinska Institute, Stockholm, Sweden, [2]Inst. for Nutrition Research, Univ. of Oslo, Oslo, Norway, [3]Dep. of Anatomy and Cell Biology, Univ. of Oulu, Oulu, Finland, [4]Igbmc, cnrs-inserm-ulp, Illkirch, France, [5]Dep. of Internal Medicine, Div. of Endocrinology, Sahlgrenska Univ. Hospital, Göteborg, Sweden.

Bone status is known to be affected by vitamin A (retinoids) as well as by organohalogen pollutants. We investigated associations between retinoid homeostasis, organohalogen exposure, and bone status by studying adult male CRBPI-KO mice, known to have an impaired retinoid storage capacity[1]. Wildtype (WT) mice of the same strain background were used as controls. With and without prior exposure to TCDD, we measured the composition of cortical and trabecular bone of tibia and femur by peripheral quantitative computed tomography (pQCT). The strength of tibia and femur was assayed by a three-point-bending test and femoral neck strength was measured by axial loading. Hepatic and serum retinyl ester, retinol, and atRA levels were measured by HPLC, serum 25(OH)D by a commercial RIA, and the osteoclast activity biomarker Trap5b by a serum solid-phase immunofixed enzyme activity assay. We saw no differences in bodyweight between untreated CRBPI-KO and WT mice although mutant tibiae were somewhat shorter. The CRBPI-KO had lower levels of both hepatic retinyl esters, retinol, and atRA levels than the WT at all times and doses. TCDD exposure reduced these levels in both genotypes. Bone mineral density (BMD) and strength were generally lower in CRBPI-KO mice. The effects of TCDD on bone length, composition, and strength 4 weeks after TCDD exposure was highly dependent on whether CRBP I had been knocked out or not; in fact, a disrupted CRBP I gene ameliorated the adverse effects of TCDD on bone. Vitamin D did not differ between the genotypes but were dose-dependently reduced by TCDD, and Trap5b followed approximately the same pattern. This study shows that a binding protein specific for the vitamin A system plays a role not only for proper retinoid storage but also for the homeostasis of the nuclear receptor ligand RA and for bone status.

Towards Quantifying the Relationship of Constitutive Skin Color to Daily Skin Dose of Vitamin D3 in Healthy Adults with Ample Summer Sun Exposure. M. Barger-Lux[1], L. Auberry-Adams*[1], J. M. Lappe[1], R. R. Recker[1], R. P. Heaney[2]. [1]Department of Medicine, Creighton University, Omaha, NE, USA, [2]Creighton University, Omaha, NE, USA.

We report here preliminary results of work to quantify the relationship of inherent skin pigmentation and summer increment of vitamin D3 among healthy adults with ample summer sun exposure and limited non-solar sources of vitamin D. The 38 subjects (aged 20 to 45 yr) classified themselves by race as black (n=20), white (n=15), or other (n=3). Data were gathered in late summer (Aug. 29 to Sept. 21). We estimated extent (% body surface area) and duration (hr/wk) of summer sun exposure by interview. We also determined BMI; fasting serum 25(OH)D, vitamin D3, 1,25(OH)2D, PTH, and Ca; fasting urine Ca-to-creatinine ratio; and Ca absorption fraction.
We used a portable colorimeter (SmartProbe, IMS Inc., Milford, CT) that utilizes the CIE L*a*b* color system to measure constitutive skin color of the upper inner arm. There was a strongly positive curvilinear relationship (R2=0.5234) between the "L" readings (a continuous darker-to-lighter scale) and 25(OH)D. The lowest and highest "L" tertiles (i.e., darkest and lightest subgroups) differed significantly in 25(OH)D (47.6 ± 12.5 vs 91.9 ± 17.3 nmol/L); vitamin D3 (0.41 ± 0.31 vs 2.87 ± 2.39 ng/mL; fasting urine Ca-to-creatinine ratio (0.033 ± 0.026 vs 0.121 ± 0.096 g/g); and sun-exposed body surface area (28.1 ± 8.1 vs 40.1 ± 12.6%); They did not differ in 1,25(OH)2D, PTH, serum Ca, or Ca absorption fraction.

ED-71, a Novel Vitamin D Analog, Promotes Bone Formation after Bone Marrow Ablation. N. Okuda*[1], Y. Higuchi*[2], T. Muneta*[1], S. Ito*[3], Y. Asou[3]. [1]Section of Orthopeadic Surgery, Devision of Bio-Matrix, Graduate School Tokyo Medical and Dental University, Tokyo, Japan, [2]Chugai Pharmaceutical Co., LTD, Tokyo, Japan, [3]Division of Molecular Tissue Engineering, Human Genes and Science Center, Tokyo Medical and Dental University, Tokyo, Japan.

1,25-Dihydroxyvitamin D_3 (VitaminD) plays an essential role in bone homeostasis. A novel vitamin D analog 2-β-(3-hydroxypropoxy)-1α,25-dihydroxyvitamin D_3 (ED-71) has high affinity with vitamin D binding protein and has greater activity than vitamin D in preventing bone loss in ovariectomized rat. However, the effect of ED-71 on bone remodeling including bone formation and resorption remains to be elucidated. Bone marrow ablation in the long bone causes vigorous new bone formation within the first week and then subsequent rapid bone resorption in the second week to regenerate bone marrow with normal levels of trabecular bones. It is a highly reproducible in vivo assay to evaluate bone remodeling. The purpose of this study was to evaluate the effect of ED-71 on bone remodeling in vivo by using mice bone ablation model. ICR mice were divided into ED-71 treatment and control groups, and all the femoral bone marrow were ablated by using K-wire . The day after operation, mice of ED-71 treatment group were intraperitoneally administered ED-71 (0.8μg/kg body weight). Mice were sacrificed 3,5,7,14days after surgery. There were no significant differences of body weight between two groups. Femoral bone marrow was observed by micro CT and histological examination. Histological examination showed that 3 and 5 days after surgery, ablated bone marrow in ED-71 treatment group were filled with more abundant matrix compared with control. 7 days after surgery, trabecular bone volume reaches at its maximal level, and more abundant and thicker newly formed trabecular bones were observed in ED-71 treatment group. Histological quantitation and micro CT analysis of the mice sacrificed 7days after surgery revealed that bone volume/tissue volume (BV/TV) were 50% more in ED-71 treatment group. By 2 weeks after surgery, newly formed trabecular bone was resorbed and the amounts of bone were similar between ED-71 treatment and control groups. As for bone resorption, the number of TRAP (tartrate-resistant acid phosphatase)-positive multinuclear cells per trabecular bone surface (N.OC/BS) was not different between ED-71 treated and control mice both 7days and 14days after surgery . These results indicated that ED-71 raised the maximal level of bone volume in the first week of administration, and possibly enhanced the bone formation activity. We concluded that ED-71 promoted bone formation in the region of rapid bone turn over after bone marrow ablation.

Potent Activity of Gemini Compounds to Suppress Renin Gene Expression. J. Kong*[1], M. Uskokovic*[2], G. Qiao*[1], Y. C. Li[1]. [1]Medicine, University of Chicago, Chicago, IL, USA, [2]BioXell, Inc., Nutley, NJ, USA.

The renin-angiotensin system (RAS) plays a central role in the regulation of blood pressure, electrolyte and extracellular volume homeostasis. Inappropriate activation of the RAS may lead to hypertension, which is one of the major risk factors for stroke, myocardial infarction, congestive heart failure, progressive atherosclerosis and renal failure. Our recent studies have shown that 1,25-dihydroxyvitamin D3 [1,25(OH)2D3] functions as a potent negative endocrine regulator of renin production, and thus plays a critical role in the regulation of the RAS and blood pressure. These studies suggest that vitamin D analogs or derivatives with less calcemic effect and/or more potent renin-suppressing activity than 1,25(OH)2D3 might potentially be used as a new class of anti-hypertensive agents to control renin production and blood pressure. As an initial step to identify such analogs, we have screened 20 vitamin D analog compounds using the As4.1-hVDR cell culture system. The activity of the analogs to suppress renin gene expression was determined by Northern blot analyses and renin promoter/luciferase reporter assays. Interestingly, of the 20 compounds screened, only the Gemini compounds, which have two side-chains at Carbon-20 position, were found to be active in suppressing renin expression, whereas all the non-Gemini compounds were inactive. Of the 13 Gemini compounds, five were inactive or less active than 1,25(OH)2D3, four were as active as 1,25(OH)2D3, and four were 10- to 100-times more active than 1,25(OH)2D3. It is known that some of these Gemini compounds have much higher animal maximal tolerance dose (MTD), thus they may offer an excellent opportunity for further animal testing.

Immunoassays for 25 Hydroxyvitamin D Demonstrate Positive Bias Compared with HPLC and Under-Recovery of 25 Hydroxyvitamin D_2 in Hip Fracture Cases. P. Glendenning[1], M. Taranto*[1], J. M. Noble*[2], A. Musk*[1], P. Goldswain*[2], W. Fraser[3], S. Vasikaran[1]. [1]Biochemistry, Royal Perth Hospital, Perth, Australia, [2]Geriatric Medicine, Royal Perth Hospital, Perth, Australia, [3]Chemical Pathology, University of Liverpool, Liverpool, United Kingdom.

Deficiency of vitamin D is commonly associated with fracture. Consequently, 25 hydroxyvitamin D (25 OHD) is frequently measured to define vitamin D nutritional status. The clinical demand for precise and accurate assays to measure 25 OHD has led to the development of a number of immunoassay methods. Lack of standardisation of 25 OHD assay methods has questioned interassay agreement. Recent evidence has challenged the ability of current immunoassays to recognise both 25 OHD_2 and 25 OHD_3 metabolites. We studied 172 patient samples from consecutive hip fracture cases to determine assay agreement when comparing the DiaSorin (DS), IDS radioimmunoassays and the Nichols Advantage automated protein binding assay (CLPBA) to HPLC. 52 of these patients were studied before and 3 months after 1000 IU of daily ergocalciferol (D_2) therapy to assess ability of each immunoassay to recognise 25 OHD_2. Linear regression analysis in pretreatment samples demonstrated a positive Y intercept of between 6 and12 nmol/L for each assay compared to HPLC and a slope that varies from 0.64 (IDS) to 0.97 (DS, CLPBA). Bland Altman analysis demonstrates all 3 immunoassays have a persistent and proportional positive bias relative to HPLC at values from 20 to 50 nmol/L. Consequently, a 25 OHD results of 30 nmol/L by HPLC translates into 42 nmol/L by DS, 33 nmol/L by IDS and 35 nmol/L by CLPBA. A 25 OHD result of 80 nmol/L by HPLC translates into 90 nmo/L by DS, 65 nmol/L by IDS and 83 nmol/L by CLPBA. These results demonstrate, in the absence of standardisation efforts, the need for assay specific decision limits. Pretreatment linear regression analysis was used to apportion 25 OHD_3 value in the post treatment sample by each immunoassay and help approximate D_2 recognition by the different immunoassays. Less than 25 % of 25 OHD_2 measured by HPLC was detected by any immunoassay. It is questionable whether any of the immunoassays are capable of adequate recognition of 25 OHD_2. The above two issues are important when defining 25 OHD decision thresholds for treatment institution and to determine treatment response to D_2 respectively.

Fully Automated Method for the Determination of Fat Soluble Vitamins by HPLC. J. M. Quesada Gómez*[1], J. M. Mata Granados*[2], M. D. Luque de Castro*[3]. [1]Mineral Metabolism Unit. University of Córdoba, Hospital Universitario Reina Sofía, Córdoba, Spain, [2]Sanyres, Prasa, Córdoba, Spain, [3]Department of Analytical Chemistry, University of Córdoba, Córdoba, Spain.

Background. There are few methods reported for the simultaneous determination of fat soluble vitamins (namely, 24,25 $(OH)_2$hidroxyvitamin D_3, 25 (OH)hidroxyvitamin D_3,1,25 $(OH)_2$hidroxyvitamin D_3 and vitamins A, E, K_1, K_3, D_3 and D_2).These methods are slow, time consuming and very difficult to automate. The necessity for routine analysis of these vitamins calls for the development of fully automated methods for their simultaneous determination.
Proposed method. A new rapid, automated and sensitive high-performance liquid chromatographic method using 1 mL of serum had been developed for the simultaneous determination of the target analytes, which involves the following steps:
Sample pretreatment by a robotic station: 1 mL of serum was mixed with 0.8 mL ethanol. After vortexing, the mixing was extracted with 4 mL 90:10 hexane-diclormethane mixture. The hexane-diclormethane layer was evaporated to dryness under an N_2 stream. The residue was dissolved in 200 μ L and located in the auto sampler of the chromatograph. Batches of 6 samples were treated with an operational time of 2 h/batch.
Chromatographic separation and detection: the initial mobile phase into which the sample was injected was a 90:10 methanol-water mixture at 1.0 mL min^{-1}, followed by a linear gradient in 4 min to obtain 90:10 methanol-isopropanol, maintained for 8 min. A second gradient was programmed at 1.2 mL min^{-1} to obtain an 1:1 methanol-isopropanol composition in 12 min, maintained until the end of the run. The equilibration time was 5 min. The eluate was monitored with a photodiode-array detector at the the maximum wavelength for each analyte.

Results. The linear range was 1-100 ng mL^{-1} for hydroxymetabolites of vitamin D_3, vitamin A and vitamin E, and was 5-100 ng mL^{-1} for vitamins K_3, K_1, D_3 and D_2. The coefficients of correlation are between 0.998 and 0.995. Limits of detection are between 1.0 and 4.0 ng mL^{-1}. Precision ranges between 5 and 9%.

Relationship of Peak Lean Tissue Accrual to Peak Bone Mineral Accrual in Boys and Girls. R. A. Faulkner, A. D. G. Baxter-Jones*, R. L. Mirwald*, D. A. Bailey. Kinesiology, University of Saskatchewan, Saskatoon, SK, Canada.

It has been postulated that muscle and bone form an operational unit; that is, factors that affect muscle will also influence bone. It also is thought that muscle action is paramount in affecting bone adaptation; if so, then it would be expected that muscle development (or lean tissue as a surrogate of muscle) during the growing years should precede bone mineral accrual. We have shown previously that this is the case for total body mass; however, in theory this relationship should be even stronger at the extremities where muscle action is more isolated. The purpose of this study was to investigate the relationship of the timing of bone-free peak lean mass accrual (PLM) to peak bone mineral mass accrual (PBM) at the arms and legs. Subjects (70 boys and 67 girls) were measured annually (DXA: Hologic 2000 QDR in array mode). Whole year velocity values were calculated for bone-free lean tissue and bone mineral content. The mean age of peak tissue accrual was then calculated as the mean of the peak. Dependent t-tests were done to test for differences between the age of PLM and PBM ($p<.05$). As shown in the following table, PLM occurred prior to PBM at both sites in both boys and girls; however, this difference was not statistically significant at the legs in girls. These preliminary data support the hypotheses that PLM (a surrogate measure for muscle mass) precedes PBM and that muscle and bone development are closely related.

Comparison of age at peak velocity (Mean + S.D.)

	PLM	PBM
Girls (Arms)	12.2 (1.3)*	12.9 (1.3)
Girls (Legs)	12.1 (1.0) NS	12.4 (1.0)
Boys (Arms)	13.7 (1.0)*	14.4 (1.3)
Boys (Legs)	13.6 (1.0)*	14.1 (1.2)

IGF-1 and IGFBP-3 Influence Bone Mass Acquisition in Children via Independent Mechanisms. J. H. Tobias[1], C. D. Steer*[2], P. M. Emmett*[2], A. R. Ness*[2], D. J. Gunnell*[3], J. M. P. Holly*[4]. [1]Rheumatology Unit, University of Bristol, Bristol, United Kingdom, [2]Alspac, University of Bristol, Bristol, United Kingdom, [3]Social Medicine, University of Bristol, Bristol, United Kingdom, [4]Surgery, University of Bristol, Bristol, United Kingdom.

Previous studies suggest that IGFBP-3 augments the stimulation of bone formation by IGF-1, which has been attributed to the ability of IGFBP-3 to prolong IGF-1 half-life. However, since IGFBP-3 is known to exert cellular actions independently of IGF-1, separate effects of IGFBP-3 on bone formation may also be involved. To explore the respective roles of IGF-1 and IGFBP-3 in regulating bone formation, we examined the relationship between serum levels of these proteins and bone mass acquisition in childhood. Serum concentrations of IGF-1 and IGFBP-3 were analysed in samples from 751 children randomly selected from the Avon Longitudinal Study of Parents and Children (ALSPAC) birth cohort at age 7.9, and whole body bone mineral content (BMC) subsequently measured in 652 of these children at age 9.9, using a Lunar Prodigy DXA scanner. Serum levels of IGF-1 and IGFBP-3 were found to be significantly associated with BMC (standardised regression coefficient = 0.299 and 0.297 for IGF-1 and IGFBP-3 respectively, $p < 0.001$). Subsequent analysis suggested that these associations reflected influences on bone growth, since equivalent relationships of IGF-1 and IGFBP-3 were observed to height, weight and DXA-derived skeletal area. Moreover, when BMC was adjusted for DXA-derived skeletal area, a significant association with serum IGF-1 and IGFBP-3 was no longer observed. Multi-variable regression analysis was then carried out to determine whether the relationships of serum IGF-1 and IGFBP-3 to bone growth which we found are inter-dependent. Highly significant associations with parameters related to skeletal growth were still observed after adjusting IGF-1 levels for IGFBP-3, and IGFBP-3 levels for IGF-1 (data shows standardised regression coefficients):-

Parameter	Versus IGF-1 (adjusted for IGFBP-3)	Versus IGFBP-3 (adjusted for IGF-1)
BMC	0.214, $p < 0.001$	0.213, $p < 0.001$
Area	0.229, $p < 0.001$	0.199, $p < 0.001$
Height	0.242, $p < 0.001$	0.201, $p < 0.001$
Weight	0.223, $p < 0.001$	0.180, $p < 0.001$

Moreover, no significant association was observed between these parameters and serum IGF-I/IGFBP-3 ratio. We conclude that serum levels of IGF-1 and IGFBP-3 are independent determinants of bone mass acquisition in childhood, suggesting that these two proteins regulate bone growth in children via distinct mechanisms.

Relationship Between Body Composition and Hip Bone Mass in Women of African Ancestry: Tobago Women's Health Study. D. D. Hill[1], J. A. Cauley[1], V. Wheeler*[2], J. M. Zmuda[1], A. Patrick*[2], P. Joseph*[2], C. Baker*[1], G. Beckles*[3], C. Bunker*[1]. [1]U of Pitt, Pittsburgh, PA, USA, [2]Tobago Regional Hospital, Scarborough, Trinidad and Tobago, [3]CDC, Atlanta, GA, USA.

Aging is often accompanied by loss of lean mass and bone mass and an increase in fat mass. Studies examining the interrelationships between body composition and bone mass have primarily on Caucasian women and limited to areal bone measures. To test the hypothesis that lean mass is related to total hip and femoral neck bone mineral density (BMD), independent of fat mass in women of African ancestry, we recruited 355 postmenopausal women, aged 50+ on the Caribbean Island of Tobago.
Body composition and BMD were measured by DXA (Hologic QDR 4500W). We estimated volumetric femoral neck BMD by calculating bone mineral apparent density (BMAD). The mean age, BMI, weight, and height of the women were 63.3 ± 8.2 years, 30.5 ± 5.7 kg/m^2, 81.1 ± 16.1 kg, and 163.1 ± 6.4 cm, respectively. In models considering soft tissue lean mass or fat mass separately, both were related to total hip and femoral neck BMD. We compared mean bone mass across tertiles of lean and fat mass, and tested for an interaction, adjusting for age and height using ANCOVA. Femoral neck BMD and BMAD increased across tertiles of lean mass, but not across fat mass. (Table 1.) We observed similar results for total hip BMD.
Our results suggest that fat mass is not significantly associated with bone mass in this population, after controlling for the effects of covariates. In conclusion, lean mass is independently related to bone mass in postmenopausal Tobagonian women of African ancestry. The stronger association between lean mass and BMD could reflect a multifactorial relationship encompassing bone strength, culture, lifestyle, genetics, hormonal, and growth factors.
Table 1. Age and Height Adjusted Mean Femoral Neck BMD (g/cm^2) and BMAD (g/cm^3) across Tertiles of Lean Mass and Fat Mass

Lean Mass	Fat Mass					
	1		2		3	
	BMD	BMAD	BMD	BMAD	BMD	BMAD
1	0.83	0.18	0.86	0.19	0.79	0.16
2	0.83	0.17	0.89	0.19	0.93	0.20
3	0.99	0.21	0.92	0.19	0.96	0.20
BMD			BMAD			
p (lean mass) < 0.001			p (lean mass) = 0.03			
p (fat mass) = 0.96			p (fat mass) = 0.93			
p (lean x fat mass) = 0.13			p (lean x fat mass) = 0.12

Growth "Tracking" of Femoral and Humeral Strength from Childhood to Late Adolescence. C. B. Ruff. Functional Anatomy and Evolution, Johns Hopkins University School of Medicine, Baltimore, MD, USA.

The degree to which skeletal parameters "track", or remain at the same level relative to other individuals during growth and development, has important implications for both early detection and future prediction of increased fracture risk. Several recent studies have indicated an apparently high level of tracking of bone mineral content (BMC), width (BW), area and/or density in children measured over periods ranging from 2 to 6 years. In this study growth tracking of femoral and humeral diaphyseal strength was assessed in a sample of children measured radiographically from infancy to late adolescence. Radiographs were obtained from the archives of the Denver Child Research Study, a longitudinal study carried out in the 1940's-1960's. 20 individuals, 10 males and 10 females, with almost complete radiographic records (average, 34.5 time points at 6 month or yearly intervals) were selected and measured. Periosteal and cortical breadths at midshaft of the femur and 40% of bone length from the distal end of the humerus were measured with sharp-tipped digital calipers, and used to calculate bone section moduli, measures of bending and torsional strength. Comparisons are presented here for a 10 year age interval, from 7 years of age to 17 years of age, representing early school-age to late adolescence. Spearman rank-order correlations of bone strength, within sex, between these two age endpoints are moderate (r=.45-.79), except for the femur in males (r=-.10). Correlations are higher for the humerus (r =.66-.79, $p <.05$) than for the femur (r=-.10-.45, n.s.). In 30% of the comparisons (12/40), individuals cross between bottom and top halves of the strength distributions between 7 and 17 years. These results argue for caution in accepting a high level of growth tracking in mechanically relevant measures of bone strength over extended time periods during pre-adult development. Previous studies of growth tracking that have included different time intervals have found lower correlations for more extended periods and for periods that include early adolescence or childhood in addition to later adolescence. The results presented here are consistent with these findings, and suggest that extrapolations from more limited time intervals to longer periods may be unwarranted. Thus, prediction of bone strength in late adolescence or adulthood from measures taken in earlier in development may be more problematic than previously indicated.

Bone Mineral Accrual During Childhood and Adolescence: An Analysis of Size-Correction Techniques. K. S. Davison*[1], R. A. Faulkner[2], D. Drinkwater*[2], D. Bailey[2]. [1]Medicine, McMaster University & University of Laval, Hamilton/Quebec City, ON, Canada, [2]Kinesiology, University of Saskatchewan, Saskatoon, SK, Canada.

The true pattern of bone mineral density changes during childhood and adolescence is unclear owing to a lack of longitudinal investigations, a lack of adequate control for maturational differences, and size-mediated errors in the measurement of areal bone mineral density (aBMD). This investigation incorporated mixed-longitudinal (distance data) and longitudinal (velocity data) designs to describe pediatric changes in bone density at the total body (TB), femoral neck (FN) and lumbar spine (LS). Maturational differences were controlled by aligning participants on their age at peak height velocity (PHV). Changes in areal BMD (aBMD) were compared with densities obtained from two methods of size correction: bone mineral apparent density (BMAD) based on geometric assumptions, and statistically-corrected BMD (sBMD), which utilizes linear regression. Correlations between bone projected area (PA) and density were strongest with aBMD, intermediate with BMAD, and generally insignificant with sBMD, supporting sBMD's size independence. With the distance data aBMD increased over the entire growth period at all sites. Contrastingly, TB BMAD declined initially and then stabilized after PHV, and FN and LS BMAD were generally stable until PHV, increasing afterward. Similarly, TB and LS sBMD decreased until PHV, increasing afterward, and FN sBMD was stable until PHV, increasing thereafter. aBMD velocity was positive at all sites and all ages. In contrast, TB and FN BMAD had a negative velocity until after PHV, and LS BMAD velocity was generally stable until near PHV, with a positive velocity afterwards. sBMD velocity was negative at the TB and LS until PHV and there was a stabilization (males) or decrease in velocity (females) in FN sBMD until PHV. Velocity curves for PA and bone mineral content displayed a consistent dissociation at all sites with bones increasing in area first and later consolidating when rapid growth ceased or slowed. The point of minimal density suggested from the corrected data coincided with PHV and is supported by epidemiological data that reports the highest rates of fracture in adolescents during this time. These results highlight the size-dependence of aBMD and cautions against its use in the pediatric population. Physiologically, sBMD appeared the more appropriate size-correction technique.

Vitamin D Status and Bone Accretion Profiles in Young Females from Childhood to Young Adulthood. N. E. Badenhop-Stevens*[1], J. D. Landoll*[1], E. Ha*[1], P. Goel*[2], B. Li*[2], B. Hollis*[3], L. Nagode*[4], A. Clairmont*[5], V. Matkovic[1]. [1]Bone and Mineral Metabolism Laboratory, OSU, Columbus, OH, USA, [2]Statistics, OSU, Columbus, OH, USA, [3]University of South Carolina, Charleston, SC, USA, [4]Veterinary Biosciences, OSU, Columbus, OH, USA, [5]OSU, Columbus, OH, USA.

Effect of vitamin D insufficiency on bone mass accumulation during growth is currently unknown. To evaluate this relationship calcidiol blood levels and bone mineral areal density (BMD) of the proximal forearm (33% site) were measured in a cohort of young females (N=236), participants of a 7-year long randomized study with calcium supplementation from childhood to young adulthood. Blood samples were collected annually while bone measurements were done every 6 months. Serum $25(OH)D_3$ was measured by a radioimmunoassay (RIA) (excluding baseline) with ^{125}I labeled tracer (Hollis et al. Clin Chem 39/3,529, 1993). BMD was measured by DXA, GE-Lunar DPX-L. Bone accretion profiles (linear mixed effect model-LME based on => 7 measuring points) versus years-since-menarche (YSM) were used to assess the effects of vitamin D status (below and above the vitamin D threshold of 31.5 ng/ml) in subjects with cumulative calcium intake above (1494±292) and below (748±161) the median (1006 mg/day). There was no difference in BMD measurements between subjects with cumulative average vitamin D levels below and above the threshold in the high calcium intake group (p=0.88, difference in BMD at YSM 4=-0.70%). However, in the low calcium intake group, the difference between BMD profiles of subjects with cumulative calcidiol levels below and above the threshold was of borderline statistical significance (p=0.08). Furthermore, the subjects above the threshold had much denser bones at YSM 4 (2.7%). Given that the sample size for this subgroups comparison is small, the results of this research indicate that vitamin D status may play an important role with regard to bone mass accumulation in young females accustomed to a relatively low dietary calcium intake.

Forearm pQCT Measurements in Young Adult Women Accustomed to Different Calcium Intakes during Adolescence. J. D. Landoll*[1], N. E. Badenhop-Stevens*[1], E. Ha*[1], S. L. Mobley*[1], A. Clairmont*[2], V. Matkovic[1]. [1]Bone and Mineral Metabolism Laboratory, OSU, Columbus, OH, USA, [2]OSU, Columbus, OH, USA.

We previously showed that calcium is an important determinant of bone mineral areal density during growth. In this study, we examined the influence of calcium on volumetric bone mineral density in the same cohort of young women (N=175; average age ~18 y) at the end of a 7-year intervention study with calcium supplementation. Volumetric bone mineral density measurements of the non-dominant radius at the distal (4%) and proximal sites (33%) were performed using a pQCT (Norland-Stratec XCT 2000) densitometer with contour, peel, and separation modes of 2,7,2 (distal site) and 2,2,2 (proximal site), respectively. Calcium-supplemented individuals had higher volumetric density at both the distal radius (394±6 vs 383±6 mg/cm^3), and proximal radius (1002±7 vs 986±6 mg/cm^3), and higher cortical/total area (CA/TA) ratio (0.789±0.005 vs 0.782±0.005) than placebo subjects, however, none of the differences were statistically significant. Dividing the subjects into subgroups according to cumulative calcium intake over time (upper and lower tercile) revealed a significant influence of calcium on volumetric bone mineral density at the distal (404±6 vs 378±8 mg/cm^3, p=0.013) and proximal (1009±7 vs 980 mg/cm^3, p=006) sites, and CA/TA (0.794±0.006 vs 0.774±0.005, p=0.018). There were minimal differences in total cross sectional areas at the distal site (251±4 vs 265±5 mm^2, p=0.03) between the upper and lower tercile subgroups, and no difference at the proximal site (92±1 vs 93±2 mm^2, p=0.5). The above analysis confirmed previous findings, suggesting that calcium exerts its action on bone accretion primarily by influencing volumetric bone mineral density.

Bone Mineral Density by Age, Gender and Pubertal Stages in Healthy Lebanese Children and Adolescents. A. Arabi[1], M. Choucair*[2], M. Nabulsi*[3], J. Maalouf*[1], R. Vieth[4], G. El-Hajj Fuleihan[1]. [1]Calcium Metabolism and Osteoporosis Program, American University of Beirut, Beirut, Lebanon, [2]Endocrinology, American University of Beirut, Beirut, Lebanon, [3]Pediatrics, American University of Beirut, Beirut, Lebanon, [4]Mt Sinai Hospital, Toronto University, Toronto, ON, Canada.

Gender, ethnicity and lifestyle factors affect bone mass acquisition during childhood, thus there is a need to have age and sex adjusted Z-scores using ethnic specific data for BMD measurement with DEXA. We have previously demonstrated that peak BMD is lower in healthy Lebanese compared to western standards. This cross-sectional study aims at obtaining normative data of BMD in healthy Lebanese children and adolescents.

363 children aged 10 to 17 years were enrolled in a randomized controlled trial evaluating the impact of vitamin D on musculoskeletal parameters. Data obtained at baseline is used in this study. Each child underwent physical examination including height, weight and Tanner staging of breast and genitalia. BMD and BMC were measured by DEXA using a Hologic 4500 A device. Apparent volumetric BMD (BMAD) of the lumbar spine and the femoral neck were calculated using the following formula: spine BMAD=BMC/A3/2 and femoral neck BMAD= BMC/A2 , where BMC is the bone mineral content and A is the projected area. Low density software was applied to all analyses and subtotal body measurements were used. Children were subdivided into 8 subgroups of one year interval, and mean±SD of BMD, BMC and BMAD were given for each age group and Tanner stage, for boys and girls separately.

The mean age was 13.13±2.04 years. There was a significant effect of age and puberty on all bone parameters by one way ANOVA, except at the femoral neck BMAD in boys. At cortical sites, all bone parameters were higher in boys than in girls, whereas at the lumbar spine girls had higher values, including BMAD. Children who completed their puberty (Tanner V) had mean BMD about 40% higher at the lumbar spine and 20% higher at cortical sites than those who started their pubertal development (Tanner II). At age 17 years, the mean BMD of the lumbar spine were 9.8% lower in boys and 9.5% lower in girls than the peak BMD of the lebanese population. Except at the trochanter, the mean BMD were low compared to western normative values. Z-score ranged between –0.25 and –1.1 (p<10-4) in both sexes.

Data obtained from this study confirms previous reports on the powerful effect of puberty and gender on bone acquisition, and provide valuable reference enabling calculation of ethnic, gender, age, and Tanner adjusted Z- scores in our pediatric population

SU009

Leptin Negatively Predicts Total Body Bone Mineral Density in Young Healthy Women. C. W. Gunther*[1], R. M. Lyle*[2], G. P. McCabe*[3], D. Teegarden[1]. [1]Foods and Nutrition, Purdue University, West Lafayette, IN, USA, [2]Health and Kinesiology, Purdue University, West Lafayette, IN, USA, [3]Statistics, Purdue University, West Lafayette, IN, USA.

The role of leptin has been widely studied in relationship to body fat and obesity. However, more recently, leptin has been shown to have a significant impact on other biological endpoints, such as bone. For example, leptin has been implicated in the inhibition of bone mass accumulation. In this prospective analysis, the relationship of leptin with total body bone mineral density (TBBMD) was assessed in 132 healthy women, aged 18-30 years old, who were participating in a one year dairy calcium intervention trial. Fasting serum leptin levels (ELISA) and TBBMD (Lunar DXA) were measured at baseline and 12 months. Baseline (B0) means ± SD were: age=20.1±2.4 yrs, weight=62.4±10.3 kg, BMI=22.6±3.3 kg/m^2, fat mass=18.5±7.4 kg, lean mass=39.8±4.4 kg, TBBMD=1.2±0.1 g/cm^2, *ln* leptin=2.4±0.7 (ng/ml). Potential confounders (age, oral contraceptive usage, assignment to the dairy calcium intervention, and B0 and 1 year changes in weight, fat mass, physical activity, dietary calcium, and calories) were assessed. As expected, the 1 year change in fat mass was significantly correlated with the 1 year change in *ln* leptin (r=0.34, p<0.0001). The 1 year change in *ln* leptin negatively predicted the 1 year % change TBBMD in a regression model (R^2=0.04, p=0.03) and remained significant when the 1 year change in fat mass was included in the model. Thus, increased serum leptin levels may contribute to a decrease in the accumulation of bone mass.

Cheese as a Source of Calcium and its Effects on Body Composition in Pubertal Finnish Girls. A. Lyytikäinen[1], M. Narva*[2], R. Korpela*[2], C. Lamberg-Allardt[3], M. Suuriniemi[4], Q. Wang*[1], S. Cheng[1]. [1]Department of Health Sciences, University of Jyväskylä, Jyväskylä, Finland, [2]Valio LTD, Helsinki, Finland, [3]Department of Applied Chemistry and Microbiology, University of Helsinki, Helsinki, Finland, [4]Department of Cell Biology, University of Jyväskylä, Jyväskylä, Finland.

The purpose of this study was to compare cheese (16% fat, 100 g/day) and calcium-tablets (calciumcarbonate, 500 mg Ca x 2/d) as a source of supplementation for calcium (1000 mg/d), and their effects on body composition in pre- and peripubertal Finnish girls. Altogether 149 girls aged 10-12 years at Tanner stage I-II were randomized into the tablet (n=75), cheese (n=38), and placebo group (n=36). The total bone mass (TBM), lean tissue mass (LTM), and fat mass (FM) were measured by DXA (Prodigy, GE Lunar). The food consumption and the intake of nutrients were evaluated with a three-day food record. At baseline, the mean intake of energy (1480/1480/1420 kcal/day), calcium (663/694/653 mg/day), protein (14/15/15 E%), and other nutrients, as well as the food consumption were similar between the groups. Neither body composition nor maturation status differed between the groups. No significant differences were found in the compliance between the groups (70/63/72 %). After the two-year intervention, the total calcium intake was 1623 in the tablet, 1335 in the cheese, and 915 mg/day in placebo group. The energy intake increased by 210/260/250 kcal/day in the groups. The tablet group was found to consume more cereals than the cheese and placebo group (p< .05). The energy intake was higher from protein (15/17/15 E%) in cheese group compared to the tablet and placebo group (p< .01), whereas the intake of saturated fatty acids (14/16/15 E%) was higher and intake of carbohydrates (53/49/51 E%) was lower in the cheese group compared to the tablet group (p< .01). There were no significant differences in the percentage increase of the TBM, LTM, and FM between groups. However, when taking into account the speed of maturation (Tanner stage at 24 months) and the compliance, the TBM of the girls at Tanner stage I at the baseline increased significantly in the cheese group compared to the tablet and placebo group (40 vs 36/35 %, p= 0.008). No differences were found in TBM between the girls at Tanner stage II. Our results indicate that adequate calcium intake by high cheese consumption (> 60 g/day) is more beneficial for the total bone mass accrual than the calcium from tablets with similar amount of calcium. This might be due to the high protein content in cheese or increased absorption of calcium induced by caseinphosphopeptides. Our results suggest that components in cheese protein has a vital role in bone mass accrual in growing girls transiting from pre- to peripuberty.

Comparison of Areal and Volumetric Vertebral Bone Densities Measured by DXA and CT in Pediatric Patients. A. Kovanlikaya*[1], T. A. L. Wren[2], X. D. Liu*[1], P. D. Pitukcheewanont*[3], V. Gilsanz[1]. [1]Radiology, Childrens Hospital Los Angeles, Los Angeles, CA, USA, [2]Orthopaedic Surgery, Childrens Hospital Los Angeles, Los Angeles, CA, USA, [3]Endocrinology and Metabolism, Childrens Hospital Los Angeles, Los Angeles, CA, USA.

Dual-energy x-ray absorptiometry (DXA) values of areal bone mineral density (BMD) in children are influenced by bone size and soft tissue composition, while computed tomography (CT) measures of volumetric bone density (BD) are not. The purpose of this study was to determine the extent to which the assessment of osteoporosis differs when it is performed using DXA versus CT. DXA areal BMD and Z-score (Z_{DXA}) and CT volumetric BD and Z-score (Z_{CT}) were compared in 45 girls and 43 boys ages 3-20 yrs who were referred for assessment of bone density and osteoporosis. Z-score represents the number of standard deviations (SD) the BMD or BD is above or below the mean for sex- and age-matched controls, and patients were considered osteoporotic if they had a Z-score below –2.5 (2.5 SD below normal). Plain radiographs of the spine were blindly and independently reviewed by two experienced pediatric radiologists. Of the 5 patients whose radiographs depicted osteoporosis, 5 had Z_{CT} <=-2.5, and 4 had Z_{DXA} <=-2.5. There was only a moderate correlation between the DXA and CT densities (r=.459, p=.0013 for girls; r=.439, p=.0029 for boys; r=.448, p<.0001 for all subjects) and between the DXA and CT Z-scores (r=.490, p=.0005 for girls; r=.537, p=.0001 for boys; r=.513, p <.0001 for all subjects). Paired t-tests indicated that the DXA Z-scores were systematically lower than the CT Z-scores (p=.0003 for girls; p=.0001 for boys; p<.0001 for all subjects). Nine of the 16 children with Z_{DXA} <=-2.5 had Z_{CT} between +1.0 and –1.0. Consequently, a substantial number of children (6/45 girls and 9/43 boys) who would not be considered osteoporotic based on CT measurements were classified as osteoporotic based on DXA results (see Table). Caution should therefore be exercised in using DXA to assess osteoporosis. Treatment for osteoporosis may not be warranted for many children who have DXA BMD values more than 2.5 SD below normal.

	Not osteoporotic based on DXA	Osteoporotic based on DXA
Not osteoporotic based on CT	37 girls (82%) 31 boys (72%)	6 girls (13%) 9 boys (21%)
Osteoporotic based on CT	1 girl (2%) 0 boys (0%)	1 girl (2%) 3 boys (7%)

Micro-Architectural Strut Analysis Study on Paediatric Bone. S. Picard[1], D. Brown*[1], F. Rauch[2], R. Travers[2], F. H. Glorieux[2], J. P. Brown[1]. [1]Groupe de recherche en maladies osseuses, Centre de recherche du CHUQ - Pavillon CHUL, Ste-Foy, PQ, Canada, [2]Shriner's Hospital for Children - Genetics Unit, McGill University, Montreal, PQ, Canada.

Bone quality is defined by a sufficient mineralization of tissue and also by an adequate micro-architecture organization. Quantitative trabecular bone micro-architecture studies from aged skeleton have already been reported but none on pediatric bones. The aim of this study was to perform strut analysis histomorphometric measurements on iliac crest biopsies from children aged 1,5 to 22,9 years. Bone biopsies from 54 healthy Caucasian subjects were obtained during surgery for various orthopaedic conditions. All subjects were ambulatory and no evidence of any metabolic bone disease was found. At least two Masson Goldner's stained slides were selected from each biopsy and JPEG images of the whole section were captured for quantification and measurement. Strut analyses were performed with Nova Prime Bioquant's (R&M biometrics, Nashville) image-analysis software. Trabecular node, free-end and node-to-free ratios have been quantified and calculated for each biopsy. Strut length has also been measured and defined as node-to-node, node-to-free, free-to-free, cortical-to-free, cortical-to-node and node-to-loop struts. The progressive increase in node number per tissue area and node-to-node strut percentage (p = 0.0013) associated with a significant decrease in free-node and free-to-free strut percentages (p = < 0.0001) show an architectural organizational change during skeleton growth. The results may suggest an architecture quality improvement which could contribute in the development of bone quality in growing children.

SU013

Fecal Calcium Density, Serum PTH, and 24-hr Urinary Calcium as Biological Indicators of Compliance with Calcium and Calcium Efficacy in a 7-year Clinical Trial. E. Ha*[1], J. D. Landoll*[1], L. Nagode*[2], P. Goel*[3], N. E. Badenhop-Stevens*[1], B. Li*[3], S. L. Mobley*[1], A. Clairmont*[4], V. Matkovic[1]. [1]Bone and Mineral Metabolism Laboratory, OSU, Columbus, OH, USA, [2]Veterinary Biosciences, OSU, Columbus, OH, USA, [3]Statistics, OSU, Columbus, OH, USA, [4]OSU, Columbus, OH, USA.

Effectiveness of biological indicators of calcium (Ca) nutritional status in predicting bone accretion at the proximal radius versus years-since-menarche (YSM; linear mixed effect models) was evaluated in a 7-year double blind placebo-controlled clinical trial with Ca supplementation (1000 mg/day) in addition to ~830 mg habitual dietary Ca intake. The data from 236 subjects were analyzed as they had =>7 out of 15 measuring points. Subjects were divided into subgroups based on each cumulative biological indicator above and below the median. The biological indicators of compliance with Ca were: fecal Ca density (FCD, Ca mg/g dry stool weight), serum PTH, and 24 hour urinary Ca excretion. Bone mass measurement by DXA (GE-Lunar DPX-L) were conducted semiannually while fecal (excluding baseline), blood (drawn between 8AM and 5PM), and urine samples were collected annually. FCD was measured according to the method previously described (Heaney RP, 1991). Ca was measured by AAS. Serum PTH was measured by Allegro immunoassay kits (Nichols Institute). The difference in bone accretion profiles between FCD subgroups was highly significant ($p<0.0001$, difference in BMD at YSM 4=2.8%). Average cumulative FCD for the subgroup above the median was 47.3 mg/g while below the median 26.1 mg/g. The difference in bone accretion profiles between PTH subgroups was significant ($p=0.035$, difference in BMD at YSM 4=-1.3%). Average cumulative PTH concentration for the subgroup above the median was 31 pg/ml while below the median 19 pg/ml. Urinary Ca excretion was a poor predictor of Ca efficacy ($p=0.564$; difference in BMD at YSM 4=0.9%). Average urinary Ca excretion in the high urinary calcium subgroup was 147 mg/day and for the low urinary calcium subgroup 65 mg/day. The above research indicate that FCD is a superior marker of Ca nutritional status and compliance with Ca intervention in a clinical trial and serum PTH is a moderately good predictor.

Compromised Skeletal Growth and Mineralization following a Period of Dietary Calcium Deficiency Are not Recovered in Prepuberal Pigs. D. K. Schneider*, C. E. Pardo*, K. L. Saddoris*, T. D. Crenshaw. Animal Sciences, University of Wisconsin, Madison, WI, USA.

Dietary Ca deficiency inhibits skeletal mineralization. The potential for recovery of skeletal growth and mineralization following a period of deficiency is not established. Failure to regain skeletal growth and mineralization during early growth stages may compromise peak bone mass. Twenty-four young pigs (6 kg, 3 wk old) were fed diets that differed in Ca (100 vs 70% of Ca requirements) for 4 wk. Both groups were then fed the same diet (108% of Ca requirements) for an additional 5 wk. Pigs were scanned using a Prodigy (GE Lunar) bone densitometer at 0, 2, 4, 6, and 9 wk of the trial. Skeletal mineralization was assessed by bone mineral density (BMD, g/cm^2) and skeletal growth was assessed by bone mineral content (BMC, g). At 4 wk, mineralization (BMD) was reduced ($P<0.001$) by 12% (0.625 vs 0.550 g/cm^2) and skeletal growth (BMC) was reduced ($P<0.001$) by >35% (256 vs 163 g). During recovery no differences were detected ($P>0.50$) in the rate of skeletal growth (BMC, g/d) during wk 4 to 6 (16.9 vs 16.6 g/d) or wk 6 to 9 (21.4 vs 21.2 g/d). The approximately 100 g differences in skeletal growth induced by dietary Ca during the first 4 wk was maintained until wk 9 (BMC, 942 vs 840 g). Likewise, no evidence was detected for recovery of skeletal mineralization. BMD at wk 9 (0.889 vs 0.838 g/cm^2) was lower ($P<0.02$) for pigs previously fed Ca deficient diets. In conclusion, a 35% reduction in BMC of rapidly growing pigs was not compensated during a recovery period that allowed a four- to five-fold increase in total skeletal growth. These results do not support an improvement in efficiency of Ca use following a period of Ca depletion.

Comparison of TGF-beta/BMP Pathways Signaled by BMP-2 and Demineralized Bone Powder in Human Dermal Fibroblasts. J. Glowacki, S. Zhou, K. E. Yates. Orthopedic Surgery, Brigham and Women's Hospital, Boston, MA, USA.

Both BMP-2 and Demineralized Bone Powder (DBP) stimulate endochondral osteogenesis in vivo. When human dermal fibroblasts (hDFs) are cultured with DBP in a porous collagen sponge for 7 days, cartilage-specific genes, aggrecan and collagen II, are upregulated and cartilage matrix accumulates around the cells in proximity to the DBP. We reported that this chondroinduction is preceded by shifts in some signaling genes. This study tests the hypothesis that DBP and BMP-2 affect similar signal pathways.

One million hDFs were cultured for 3 days in each porous 3D collagen sponge containing 0 or 3 mg DBP, or 6 μg/4 μL rhBMP-2 or PBS/BSA solution (manufacturer's recommended conc.) The rhBMP was delivered in a 4x4x2 mm coupon of the absorbable collagen and inserted into the porous collagen sponges. The absorbable collagen and rhBMP-2 were generously provided by Wyeth, Cambridge, MA. After 3 days, specimens were prepared for histology, for cDNA macroarrays for BMP/TGFb Signaling Pathways (SuperArray HS-023), RT-PCR, and Northern hybridization.

Histology showed homogeneous cellularity through each of the sponges at day 3. Similarities and differences in gene expression were observed (Figure), confirmed by RT-PCR. First, there were very similar responses of some genes, such as IGFBP3, ID2, and ID3, to DBP and rhBMP-2. This finding suggested that the dosing and timepoint were apt. In contrast, some of the genes that were most dramatically increased by DBP, such as TGFβ-Induced protein (1260%) and Collagen 3A1 (1770%), were barely affected by rhBMP-2. Although there was concordance with ID2 and ID3, ID4 was decreased by DBP by 60% and by rhBMP-2 by only 10%. Both PAI-1 and TIMP1 were greatly increased by DBP, but PAI-1 was decreased by rhBMP-2 (30%) and TIMP was not at all changed. DBP increased cyclin-dependent kinase inhibitor P21/Waf1/Cip1 by 260%, whereas it was decreased (30%) by rhBMP-2. It is possible that DBP's inhibition of proliferation may contribute to its effects to promote differentiation. Cbfa1 was highly expressed in target hDFs but was moderately decreased by both DBP (10%) and rhBMP-2 (20%). Smad 6 and 7 were increased by only rhBMP-2, but smad 2-5 and 9 were low in hDFs and were not modulated by either BMP-2 or DBP. In sum, although BMP was originally isolated as the active factor in DBP, rhBMP-2 alone and DBP do not affect all the same genes.

Intraosseous Delivery of rhBMP-2 in HYAFF-11/P65 Paste Rapidly Increases Trabecular Bone Mass in Nonhuman Primates. E. A. Smith-Adaline, H. J. Seeherman, X. J. Li, H. Kim*, R. Li*, M. L. Bouxsein, J. M. Wozney. Women's Health and Bone Division, Wyeth Research, Cambridge, MA, USA.

Recombinant BMP-2 (rhBMP-2) is a potent osteoinductive factor with the potential to lower the risk of hip and wrist fractures in osteopenic patients by inducing dramatic anabolic bone formation following local injection. However, previous research has shown that local administration of rhBMP-2 can result in transient bone resorption that precedes bone formation (Seeherman HJ, *et al*., ASBMR 2001). This study evaluated the efficacy of intraosseous (IO) delivery of rhBMP-2 to increase bone mass locally when co-administered with bisphosphonates (BP) to block the initial resorption phase. One distal radius of ten adult male cynomolgus monkeys received a single 0.25ml IO injection of 2mg/ml rhBMP-2 delivered in a hyaluronan paste (HYAFF-11/p65, Fidia Advanced Biopolymers) (BMP/p65). The contralateral radius was not treated. Animals were divided into groups receiving 1) no BP (n=4), 2) oral alendronate (2.7mg daily for 4 weeks, n=3), or 3) IV zoledronate (0.067mg/kg weekly for 4 weeks, n=3). Four weeks after BMP/p65 injection, trabecular BMD decreased 28.3±13.2% in animals not receiving BP. While oral alendronate was not effective (ΔBMD = -22.9±8.3%), IV zoledronate eliminated bone resorption at 4 weeks (ΔBMD = +1.6±7.5%) (Fig. 1). Trabecular BMD (pQCT) increased 42.3±15.1% and 45.8±17.8% by 4-6 months respectively in all groups after BMP/p65 treatment compared to baseline values (Fig. 1). In contrast, BP had no effect on BMD of the contralateral untreated radius (6 mo ΔBMD = -0.5±6.4%). Histological evaluation demonstrated both *de novo* and appositional bone formation in response to BMP/p65. Abundant osteoid present on bone surfaces 6 months after treatment indicated an ongoing anabolic effect of BMP at this time. Additional studies in OVX female cynomolgus monkeys demonstrated that a single injection of zoledronate (0.067mg/kg, IV) administered 3 days after IO injection also minimized BMP-induced bone resorption. In summary, local administration of BMP/p65 resulted in a rapid 46% increase in trabecular BMD, and co-administration with zoledronate eliminated the transient resorption phase. This combination treatment represents a promising anabolic therapy for prevention of osteoporosis-related hip, wrist and spine fractures.

Osteoinduction by Genetically Modified Ligamentum Flavum With Human BMP-2 Gene. K. Yang*, S. Moon*, H. Kim*, K. Kim*, U. Kwon*, H. Kim*, J. Jahng, H. Lee*. Department of Orthopaedic Surgery, Yonsei University College of Medicine, Seoul, Republic of Korea.

Ossification of spinal ligament can be found in certain pathologic conditions. Recently spontaneous expression of osteogenic phenotype from degenerated ligamentum flavum (LF) was demonstrated in vitro study. Furthermore in vivo application of recombinant human bone morphogenetic protein-2 (BMP-2) to spinal ligament resulted in ossification of ligament. Biologically modified LF with human BMP-2 gene can be an agent for osteoinduction. Therefore, we implanted genetically modified LF to nude mice to test feasibility of LF as bone graft substitution and a carrier for ex vivo gene therapy.

LF tissue was harvested and cultured. Type 5 adenovirus constructs with lacZ and BMP-2 cDNA (Ad/lacZ, Ad/BMP-2) were prepared. LF cell cultures were exposed to Ad/lacZ and stained with X-gal. Also cultures were exposed to Ad/BMP-2 and stained with alkaline phosphatase, Alizarin Red-S, Von Kossa method. Transgene expression and expression osteocalcin were assessed by immunocytochemistry and Western blot with BMP-2 and osteocalcin antibody. RT-PCRs for mRNA expression of collagen type I, II and osteocalcin were also performed. For in vivo assessment of osteoinductivity by Ad/BMP-2, control group was injected saline and osteoinductive group was injected 1x1011particle to human donor LF tissue, which were implanted to immune-deficient mice. At 1 and 2 month postimplantation, all animals were sacrificed for histological evaluation. Implant tissue were isolated and immunohistochemical staining with osteogenic marker antibody.

Ad/lacZ efficiently transduced LF cells. Culture with Ad/BMP-2 demonstrated transgene expression (BMP-2), expression of osteocalcin in immunocytochemisty and Western blot. Culture with Ad/BMP-2 showed strong reactivity in alkaline phosphatase, Alizarin Red-S, Von Kossa stain. In RT-PCR, cultures with Ad/BMP-2 showed upregulation of mRNA expression for collagen type I and osteocalcin. Newly bone formation was observed in the section from the Ad/BMP-2/hLF tissue implanted side while no bone formation was detected on the control side.

This study demonstrated feasibility of gene transfer to LF and also osteoinductive gene transfer to LF clearly upregulated osteogenic phenotype and induced osteogenesis. In the surgery of spinal stenosis, large amount of LF is removed and destabilized spinal segment is often restabilized with instrumented fusion with autogenous bone graft. The results of this study imply that removed LF can be a carrier for ex-vivo gene therapy and an osteoinductive agent to augment autogenous bone graft through genetic modification.

Prostaglandin E EP4 Receptor Agonist Enhances Ectopic Bone Formation Induced by rhBMP-2. H. Terai, R. Sasaoka*, H. Toyoda*, Y. Imai*, R. Sugama*, K. Takaoka. Orthopedic Surgery, Osaka City University Graduate School of Medicine, Osaka, Japan.

For clinical use, it is important to establish methods to maximize the effects of recombinat human bone morphogenetic protein- 2 (rhBMP- 2). In the present study, we investigated the synergic effects of Prostaglandin E EP4 receptor agonist (ONO-4819) in ectopic bone formation induced by rhBMP-2 in mice.

Forty lyophilized disks (6mm diameter) of bovine type I tendon- derived collagen containing 5 μg of rhBMP-2 were implanted respectively on the paravertebral muscle of 4 weeks old ICR mice. These mice were divided into four groups (n=10 per each group) according to the single administrated concentration of Prostaglandin E EP4 receptor agonist; (1) 0 μg/kg, as controls (2) 10 μg/kg (3) 30 μg/kg (4) 100 μg/kg . Prostaglandin E EP4 receptor agonist was injected subcutaneously every 8 hours after implantation until sacrifice. After 3 weeks of implantation, all mice were sacrificed and disks and left tibias were harvested. Soft X- ray photographs were taken for all specimens. All harvested disks and tibias were received histological analysis after measurements of bone mineral density (BMD) and bone mineral content (BMC) by dual energy X-ray absorption (DEXA). In another experimental protocol, serum osteocalcin, phosphate, calcium and ALP were measured under the administration of Prostaglandin E EP4 receptor agonist without rhBMP- 2. Forty- five mice were divided into 3 groups (n=15 per each) according to the administrated concentration and the interval; (I) 0 μg/kg, every 8 hours, as controls (II) 30 μg/kg, every 8 hours (III) 90 μg/kg, every 24 hours. Five mice were sacrificed every week in each group to collect blood samples.

BMD values (mg/cm2) of group 4 (15.7±4.1) and group 5 (16.8±4.5) were significantly higher than in the group 1 (8.1±2.2) ($p< 0.01$). BMC value (mg) of group 4 (7.9±2.8) was significantly higher than in the group 1 (4.4±3.6) and group 2 (3.9±2.1) ($p< 0.01$). No difference was observed in BMD or BMC values of tibiae among any groups. Serum osteocalcin and ALP were significantly higher in group II at 2 weeks ($p< 0.05$).

We concluded that Prostaglandin E EP4 receptor agonist enhanced the ectopic bone formation induced by rhBMP- 2 in mice. The optimal administrative dose was 30 μg/kg when injected subcutaneously every 8 hours, in which dose there was no effect to BMD or BMC of tibiae.

BMC and BMD of implanted collagen disks

Regulation of BMP Signaling by Smurfs. T. Imamura*, S. Maeda*. Biochemistry, The JFCR Cancer Institute, Tokyo, Japan.

Smurf1, a HECT type E3 ubiquitin ligase, has been reported to interact with receptor-regulated Smads (R-Smads) for bone morphogenetic proteins (BMPs), Smads 1 and 5, and promotes their degradation. Here we show that, in addition to direct binding to BMP-R-Smads, Smurf1 also interacts with inhibitory Smads (I-Smads), Smads 6 and 7, to form E3 ubiquitin ligase complexes to target BMP type I receptors (BMPR-Is) and activated BMP-R-Smads for degradation. Smurf1 interacts with nuclear I-Smads and induces their translocation to the cytoplasm in a nuclear export receptor (CRM1)-dependent fashion. Smurf1 then associates with BMPR-Is, and enhances turnover of the receptors. Furthermore, Smad6-Smurf1 complex binds to activated BMP-R-Smads, and induces their ubiquitination and degradation. Consistence with these data, Smurf1 synergies with Smad6 to inhibit BMP signaling in Xenopus. These results elucidate novel mechanisms whereby I-Smads-Smurf1 complexes inhibit BMP signaling both in vitro and in vivo, by mediating downregulation of activated BMPR-Is and activated BR-Smads.

Use of LMP-1 Fusion Protein to Induce Bone Formation without Risks of Gene Therapy. S. Sangadala*, L. Titus, M. Viggeswarapu, Y. Liu, G. A. Hair*, E. Gibson*, C. Oliver*, S. D. Boden. Orthopaedic Surgery, Emory University, Decatur, GA, USA.

LMP-1, an intracellular osteoinductive protein, can induce multiple BMPs and facilitate spine fusion in vivo. Induction of bone formation by LMP-1 has required gene therapy techniques to deliver its cDNA. The goal of this study was to determine the feasibility of delivering a recombinant LMP-1 fusion protein directly into cells. The fusion protein includes an 11 amino acid cationic transduction domain from the HIV TAT protein that facilitates entry into cells without the need for chemicals or electrical stimulus. Phase I: Athymic rats (N=58) received 3-4 subcutaneous (SQ) implants consisting of a collagen disc loaded with 1-1.5 million buffy coat cells from rabbit, human or non-human primate peripheral blood. The cells were treated with TAT-LMP-1 fusion protein (0.08 to 200 nM) for 30 min before implantation. Phase 2: 46 adult New Zealand white rabbits underwent a posterolateral lumbar spine fusion with a collagen sponge loaded with 6 million autologous buffy coat cells per side after 30 min treatment with TAT-LMP-1 protein (0.25 to 60 nM). Spines and SQ implants were harvested after 4 weeks and assessed by radiographs for bone formation. In rats bone nodules were formed in 2 experiments with the non-lyophilized TAT-LMP-1 protein at doses of 0.6 nM (4/4 implants), 1.2 nM (4/4), or 1.6 nM (2/3). The lyophilized protein appeared more stable and made bone in 3 experiments at 2.5 nM (11/11) when rabbit buffy coat cells were used. In addition human and non-human primate cells transduced with TAT-LMP-1 induced bone formation at 20 nM (6/6, human; 4/6, non-human primate). The challenging rabbit posterolateral spine fusion model also demonstrated the successful use of recombinant TAT-LMP-1 protein. Palpable fusion masses were formed in 2 experiments with the non-lyophylized TAT-LMP-1 protein at 5.0 nM (3/3) or 5.5 nM (2/2). The lyophilized TAT-LMP-1 protein was successful in 3 experiments at 5.0 nM (7/8) and in 2 experiments at 5.5 nM (5/5). In all of the above experiments higher and lower doses of TAT-LMP-1 had a lower rate of success or failed to induce bone formation. This study shows that a short peptide sequence (TAT) added to recombinant LMP-1 protein will facilitate the entry of the protein itself directly into buffy coat cells and initiate ectopic bone formation in rats and spine fusions in adult rabbits. Induction of bone formation by rabbit, human, or non-human primate buffy coat cells transduced with TAT-LMP-1 allows the ectopic rat model to be used to optimize delivery of TAT-LMP-1 prior to spine fusion studies in these species. This approach can avoid the challenges of gene therapy for LMP-1 delivery to induce bone formation.

Bone Formation Induced by Bone Morphogenetic Protein Is Stimulated by Prostaglandin E EP4 Receptor Agonist in its Early Phase. T. Hiromitsu*, H. Terai, R. Sasaoka*, Y. Imai*, R. Sugama*, K. Takaoka. Orthopedic Surgery, Osaka City Univerity Graduate School of Medicine, Osaka, Japan.

Administration of Prostaglandin E EP4 agonist (EP4, ONO-4819) enhances ectopic bone formation induced by recombinant human bone morphogenetic protein (rhBMP-2) in mice. It is important to investigate the mechanism by which Prostagrandin E EP4 receptor agonist regulates bone formation induced by rhBMP-2. In this study, we examined the effects of Prostaglandin E EP4 agonist *in vivo* and *in vitro* to determine the phase of its action in BMP inducing bone formation.

Mouse MC3T3-E1 cell line and ST-2 cell line were grown in 24- well plates with alpha MEM containing 10% fetal bovine serum. Cells were exposed to various concentration of Prostaglandin E EP4 agonist with or without BMP when they were reached to 60% of confluence. After 3 days of incubation, Alkaline phosphatase (ALP) activity was measured in each well. ALP activity values were analyzed statistically. In another protocol, 15 lyophilized disks (6 mm diameter) of bovine type I tendon- derived collagen containing 5 μg of rhBMP- 2 were implanted respectively on paravertebral muscle of 4 weeks old ICR mice. All mice were received 30 μg/kg of EP4 subcutaneously every 8 hours until sacrifice (3 weeks after implantation). These mice were divided into 3 groups (n=5 in each group) by administrated period of EP4; Group (I) for 3 weeks after implantation, Group (II) for 2 weeks (from 1 week after implantation), Group (III) for 1 week just prior to sacrifice (2weeks after implantation). After 3 weeks of implantation, all disks were harvested and examined bone mineral content (BMC) and bone mineral density (BMD) by dual energy X- ray absorption (DEXA).

Administration of EP4 to ST2 cell lines increased ALP activity levels in dose- dependent manner in the presence and absence of BMP. However, ALP activity levels in 3T3E1 cell lines were not increased in dose- dependent manner in the absence of BMP. In vivo study, the values of BMC and BMD of specimens in Group (I) were significantly higher than in other groups (See table). We concluded that Prostaglandin E EP4 receptor agonist enhanced ectopic bone formation induced by BMP by stimulating osteogenic cells in the early stage of bone formation.

BMC and BMD of implanted collagen disks

Group	(I)	(II)	(III)

Durable Adeno-Associated Virus Delivery of a Systemic Noggin Mutein Prevents BMP Induced Heterotopic Ossification. D. L. Glaser*[1], A. N. Economides*[2], L. Wang*[3], K. V. Sachs*[1], N. Stahl*[2], J. M. Wilson*[3], F. S. Kaplan[1], E. M. Shore[1]. [1]Orthopaedic Surgery, University of Pennsylvania, Philadelphia, PA, USA, [2]Regeneron Pharmaceuticals, Tarrytown, NY, USA, [3]Department of Medicine, University of Pennsylvania, Philadelphia, PA, USA.

Heterotopic ossification (HO) occurs in a wide variety of diseases, and prevention regimens have had varying success. In patients with fibrodysplasia ossificans progressiva (FOP), a catastrophic genetic disorder of HO with no available treatment, evidence supports an imbalance in the BMP4 pathway with inductive signals overwhelming antagonist signals. We previously demonstrated that a circulating mutein of Noggin (hNOGΔB2), a BMP antagonist, delivered by an adenovirus gene therapy approach was effective in preventing BMP4 induced HO, although transient viral expression with immunogenicity was observed. To develop an effective gene therapy for HO, sustained and controllable expression is required. This study investigated AAV-mediated gene transfer of systemic Noggin mutein for durable expression that is sufficient to prevent induced HO.

A mouse model of BMP-induced HO was used. C57/Bl6 mice (5 groups of 10) were treated with control virus, or one of two serotypes of AAV (2/5 or 2/8TBGhNOGΔB2) at either $1x10^{11}$ or $1x10^{10}$ GC/mouse. Serum Noggins level were monitored by ELISA at 1, 7, 14, 21 and 28 days. On day 28, the abdominal musculature was injected on one side with carrier alone, and on the other with carrier + BMP4. Serum Noggin levels and implants were studied at 7 and 14 days after implant. Histologic stages of bone formation were evaluated by standard methods.

Implants containing BMP4 induced an aggressive, fibroproliferative lesion with cartilage formation at 7d and HO at 14d. In animals treated with AAV 2/8TBGhNOGΔB2 at a viral titer of $1x10^{11}$, implants with BMP4 demonstrated a minimal, mixed inflammatory cell infiltrate at 7d and a thin pseudocapsule several cell layers thick surrounding the unresorbed plug at 14d, indistinguishable from carrier implants with no BMP. HO was evident in low titer AAV 2/8, high and low titer AAV 2/5, and control groups. Serum Noggin levels were detected as early as 7 days after viral injection. By 24d, Noggin levels of <1ug/ml were detectable in the 3 AAV groups that formed HO, while, in the therapeutic group, Noggin levels ranged from 9 ug/ml to 21 ug/ml.

This study demonstrates that delivery of a systemic Noggin mutein through AAV gene therapy provides durable gene delivery at therapeutic levels, suggesting that gene transfer of a circulating BMP4 antagonist may offer a solution to catastrophic disorders of progressive HO when all other modalities have failed.
